# Modeling scope ambiguity resolution as pragmatic inference: Formalizing differences in child and adult behavior 

K.J. Savinelli, Gregory Scontras, and Lisa Pearl<br>\{ksavinel, g.scontras, lpearl\} @uci.edu<br>University of California, Irvine

#### Abstract

Investigations of scope ambiguity resolution suggest that child behavior differs from adult behavior, with children struggling to access inverse scope interpretations. For example, children often fail to accept Every horse didn't succeed to mean not all the horses succeeded. Current accounts of children's scope behavior involve both pragmatic and processing factors. Inspired by these accounts, we use the Rational Speech Act framework to articulate a formal model that yields a more precise, explanatory, and predictive description of the observed developmental behavior.

Keywords: Rational Speech Act model, pragmatics, processing, language acquisition, ambiguity resolution, scope

## Introduction

If someone says "Every horse didn't jump over the fence," do you think any horses made it over the fence? If you think not, then you've interpreted this utterance as something like (1a). In contrast, if you think it's possible some horses made it, you've interpreted this utterance as something like (1b). These two different interpretations are possible because the utterance is scopally ambiguous. That is, it contains two scope operators: a quantifier (every $=\forall$ ) and a negation ( $n^{\prime} t=\neg$ ). Either element can take scope over the other (indicated as $\gg$ in (1)), and so yield two different interpretations.
(1) Every horse didn't jump over the fence.
a. $\quad \forall \gg \neg$ (surface scope):

None of the horses jumped over the fence.
b. $\quad \neg \gg \forall$ (inverse scope):

Not all of the horses jumped over the fence.
While adults can access both interpretations given appropriate context, 5 -year-old children typically struggle to obtain the inverse scope in (1b) (Musolino, 1998; Lidz \& Musolino, 2002; Musolino \& Lidz, 2006; Musolino, 2006; Viau et al., 2010; Tieu, 2015). For example, in a context where two out of three horses did in fact jump over the fence, only the inverse scope interpretation in (1b) is true. Adults charitably interpret the ambiguous utterance in a way that makes it a true statement (i.e., with the inverse scope in a two-out-of-three scenario), but 5-year-olds stick with the surface interpretation in (1a), which is false. Why does children's behavior differ from adults' in this context?

Previous accounts of children's scope interpretation behavior have recognized that both processing and pragmatic factors may contribute to non-adult-like behavior. Musolino $(1998,2006)$ observed that the surface scope interpretation in (1a) may be easier to process because the scope relationship in the semantics (i.e., $\forall$ scopes over $\neg$ ) aligns with the linear
order of these elements in the utterance (i.e., Every precedes $n ' t)$. In contrast, for the inverse scope interpretation in (1b), this isomorphism does not hold, with the scope relationship (i.e., $\neg$ scopes over $\forall$ ) opposite the linear order of the elements in the utterance. Musolino hypothesized that this lack of isomorphism would make the inverse scope interpretation more difficult to access. In line with this prediction, Conroy et al. (2008) found that when adults are time-restricted, they favor the surface scope interpretation. We thus see a potential role for processing factors in children's inability to access the inverse scope. Perhaps children, with their still-developing processing abilities, can't allocate sufficient processing resources to reliably access the inverse scope interpretation.

In addition to this processing factor, Gualmini et al. (2008) noted that discourse properties, such as what children consider the question under discussion (QUD), may impact their scope interpretation behavior. Formal theories of pragmatics suggest that all discourse transpires with respect to some QUD, whether implicit or explicit; utterances in the discourse need to (at least partially) answer the QUD to be pragmatically felicitous (Roberts, 2012). Gualmini and colleagues (Hulsey et al., 2004; Gualmini et al., 2008) suggest that children are very sensitive to this requirement. In particular, children may be able to access the inverse scope interpretation but nonetheless choose the surface scope interpretation because it better answers the perceived QUD in the contrived experimental setups. So, children's observed behavior would derive from a still-developing ability to manage the contextual information available and correctly infer the intended QUD.

Thus, children's developing processing and pragmatic abilities may both be a source of the observed non-adult-like behavior (Viau et al., 2010), though current experimental studies have struggled to clearly isolate the influence of each type of factor. To this end, we formally articulate the mechanism of scope ambiguity resolution using the Bayesian Rational Speech Act (RSA) computational modeling framework (Frank \& Goodman, 2012; Goodman \& Frank, 2016) in order to identify the separate contributions of processing and pragmatic factors.

We first summarize key experimental results from the literature on child scope ambiguity resolution, noting three core variables (one processing, two pragmatic) that affect children's scope disambiguation behavior. We also highlight the nature of the task children are being asked to engage in, which we then formally articulate using an RSA model that specifies the role of each of these three variables. Our results suggest that pragmatic factors play a larger role than processing fac-
tors in explaining children's non-adult-like scope ambiguity resolution behavior, and the computational modeling framework allows us to understand exactly why that's so. These results additionally suggest targeted future behavioral experiments to verify the impact of the specific pragmatic factors we identify. More generally, our model yields a more precise, explanatory, and predictive description of the observed developmental scope ambiguity resolution behavior.

## Background: Experimental results

Children's ability to access the inverse scope interpretation has been shown to be sensitive to manipulations of experimental context. The methodology typically used to assess children's scope disambiguation is the Truth Value Judgment Task (TVJT; Crain \& McKee, 1985). In the basic TVJT, children are presented with a background story about the actorsfor example, horses engaging in some activities. After this background story, children watch as the horses attempt to complete an action, such as jump over a fence. The critical not-all result state meant to prompt the inverse scope interpretation is illustrated in Figure 1, where the white horse fails to jump over the fence.

Figure 1: Sample not-all scenario from Musolino and Lidz (2006): 2 of 3 horses succeed at jumping over the fence.

In this scenario, the surface scope interpretation of the scopally-ambiguous utterance Every horse didn't jump over the fence (i.e., none of the horses jumped over the fence) is false, and the inverse scope interpretation (i.e., not all of the horses jumped over the fence) is true. A puppet then says the scopally-ambiguous utterance, and the child is asked to state if the puppet is right. That is, the child is asked whether $\mathrm{s} / \mathrm{he}$ would endorse the puppet's utterance as a true description of the scenario. Typically, children refuse to endorse the puppet's utterance, saying that the puppet is wrong. This behavior has been interpreted as children failing to access the inverse scope interpretation that would make the utterance true.

Interestingly, various alterations to the TVJT setup have yielded more adult-like behavior in children, namely greater rates of endorsing the puppet's ambiguous utterance in not-all scenarios. Musolino and Lidz (2006) observed that negation in an utterance might require certain felicity conditions to be met. In particular, negated utterances require a preceding $a f$ firmative context to contrast with (Wason, 1965). Musolino
and Lidz augmented the basic TVJT to include an additional contrast condition in which the puppet precedes its negative scopally-ambiguous utterance with a contrasting affirmative clause. This additional clause describes a previous successful story action (i.e., early-success), such as Every horse jumped over the log, but every horse didn't jump over the fence. This early-success contrast manipulation increased children's willingness to accept the scopally-ambiguous utterance in the not-all scenario: Children in the baseline condition endorsed the puppet's statement just $15 \%$ of the time, while children in the early-success affirmative context condition endorsed the puppet's statement $60 \%$ of the time. Viau et al. (2010) later replicated this increase in utterance endorsement using only an early-success story context. That is, the utterance endorsement rate was maintained by an early-success story context alone, and children didn't need an explicit contrast clause in the test utterance.

Notably, the early-success affirmative context manipulation potentially changes several aspects of the experimental context. First, it can shift participants' expectations about successful outcomes in the experimental world. This shift then potentially increases the salience of a QUD targeting this success, such as "Did all the horses succeed?" (all?). Recognizing this QUD's potential significance, Gualmini (2004) attempted to manipulate the experimental context so it favored the all? QUD. With all? as the salient QUD, children's endorsement of a scopally-ambiguous utterance that perfectly answers all? in the critical not-all scenario increased to $90 \%$. Even for a scopally-ambiguous utterance that does not answer the all? QUD, children's endorsement rate was at $50 \%$-markedly higher than the $15 \%$ baseline from the original study by Musolino and Lidz (2006). This finding highlights that privileging the all? QUD increases children's utterance endorsement in these scenarios.

A third potential impact of the affirmative context manipulation involves scope access. By altering the experimental world expectations and/or QUD to increase access to the inverse scope, the inverse scope interpretation may also become more accessible for later use. Viau et al. (2010) term this structural priming. Children who are better able to access the inverse scope are then more likely to endorse the scopallyambiguous utterance in subsequent not-all scenarios. Viau et al. investigated structural priming explicitly by attempting to directly alter the accessibility of the inverse scope interpretation. In one modified TVJT, they attempted to prime the access of the inverse scope interpretation, and in another modified TVJT, they attempted to directly prime the inverse scope's logical structure (e.g., $\neg \gg \forall$ ).

The first structural priming manipulation was implemented via the now-familiar affirmative context (i.e., pragmatic) manipulation. For the first three trials, the prior experimental context indicated successful outcomes and the effect was that children endorsed the scopally-ambiguous utterance $50 \%$ of the time. Crucially, the subsequent three trials removed the supportive affirmative context manipulation-yet children
continued to not only endorse the scopally-ambiguous utterance, but to endorse it more than they had before ( $80 \%$ ). Viau et al. (2010) attribute this result to a priming effect of the inverse interpretation from the first three trials. Interestingly, the increase in utterance endorsement could be due to priming multiple factors that are products of the affirmative context manipulation: (i) the expectations about successful outcomes in the experimental world, (ii) the salience of the all? QUD, or (iii) the ease of access to the inverse scope interpretation.

The second structural priming manipulation removed the affirmative context story in the first three trials. In its place, children were asked whether they would endorse a scopallyunambiguous utterance (e.g., "Not every horse jumped over the fence") whose interpretation had logical operators in the same order as the inverse scope interpretation of the scopallyambiguous utterance (e.g., $\neg \gg \forall$ ). Children endorsed this utterance $80 \%$ of the time. In the subsequent three trials, children were asked if they would endorse the scopallyambiguous utterance in the same experimental scenario-and their endorsement rate remained at $80 \%$. Viau et al. (2010) interpret this effect as priming of the relevant logical form: The inverse scope was easier to access in the scopally-ambiguous utterance because it was so recently accessed in the unambiguous utterances. The authors argue that this priming effect proceeded in the absence of manipulations to the pragmatic context, yet even here, there may still be pragmatic factors at work. The unambiguous utterance accomplishes three things: (i) it provides an instance of the $\neg \gg \forall$ configuration, (ii) it provides information about successful outcomes, and (iii) it suggests the all? QUD, answering it with no. Thus, in this attempt to prime the inverse logical form, the authors may have also altered expectations about the pragmatic context of the experiment, as related to the successful outcomes and relevant QUDs.

These experimental studies highlight at least three core factors (two pragmatic, one processing) that underlie children's utterance endorsement behavior in the TVJT: (i) pragmatic: expectations about the experimental world (e.g., how likely successful outcomes are), (ii) pragmatic: expectations about the QUD (e.g., whether all outcomes were successful), and (iii) processing: the accessibility of the inverse scope (i.e., the ease by which the logical form is accessed). These experimental studies have also supported different theoretical proposals for the source of children's differences. The proposals split on whether they attribute the differences solely to an inability to manage contextual information (i.e., pragmatic factors; Gualmini, 2008) or whether processing deficits also significantly contribute (i.e., difficulty accessing inverse scope; Viau et al., 2010). Importantly, it is not obvious from any of the existing experimental manipulations how to separate the independent contributions of these components. To capture and independently manipulate the contributions of each of the pragmatic and processing factors, we formalize their role in the interpretation of scopally-ambiguous utterances, using tools from probabilistic modeling.

## The model

We model ambiguity resolution within the Bayesian Rational Speech Act (RSA) framework (Goodman \& Frank, 2016). This framework views language understanding as a social reasoning process. A pragmatic listener $L_{1}$ interprets an utterance by reasoning about a cooperative speaker $S_{1}$ who is trying to inform a literal listener $L_{0}$ about the world. Our model is a "lifted-variable" extension wherein the ambiguous utterance's literal semantics is parameterized by interpretation-fixing variables (e.g., the relative scope of the quantificational elements; Lassiter \& Goodman, 2013). Hearing an ambiguous utterance, a pragmatic listener reasons jointly about the true state of the world (e.g., how many horses jumped over the fence), the scope interpretation that the speaker had in mind (i.e., surface vs. inverse), as well as the likely QUD that the utterance addresses (e.g., all?).

To connect our model's predictions with the available TVJT data, we follow Degen and Goodman (2014) and Tessler and Goodman (2016), modeling participants’ TVJT behavior as the (relative) endorsement of a pragmatic speaker $S_{2}$ for an utterance about an observed situation. That is, we model whether a speaker would endorse the scopallyambiguous utterance as a description of the observed state, or whether the speaker would prefer to say nothing at all. The pragmatic speaker $S_{2}$ makes this decision by reasoning about the probability that a pragmatic listener $L_{1}$ (who is reasoning about a speaker $S_{1}$ reasoning about a literal listener $L_{0}$ ) would arrive at the correct world state after hearing the utterance.

We take world states $w \in W$ to correspond to the number of successful outcomes, for example, the horses that successfully jumped over the fence $(W=\{0,1,2,3\})$. We assume a simple truth-functional semantics where an utterance $u$ denotes a mapping from world states to truth values (Bool $=\{$ true, false $\}$ ). We parameterize this truth function so that it depends on the scope interpretation $i \in I=$ \{inverse, surface\}, $[u]_{]^{i}}^{i}: W \rightarrow$ Bool. We consider two alternative utterances $u \in U$ : the null utterance (i.e., saying nothing at all, and so choosing not to endorse the utterance) and the scopally ambiguous utterance amb (e.g., "Every horse didn't jump over the fence"). So, $U=\{$ null, amb $\}$. The utterance semantics appears in (2), where the parameterization only impacts the truth value for utterance amb (since that's when multiple interpretations are available). If inverse is active, this corresponds to the not all reading, and so is true as long as not all (i.e., $w \neq 3$ ) outcomes were successful. If surface is active, this corresponds to the none reading, and so is only true in world state 0 .
(2) Utterance semantics $\llbracket u \rrbracket^{i}$ :
a. $[$ null $]]^{i}=$ true
b. $\quad[\mathrm{amb}]^{i}=$ if $i=$ inverse [inverse],
else [【surface]】
where:

$$
\llbracket \text { inverse }]=\lambda w . w \neq 3
$$

$$
\llbracket \text { surface }]=\lambda \mathrm{w} \cdot \mathrm{w}=0
$$

We consider three QUDs $q \in Q$ : (i) "How many horses made it over?" (how-many?), (ii) "Did all the horses make it over?" (all?), and (iii) "Did none of the horses make it over?" (none?). The QUDs serve as projections from the inferred world state to the relevant dimension of meaning, $q: W \rightarrow X$ (Kao, Wu, et al., 2014; Kao, Bergen, \& Goodman, 2014). In practice, the QUDs establish partitions on the possible world states, as shown in (3): how-many? is an identity function on world states, all? returns true only if all three outcomes were successful, and none? returns true only if none of the outcomes were successful.

QUD semantics $\llbracket q \rrbracket$ :
a. $\quad[$ how-many? $]]=\lambda \mathrm{w} . \mathrm{w}$
b. $\quad[$ all? $]]=\lambda \mathrm{w} . \mathrm{w}=3$
c. $[$ none? $]=\lambda w . w=0$

The literal listener $L_{0}$ has prior uncertainty about the true state, $P(w)$, and updates beliefs about $w$ conditioned on the the literal semantics. That is, $L_{0}$ restricts prior beliefs to those worlds that $\left[[u]^{i}\right.$ maps to true. The function $\delta_{\llbracket u]^{i}(w)}$ maps the Boolean truth value to a probability, 1 or 0.

$$
P_{L_{0}}(w \mid u, i) \propto \delta_{[u]^{i}(w)} \cdot P(w)
$$

To capture the notion that communication proceeds relative to a specific QUD $q, L_{0}$ must infer not only the true world state $w$, but also the value of the QUD applied to that world state, $[\lfloor q](w)=x$.

$$
P_{L_{0}}(x \mid u, i, q) \propto \sum_{w} \delta_{x=\llbracket q \rrbracket(w)} \cdot P_{L_{0}}(w \mid u, i)
$$

The speaker $S_{1}$ chooses an utterance $u$ in proportion to its utility in communicating about the true state of the world $w$ with respect to the QUD $q, \llbracket q \rrbracket \rrbracket(w)=x$. Thus, the speaker maximizes the probability that $L_{0}$ arrives at the intended $x$ from $u$. This selection is implemented via a softmax function (exp) and free parameter $\alpha$, which controls how rational the speaker will be in utterance selection.

$$
P_{S_{1}}(u \mid w, i, q) \propto \exp \left(\alpha \cdot \log \left(L_{0}(x \mid u, i, q)\right)\right)
$$

Utterance interpretation happens at the level of the pragmatic listener $L_{1}$, who interprets an utterance $u$ to jointly infer the world state $w$, the interpretation $i$, and the QUD $q$. We therefore model ambiguity resolution as pragmatic inference over an under-specified utterance semantics (i.e., the interpretation variable $i$ ). To perform this inference, $L_{1}$ inverts the $S_{1}$ model by Bayes rule, and so the joint probability of $w, i$, and $q$ is proportional to the likelihood of $S_{1}$ producing utterance $u$ given world state $w$, interpretation $i$, and QUD $q$, as well as the priors on $w, i$, and $q$.

$$
P_{L_{1}}(w, i, q \mid u) \propto P_{S_{1}}(u \mid w, i, q) \cdot P(w) \cdot P(i) \cdot P(q)
$$

To model the utterance endorsement implicit in TVJT, we need one more level of inference. The pragmatic speaker $S_{2}$ observes the true world state $w$ and selects $u$ by inverting the
$L_{1}$ model, thus maximizing the probability that a pragmatic listener would arrive at $w$ from $u$ by summing over possible interpretations $i$ and QUDs $q$ that accompany world $w$.

$$
P_{S_{2}}(u \mid w) \propto \exp \left(\log \sum_{i, q} P_{L_{1}}(w, i, q \mid u)\right)
$$

To generate model predictions, we must fix various model parameters. The $S_{1}$ speaker rationality parameter $\alpha>0$ is set to 2.5. The priors $P(w)$ and $P(q)$ correspond to expectations for the discourse context (i.e., likely world states or QUDs). In the default case, we set these priors to be uniform over their possible values: $P(w=0)=P(w=1)=P(w=2)=P(w=3)=\frac{1}{4}$; $P($ how-many $?)=P($ all $?)=P($ none $)=\frac{1}{3}$. The interpretation prior $P(i)$ corresponds to how easy it is to access the inverse scope interpretation. Experimental literature on scope ambiguity resolution suggests that speakers more readily access the surface interpretation (Anderson, 2004; Conroy et al., 2008). We model this tendency by setting these default values: $P($ surface $)=0.7$ and $P($ inverse $)=0.3$. Importantly, to better understand children's utterance endorsement behavior with scopally-ambiguous utterances, we can independently manipulate the values of the priors on $W, Q$, and $I$, and observe their impact on utterance endorsement.

## Results

To test how pragmatic and processing factors contribute to non-adult-like utterance endorsement in the TVJT, we systematically manipulate the relevant priors to favor specific parameter values, shown in Figure 2.

For the world state prior (Figure 2, left), we systematically favor specific world states by setting their prior probability to 0.9 ; if a world state is not favored, it receives a prior probability of $0.1 / 3=0.033$. Holding the QUD and scope priors at their default values, we see a marked increase in endorsement of the ambiguous utterance in the not-all scenario as beliefs about horse success increase. Utterance endorsement is at its lowest ( 0.25 ) when prior knowledge suggests that horses are particularly unlikely to succeed at jumping; utterance endorsement is at its highest (i.e., most adult-like: 0.90) when we believe horses are very likely to succeed.

Just as with the world state prior, we can systematically manipulate the QUD prior (Figure 2, center). Favored QUDs receive a prior probability of 0.9 ; other QUDs receive a prior probability of 0.05 . Holding the other priors at their default values, we see an increase in utterance endorsement from the none? (did no horses succeed?; 0.28) to how-many? (how many horses succeeded?; 0.37) to all? (did all horses succeed?; 0.64) QUDs. The model predicts the most adult-like behavior when the QUD concerns whether all the horses succeeded.

Finally, for the binary scope prior (Figure 2, right), we systematically manipulate the prior probability of inverse from 0.1 to 0.9 . Holding the other priors at their default values, we see a monotonic increase in utterance endorsement as the probability of inverse increases. At its most adult-like, the

Figure 2: Model predictions for ambiguous utterance endorsement (e.g., Every horse didn't jump over the fence) in a not-all scenario (e.g., two-out-of-three horses jump over the fence). Lower endorsement probability corresponds to less adult-like (i.e., more child-like) behavior. For the pragmatic variables (world state, QUD), the favored parameter value receives most of the prior probability weight $(P($ favored $)=0.9)$. For the processing variable (scope), the prior corresponds to how strongly the inverse scope is favored.
model predicts an endorsement probability of 0.57 when the prior probability of inverse is at its highest (0.9)—at its lowest (0.1), endorsement only drops to 0.4 .

To summarize, the world state and QUD priors have a more dramatic impact on utterance endorsement than the scope prior. There are two main reasons for this. First, for the world state prior, when expectations favor success (i.e., $w=3$ ), the ambiguous utterance is maximally informative regardless of the scope interpretation it receives: amb communicates to a listener that prior expectations do not hold (i.e., None/Not all of the horses succeeded goes against the expectation that all three horses would succeed). So, amb is particularly useful for communicating about the a priori unlikely not-all world states that appear in the experimental scenarios. Second, for the QUD manipulation, when all? is favored, either interpretation of amb fully resolves the QUD: whenever amb is true (i.e., whether None or Not all the horses succeeded), it is not the case that all the horses succeeded. A pragmatic speaker recognizes the utility of amb as an answer to all? in a not-all world state, irrespective of the intended scope interpretation.

Figure 3: Model predictions for ambiguous utterance endorsement when optimal world state $(w=3)$ and optimal QUD (all?) are favored $(P($ favored $)=.9)$.

So far, we have considered independent manipulations to the factors of interest. Figure 3 shows the interaction of all three factors for utterance endorsement when $w=3$ and all?
are favored. Here we see the additive effects of the world state and QUD priors; together, they lead to near-total endorsement of the ambiguous utterance. We also see more clearly the relatively small contribution of the scope prior, where changing the prior probability of inverse from 0.1 to 0.9 leads to just a 0.01 increase in endorsement probability. Thus, we see how the priors on the pragmatic factors overwhelm the processing scope prior. When the optimal (i.e., optimal for endorsement) QUD and world state are favored, even when inverse is highly inaccessible (i.e., $P$ (inverse) $=0.1$ ), we still predict massive utterance endorsement (0.99).

## Discussion

Our model of ambiguity resolution qualitatively captures the changes in children's utterance endorsement from the experimental literature; our results suggest that when it comes to understanding non-adult-like behavior in the TVJT, there is a stronger role for the pragmatics of context management (as realized in priors on world state and QUD) than for grammatical processing (as realized in the prior on scope interpretations), although there is likely a role for both. So, the observed failure of children to endorse scopally-ambiguous utterances in not-all scenarios likely stems more from children's beliefs about the world of the experiment (e.g., whether horses are a priori likely to succeed) and about the topic of conversation (e.g., whether the conversational goal is to determine if all the horses succeeded), than their inability to grammatically derive the inverse scope interpretation in real time. Indeed, our model predicts the highest rates of utterance endorsement to occur when resolving the scope ambiguity is irrelevant for communicating successfully about the not-all world-that is, when expectations favor total success (i.e., $w=3$ ), or when the QUD asks if all? of the horses succeeded. In either case, both scope interpretations serve to inform a listener, either that the a priori likely $w=3$ isn't true or that the answer to the all? QUD is no.

These results also underscore the need for well-defined
mapping hypotheses from observed experimental behavior to the psychological processes they inform, particularly for the sophisticated reasoning that occurs in tasks like the TVJT. In our brief review of the experimental literature, we were careful to point out alternative interpretations of the various experimental manipulations and their potential, unintended pragmatic consequences. At the very least, we hope to have demonstrated that utterance endorsement is not simple. A TVJT participant must reason recursively about the potential informativity of the utterance, attending to knowledge about the world of the experiment and the likely topic of conversation. That children stumble when attempting to perform these complex recursive inferences isn't so surprising. We suggest that a plausible source of differences in child and adult behavior on the TVJT is children's inability to successfully manage pragmatic information. We therefore propose to move the discussion away from the fragility of accessing inverse scope in children as a grammatical processing deficit and toward the complexity of behavior that scope interpretations require.

In addition to formalizing the pragmatics of ambiguity resolution in context, our results also motivate future experimental investigations that explicitly measure children's (and adults') expectations about the world and topic of conversation. We saw how past experiments did not completely deconfound the relevant factors. Perhaps the most straightforward way of testing these factors' effects is to measure the prior knowledge that participants bring to bear in the TVJT. These explicit measurements of pragmatic context can then form the basis of future modeling studies in this framework that could quantitatively match the behavioral results.

More generally, our results provide the foundation for more complete theories of the developmental process underlying scope ambiguity resolution. Children's relative lack of experience managing world and conversational knowledge likely contributes to their sensitivity to the experimental context. In short, five-year-olds may know the right interpretation, but they're still figuring out whether it's the best answer in the context of the experimental conversation.

# Surprisingly: Marker of Surprise Readings or Intensifier? 

Anthea Schöller and Michael Franke<br>(anthea.schoeller@uni-tuebingen.de, mchfranke@gmail.com)<br>Department of Linguistics, Wilhelmstraße 19<br>72074 Tübingen, Germany

#### Abstract

We investigate the influence of the adverb surprisingly on the meaning of the quantity words few and many, which themselves have been associated with a reading expressing surprise. To learn about the meaning contribution of "surprise", we compare surprisingly with the intensifier incredibly and a compared to phrase explicitly marking surprise. Based on an empirical measure of subjects' expectations about everyday events, a Bayesian model uses data from a sentence judgment task to infer likely levels of surprise associated with the different constructions of interest.

Keywords: intensifier, surprise, computational modeling, few, many, surprisingly

## Introduction

A long tradition in psychology has acknowledged the role of prior expectations in the use of vague and context-dependent expressions like tall, heavy, few and many (e.g. Clark, 1991; Sanford, Moxey, \& Paterson, 1994). Fernando and Kamp (1996) spell out a semantic theory which makes the truth conditions of few and many dependent on prior expectations. Socalled "cardinal surprise readings" convey that a cardinality is smaller or greater than what is expected for the situation:
(1) For a man from the US, Chris saw few/many movies last year. $\rightsquigarrow$ Chris saw less/more movies than expected for a US male.

Such a surprise-based account raises interesting questions. First, how can expected cardinalities be distinguished from surprising ones? Fernando and Kamp (1996) stipulate that the lexical meanings of few and many comprise contextually-stable thresholds $\theta_{\text {few }}$ and $\theta_{\text {many }}$ which operate on a contextually-variable representation of a priori expectations. Second, if sentences with few and many express that a cardinality is surprising anyway, are they different from sentences in which the surprise element is overtly marked? The surprise reading can be made salient by a compared to phrase (2) or by modifying few and many with an adverb like surprisingly (3).
(2) Compared to what you would expect for a man from the US, Chris saw few / many movies last year.
(3) For a man from the US, Chris saw surprisingly few / many movies last year.

If surprise were the single factor which determines truth conditions of the cardinal surprise reading, we should not find a meaning difference between (1) and the overtly marked surprise reading in (2) and (3). Alternatively, it could be hypothesized that surprisingly in (3) acts not as a marker of surprise but as an intensifier, yielding a higher $\theta_{\text {surpr. many }}$ than $\theta_{\text {many }}$
and a lower $\theta_{\text {surpr. few }}$ than $\theta_{\text {few }}$. The pragmatic theory of intensifiers by Bennett and Goodman (2015) would predict that surprisingly has very similar effects to incredibly (see below).

We set out to experimentally test the influence of the modifiers surprisingly, incredibly and compared to on the threshold values predicted for Fernando and Kamp (1996)'s surprise readings of few and many. We employ linear mixed effects regression to compare judgment data and a computational model to infer said thresholds from our data.

## A Surprise-based Semantics for few and many

Partee (1989) characterized cardinal many as describing cardinalities which are at least $x_{\min }$, where $x_{\min }$ is a large number, and few as describing cardinalities which are at most $x_{\text {max }}$, where $x_{\text {max }}$ is a small number, see (4).
(4) Cardinal reading of "Few/Many As are B"

$$
\text { Few: }|A \cap B| \leq x_{\max } \quad \text { Many: }|A \cap B| \geq x_{\min }
$$

One concrete proposal of how $x_{\text {min }}$ and $x_{\text {max }}$ might be identified is presented by Fernando and Kamp (1996). The "cardinal surprise reading" of few and many in sentences like (1) is an intentional comparison between the actual number of movies that Chris saw last year and a probabilistic belief $P_{E}$ about the expected number of watched movies in some contextually provided comparison class. The for-phrase in (1) triggers a comparison class of US males. The prior expectation $P_{E}$ is highly context-dependent. In contrast, $\theta_{\text {few }}$ and $\theta_{\text {many }}$ are context-independent. They are fixed thresholds on the cumulative distribution of $P_{E}$. Truth conditions of the surprise reading of sentences like (1) are given in (5).

$$
\begin{array}{ll}
\text { a. } & \llbracket \text { Few As are } \mathrm{B} \rrbracket=1 \text { iff }|A \cap B| \leq x_{\text {max }} \text { where }  \tag{5}\\
& x_{\max }=\max \left\{n \in \mathbb{N} \mid P_{E}(|A \cap B| \leq n)<\theta_{\text {few }}\right\} \\
\text { b. } & \llbracket \text { Many As are } \mathrm{B} \rrbracket=1 \text { iff }|A \cap B| \geq x_{\text {min }} \text { where } \\
& x_{\text {min }}=\min \left\{n \in \mathbb{N} \mid P_{E}(|A \cap B| \leq n)>\theta_{\text {many }}\right\}
\end{array}
$$

From (5b), entities which have properties $A$ and $B$ can be described as "many" if their cardinality is at least $x_{\min } . x_{\text {min }}$ is the lowest number for which the cumulative density mass of prior expectation $P_{E}$ about the number of As with property B is higher than the threshold $\theta_{\text {many }}$. In other words, "Many As are B" is a true description of cardinalities which are surprisingly high with respect to the contextually given $P_{E}$ and the context-independent threshold $\theta_{\text {many }}$ on $P_{E}$.

To illustrate, consider the example in Figure 1 for the many-sentence in (1). Prior expectations $P_{E}$ could look like in Figure 1a: they would assign a probability to any natural number $n$, indicating how likely we think it is that Chris saw $n$

Figure 1: Illustration of a surprise-based semantics
movies last year. Figure 1 b shows the cumulative distribution of the distribution in Figure 1a. If $\theta_{\text {many }}$ was fixed to, say, 0.8 , then the semantics would identify $x_{\min }$ to be 23 . Accordingly, for this $P_{E}$, the many-sentence in (1) would be false for any $n<23$ and true for any $n \geq 23$. Schöller and Franke (2015) present evidence for the fixed threshold hypothesis by identifying fixed values for $\theta_{\text {few }}$ and $\theta_{\text {many }}$, which correctly predict the applicability of few and many in different contexts, given experimentally measured prior expectations.

## Surprisingly: Intensifier or Marker of Surprise?

Two views are prima facie plausible for the meaning contribution of the adverb surprisingly. On the one hand, surprisingly can be taken to intensify the meaning of few and many just like other intensifiers like incredibly or very do. As a result, surprisingly many might be associated with a threshold $\theta_{\text {surpr. many }}$ higher than $\theta_{\text {many. }}$. The contrasting view is to classify surprisingly as a marker of the surprise reading, which overtly marks that truth-conditions must draw on a threshold on a measure of surprise. This view is supported by the semantic literature which suggests that "being surprisingly tall comes to mean taller than expected" (Nouwen, 2011, 154).

Note that our hypotheses for surprisingly apply to sentences with a salient cardinal surprise reading and a restricted comparison class. To discriminate between the two views on surprisingly, we deduce two experimentally testable hypotheses. Another two auxiliary hypotheses are tested alongside to complement our understanding of modified few and many, see Table 1. In what follows, we spell out these general hypotheses in terms of their predictions about the threshold values $\theta_{\text {few }}$ and $\theta_{\text {many }}$ as assumed by Fernando and Kamp (1996) and test them with a computational model which infers these threshold values on the basis of experimental data.
Salient surprise reading. We cannot exclude that few and many may also denote a small or large cardinality, independent of prior expectations. To test the auxiliary assumption that the most salient readings of our experimental test sentences (see Appendix) are cardinal surprise readings given the comparison class for which we measure subjects' prior expectations (see below), we contrast sentences with bare few and many with sentences modified by the compared to phrase in (2) which makes the relevant expectations overt. It is necessary to test this because if few and many did not have the intended surprise reading, differences between few/many and surprisingly few/many could be due to different readings and possibly different threshold values associated with them. Alongside few and many's intrinsic surprise reading, we test another related assumption: the for- phrase used to mark the comparison class triggers the same prior expectations $P_{E}$ as the compared to phrase which openly addresses expectations, see (7).
Marker of surprise. If the function of surprisingly is to mark a cardinal surprise reading, thresholds are the same as for unmodified few/many, where these cardinal surprise readings are most salient anyway (see above). Furthermore, sentences with surprisingly should not be different from sentences with compared to, as in (2).
Intensifier. Modification by surprisingly raises the threshold of many and makes it applicable to a smaller range of cardinalities, resulting in a stronger statement than the alternative with bare many. Few's threshold decreases.
Bennett \& Goodman. The intensifier hypothesis is in line with work by Bennett and Goodman (2015) who explain the

|  | intensifier | marker of surprise | salient surprise reading |
| :--- | :---: | :---: | :---: |
| predictions | many $\leq$ surprisingly many | many $=$ surprisingly many | many $=$ compared to... many |
|  | few $\geq$ surprisingly few | few $=$ surprisingly few | few $=$ compared to... few |
|  | surprisingly $=$ incredibly | surprisingly $=$ compared to | few |
| results | few: $\times$ many: $\checkmark$ | few: $\checkmark \quad$ many: $\times$ | few: $\checkmark$ many: $\checkmark$ |

Table 1: Hypotheses and results
strength of an intensifying degree adverb as "pragmatic inference based on differing cost [(their length and frequency)] rather than differing semantics" (p. 1). However, they do not test surprisingly. From the adverbs tested by Bennett and Goodman (2015), incredibly comes closest to surprisingly, as they have the same number of syllables and the most similar frequency in an updated version of the corpus Bennett and Goodman (2015) used, the Google Web 1 T 5grams corpus $(4,987,059$ occurrences as compared to $4,373,670$ occurrences of surprisingly). Following Bennett and Goodman (2015), we hypothesize that the thresholds of surprisingly few/many are roughly the same as for incredibly few/many.

## Experiments

To test the hypotheses in Table 1, two experiments were conducted to gather acceptability ratings of sentences with (modified) few and many and to measure participants' prior expectations. Prior expectations will be input to the computational model, which is presented in the next section.

## Experiment 1: Prior elicitation

Design. To get an empirical estimate of participants' prior expectations, we used a binned histogram task. Participants saw descriptions of a context as in (6a) and a question as in (6b). Subjects were presented with 15 intervals, whose ranges were determined by a pre-test (in which we asked for the most likely, lowest and highest possible cardinality). Subjects rated the likelihood that the true value lies in each of the intervals, by adjusting a slider labeled from "extremely unlikely" to "extremely likely." For example, they would adjust a slider each for the probability that Chris saw 0-2, 3-5, ..., $39-41$ or more than 42 movies last year.

## (6) Prior elicitation example

a. Background: Chris is a man from the US.
b. How many movies do you think he saw last year?

Participants. 80 subjects were recruited via Amazon's Mechanical Turk with US-IP addresses.

Materials \& Procedure. After reading instructions, each subject saw all of the 14 experimental items (see Appendix), one after another. For each item, the 15 intervals were presented horizontally on the screen and paired with a vertical slider. Participants had to adjust or at least click on each slider before being able to proceed.

Results. Two participants were excluded for not being native speakers of English. For each item, each participant's ratings were normalized and these normalized ratings were then averaged across participants. We understand these probability distributions $P_{E}$, see Figure 2, as approximations of the beliefs held in the population (Franke et al., 2016).

## Experiment 2: Judgment task

Design. In a binary judgment task we measured acceptance of sentences with few and many with and without modifiers (surprisingly, incredibly or compared to). Participants were presented with a context which introduced a situation and an interval as in (7a). The interval was randomly chosen from 8 of the 15 intervals from the prior elicitation task (see Appendix). We presented only four low intervals for few and four high intervals for many to avoid a large number of combinations. The context was described by a statement as in (7b) which contained either few or many. We elicited data of four groups of participants which each saw a different modifier.

## (7) Production study example

a. Context: Chris is a man from the US who saw [0-2 | 6-8 | $\ldots \mid 42$ or more] movies last year.
b. Statement: [For | Compared to what you would expect for] a man from the US, Chris saw [-| surprisingly | incredibly] [few | many] movies last year.

Materials \& Procedure. Each participant was randomly assigned to one modifier condition (unmodified, compared to construction, surprisingly, incredibly). After reading a short explanation of the task, each subject saw all of the 14 contexts from the Appendix one after another in random order. Sentences with unmodified few and many or incredibly or surprisingly were introduced by a for-phrase which made the intended comparison class overt. The fourth group saw a compared to phrase which additionally made expectations salient. For each context, a quantity word and one of its four associated intervals were assigned randomly. Participants had to click on one of two radio buttons labeled with TRUE or FALSE before being able to proceed to the next item.
Participants. We recruited 787 participants with US-IP addresses via Amazon's Mechanical Turk, among them 301 participants in the unmodified condition and 162 participants

Figure 2: Empirically measured prior expectations. Error bars are estimated 95\% confidence intervals.

Figure 3: Proportion of TRUE answers from Experiment 2.
each in the other three conditions. The unmodified condition had more participants because it was part of a previous experiment in which we presented 8 of 15 intervals for both few and many. For the analysis only data from those intervals presented in the other three conditions was used.
Results. Data was excluded of 25 participants who reported not to be native speakers of English or to not having understood the task. Figure 3 shows the proportion of TRUE answers.

For each of the quantity words few and many we specified a linear mixed effects regression model predicting the proportional acceptance of statements as in (7b). During a guided search through the model space, we started out with a model containing only the random effect ITEM and added fixed effects if this significantly increased the model's fit to the data
(measured by AIC).
For many, the final model includes the fixed effects INTERVAL and MODIFIER and their interaction. Significantly more participants accepted the statements for higher intervals $(\beta=0.02, S E=0.007, p<0.01)$. The modification of many by surprisingly leads to a lower acceptance ( $\beta=$ $-0.59, S E=0.12, p<0.001$ ) than of sentences with unmodified many. This suggests that surprisingly intensifies the meaning of many. The same is the case for sentences with incredibly, which were also rated lower than unmodified many ( $\beta=-0.53, S E=0.12, p<0.001$ ). There is no difference between sentences with a compared to phrase and unmodified many ( $\beta=-0.17, S E=0.12, p<0.15$ ), which suggests that many receives a surprise reading in both cases. Surprisingly and compared to are rated significantly different
( $\beta=-0.42, S E=0.12, p<0.001$ ), but there is no difference between surprisingly and incredibly. Furthermore, there is a significant interaction between INTERVAL and MODIFIER for surprisingly $(\beta=0.03, S E=0.01, p<0.001)$ and incredibly ( $\beta=0.02, S E=0.01, p<0.01$ ).

For few, the final model, obtained by the same procedure, includes the fixed effects interval and modifier. The proportion of participants accepting the statement is significantly lower for higher numbers $(\beta=-0.12, S E=0.004, p<$ 0.001 ). Among the modifiers only incredibly is significantly different from bare few $(\beta=-0.05, S E=0.02, p<0.05)$; for surprisingly and compared to this is not the case. No significant difference between surprisingly and compared to is found, but incredibly is rated significantly lower than surprisingly ( $\beta=-0.05, S E=0.02, p<0.05$ ).

These results are expected under the "salient surprise reading" hypothesis. While surprisingly seems to behave like an intensifier for many, for few it seems to redundantly mark surprise.

## Computational Model

The regression models reported above include a random effect for items but do not constrain these to reflect prior expectations. Moreover, regression models do not predict judgments as a function of thresholds on expectations. It is therefore insightful to complement regression modeling with an explicit theory-driven model of a possible datagenerating process. We use the computational model of Schöller and Franke (2015) for this purpose. The model takes empirically measured prior expectations as input and treats $\theta_{[i] f e w}$ and $\theta_{[i] m a n y}$ for each modifier condition $i$ (unmodified, surprisingly, incredibly, compared to) as latent parameters, whose values will be estimated to fit experimental data. The model specifies a likelihood function $P$ (Observation $\left.\theta_{[\mathrm{i}] \text { many }}, \theta_{[\mathrm{i}] \text { few }}\right)$ which assigns to values of latent parameters a probability of seeing a particular experimental observation. Bayesian inference is one way to infer plausible threshold values, given the likelihood function and a prior:
$P\left(\theta_{[\mathrm{i}] \text { many }}, \theta_{[\mathrm{i}] \text { few }} \mid \mathrm{O}\right) \propto P\left(\theta_{[\mathrm{i}] \text { many }}, \theta_{[\mathrm{i}] \mathrm{few}}\right) P\left(\mathrm{O} \mid \theta_{[\mathrm{i}] \text { many }}, \theta_{[\mathrm{i}] \mathrm{few}}\right)$
Our goal, then, is to see for each modifier which pairs of threshold values $\theta_{[i] m a n y}$ and $\theta_{[i] f e w}$ are likely given the data. We estimate the a posteriori credible threshold values and compare how similar they are across conditions. We focus on many in the exposition, but the case for few is parallel. Straightforwardly, (5) translates into a probabilistic rule $P$ ("[modifier $i]$ many" $\left.\mid n, P_{E} ; \theta_{[\mathrm{i}] \text { many }}\right)=\delta_{n \geq x_{\text {mini, }, ~}}$, where $x_{\text {min, }}$ is derived from $P_{E}$, as in (5), based on $\theta_{[i] m a n y}$. This is a degenerate probabilistic rule because it maps the applicability of "many" to 0 and 1 only. To allow for noise, we look at a parameterized, smoothed-out version.
$P\left("[i]\right.$ many" $\left.\mid n, P_{E} ; \theta_{[\mathrm{i}] \text { many }}, \sigma_{j}\right)=\sum_{k=0}^{n} \int_{k-\frac{1}{2}}^{k+\frac{1}{2}} \mathcal{N}\left(y ; x_{\text {min, } \mathrm{i}}, \sigma_{j}\right) \mathrm{d} y$

Figure 4: Estimated $95 \%$ credible intervals for $\theta_{\text {few }, \mathrm{i}} \& \theta_{\text {many,i }}$

Here, $\sigma_{j}$ is another free model parameter that regulates the steepness of the curve, and $\mathcal{N}\left(y ; x_{\min , \mathrm{i}}, \sigma_{j}\right)$ is the probability density of $y$ under a normal distribution with mean $x_{\min , \mathrm{i}}$ and standard deviation $\sigma_{j}$. This rule predicts noisy acceptability ratings under a surprise-based semantics where the amount of noise is controlled by $\sigma_{j}$, see Figure 1c. Noise can be caused by uncertainty about the exact shape of $P_{E}$ and the amount of uncertainty differs across contexts. This is why we allow an individual value of $\sigma_{j}$ for each context $j$. Furthermore, we assume that the parameter values $\theta_{[i] m a n y}, \theta_{[i] f e w}$ and $\sigma_{j}$ are independent of each other and that they have uniform priors over an interval that is large enough to accommodate a range of plausible values without weighting them.

$$
\begin{aligned}
P\left(\theta_{[i] m a n y}, \theta_{[\mathrm{i}] \text { few }}, \sigma_{j}\right)= & \operatorname{Uniform}_{[0 ; 1]}\left(\theta_{[\mathrm{i}] \text { many }}\right) . \\
& \text { Uniform }_{[0 ; 1]}\left(\theta_{[i] \mathrm{few}}\right) \cdot \operatorname{Uniform}_{[0 ; 10]}\left(\sigma_{j}\right)
\end{aligned}
$$

To approximate the joint posterior distribution, we used MCMC sampling, as implemented in JAGS (Plummer, 2003). We collected 10,000 samples from 2 MCMC chains after a burn-in of 10,000 . This ensured convergence, as measured by $\hat{R}$ (Gelman \& Rubin, 1992). Figure 4 shows the estimated $95 \%$ credible intervals for the marginalized posteriors over thresholds per modifier. Where intervals (clearly) do not overlap, there is reason to believe that thresholds differ. For example, $\theta_{\text {surpr.many }} \in[0.863,0.903]$ tells us that surprisingly many describes cardinalities which are higher than at least $86 \%$ of the cumulative density mass of $P_{E}$. This threshold is higher than bare many's, $\theta_{\text {many }} \in[0.657,0.701]$. Taken together, the model predicts that surprisingly many is restricted to describe higher cardinalities than unmodified many.

## Discussion and Conclusions

Table 1 summarizes the results from regression and theorydriven modeling. The data supports the "salient surprise reading" hypothesis assumed by Fernando and Kamp (1996) and suggests that an expectation-based reading is the canonical interpretation of cardinal few and many in our test sentences. There is no difference between unmodified sentences and sentences in which expectations are made salient by a compared to phrase.

For surprisingly, the picture is less clear. Sentences with many provide support for the "intensifier" hypothesis. Speakers prefer it for higher cardinalities than those which render unmodified many or sentences with a compared to construction true. Furthermore, we do not find a difference with incredibly. When combined with few, however, surprisingly does not appear to be an intensifier. Sentences with few, surprisingly few and compared to are rated equally, speaking in favor of a "marker of surprise" hypothesis. For the comparison between surprisingly and incredibly, we get conflicting results from the regression and the theory-driven model. The regression analysis finds that incredibly few is rated lower than surprisingly few, but the computational model identifies an overlap in the estimated credible intervals. However, we want to once more stress that we are here comparing conclusions based on models which are decidedly different. Whereas the computational model is theory-driven and includes experimentally measured prior expectations, the regression model only looks at numerical differences in the ratings. Ultimately, we believe in the computational model.

Keeping in mind that few only applies to small cardinalities, the lack of a difference could also be due to a floor effect. This is where future research should tie in. Few should be presented in contexts like book or facebook, in which large cardinalities are plausible and few can operate away from 0 . Additionally, the presented intervals should be more finegrained. A follow-up study as well as further discussion of the semantic differences between few and many are presented in Schöller (2017).

## Experimental material

1. book - A friend's favorite book has been published only recently (and has [0-40, 81-120, 161-200, 241-280, 321-360, 401-$440,481-520,560$ or more] pages).
2. bus - Vehicle No. 102 is a school bus (which has seats for [0-4, $10-14,20-24,30-34,40-44,50-54,60-64,70$ or more] passengers).
3. calls - Lisa is a woman from the US (who made [0-4, 10-14, $20-24,30-34,40-44,50-54,60-64,70$ or more] phone calls last week).
4. class - Erin is a first grade student in primary school. (There are [0-2, 6-8, 12-14, 18-20, 24-26, 30-32, 36-38, 42 or more] children in Erin's class.)
5. coffee - Andy is man from the US (who drank [0-1, 4-5, 8-9, 12-13, 16-17, 20-21, 24-25, 28 or more] cups of coffee last week).
6. cook - Tony is a man from the US (who cooked himself [0-3, 8-11, 16-19, 24-27, 32-35, 40-43, 48-51, 56 or more] meals at home last month).
7. facebook - Judith is a woman from the US (who has [0-69, 140-209, 280-349, 420-489, 560-629, 700-769, 840-909, 980 or more] Facebook friends).
8. friends - Lelia is a woman from the US (who has [0-1, 4-5, 8-9, 12-13, 16-17, 20-21, 24-25, 28 or more] friends).
9. hair - Betty is a woman from the US (who washed her hair [0-2, 6-8, 12-14, 18-20, 24-26, 30-32, 36-38, 42 or more] times last month).
10. movie - Chris is a man from the US (who saw [0-2, 6-8, 12-14, 18-20, 24-26, 30-32, 36-38, 42 or more] movies last year).
11. poem - A friend wants to read you her favorite poem (which has $[0-3,8-11,16-19,24-27,32-35,40-43,48-51,56$ or more] lines).
12. restaurants - Sarah is a woman from the US (who went to [0-3, 8-11, 16-19, 24-27, 32-35, 40-43, 48-51, 56 or more] restaurants last year).
13. shoes - Melanie is a woman from the US (who owns [0-2, 6-8, 12-14, 18-20, 24-26, 30-32, 36-38, 42 or more] pairs of shoes). - intervals:
14. tshirts - Liam is a man from the US (who has [0-2, 6-8, 12-14, 18-20, 24-26, 30-32, 36-38, 42 or more] T-shirts).

#### Abstract

In problem solving situation, cognitive flexibility appears to be a major skill. Fostering cognitive flexibility is therefore a specific stake in mathematics education. This research introduces a learning method to develop mathematical concepts when solving word arithmetic problems. The study was conducted with 8 classes $\left(4^{\text {th }}-5^{\text {th }}\right.$ Grades) from highpriority education schools in the Paris area following this protocol: pre-tests, 5 learning sessions for experimental and control groups, post-tests. During learning sessions, students studied arithmetic word problems that can be solved in two different ways: an expansion strategy and a factorization one. The experimental teaching method, based on a recategorization principle, allowed experimental students to improve more than the control students in ability to use the factorization strategy even in contexts where it is the less intuitive and to consider the two successful strategies. Educational entailments of our finding are discussed.

Keywords: cognitive flexibility, evidence-based education, categorization, learning method, word arithmetical problem

## Introduction

In mathematics, proposing flexible and adaptive representations and strategies reflects higher problem solving skills (Heinze, Star \& Verschaffel 2009). We proposed to study not only strategies in algebra problems but also the related representations derived from word problem. Indeed when solving word problems, novices intuitively induce a superficial structure, triggering a misleading categorization of the situation (Chi, 2008). The present study aimed to improve pupil's cognitive flexibility in problems solving in order to develop an expert categorization on problems that reflects a better mastering of the underlying mathematical notions. Students are encouraged to reelaborate the notion's representation, which leads to recategorize it. Based on recategorization principle, this method is applied on problems involving the distributive property. The distributive property problems admit two solving strategies whose preferential use depends on the representation built by the solver.

## An induced representation

Phrasing of mathematical word problems can influence the induced representation of the problem by students (Vergnaud, 1982; Hudson, 1983; De Corte, Verschaffel \& De Win, 1985). But in addition to linguistic features, semantic effects also rely on semantic relations or scenario depicted in the problem: when solving a word problem, students build a mathematical representation based on semantic relations inferred from real-word objects (Bassok \& Olseth, 1995, Bassok, Chase \& Martin, 1998). For instance, a problem involving apples and baskets is likely to evoke the asymmetric "contain" relation. So students align this semantic relation with structurally analogous mathematical relations: apples and baskets support the semantic relation contain (content, container) and thus the mathematical relations of division (dividend, divisor). This spontaneous encoding of problem situations results from the properties and relations of the entities or objects depicted in a problem. Semantic alignment, namely alignment between the semantic and mathematical relations, influences the difficulty of mathematical problems.
A way to study this effect of semantic content on the spontaneous encoding is to use problems solvable by two strategies. Indeed the semantic context can influence the encoding of the problem and thus lead to a preference for one of the two strategies. Several studies showed that the variable involved in the problem impacts the problem's representation built by the solver (Bassok et al., 1995; Vicente, Orrantia \&Verschaffel, 2007; Gamo \& Sander, 2010). In Gamo et al.'s study, 4th and 5th grade students had to solve isomorphic problems involving one of the three following variables - the number-of- elements, price, and age -. This type of problem ("Antoine took painting courses at the art school for 8 years and stopped when he was 17 years old. Jean began at the same age as Antoine and took the course for 2 years less. At what age did Jean stop?") can be solved by two strategies: a "complementation" strategy (in three steps: $17-8=9 ; 8-2=6 ; 9+6=15$ ) and a 'matching'" strategy (in one step: $17-2=15$ ). But the variable involved in the problem fosters one of the two representations of the problem: (a) a part-whole schema that
underlies unordered units which triggers the computation of the difference between the part and the whole given in the first half of the problem; and (b) a comparison schema that underlies ordered units. Number-of-elements problems are spontaneously encoded according to the part-whole schema and lead to the complementation strategies whereas the age problems foster the matching strategy but not exclusively.

## Cognitive flexibility in problem solving

Even after instruction, non-relevant representations remain: experts do not systematically use the most efficient strategy when solving arithmetic problems (Star \& Newton, 2009) even though they master it. Therefore, arithmetic problem solving raises the question of the influence of problem representations on the possibility to choose flexibly the most efficient strategy. Cognitive flexibility seems to be critical while solving problems (Clement, 2006). Indeed, it refers to the ability to select adaptively among multiple representations of an object, perspectives or strategies in order to adjust to the demands of a situation (Cragg \& Chevalier, 2012; Diamond, 2013). Through the problem of 'water-jug measuring problems' (Luchins, 1942), Clement (2006) proposed the concept of representational flexibility in problem solving: following an impasse situation, individuals recode the situational properties and adopt a new representation that leads to transfer the right strategy. Hence, cognitive flexibility is related both to abstraction and transfer. Cognitive flexibility can therefore be measured through the mastering of multiple strategies and of their appropriate use (Rittle-Johnson \& Star, 2007; Star \& Seifert, 2006). Students with high flexibility in problem solving are more likely to adapt existing strategies when faced with unfamiliar transfer problems and to better understand domain concepts (Hiebert \& Wearne, 1996; Rittle-Johnson \& Star, 2007).

## Recategorization in problem solving

Studies on cognitive flexibility in mathematics focused either on interpretation of the situation or on strategies (Heinze et al., 2009). Being able to adopt a multiplicity of categorization makes it possible to change point of view according to the needs of the situation. For example, a physicist who sees a glass falling down does not need to categorize a glass as a body under the law of gravitation and on which forces are exerted. Categorizing a glass only as "an object made of a fragile material" is sufficient to act in the appropriate way, namely to catch up the glass. Thus, the more an individual diversifies his repertoire of categorization, the more he is able to adopt different perspectives. By articulating different points of view on the same situation, the individual can embrace its complexity (Hofstadter \& Sander, 2013).

In the present study, we proposed to focus on recategorization as a mechanism to recode a representation and transfer the adapted strategy to a new context. Evidences from social psychology showed that if an individual seems to be inconsistent with his/her category
membership, perceivers would integrate other information and recategorize the individual in the newly applied category (Gawronski \& Creighton, 2013). When it comes to solving problems, a same situation or entity can be categorized at different levels of abstraction in multiple ways. The categorization adopted has been identified as an indicator of expertise. For example, in physics, novices categorize problems according to the objects used (problems of pulley or inclined planes), while experts categorize problems according to the physical principle (e.g. Newton's third law) (Chi, Feltovich, and Glaser, 1981, Chi et al., 1989). Unlike the experts, the novices therefore construct their categories mainly on the basis of superficial information, such as specific objects (Schoenfeld \& Herrmann, 1982). Experts rely on a greater number of categories and levels of categorization than novices to represent a situation. Since novices use some superficial cues, they can make negative transfers, using an irrelevant strategy by analogy with a problem that share the same superficial traits (vocabulary, object, theme) (Chen, 2002). Teaching to recategorize in a relevant manner seems to be a lever to develop students' ability to transfer strategies.

Thus, training cognitive flexibility is a challenge for developing learning method. Teaching experiments in mathematics mainly studied number calculations: multidigit addition and subtraction (Carpenter et al., 1997), decomposition (Klein, Beishuizen, \& Treffers, 1998) and linear equations (Rittle-Johnson \& Star, 2007). Evidences have therefore been obtained for the algorithmic aspects but are sparser when it comes to word problems. One method consists in comparing two strategies for the same problem (Brissiaud, 1994). Gamo et al. (2010) proposed a training method in order to develop mathematical concepts through the semantic recoding of the word problem. The principle is to recode the semantically induced structure into a more apt mathematical structure. By recoding the problem, the students adopts a new point of view, which leads them to develop a representation of the problem that corresponds to the mathematical structure and succeed to use more expert solving strategies. In Gamo et al.'s study, students in Grade 4 and 5 had to solve problems sharing the same deep structure but being spontaneously categorized as problems solvable by complementation strategy and not by the most efficient one (the matching strategy). During the training session, students compared the problems to stress the common structure. At post-test, students improved their use of matching strategy. Whereas interpretation initially realized at a level of abstraction based on the semantic structure, students acquired an additional degree of abstraction based on the mathematical structure, after semantic recoding. Comparison fosters a more abstract representation of the problems.

## The present study: a training method based on recategorization

Because of the lack of understanding of abstract ideas, when they are not operationalized (Willingham, 2009), and
the difficulties of transferring solving strategies (Ross, 1984), the learning method to develop students' cognitive flexibility is applied in a specific school context: word arithmetic problems on the distributive property. This type of problems -listed in the French curricula in $4^{\text {th }}$ and $5^{\text {th }}$ grade- has the methodological interest to be solvable by two strategies. Moreover, the nature of the variable involved in the problems favor one of the strategies (expansion or factorization) (Sander, 2008; Moreau \& Coquin-Viennot, 2003).

The main goal of this method is to allow students to overcome the spontaneous encoding of problem situations. In order to develop learning methods favoring abstraction, while taking into account the difficulties of transfer, the training of recategorization was conducted through a semantic analysis and was supported by an explicit method built with students. This method consisted in allowing students to switch between two conceivable points of view on the same situation. Then they were prompted to choose their own one. This choice of point of view by students is related to a reflexive level and is consistent with previous work (Siegler, 1999; Blöte, 2001) that stressed the flexible use of strategies and encouraged students to think about the value of different procedures for solving a given problem. The different steps of the experimental training are detailed in Method, Training sessions.

## Hypothesis

We therefore hypothesized that the experimental training method should favor students' cognitive flexibility on a mathematical concept- the distributive property- involved in arithmetic word problems.

Students should be able to adopt the two points of view on the problem and use the two strategies (expansion and factorization) without depending on the semantic context. For the training problems, no significant difference in factorization and dual strategies use between the two groups should be observed, since they are both trained to solve this kind of problems (Hypothesis 1). Yet, the experimental method based on recategorization should favor far-transfer compared to the traditional method. Thus the experimental group should propose significantly more factorization and dual strategies than the control group at the post-test and higher progression should be observed for the experimental group for the non-trained problems (Hypothesis 2).

## Method

## Participants

The experiment was conducted with eight classes from four elementary schools located in high-priority education network in Paris region during regular classwork school hours. 142 students took part in the study: 74 were fifth graders and 68 were fourth graders (mean age $=10$ years and 3 months, $\mathrm{SD}=6$ months, 78 boys, 64 girls).

The experimental group included 66 students ( 375 th graders from 2 classes and $294^{\text {th }}$ graders from 2 classes. The control group included 76 students ( $375^{\text {th }}$ graders from

2 classes and 39 were 4th graders from 2 classes).

## Design

The experiment included three phases: pretest, training sessions, post-tests. The pre- and posttest were strictly identical. Both the experimental group (EG) and the control group (CG) followed training sessions taught by the experimenter. Within each group, training sessions were identical in their duration, organization and problems statements.

## Material

## Pre and post-tests

The material was composed by 8 isomorphic distributive word problems (Table 1) and 5 filler problems. Indeed, filler problems were proposed between distributive problems, in order to make the structural similarities between the distributive problems less salient for the students.

Each distributive problem describes a situation involving one factor and three summands. The final question whose structure is "How much/many ... in all?" was placed at the end of the text. Two main solving strategies make it possible to reach the solution: Expansion strategy (sum of each part multiplied by the factor: $4 \times 6+$ $4 \times 7+4 \times 8$ ) and Factorization strategy (sum of the parts, then multiplied by the factor: $(6+7+8) \mathrm{x} 4)$. We selected four different variables (Numbers, Duration, Price, Weight). For each variable, a statement whose summands are said specific categories and a problem whose summands are called general categories were proposed (Table 1). The summands of the specific category problem are grouped at a base level, while those of the general category problem at a more abstract level than the base level (in the context of a treat cone, 3 balloons, 8 cookies, 4 figurines or 7 lollipops, 8 8 candies, 3 chocolates). So summing them as a whole is easier for specific than general category, and could influence the strategy.

The distributive problems were constructed by controlling the familiarity of the vocabulary and the numerical values at stake. The numerical values had different features in common in order to limit numbers' effects. Factor value was between 4 and 8 ( 5 was excluded since the associated multiplication table is easier). The three summands were between 2 and 8 ( 5 is excluded). Their sum lied between 11 and 21. And the result was inferior to 100 (between 72 and 98 ) in order to control the level of calculation difficulty.
A pedagogical advisor of the French National Education was involved in the conception of all sessions, in order to assure ecological material and ecological pedagogical acts. Therefore, 8 booklets were constructed by controlling the numerical values, the order of presentation of the problems variable and problems versions. On each page of the booklet, the problem was presented in written form with two sections in order to propose two strategies. The instruction for solving the problem with two strategies was both orally given by the experimenter and written on each page:

| Variables | Duration | Numbers | Weight | Price |
| :---: | :---: | :---: | :---: | :---: |
| Context | X has made a list of purchase for y years. Each year, X's purchases are: | X wants to prepare a treat cone per child. There are y children. Making a treat cone requires the following items: | X wants to fill his/Her pencil case with items that weight y grams each. <br> In the pencil case, there are: | $X$ is at the checkout of a supermarket. He bought some items. For each item, he took y in his basket: |
| Specific Categories | Printers <br> Computers <br> Scanners | Lollipops <br> Candies <br> Chocolates | Pens <br> Gums <br> Markers | Buns Cakes Pies |
| General Categories | Microscopes Desks Hamsters | Balloons <br> Cookies <br> Figurines | Shells, Key-rings Candies | Ice Plants Plates |
|  | In all, how many purchases has X bought? | In all, how many objects does X need? | In all, how much does these items weight? | In all, how much did X spend? |

Table 1: The 8 problems at pre and post-tests

Write all your calculations and the result in the following section:

Do you see any other method to come up with the same result? If yes, write it down while writing all calculations you performed to find the result.

Tests lasted 45 minutes. Students were given 3 minutes to solve each problem. Students were instructed that they could ask the experimenter or the teacher to read aloud the problem in order to bypass reading difficulties, and that they had to write down all calculations. When the time was over, students had to turn the page and begin the new problem when the experimenter gave the instruction. They could not modify their answer once they turned the page.

## Training sessions

Training sessions took place in 5 sessions over 5 weeks ( 45 minute session each week) for each class (Table 2).

Usual French textbooks inspired the pedagogical method used by the control group for Grades 4 and 5 (Vive Les Maths and Companion Math). The experimental method was built for this study. The two approaches did only differ in their treatment of the problem. In the control group, students learnt to select relevant information in statements and choose operations. And the experimental group looked for the semantic relations (the sum of the parts forms a whole) and chose the point of view it wished to adopt. For instance, one of the training problem was the following: « $A$ team of 5 athletes participated in a relay: each athlete ran on a loop of 8 km , then on a straight line of 2 km and finally on a loop of 6 km . How many kilometers has the team traveled? »
To find the number of kilometers, two strategies are possible. Experimental group learnt to choose between:

- adopting the point of view of each part of the relay (loop and line): each loop/line is a separate part and we realize an expansion strategy: $5 \times 8+5 \times 2+5 \times 6=80 \mathrm{~km}$
- adopting the more abstract point of view of the relay: the different parts (loops and line) form the relay, we carry out a factorization strategy: $(8+2+6) \times 5=80 \mathrm{~km}$

Thus whereas categorizing each addend as a part leads to an expansion strategy, categorizing them as a whole leads to a factorization strategy.

Regarding all other aspects, session organization was similar between the two groups: students began by exercising on the slate, in order to engage them in the task.

Then the students had to answer on an exercise sheet, whose support was also projected on the blackboard. Finally, students ended the session by answering the question "What did I learn today? " and then a general conclusion was proposed by the experimenter and was written by the students. The distributive problems studied in the sessions 3, 4 and 5 were identical between the two groups and involved only two types of variables: Number-of-Elements and Distance.

## Coding and scoring

For pre and post-test, problems were analyzed under two criteria:

- the use of factorization strategy (correct reasoning and calculation) to solve the problem as a first or second strategy
- the use of double strategy (reasoning and correct calculation)
Then a global improvement score was calculated. At pre and post-test, each problem was coded as 1 when it was solved by an expansion, by 2 when it was solved by a factorization, by 4 when it was solved by dual-strategies and 0 if otherwise. Then the difference between post and pre-test was computed. Each student got therefore an improvement score, reflecting his/her progress between the pre and posttest.

## Results

Hypothesis 1 stated that the frequency of factorization and dual-strategies by students was not expected to be different between the two groups for the training problem (Number-of-elements) due to the effect of training in both groups. The improvement score was 0.34 for the control group and 0.37 for the experimental group ( $\mathrm{p}>0.5$ ) for factorization strategy and 0.30 for dual-strategy for each group $(\mathrm{p}=1)$.

|  | Experimental Group | Control Group |
| :---: | :---: | :---: |
| Session 1 | A problem: way of seing a situation, parts and whole | A problem: a question, useful data, operations |
| Session 2 | Multiplication and commutativity by semantic recoding | Multiplication and commutativity by repeated addition |
| Session 3 | Distributivity: semantic relations and choice in point of view | Distributivity: useful data and choice in operations |
| Session 4 | Dual strategies <br> by change in point of view | Dual strategies <br> by equivalency of procedures |
| Session 5 | Distributivity problems: choice in points of view | Distributivity problems: useful data, operations |

Table 2: The training sessions

|  | PreTest |  | PostTest |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Factorization | Dual Strategy | Factorization | Dual Strategy |
| CG | $0.14(0.24)$ | $0.05(0.14)$ | $0.47(0.40)$ | $0.36(0.40)$ |
| EG | $0.18(0.27)$ | $0.07(0.18)$ | $0.63(0.38)$ | $0.47(0.43)$ |

Table 3: Means (and SD) of factorization and dual strategy frequency by students at pre and post-test in use of in the experimental group and control group

## Discussion

This absence of difference between the two groups for the trained problems reflects the similarity in terms of learning method between the two groups: they both learned to use dual-strategies (expansion and factorization) for the distributive problems. The control group focused on relevant information in statements, digits and operations whereas the experimental group focused on semantic relations, words and point of view. At the pretest, repeated measure ANOVAs with group as the between factor and problem variable as the within-subjects factor showed that there was no difference regarding the use of factorization ( $\mathrm{F}<1, \mathrm{~ns}$ ) or dual strategies, ( $\mathrm{F}<1$, ns). Both groups showed the same pattern of choice of strategies for each type of problem.

Hypothesis 2 stated that a better transfer should appear in the experimental group for non-training problems. At the posttest, reapeated measure ANOVAs with group as the between subjects factor and problem variable as the withinsubjects factor were performed: the experimental group was significantly superior to the group control for the use of factorization $(\mathrm{M}=0.63$ vs $\mathrm{M}=0.47 \mathrm{~F}(1,140)=6.15, \mathrm{p}=0.01)$ and we observed a marginal trend for the use of dual strategies $(\mathrm{M}=0.47$ vs $\mathrm{M}=0.36, \mathrm{~F}(1,140)=2.72, \mathrm{p}=0.1)$ (Figure 1 and Table 3).

Then we analyzed the improvement score. The global improvement score raised 1.46 for the experimental group and the control group's one raised 1.10. A repeated measure ANOVA was performed. The difference in improvement between the groups got a statistically significant trend $(\mathrm{F}(1,140)=3.5, \quad \mathrm{p}=0.06)$. For problems from general category, we observed an improvement score by 1.59 for the experimental group compared to 1.10 for the control group. A repeated measure ANOVA was performed (Table 4). Therefore, the improvement score for the more abstract problems (general category) was significantly higher for the experimental group $(\mathrm{F}(1,140)=6.12, \mathrm{p}=0.014)$.

Figure 1: Mean in factorization by students at Post-Test

The learning method based on both the resolution strategy comparison and the explicit analysis of semantic relations during classroom activities showed its success in promoting transfer. The experimental group was more successful in transferring the factorization strategy and dual strategies to non-trained problems in the post-test. The Price, Duration and Weight variables in post-test problems had not been trained during the learning sessions. The progression in terms of factorizing strategy and dual strategy suggests that the experimental group became less dependent on the choice of the variable than the control group. That means that the experimental group shows a greater ease in independence to context. They were successful switching from the spontaneous representation influenced by the variables of the problem to flexible representation based on the mathematical structure. Since progress for trained problems are similar between groups, the added value of the recategorization method lies in the success of far transfer.

The use of isomorphic problems made it possible to identify more precisely the robustness of the transfer effects from the learning method. Indeed as we studied the nontrained problems, the greater progression for the experimental group shows that the training was not superficial. This transfer reflects a semantic change by students that could adopt a double point of view on the problem.

In addition, our findings support the work of Vicente et al. (2007) who pointed out that the difficulty for students lies in developing the conceptual relations between the entities of the problem. Thus, in their study, the success rate of problems whose rewording shed light on "part-whole" relationships was higher than problems with additional information about the problem's situation. The properties and relations of the entities or objects depicted in a problem are therefore key in the choice of strategies. In our study, we did not use a conceptual rewording that underlines the underlying semantic relations but the experimental method consisted in orienting students to establish these relations because their categorizations of the elements of the problems were based on them.

## Conclusion

The students from the training group became less dependent from semantic context. Their choice of strategy was less constrained by the nature of the variable. The substantial transfer of the non-preferred strategy (factorization) illustrates the ability to adopt a new point of view on the situation. Thus students were able to change their encoding based on spontaneous representations to an encoding based on conceptual relations. To adopt this flexible and multiple
points of view on a problem, the training method based on recategorization seems to be promising. In addition to improve semantic analysis, students were encouraged to adopt a reflexive attitude thanks to the notion of point of view. Thus students developed their cognitive flexibility: developing flexible strategies with the ability to transfer them to new problems. Yet studying the extent of this transfer could be the goal of further research. The teaching method appears to be a useful framework to identify if cognitive flexibility is domain-general or domain-specific. Indeed, fostering cognitive flexibility takes part of a broader goal, namely promoting conceptual development.

# Aging of the Exploring Mind: Older Adults Deviate more from Optimality in Complex Choice Environments 

Job J. Schepens<br>(job.schepens@fu-berlin.de)<br>Center for Cognitive Neuroscience Berlin<br>Freie Universität, Berlin 14195, Germany<br>Ralph Hertwig, Wouter van den Bos<br>(\{hertwig, vandenbos\}@mpib-berlin.mpg.de)<br>Center for Adaptive Rationality<br>Max Planck Institute for Human Development, Berlin 14195, Germany

#### Abstract

Older adults (OA) need to make many important and difficult decisions. Often, there are too many options available to explore exhaustively, creating the ubiquitous tradeoff between exploration and exploitation. How do OA make these complex tradeoffs? We investigated age-related shifts in solving exploration-exploitation tradeoffs depending on the complexity of the choice environment. Participants played four and eight option bandit problems with numbers of gambles and average rewards available on the screen. OA reliably performed worse in a more complex choice environment and were also more deviant from an optimality model (Thompson sampling), which keeps track of uncertainty beyond just the mean or last reward. OA seem to process important information in more complex choice environments sub-optimally, suggesting limited representations of future rewards. This interpretation fits to multiple contexts in the complex cognitive aging literature, in particular to the context of challenges in the maintenance of goal-directed learning.

## Introduction

In today's aging societies, more and more older adults (OA) are making cognitively demanding decisions about work, finances, their health, etc. Many such decisions benefit from thinking about future goals because the options available create explore-exploit tradeoffs. How do OA usually respond to these cognitive challenges in increasingly complex choice environments?

Decision makers generally have access to a number of learning mechanisms, habitual experience-based learning, and goal-directed learning. Goal-directed learning depends on some internal model, so that learning can be adapted flexibly, for example like when managing a research project. Habitual learning has been related to a dorsolateral striatal to sensorimotor cortex control loop while goal-directed learning has been related to a dorsomedial striatal to ventromedial and lateral prefrontal cortex control loop (Daw \& O'Doherty, 2014). Importantly, goal-directed learning is impaired in OA and this impairment has been associated to lower activation in prefrontal cortex areas (Eppinger \& Bruckner, 2015; Eppinger, Walter, Heekeren, \& Li, 2013). OA rely relatively more often on experience-based learning, which may arise from white matter integrity changes in the ventromedial and lateral prefrontal cortex (Chowdhury et al., 2013; Eppinger et al., 2013; Samanez-Larkin \& Knutson, 2015).

It is unclear how such changes in learning mechanisms in OA depend on the relative complexity of a task. Such a dependency would be likely, however, from the perspective of ecological rationality (Mata et al., 2012), which focusses on adaptation effects between the mind and the environment. For example, when OA need to explore among many options in order to choose between them later, OA rely on more minimal exploration strategies than YA (Frey, Mata, \& Hertwig, 2015). Here, we study such age-related performance changes in explore-exploit tradeoffs with varying cognitive demands. Analyzing effects of the complexity of choice environments this way could help to better understand the effects of task demands on age-related changes in learning mechanisms.

We used typical N -armed bandit problems to study changes in learning mechanisms across choice environments. Participants made inferences about risky options by sampling information from a four and eight option choice environment. Rewards were consequential, ensuring that participants needed to trade-off exploration and exploitation. Participants had to find options that give them the most money while having to minimize sampling from low reward options. N -armed bandit problems are well studied and afford detailed analysis of information processing in terms of continuation and switching behavior. Theoretically, expectations of future reward should rise with adequate, but not excessive, exploration. Such "smart" exploration requires one to have a good representation of the task and its structure, which typically weighs already observed rewards by the degree to which an option has been explored. This would thus involve an internal model of the task contingency between average payoff and average payoff uncertainty (see also Worthy, Cooper, Byrne, Gorlick, \& Maddox, 2014). Good performance in the task thus depends on learning mechanisms that use adequate future reward representations while performance anomalies will involve inadequate future reward representations.

We hypothesized that OA achieve lower performance and arrive slower at the higher reward options, depending on the number of options. If OA focus more on reward in current states, their rewards in future states should suffer. Such shortterm planning would more closely resemble experience-based learning rather than goal-directed learning. OA not arriving

Figure 1: Example eight-option choice profiles. Green indicates rewards and red indicates no rewards on a trial.
at the higher reward options at all would show a lack of an explore-exploit trade-off. We assumed that problems with a larger number of options are relatively more cognitively demanding because of a larger search space, which increases the amount of necessary information processing and representation.

Next, we describe methods and results from six kinds of data analyses: choice proportions statistics, choice proportions over trials, regret over trials, comparisons to an optimality model, comparisons to a fitted optimality model, and one-step ahead predictions of a fitted optimality model. We end with a discussion.

## Methods

Participants 32 older adults ( $\mathrm{OA}, M_{\text {age }}=70.5,65-74,38 \%$ female) and 29 younger adults (YA, $M_{\text {age }}=24.3,19-30$, 45\% female) participated in this study. All participants were healthy, right-handed, native German speakers with normal or corrected to normal vision, and without a history of psychiatric or neurological disorders. There were no group differences in gender proportion, educational level, and socioeconomic status. Compensation amounted to about 10 Euro per hour, plus on average 2 Euro performance-dependent bonus. Participants were recruited using advertisements.

Task The task of the participants was to maximize the sum of rewards in a total of 16 alternating four and eight-armed bandit problems. Rewards could be earned by selecting pictures of casino-style gambling machines presented on a computer screen using a keyboard or mouse. The gambling machines provided random rewards ( 1 or 0 ) with a hidden probability that was specific to each machine. The rewards were displayed on the respective bandit after each play. Participants had 100 trials for every problem to explore the hidden reward probabilities and to exploit those machines that give rewards most often. Remaining trials were displayed on the screen. Also, every bandit showed the number of plays so
far and the probability of a reward based on the observed rewards so far. This information is sufficient to make an optimal choice at any point in time, reducing the role of working memory. Of course, participants still need to figure out how they want to trade off exploration and exploitation. $89 \%$ of YA and $70 \%$ of OA ( $\mathrm{p}=.14$, test of equal proportions) indicated in a post-task questionnaire that "the extra information regarding the options" was helpful.

Procedure Participants were instructed 1) to maximize the sum of rewards, 2) how the task looked and worked, 3) that each trial is independently generated, and 4) that the best gambling machine in every individual problem had $p_{\text {opt }}=.6$ (to help comparability across problems). All participants had taken part in an unrelated fMRI study on risk-taking preference several weeks beforehand. Ethics approval was granted by the Institutional Review Board of the Max Planck Institute for Human Development.

Design The experiment made use of a repeated withinsubject condition (four vs eight options), and a betweensubject condition (age group). We chose the other hidden probabilities in steps of .075 below .6. Reliably finding the better options thus required a significant part of exploration out of the 100 available trials. See also Figure 1 for example choice profiles and the unique hidden probabilities. All participants saw the same randomly generated rewards for all 16 problems. This allowed comparison of the problem difficulty across participant groups as well as a reduction of an unnecessary source for variance in performance while keeping the probabilistic character of the task intact. Four different problem orders were generated and counterbalanced across participants. Two different orders started with four options and two different orders started with eight options. Between problems, performance was displayed on the screen and a keypress was required to continue with the next problem. Participants in both groups took about half an hour to

Figure 2: Predictions from a mixed effects model with the hidden reward probabilities of participant's choices as dependent variable and interaction effects between age, number of options, trial, and gender.
finish the experiment. The minimum response time was set to 200 milliseconds.

## Results

We first investigated age-related differences in task performance. Proportions of choices for each option revealed that OA chose the option with the highest hidden probability about $5 \%$ less often than YA did in both four and eight option conditions (four option 95\% HDI: .003-.093; eight option 95\% HDI: . 018 - .096; Bayesian ANOVA with logit function and broad prior), see Figure 4 for the differences for all options. We also tested a linear mixed effects model with the hidden probability of every chosen bandit as dependent variable and with participant ID, problem ID, and bandit position ID as random effects. We used Satterthwaite's approximations of p-values ( ${ }^{* * *}$ indicating $\mathrm{p}<.001$ ). We found negative interaction effects for OA in eight options $\left(\mathrm{B}=-.021^{* * *}\right)$ and for OA in eight options over trials ( $\mathrm{B}=-.011^{* * *}$ ). Together, these indicated a lower performance for OA in eight options, as well as an increasingly lower performance over trials. We also found a positive interaction effect for both YA and OA in eight options over trials ( $\mathrm{B}=.021^{* * *}$ ), as participants could improve relatively more over time for eight options. There still was a main negative effect of eight options ( $\mathrm{B}=-.092^{* * *}$ ) and a main positive effect of trial number ( B $=-.009 * * *)$. No significant difference or decrease over trials for OA remained, so the age effect is captured only by the higher-level interactions. Furthermore, we also controlled for gender effects, which indicated that male OA performed better over trials $\left(\mathrm{B}=.010^{* * *}\right)$ and that male OA performed better with 8 options $\left(\mathrm{B}=.024^{* * *}\right)$, and that males generally performed better $\left(\mathrm{B}=.003^{* *}\right)$. For visualizing these high level interactions, we generated predictions from this model using the package merTools, see Figure 2 Note that the visualization does not show raw data and that the differences in intercepts and slopes for the lines displayed should be inter-

Figure 3: Predictions from a mixed effects model with switching as dependent variable and three-way interaction effects between age, number of options, trial, reward, and the hidden probabilities of participant's choices.
preted in the light of all data included in the model. Besides performance, we used a similar statistical analysis to test age differences in switching probability over time. The resulting logistic regression model included age, number of options, trial number, the hidden probability, the reward for the participant's choices, and all three-way interactions. Together, the estimated effects on switching indicated that OA switch less often (**), OA switch away less often after sampling from an option with a relativey low hidden probability ( ${ }^{* * *) \text {, espe- }}$ cially in eight options over trials $\left({ }^{* *}\right)$. Beta's were not easily comparable for this model. We again generated predictions from this model to visualize these switching patterns, see Figure 3

Second, we examined development of age-differences in choice proportions over trials, see Figures 6 a and 6 b. For every trial, the solid lines represent the average number of times that participants chose an option. The local instabilities in the trajectories may result from individual differences and variation across the several problems. On average, the third best option stops overlapping with the second best option after about 25 trials for YA. For OA, the same separation exists between the second and third option after twice as many trials, see the right panel of Figure 6 In the eight option condition, YA separate between the better three options and the worse five options after about 50 trials. OA do this after about 75 trials. These 2-2 and 3-5 separations could reflect the participants' psychologically most salient explore-exploit representations. Together, the choice trajectories show that already from the beginning onwards, YA choose more often from the better options.

Third, we analyzed another measure of performance to compare performance across all of the options at once. We

Figure 4: Boxplots of variation in average choice proportion across participants for both choice environments.
choose to measure regret (a common measure in machine learning) as it generalizes over the specific outcomes of the random number generation process. Regret can be computed as $R_{T}=\sum_{i=1}^{100}\left(p_{\text {opt }}-p_{B(i)}\right)$, where $p_{\text {opt }}=.6$ and $p_{B(i)}$ is the hidden probability of a reward for the chosen bandit. It follows that randomly behaving agents get a total regret of 11.25 points for four options and 26.25 points for eight options. Overall, the age effect on regret was large ( $\mathrm{p}<.01$, Cohen's d .707) for eight options ( $M_{O A}=19.87, S E=.79, M_{Y A}=16.84$, $S E .75$ ) and medium ( $\mathrm{p}<.05$, Cohen's d .550) for four options $\left(M_{O A}=9.16, S E=.32, M_{Y A}=8.17, S E .33\right)$. These agerelated differences varied slightly across the unique problems, which only differed by random number generation, see Figure 5. We also investigated how regret differences emerged using the shapes of the exploration-exploitation trade-offs over trials within the choice profiles. We observed a slowing increase in regret over time in general but increasing age-related differences for both conditions, see Figure 7. Age-differences became significant after trial 24 in eight options and 23 trials in four options. It seems that exploration in OA happens less effectively. Regret was significantly ( $\mathrm{p}<.05$, t.test) better compared to a random agent (four options: YA after trial 17, OA 32; eight options: YA after trial 15, OA 16).

Fourth, we wanted to know how participant performance differed from optimality. We used Thompson sampling as an optimality model (Thompson, 1933), but we observed that differences in regret for similar algorithms are small in the context of the present task. Thompson sampling uses an inverse cumulative distribution function (also known as percentage point function or quantile function) that is used to choose the bandit with the highest certainty that the hidden probability of a bandit is smaller or equal than some randomly generated value. This way, the algorithm minimizes uncertainty that there exists a better option by making sure that the probability of choosing a certain bandit is proportional to the probability of it being the best bandit. By taking uncertainty into account, the algorithm affords a way of more rapidly adapting its decision if not only the mean of a certain

Figure 5: Variation in performance across the 16 different problems in the task.
bandit gets overtaken by another mean, but the whole posterior probability distribution. Conceptually, the algorithm keeps track of beliefs about the hidden probabilities of the bandits and then updates these beliefs each time after seeing an outcome. The algorithm is initialized by setting a uniform prior for all options. The algorithm then plays option x proportional to the probability of it being the best. Finally, it updates its priors using the newly collected information. See also Table 1 Regret as computed from applying Thompson sampling 29 times to the same games as participants played was significantly worse compared to participants (four options: YA after trial 14, OA 11; eight options: YA after trial 16, OA 16). Expected regret was 6.5 points for four options and 11.0 points for eight options, which is considerably better than YA performed on average ( $170 \%$ larger than the gap between YA and OA for four options and $193 \%$ for eight options). Interestingly, 5 out of $32 \mathrm{OA}(16 \%)$ and 9 out of 29 YA ( $31 \%$ ) achieved a median regret score within $10 \%$ of Thompson sampling for four options, while this was 1 (3\%) and 4 (14\%) for eight options. Some individuals were thus able to achieve regret scores similar to Thompson sampling.

Table 1: Thompson sampling in r pseudocode, with n being the number of bandits, $x$ a randomly generated probability, and qbeta for looking up quantiles from the Beta distribution.

| Step | Computation |
| :--- | :--- |
| Init | wins $=\operatorname{rep}(0, n)$ |
|  | pulls $=\operatorname{rep}(0, n)$ |
| Choose | softmax $(q, \theta)$ |
|  | $q=\max (q$ beta $(x, \alpha, \beta))$ |
| Update | wins $=$ wins + reward |
|  | pulls $=$ pulls +1 |
|  | $\alpha=1+$ wins |
|  | $\beta=1+$ pulls - wins |

Fifth, we wanted to know how well a fitted optimality model predicted participant's decisions. Thompson sampling

Figure 6: Observed choice proportions and one-step ahead predictions for fitted Thompson sampling. The color of the lines corresponds to the value of the hidden probabilities, where blue colors represent lower probabilities. Local polynomial regression was used as a moving window to smooth the trajectories (using a neighborhood of $40 \%$ of all points where neighboring points are also being weighted by their distance tricubically)
was fitted to individual games by scaling predicted choices using a softmax function with a fitted inverse temperature parameter $\theta$, ranging from 0.003 to 30 (higher $\theta$ values produced more randomness). OA deviated more from fitted Thompson sampling than YA did ( $\mathrm{p}<.05$, Wilcoxon tests, Cohen's d = . 57 for four options and Cohen's d $=.53$ for eight options). $\theta$ was also significantly lower for YA than for OA ( $p<.05$, Wilcoxon test, Cohen's d $=.96$ for four and 2.68 for eight options), indicating more randomness and worse matches to predictions of Thompson sampling in OA than in YA. OA and YA both significantly decreased their median $\theta$ for eight options compared to the four option condition ( $\mathrm{p}<.05$, Wilcoxon tests), see Figure $8 \theta$ for OA significantly varied more in both conditions than for YA ( $\mathrm{p}<.01$ for both conditions, Wilcoxon tests) and average variation across games was significantly lower in four options for YA, but for OA this was similar in both conditions ( $\mathrm{p}<.01$ vs. $\mathrm{p}=.4$, Wilcoxon tests). In all, OA adults were more random and less homogeneous, possibly indicating more strategy changes.

Finally, we compared the shapes of the mean observed exploration-exploitation trade-off trajectories to shapes from one-step-ahead predictions across all trials. These predictions are plotted in Figures 6 a and 6 b using dashed lines. We used the median $\theta$ of every participant for both conditions as data scaling parameter. The predictions from this fitted Thompson sampling model resulted in accurately ordered trajectories for both groups and for both conditions: The orderings of solid and dashed lines were identical for all four graphs for most trials, except in the first few trials. The latter may indicate more rapid exploration in Thompson sampling and that both YA and OA explore less rapidly, with OA taking the longest.

## Discussion and Conclusions

We aimed to identify changes in the ways OA and YA make goal-directed choices depending on the complexity of the
choice environment. We found a large age-related effect on performance in a typical eight-armed bandit task and a smaller effect in a four-armed bandit task. YA also deviated less from optimality than OA did. Choice trajectories showed that age effects were already observable in the early exploration stage, suggesting that OA explore longer or less efficiently. Theoretically, the early stages require fast exploration using not only average rewards but also their associated uncertainty. This was illustrated here using Thompson sampling, which is a kind of randomized probability matching algorithm. Participants diversified their choices similar to Thompson sampling, in line with previous work (Konstantinidis, Ashby, \& Gonzalez, 2015; Speekenbrink \& Konstantinidis, 2015). Furthermore, OA had higher and more variable inverse temperature parameter estimates across choice environments, indicating more randomness in OA. OA thus rely on less effective learning strategies that consider important information less effectively, in particular in the more complex environments.

Why would OA fail to represent important information like uncertainty or a specific task model? The role of working memory influences should be minimal as this is not strictly necessary to perform well in the task. General "slowing", gender effects, and more cautious risk taking, all of which could favor exploitation of short-term rewards, also mark cognitive aging. We did indeed observe gender interactions, age-differences in reaction times, and in standard neuropsychological test results (working memory, fluid intelligence, and risk-taking). However, as performance is mainly determined by a cognitively costly explore-exploit tradeoff and adequate future reward representations, our findings specifically point towards underreliance on goal-directed learning.

A logical next step is to assess if fits of simple learning strategies can indeed better accommodate OA. Specifically, the exploration phase seems to happen sub-optimally in OA

Figure 7: Age-differences in the increase in regret at every trial with standard deviations displayed around the means (standard errors were too narrow to visualize). Regret increased quickly first and increased slower later on, but slower for YA.
and in a more varied way. Favoring short-term rewards could be a sign of a learning mechanism that sub-optimally represents future rewards. More varied or reduced processing of important information such as uncertainty would be able to account successfully for the observed age-related changes. Furthermore, if the task indeed probes OA to rely less on goal-directed learning, we may also expect differences in connectivity to prefrontal regions (pending analyses). In all, OA may be using less effective learning strategies the more demanding the choice environment becomes. Identifying such task-dependent differences is typically neglected in neuro-computational models of decision-making. In the context of cognitive aging, this may be useful for empowering aging decision makers to navigate cognitively demanding choice environments.

#### Abstract

A supporting effect of sleep on memory consolidation was reported for different contents. Here, we investigated the influence of sleep on the transformation of previously learned route and place knowledge into survey knowledge, a more abstract representation. The results support the assumption of both a consolidating as well as transforming effect: the wayfinding performance in the test session - namely the usage of unfamiliar shortcuts - suggests a consolidating effect of sleep.

# The roles of item repetition and position in infant sequence learning

#### Abstract

We examined mechanisms underlying infants' ability to detect, extract, and generalize sequential patterns, focusing on how saliency and consistency of distributional information guide infant learning of the most "likely" pattern in audiovisual sequences. In Experiment 1, we asked if 11- and 14-month-old infants could learn a "repetition anywhere" rule (e.g., $\mathrm{ABBC}, \mathrm{AABC}, \mathrm{ABCC}$ ). In Experiment 2 we asked if 11 - and 14-month-olds could generalize a "medial repetition" rule when its position is consistent in sequence, and in Experiment 3 we asked if 11 -month-olds could identify a nonadjacent dependency occurring at edge positions. Infants were first habituated to 4-item sequences (shapes + syllables) containing repetition- and/or position-based structure, and were then tested with "familiar" structure instantiated across new items or combinations of items vs. "novel" (random) sequences. We found that 11 -month-olds failed to learn the repetition rule both when the structure appeared in initial, medial, or final position (Experiment 1) and when it was restricted to the medial position (Experiment 2). Fourteen-month-olds learned repetition rules under both conditions. Finally, in Experiment 3 11-month-olds succeeded in learning a nonadjacent dependency in sequences identical to those used to test repetition learning in Experiment 2. Our results suggest that infants at 11 months, like adults, are relatively insensitive to patterns in the middle of sequences.

Keywords: infant learning; rule learning; sequence learning

## Introduction

In the present paper, we examine mechanisms underlying infants' ability to detect, extract, and generalize sequential patterns. Sequence learning is essential for processes ranging from the acquisition of language to everyday activities such as preparing for bed, learning to count, learning to read, and getting ready for school. Insights into development of sequence learning in infancy, therefore, are vital for theories of developmental and cognitive function across a variety of domains.

What kinds of learning mechanisms are available to infants, and what are the limits of these mechanisms? Our particular focus is on two means of knowledge acquisition, "statistical learning" and "rule learning": the extent to which infants can use transitional probability information among items to extract units from an unbroken stream of stimuli
(e.g., Saffran, Aslin, \& Newport, 1996) or the extent to which infants can distinguish simple reduplicative patterns from one another (e.g., Gerken, 2006; Marcus, Vijayan, Rao, \& Vishton, 1999), respectively. Sequence learning is guided by multiple mechanisms (Arciuli, 2017; Krogh, Vlach, \& Johnson, 2013; Thiessen, Kronstein, \& Hufnagle, 2013), and its development in infancy can be better understood by investigations of the salience and consistency of statistical and rule-governed structures (Aslin \& Newport, 2012, 2014). Some structures, such as identity relations or positions of items in order, might serve as "perceptual primitives," processed by specialized mechanisms to detect and remember specific features in patterned sequences (Endress, Nespor, \& Mehler, 2009).
The Saffran et al. (1996) transitional probability task, a well-known example of statistical learning, presented 8-month-olds an auditory stimulus consisting of four unique strings (e.g., tupiro, golabu, bidaku, and padoti) presented in random order as a continuous, unsegmented stream for 2 minutes. Infants then heard isolated strings in repetition (e.g., tupiro, tupiro, tupiro...) alternating with "part-word" strings composed of parts of two of the familiar words (e.g., rogola, rogola...) from a speaker located either to the left or right. Infants exhibited a postfamiliarization novelty preference for the part-words relative to the words, implying that they detected the differences in transitional probability across word boundaries in the input sequence.

Rule learning in sequential patterns was assessed by Marcus et al. (1999), who exposed 7-month-olds to strings that followed either an "ABA" pattern (e.g., gah tee gah) or an "ABB" pattern (e.g., gah tee tee). After 2 minutes of exposure, the infants heard the same (familiar) pattern instantiated by different phonemes (e.g., woh fei woh, dee koh dee), and a second (novel) pattern on alternating trials and showed a preference for the novel, a result that extended to a test of ABB vs. AAB. Because transitional probabilities between test-string syllables were zero, performance could not have been based on statistical learning.

Studies of infant rule learning have produced mixed results with respect to the learnability of a simple repetition rule (adjacent, as in AAB or ABB , or nonadjacent, as in ABA). Overall, the findings of these experiments seem to
differ based on how familiar the infants may be with the stimuli: 7-month-olds successfully learn ABA vs. ABB , $A B B$ vs. $A A B$, and $A A B$ vs. $A B B$ patterns when the stimuli are auditory (Marcus et al., 1999, 2007) or familiar visual stimuli (e.g., faces and animals; Bulf et al., 2015; Saffran et al., 2007). However, when stimuli consist of sequences of colored shapes, learning seems to be more difficult, perhaps because learning visual sequential input is constrained by limits in visual working memory (Johnson et al., 2009). In this case, 8 -month-olds learned a late repetition rule (adjacent repetition in the final edge position) when tested vs. nonadjacent repetition ( ABB vs. ABA ), but failed to learn late vs. early repetition ( ABB vs. AAB ), early vs. nonadjacent repetition (AAB vs. ABA ), and nonadjacent vs. late repetition (ABA vs. ABB ). Eleven-month-olds learned all these rules except nonadjacent vs. late repetition.

Adults' learning of repetition-based structure also appears to be constrained by position (Endress, Scholl, \& Mehler; 2005): Adults discriminated seven-syllable sequences from sequences of new items based on differences in internal vs. edge repetitions (e.g., ABCDDEF vs. ABCDEFF), but could only generalize when given edge repetitions. In summary, repetition structures in edge positions appear to be reliably learned by both infants and adults, but learnability of internal repetitions remains unknown for infants because the structures tested in previous structural learning studies only involved repetitions located at either the initial or final edge of the sequence ( $\mathrm{AAB}, \mathrm{ABA}$, and ABB ).

In Experiment 1, we asked if 11- and 14-month-olds can detect, extract, and generalize a "repetition anywhere" rule (i.e., $\mathrm{ABBC}, \mathrm{AABC}, \mathrm{ABCC}$ ). If infants detect repetition of items during a learning phase, they may subsequently recognize repetitions of new items (in new sequences), which we take as evidence for generalization. However, it may be that consistent position information is a key part of repetition learning at this age, as it appears to be for adults; in this case, variability in the position of the repetition might pose difficulty in its identification and recall.

In Experiment 2, we used a sequence with two possible underlying patterns to examine how consistency and salience contribute to sequence learning. In this experiment, we asked whether 11 and 14-month-olds could generalize a "medial repetition" rule when its position is consistent in sequence, but not at an edge. In Experiment 3, using the same sequence types as Experiment 2, we asked whether 11-month-olds could identify a nonadjacent dependency occurring at initial and final edge positions that may be more salient than the medial position of the repetition.

In all experiments we used an intermodal presentation method in which looming shapes were accompanied by spoken syllables, a method known to facilitate rule learning, relative to visual or auditory only, in 5- and 7-month-olds (Frank, Slemmer, Marcus, \& Johnson, 2009; Thiessen, 2012). Because infants as young as newborns look longer at randomly-ordered shape sequences vs. sequences with statistical structure (Addyman \& Mareschal, 2013; Bulf, Johnson, \& Valenza, 2011; Kirkham, Slemmer, \& Johnson,
2002), we reasoned that longer looking at novel vs. familiar sequences (i.e., random vs. structured, respectively) in the current studies would reflect learning and/or generalization of structural and/or statistical structure during habituation.

## Experiment 1

## Method

Participants Twenty 11-month-olds ( $M_{\text {age }}=11.25$ months; $S D=.297 ; 8$ girls $)$ and 2014 -month-olds $\left(M_{\text {age }}=14.20\right.$ months; $S D=.313 ; 9$ girls) participated. An additional ten 11-month-olds were tested but excluded for failure to habituate (7), fussiness (2), or preterm birth (1). an additional twelve 14 -month-olds were tested but excluded for failure to habituate (8) or fussiness (4).
Materials and Apparatus Visual stimuli consisted of 18 colored shapes (see Figure 1). Auditory stimuli consisted of an inventory of 18 spoken syllables produced with a speech synthesizer and identical to those used in Marcus et al. (1999) (e.g., bah, dee, doo, gei, jai, jah, kei, poh).

Figure 1: Schematic depiction of example habituation and test sequences for Experiment 1.

Shape-syllable pairings were determined randomly (see Figure 1). Sequences were assembled from a randomly chosen set of nine (out of the total 18) shape-syllable combinations (hereafter called "items" for simplicity), so that three items composed each four-item sequence by repeating one of the three items, either the first, second, or third (determined randomly) to yield a repetition in the initial, medial, or final position. Items always appeared in the same order within each habituation sequence.
Procedure Stimuli were presented using Macromedia Director on a Macintosh computer and a 53 cm color screen. In a separate room, the experimenter used closed-circuit video to view the infant and record his or her looking times during the experiment; the experimenter was blind to what was being presented on the screen. Before each habituation trial, a visual attention-getter appeared in the center of the screen to draw the infant's attention. Each shape was presented on a black background and increased in size from 4 cm to 24 cm high (2.4-14.6 ${ }^{\circ}$ visual angle) over a period of 667 ms ; onset of syllables ( M duration 338 ms ) was coincident with the appearance of each shape. Thus each sequence was 2 s long, and sequences were separated by a 667 ms black screen. The 4 -item sequences were randomly displayed one after another with no immediate repetition of any specific sequence. When the mean looking time over
four consecutive trials fell to less than $50 \%$ compared to the mean looking time for the first four habituation trials (i.e., habituation) infants viewed the test sequences.

At test, infants viewed "familiar" and "novel" four-item sequences drawn from the remaining nine in the total inventory that were not shown during habituation. Familiar test sequences followed the same constraints as those described previously for the habituation sequences. Novel test sequences were composed of the same nine items, presented in sequences of four, and random ordering of items with no constraints except no repeated items in any single sequence. Infants viewed six alternating familiar and novel trials presented in pairs (i.e., three test trial blocks), and viewing order was counterbalanced such that half the infants viewed a familiar trial first (followed by a novel trial) and half the infants viewed a novel trial first (followed by a familiar trial). Preliminary analyses examining sex differences in performance revealed no reliable effects in any of the experiments in this report (all $p \mathrm{~s}>.05$ ).

## Results and Discussion

A 2 (age group) $\times 2$ (trial type - novel or familiar) $\times 2$ (order - novel or familiar first) x 3 (test trial block) mixed ANOVA on posthabituation looking times revealed a main effect of test trial block, $F(2,72)=4.79, p=.011, \eta^{2}{ }_{\mathrm{p}}=.12$, the result of a decline in looking across trials, and an age group x trial type interaction, $F(1,36)=8.03, p=.008, \eta^{2}{ }_{p}$ $=.182$. There were no other significant effects. Follow-up ttests indicated that 11-month-olds did not look differently to novel and familiar test stimuli, $t(19)=-.916, p=.371$, ns, but 14 -month-olds looked longer at novel vs. familiar sequences, $t(19)=3.06, p=.006$. Thus 11 -month-olds provided no evidence for learning a "repetition anywhere" rule, whereas 14 -month-olds appeared to do so.

## Experiment 2

Because 11-month-olds showed no evidence of learning repetitions in variable locations in Experiment 1, in Experiment 2 we examined the role of positional consistency in sequence learning. Here, we tested 11 and 14-month-olds' learning of a medial repetition rule. Habituation sequences comprised two different patterns that could be extracted: a medial repetition rule (a changing identity in the AxxC pattern), and a nonadjacent dependency (between A and C in the AxxC pattern). Experiment 2 specifically tested rule learning, and as in Experiment 1, we reasoned that this learning would be reflected in longer looking during novel vs. familiar test trials.

## Method

Participants Twenty 11-month-olds (Mage $=11.15$ months, $\mathrm{SD}=.34 ; 14$ girls ) and twenty 14 -month-olds ( $M_{\text {age }}=14.14$ months, $S D=.39$; 9 girls) participated in Experiment 2. Six additional 11-month-olds were tested but excluded for failure to habituate (4) or fussiness (2). Eight additional 14-month-olds were tested but excluded due to failure to habituate (2), technical error (2), or fussiness (4).

Materials and Apparatus The item stimuli and presentation apparatus were the same as in Experiment 1. Habituation sequences contained both a medial repetition and a nonadjacent dependency between the first and fourth items of the sequence (see Figure 2). Sequences were assembled from a randomly chosen set of ten from the inventory of 18. Again, three items composed each fouritem sequence, but the second item was always repeated, instantiating a medial repetition rule. Four items were selected (from the ten) for first and fourth positions in two unique sequences, and three items were selected for the medial positions in each sequence (e.g., ABBC, DEEF, AGGC, DHHF, etc.). The two sequences were presented in alternation during habituation.

The test sequences were constructed such that familiar sequences tested the generalization of the medial repetition rule with new exemplars that did not use consistent shapes/syllables in the first and fourth positions across sequences. Familiar sequences were composed of items drawn from the entire shape inventory, with the constraints that the second item always repeated, and the first and fourth items in sequence could not be one of the four items that occupied those positions in the habituation sequences. The novel sequences followed the same constraints described in Experiment 1.

Figure 2: Schematic depiction of example habituation and test sequences for Experiments 2 and 3.

Procedure The procedure was the same as in Experiment 1. Infants were habituated to sequences that contained a medial repetition and a nonadjacent dependency (described above), and an infant-controlled habituation paradigm was used. At test, infants saw six trials that alternated between familiar (i.e., contained a medial repetition) and novel, viewing three of each trial type in total. Infants were randomly assigned to see either a familiar trial or a novel trial first.

## Results and Discussion

A 2 (age group) $\times 2$ (trial type) $\times 3$ (test trial block) mixed ANOVA revealed a significant 3-way interaction, $F(2,76)=$
$5.71, \mathrm{p}=.022, \eta_{\mathrm{p}}^{2}=.13$, which stemmed from a relatively precipitous decline in looking across novel trials by older infants but not younger infants. More importantly, there was an age x trial type interaction, $F(1,38)=7.42, p .=010, \eta^{2}{ }_{\mathrm{p}}$ $=.16$, due to differences in looking at novel and familiar test sequences. Although this analysis yielded a significant main effect of trial type, $F(1,38)=4.36, p=.044, \eta_{\mathrm{p}}^{2}=.10$, this effect was driven by 14-month-olds' longer looking to novel test trials, as 11 -month-olds looked equally to novel and familiar test trials. There was also a significant main effect of test trial block, $F(2,76)=25.11, p<.001, \eta^{2}{ }_{\mathrm{p}}=.40$, due to a decline in looking times across trials.
14 Month Olds A 2 (trial type) x 2 (order) x 3 (test trial block) mixed ANOVA revealed a significant main effect of trial type, $F(1,18)=8.20, p=.010, \eta_{\mathrm{p}}^{2}=.313$, due to longer looking overall at the novel test sequence. There was also a reliable main effect of test trial block, $F(2,36)=22.37, p<$ $.001, \eta_{\mathrm{p}}^{2}=.55$, due to a decline in looking across trials. These main effects were qualified by a significant trial type x test trial block interaction, $F(2,36)=10.70, p=.004, \eta_{\mathrm{p}}^{2}=$ .37 and a significant trial type x order x test trial block interaction, $F(2,36)=9.25, p=.007, \eta_{\mathrm{p}}{ }^{2}=.34$. There were no other significant effects. The two higher-order interactions were a result of longer looking during the first trial block toward the novel sequence by infants in the novel-first order, relative to infants in the familiar-first order, $t(18)=2.29, p=.034$; comparisons across the second and third trial blocks were $n s, p s>.16$.
11 Month Olds A 2 (trial type) x 2 (order) x 3 (test trial block) mixed ANOVA yielded a main effect of test trial block, $F(2,36)=5.50, p=.031, \eta_{\mathrm{p}}^{2}=.23$, the result of a decline in looking across trials, and a significant trial type $x$ order interaction, $F(1,18)=6.44, p=.021, \eta_{\mathrm{p}}{ }^{2}=.23$, due to a (nonsignificant) tendency for infants in both order conditions to look longer at the trial type that was presented first. There were no other significant effects; the trial type effect was ns at $p=.364$. These results support the conclusion that the 14 -month-olds generalized the medial repetition rule, whereas the 11 -month-olds did not.

## Experiment 3

Because 11-month-olds failed to learn the "medial repetition" rule in Experiment 2, Experiment 3 addressed the possibility that learning structures in 4 -item sequences is too difficult for 11-month-olds, perhaps due to limits in visual working memory. We used the same habituation sequences as Experiment 2 but instead tested for statistical learning (specifically, the nonadjacent dependency between A and C in the AxxC pattern). As in previous experiments, we reasoned that this learning would be reflected in longer looking during novel vs. familiar test trials.

## Method

Participants Twenty 11 -month-olds $\left(M_{\text {age }}=11.16\right.$ months, $S D=.32 ; 6$ girls) participated in Experiment 3. An additional nine infants were tested but excluded due to failure to habituate (8) or fussiness (1).

Materials and Apparatus The item stimuli and presentation apparatus were the same as in Experiments 1 and 2.
Procedure The procedure was the same as in Experiment 2, except for the structure of the test sequences. The familiar test trials maintained the relation between the first and fourth items across two sequences, using the exact same first and fourth items from habituation, but had no repetitions (i.e., each familiar sequence was composed of four unique items; see Figure 2). The novel test trials followed constraints described previously.

## Results and Discussion

A 2 (trial type) x 2 (order) x 3 (test trial block) mixed ANOVA yielded a reliable main effect of trial type, $F(1,18)$ $=7.86, p=.012, \eta_{\mathrm{p}}^{2}=.30$, due to longer looking overall at novel vs. familiar test sequences (see Figure 4). There was also a main effect of trial block, $F(2,36)=7.82, p=.012$, $\eta_{\mathrm{p}}^{2}=.30$, due to a decline in looking across trials, and a significant interaction between trial block and trial type, $F(2,36)=9.63, p=.006, \eta_{\mathrm{p}}^{2}=.35$. Infants looked more toward the novel sequence than the familiar in the first block, $t(19)=2.75, p=.013$, and in the second block, $t(19)$ $=2.80, p=.011$, but not in the third block, $t(19)=.22$, $n s$. The overall presence of a novelty preference suggests that infants abstracted the nonadjacent dependency pattern during habituation.

We compared performance of the 11-month-olds in Experiments 2 and 3 with a 2 (experiment) x 2 (trial type) x 3 (test trial block) mixed ANOVA. This analysis revealed a significant main effect of test trial block, $F(2,76)=11.44, p$ $<.001, \eta_{\mathrm{p}}^{2}=.23$, due to a decline in looking times across trials. More importantly, there was an experiment x trial type interaction, $F(1,38)=6.83, p=.013, \eta_{\mathrm{p}}^{2}=.15$, due to differences in looking at novel and familiar test sequences, as noted earlier. Taken together, therefore, the results of Experiments 2 and 3 provide evidence that when both statistical and rule-bound information was available in habituation sequences, 11 -month-olds detected the presence or absence of nonadjacent dependencies (ordinal positions of initial and final shapes in sequence; i.e., statistical information) across habituation and test, but not a medial repetition (i.e., rule-bound information).

## General Discussion

In a departure from past studies showing that 11-month-olds learn an adjacent repetition rule when the repetition appears in the initial or final positions in sequence (Johnson et al., 2009), we discovered that 11-month-olds failed to learn this rule when the repetition appeared in any position (initial, medial, or final, Experiment 1), or when it was restricted to the medial position (Experiment 2). Fourteen-month-olds, however, appeared to learn repetition rules under both conditions. Finally, in Experiment 3, 11-month-olds succeeded in learning a nonadjacent dependency in sequences identical to those used in Experiment 2. We conclude that 11 -month-old infants do not seem to
recognize repetitions when they appear in multiple positions in sequence, or in a consistent middle position, although items at edge positions in sequence appear to be distinctly salient. Similar findings for adults were reported by Endress et al. (2005, 2010).

## Repetition and Position as Perceptual Primitives

Infant sequence learning is constrained by saliency and consistency of information well as general limits in attention and memory (Aslin \& Newport, 2012, 2014). Some of these constraints are specific to modality (e.g., speech cues; Johnson \& Jusczyk, 2001; Thiessen \& Saffran, 2003) or the experimental setting (e.g., gaze or action cues; Baldwin, Andersson, Saffran, \& Meyer, 2008), but others, such as repetition and position, are domain-general and may operate similarly across contexts. Evidence from the 11-month-olds in Experiment 2 is consistent with findings from adults, who generalized a repetition to new items when it appeared in final position, but not a medial position, in 7-item syllable sequences (Endress et al., 2005). These studies suggest that item position, most notably final position, is more salient than item repetition, relatively speaking; these findings are consistent with the well-documented serial position curve (Ebbinghaus, 1885) and the recency effect in memory (Baddeley \& Hitch, 1974)

Because any particular set of items in a group potentially supports an infinite number of possible structures and generalizations thereof, a learner must determine the most likely pattern given a limited amount of experience with it. One way in which this problem may be constrained is by a "gradient of generalization:" the most consistent information across a distribution produces the best learning (Aslin \& Newport, 2014; Gerken, 2006). In Experiments 2 and 3 , information for medial repetition and nonadjacent dependency was available, yet 11-month-olds learned only the statistical information. Notably, 14 -month-olds appeared to learn a repetition rule both when it was restricted to the medial position (Experiment 2) and when it was free to appear in initial, medial, or final position (Experiment 1), implying that important developments in structural learning consist of the "separation" of perceptual primitives such that they become less interdependent and perhaps more salient on their own.

## Infant Sequence Learning in Context

Rule learning and generalization for shorter sequences can be observed in infants as young as 4 months (Dawson \& Gerken, 2009). Rule learning in 5-month-olds from 3-item shape-syllable sequences was also reported, using a similar design (Frank et al., 2009). Studies that tested for statistical learning reported that 3-month-olds appeared to recognize violations of serial order in 3-item shape-sound sequences (Lewkowicz, 2008), and 5-month-olds segmented shape sequences from differences in transitional probability (Marcovitch \& Lewkowicz, 2009; Slone \& Johnson, 2015). (To our knowledge, there is no published evidence for rule or statistical learning in auditory or visual sequences prior to

4 months.) By 8 months, infants seem to use a "chunking" mechanism to segment shape sequences when tested for learning of "illusory" sequences or "embedded" units in streams of looming shapes (Slone \& Johnson, 2016; cf. Endress \& Mehler, 2009; Giroux \& Rey, 2009).

Finally, consider the findings (from Experiments 2 and 3) that 11-month-olds extracted statistical patterns, but not rules, from identical sequences. In a previous test of multiple pattern learning, adults listened to speech streams that could be interpreted in terms of rules or statistical relations (Endress \& Bonatti, 2007). With briefer listening times, participants learned the rules, but did not identify the statistical structure without substantially longer exposure durations. This result led to the claim that there is a fastworking mechanism for extracting rule-bound patterns, and a second slower mechanism that requires additional time to learn associations among items. Yet the infants we observed appeared to learn statistical relations, but not rules, during a relatively brief period of habituation. The reasons for this effect are unclear. Recently, 8-month-old infants were found to learn different statistical structures (transitional probabilities and "chunks" of items) as a function of exposure time (Slone \& Johnson, 2016), and it may be that 11-month-olds would learn rules in the current stimulus set if they accumulated more looking times than allowed for by the infant-controlled habituation method. Nor is it clear from the current studies or the larger literature whether, in general, rule learning systems might come "on line" earlier during development than statistical learning systems, or vice-versa. These questions await future study.

## Conclusions

Perceptual primitives may be best thought of as helping to support learning by attracting learners' attention and memory resources to likely structures in the environment. Yet they do not seem to attract attention automatically, as do some sensory primitives such as motion or high contrast, nor are they automatically committed to memory, for either infants or adults. Rather, evidence to date suggests that infants at birth can discriminate certain rules and statistical patterns when compared to unstructured input, but learning and generalization of rules develop across the first year after birth and beyond. On this account, perceptual primitives such as repetition and position serve as building blocks upon which more complex structures can be built.

# Silent gesture and noun phrase universals 

Marieke Schouwstra, Simon Kirby, Jennifer Culbertson<br>Centre for Language Evolution<br>University of Edinburgh

#### Abstract

In this paper we investigate a hypothesized cognitive bias for isomorphic mappings between conceptual structure and linear order in the noun phrase. This bias has been proposed as a possible explanation for a striking asymmetry in the typology of the noun phrase-linear orders which place the adjective closest to the noun, then the numeral, then the demonstrative, are over-represented in the world's languages. Previous experimental work has provided evidence that an isomorphism bias affects English-speaking learners' inferences about the relative order of modifiers in an artificial language. Here, we use the silent gesture paradigm to explore whether the isomorphism bias influences spontaneous gestures innovated by participants in a modality with which they have relatively little prior experience. We find that gesture string order largely conforms to the same striking pattern found in noun phrase typology, supporting the role of the isomorphism bias in shaping the emergence of language (and language-like) systems.

Keywords: silent gesture; noun phrase; word order; linguistic universals; cognitive biases

## Introduction

Linguists studying word order have long noticed striking differences in frequency among possible word order patterns. Explaining why certain patterns are more common than others is a source of ongoing debate. On the one hand, these typological differences may reflect evolved properties of human cognition. On the other hand, they may be the result of a complex interplay between various non-cognitive factors: genetic and areal relationships between languages, social or cultural pressures, and accidents of history (Evans \& Levinson, 2009; Dunn, Greenhill, Levinson, \& Gray, 2011; Piantadosi \& Gibson, 2014; Ladd, Roberts, \& Dediu, 2015).

In this paper we will investigate a well-known pattern in language typology relating to the structure of the noun phrase, using a experimental methodology that has not yet been applied in this domain, in which participants must improvise gestures to communicate pictures or scenes. What we find is a clear preference for gesture orders which conform to a structural template that is found in the majority of languages. These orders do not in general follow the typical linear order of noun phrases in their native language, English. Most prominently, they often produce adjective gestures following the noun. We argue that the results of our experiment reflect the underlying conceptual structure of the noun phrase, suggesting a cognitive explanation for the typological pattern.

## Universal 20 and the isomorphism bias

Greenberg (1963) formulated a number of typological 'universals', based on the relative frequency of syntactic patterns in 30 different languages. Universal 20 concerns the Noun Phrase, in particular the order of the noun and its modifiers.

It states that when any or all of the items (demonstrative, numeral, and descriptive adjective) precede the noun, they are always found in that order. If they follow, the order is either the same or the exact opposite (Greenberg, 1963).

In other words, the three most common NP orders according to Greenberg are Dem-Num-Adj-N ('these five large houses'), N-Dem-Num-Adj ('houses these five large'), and N-Adj-Num-Dem ('houses large five these'). More recent analyses, based on a larger set of languages have found that of the three orders, N -Dem-Num-Adj does occur, but is far less frequent than the other two (Cinque, 2005; Dryer, 2009).

To explain the difference in frequency between Greenberg's two post-nominal orders ( $\mathrm{N}-\mathrm{Adj}$-Num-Dem and N-Dem-Num-Adj), Culbertson and Adger (2014) appeal to the notion of isomorphism, present in some form in a number of theoretical accounts of this universal (Cinque, 2005; Rijkhoff, 2004). In general, isomorphism refers to a transparent relationship between meaning and structure. To see how this applies to the noun phrase, consider the distinct semantic contributions of the different modifier types (Culbertson \& Adger, 2014). Adjectives modify properties that are inherent to the noun, numerals group together these smaller units, and demonstratives connect these grouped units to the external discourse.

In a complex noun phrase, the adjective is thus conceptually closest to the noun, followed by the numeral, and finally the demonstrative. These relations determine constituency, and can be seen, for example, in semantic scope. A numeral (like 'five) takes scope over the noun+adjective unit (like 'large houses'); the meaning of the numeral applies to the noun as well as to the adjective. Similarly, a demonstrative takes scope over a noun+adjective+numeral unit (such as in 'these five large houses') to connect it to the discourse. ${ }^{1}$ These conceptual relations are illustrated in Figure 1.

Figure 1: The conceptual structure of the noun and its modifiers: the adjective modifies the meaning of the noun most closely; the numeral takes scope over this unit; the demonstrative is conceptual most distant, taking widest scope.

[^476]Note that the conceptual structure does not fully determine linear order, rather there are several possible ways to map structure to order, all of which preserve the underlying relations between elements. For instance, Dem-Adj-N-Num, Dem-N-Adj-Num, and Adj-N-Num-Dem can all be 'read off' the structure in Figure 1 directly, without perturbing the constituency relations. On the other hand, Adj-Dem-N-Num cannot be read off the structure directly, the only way to get this order is to move Adj outside of its unit with N . There are in fact eight ways of forming a structure-preserving string, these are the isomorphic orders. They make up one third of the 24 possible ways of ordering Dem, Num, Adj and N.

Returning to the two post-nominal orders mentioned above, N-Adj-Num-Dem and N-Dem-Num-Adj, we can now see that isomorphism is a possible explanation for the frequency asymmetry between them: the more frequent N -Adj-Num-Dem is isomorphic, while the infrequent N -Dem-Num-Adj is not. More generally, isomorphic orders tend to be more frequent than non-isomorphic ones, as shown in Figure 2.

Figure 2: Frequency of NP structures: isomorphic orders are all among the most common in this sample (Cysouw, 2010).

To investigate whether a bias for isomorphism plays a role in language learning, Culbertson and Adger (2014) conducted a series of experiments in which participants were trained on an artificial language with simple noun phrases consisting of a noun plus a single modifier (either an adjective, a numeral or a demonstrative). Participants were then tested on complex noun phrases with more than one modifier (i.e., an adjective and a demonstrative), which they had not seen before. For instance, participants who learned N-Adj and N-Dem strings in the training phase were then prompted to construct a phrase containing all three elements. They could either choose N -Adj-Dem, which is isomorphic, or N -Dem-Adj, which shares the modifier order of English (Dem-Adj) but is
non-isomorphic. Participants chose isomorphic structures in the majority of cases, suggesting that relative order of modifiers was inferred based on an underlying assumption of isomorphism rather than surface similarity to English.

## Silent gesture: evidence from improvisation in the lab

The findings of Culbertson and Adger (2014) are limited in the extent to which they provide evidence for an isomorphism bias reflecting a general property of human cognition, since participants may have learned (through learning their native language) at a more abstract level that surface order is isomorphic to conceptual structure. Recent work using the 'silent gesture' paradigm offers a potential method for tapping into biases in word order while bypassing the effects of prior linguistic knowledge. In silent gesture experiments, participants with no knowledge of sign language are asked to convey information using only their hands and no speech. Existing work using this method has mainly focused on basic word order (sequences expressing information about who did what to whom). This research has found that when participants use silent gesture to describe simple transitive events, they do not rely on the dominant order of their native language (GoldinMeadow, So, Özyürek, \& Mylander, 2008), but instead take the semantic properties of the event into account (Gibson et al., 2013; Hall, Mayberry, \& Ferreira, 2013; Schouwstra \& de Swart, 2014; Schouwstra, 2016).

## Experiment 1

To investigate the isomorphism bias in a modality distinct from participants' previous language experience, we conducted an experiment in which adult participants used silent gesture to describe pictures of objects modified in various ways. We hypothesise that the ordering of these gestures will conform to isomorphism, even when they do not reflect the linear order of English Noun Phrases.

## Materials, participants, and procedure

We created a stimulus set consisting of images of groups of 4 or 5 (Num) shapes, which were either squares or triangles (N), either striped or spotted (Adj), and appeared in a proximal or a distal (Dem) location. Locations were represented by two iPads on which the images could appear-one closer to the participant, the other further away. Figure 3 provides example images, and Figure 4 shows the position of the iPads relative to the participant. The set of 8 different images, presented on two different iPads, together formed 16 total items.

Participants ( $\mathrm{N}=20$, native speakers of English, no experience with sign languages) were seated across the table from the experimenter, with the two iPads in front of them, as in Figure 4. They were filmed using a Logitech webcam connected to a MacBook Air. Before starting the silent gesture part of the experiment, participants were shown the full set of stimuli as printed pictures. Subsequently, they were asked to describe each stimulus item using only their hands, so that someone watching the recording would be able to work out

Figure 3: Example stimuli: 'five striped squares' and 'four spotted triangles'.

Figure 4: Experiment set-up. Note that the two iPads were placed on the table, in front of the participant: one close to the participant, and one further away.
which of the images appeared on which screen. The stimuli were presented twice in random order for each participant, with a brief break after the first run of the stimuli ( 32 trials in total).

## Results

The videos were coded by identifying which of the gestures indicated information associated with $\mathrm{N}, \mathrm{Adj}$, Num, or Dem. ${ }^{2}$ Occasionally, participants specified the spatial layout of the figures. This information was invariably provided in addition to other gestures referring to the number or the object, and was ignored for our coding purposes. In addition, some gestures included combinations of two elements (e.g., N with Adj ). No relative ordering information can be determined for combined elements, therefore these were excluded from relevant analyses. We focused on two measures in analyzing this data: how were modifiers ordered relative to the noun (were they pre- or post-nominal), and how were modifiers ordered relative to each other (were they isomorphic given the position of the noun, or not). To code for isomorphism we looked at each modifier pair that appeared on the same side of the noun. For instance, a string N -Num-Adj-Dem would be coded as non-isomorphic for Num-Adj, but isomorphic for Dem-Num and Dem-Adj. Modifier pairs that were on different sides of the noun were excluded from this part of the analysis as these do not provide information about isomorphism. Finally, overall isomorphism for each full gesture string was

[^477]coded according to whether any isomorphism violations were present. For this overall measure (contrary to what we did for the modifier pairs) we did include strings that had modifiers on different sides of the noun. Strings that excluded any of the modifiers (such as $\mathrm{N}-\mathrm{Adj}-\mathrm{Num}$ ) were excluded.

Figure 5: Results of Experiment 1: Proportion of modifiers placed post-nominally, by modifier type.

Figure 6: Results of Experiment 1: Proportion of modifier pairs conforming to isomorphic order, by modifier pair, in pre- and post-nominal position, plus overall scope isomorphism (last column). The dotted line represents chance level. Note that for overall isomorphism, chance level is at 0.33 (8 isomorphic orders/24 possible orders).

The typical order of English noun phrases is Dem-Num-Adj-N. Analysis of overall rates of pre- vs. post-nominal placement for each type of modifier reveal that participants' gestures deviate from pre-nominal order most obviously when it comes to the placement of Adj. Indeed, as shown in Figure 5, there was a strong preference for post-nominal placement. By contrast for Dem, participants preferred a pre-nominal position. Num fell in between. This was confirmed by one sample $t$-tests comparing average placement by participant to chance for each modifier type ( t $=-0.2717, \mathrm{df}=18, \mathrm{p}=0.79$ for Num , and $\mathrm{t}=-6.9561$, $\mathrm{df}=$ $15, \mathrm{p}<.001$ for Dem; because Adj was used post-nominally without exceptions, a t-test cannot be performed on that
data). ${ }^{3}$.
Turning to isomorphism, as Figure 6 shows, participants had a strong tendency to provide gesture strings which conformed to isomorphic ordering for all modifier pairs. Importantly, this was the case both for pre-nominal and postnominal pairs. A one sample t-test confirms that proportions of isomorphic word orders are significantly different from chance $(\mathrm{t}=65.1549, \mathrm{df}=15, \mathrm{p}<.001)$.

## Discussion

Participants' overwhelming preference for isomorphic order in silent gesture strings provides support for a link between cognitive biases and this typological tendency. A further surprising finding is that participants very consistently produced post-nominal adjectives. This pattern is not dominant in the native language of the participants (English), although it is in fact more common typologically (Dryer, 2009).

However, two properties of our stimulus items suggest the possibility that our results may not generalize to other Noun Phrase types. First, the most common gesture order used by participants was Dem-Num-N-Adj. This corresponds to the physical layout of the information in each item: the iPad was the outermost, largest element, the numeral information was in some sense the next largest part of the scene, then the object shape itself, and finally, the adjective information (stripes or spots) which was always inside the object (Figure 3). If participants were starting from the outermost information and proceeding in, then, our stimuli could have set participants up to place the adjective after the noun.

Further, as mentioned above, some responses contained gestures which combined information for two of the elements present. For example, participants sometimes conveyed information about the numeral and the adjective simultaneously, for example by repeatedly drawing spots or stripes (Adj) four or five (Num) times. Such combinations were much more likely to involve the adjective, making it impossible to determine either isomorphism (for Adj combined with other modifiers), or position relative to the noun (for Adj combined with N ) in a number of cases.

We therefore conducted an additional experiment using stimuli in which the adjective is not depicted inside the object, and which discourage the use of combined gestures.

## Experiment 2

To address the concerns pointed out above, and to further investigate the prevalence of post-nominal adjectives, we conducted a second silent gesture experiment, using different stimuli, as described below.

## Materials, participants, and procedure

Our stimuli consisted of line drawings of groups of 4 or 5 (Num) objects, which were either toothbrushes or pencils ${ }^{4}$ (N),

[^478]either big or small (Adj), and appeared on a proximal or a distal (Dem) location. The adjectives 'big' and 'small' were chosen on the basis of their visual properties: when depicted, the adjective information is not visually inside the object. Moreover, we expected that these adjectives would lead to fewer combined gestures, particularly with the noun (since both likely require difference handshapes). ${ }^{5}$

Figure 7: Example stimuli: 'five large pencils' and 'four small pencils'.

The procedure of the experiment was identical to that of experiment 1 , except for the number of trials: participants ( $\mathrm{N}=20$, native speakers of English, no experience with sign languages) described each of the stimuli once ( 16 trials in total).

Figure 8: Results of Experiment 2: Proportion of modifiers placed post-nominally, by modifier type.

## Results

As in Experiment 1, we coded the videos by identifying which portion of the gesture string indicated $\mathrm{N}, \mathrm{Adj}$, Num, or Dem. From this we determined whether the modifiers were placed pre- or post-nominally, and obtained isomorphism scores for modifier-pairs as well as full strings. The results show that although the proportions follow the pattern found in experiment 1 (note, however, that the proportion of postnominal adjectives is no longer significantly greater than 0.5 ; $\mathrm{t}=0.5138, \mathrm{df}=18, \mathrm{p}=0.61$ ). Additionally, there was again

[^479]an overall preference to produce isomorphic structures: a one-sample T-test confirms that the proportion of isomorphic strings differs from chance $(\mathrm{t}=5.7149, \mathrm{df}=16, \mathrm{p}<0.001) .{ }^{6}$ However, this tendency was less deterministic than in Experiment 1.

Zooming in on the scores for different modifier pairs, participants are less likely to produce isomorphic order for Adj-Num combinations, in contrast to Experiment 1. When these two modifiers were placed post-nominally, they were no longer isomorphic (see Figure 9; $\mathrm{t}=0.9077, \mathrm{df}=10, \mathrm{p}=$ 0.39).

Figure 9: Results of Experiment 2: Proportion isomorphic orders, by modifier pair, plus overall scope isomorphism (last column). The dotted line represents chance level. Note that for overall isomorphism, chance level is at 0.33 ( 8 isomorphic orders/24 possible orders).

## General discussion

Isomorphism is a hypothesized cognitive principle proposed to explain the way Noun Phrases tend to be ordered in languages of the world. Languages which obey isomorphism are much more frequent than those which don't. However, given the many other factors likely to influence typological distributions, evidence which explicitly links isomorphism to a cognitive bias is needed. Previous experimental studies confirmed that isomorphism appears to play a role in the kinds of inferences people make when learning an artificial language with word order that differs from their native language (Culbertson \& Adger, 2014). However, the linguistic systems individual speakers of a given language know have already solved the problem of going from a multidimensional conceptual structure (see Figure 1 above) to a linear representation. In this paper, we investigated what happens when people start 'from scratch' and improvise utterances in the absence of a conventional system, by conveying information presented as images using only their hands and no speech.

[^480]This silent gesture paradigm has been shown to be a fruitful way of investigating what happens when people are forced to communicate without being able to use existing word order conventions. However, previous work using this paradigm focuses mainly on the order of major sentence constituents. The structure of the noun phrase has never before been studied using silent gesture.

Our experiments showed that the gestures improvised by participants to describe pictures with N, Adj, Num, and Dem information, are ordered in a way that is isomorphic to the underlying conceptual structure-adjective property closer to the noun than numerosity, and distal/proximal location furthest away. This result, combined with the fact that participants did not simply use English NP order for their gestures, supports the claim that a bias for isomorphism affects linear order independently of prior linguistic experience. This general bias therefore plays a plausible role in explaining the frequency distribution of NP orders across languages.

The clearest difference between the gesture orders participants provided and their native language experience is in the placement of the adjective. Experiment 1 showed an extremely strong preference to place the Adjective postnominally (unlike in English), and in Experiment 2, though the placement was more variable, there was still no overall preference for pre-nominal adjectives. As mentioned above, post-nominal adjectives are in fact more common cross-linguistically, and this may represent a second active bias. Interestingly, Adj and Num gestures in Experiment 2 showed no isomorphism bias, ${ }^{7}$ whereas they did in Experiment 1. One possible explanation for this may lie in the nature of the adjectives used in our two experiments. Adjectives describing a texture were used in Experiment 1, while adjectives for size were used in Experiment 2. Size adjectives are gradable (Kennedy, 2007), a property which affects the role of contextual information in their interpretation: for gradable adjectives, context is needed to determine what counts, e.g., as 'large' or 'small'. This closer connection to the context may make the adjectives in the second experiment less conceptually tied to the noun. Perhaps relatedly, size adjectives are general argued to scope higher, relative to other adjectives (Kemmerer, 2000), including 'striped' and 'spotted' (as reflected in their order: e.g., 'small striped triangle' sounds more natural than 'striped small triangle'). An nonisomorphic order of a numeral and a wider-scoping adjectives may thus be a weaker violation of isomorphism compared to a lower-scoping adjective. Additional investigating with a wider range of adjectives is needed to justify these claims. Note however, that they are related to a similar finding in Culbertson and Adger (2014), in which non-isomorphic orders were more likely to be chosen for structurally less distant modifier pairs (i.e., Adj with Num, compared to Adj with Dem).

[^481]
## Conclusion

The experiments reported here show that when people improvise gestures corresponding to simple pictures of objects with different properties, numerosities, and locations, they order their gestures in a way that corresponds to the underlying conceptual structure of these elements. This same structure is respected by the majority of languages in the way they order elements in the Noun Phrase (nouns, adjectives, numerals, and demonstratives), suggesting that a cognitive bias for isomorphism between meaning and linear order might shape linguistic systems in this domain.

Experiments that use improvised silent gesture, like the ones presented here, provides a window into the evolution of linguistic systems. The method gives us an experimental analog to real world situations in which language rules spontaneously emerge; for example, homesign (Goldin-Meadow \& Brentari, in press), emerging sign languages (Meir et al., 2017) and early stages in spontaneous second (spoken) language acquisition by adults (Schouwstra, 2016). Accordingly, we believe that a fruitful line for future research will be an investigation of the structure of the noun phrase in these systems, providing an invaluable naturalistic complement to laboratory experiments.

# Discourse continuity promotes children's learning of new objects labels 

Jessica F. Schwab (jschwab@princeton.edu)<br>Casey Lew-Williams (caseylw@princeton.edu)<br>Department of Psychology, Princeton University, Peretsman-Scully Hall<br>Princeton, NJ 08540 USA

#### Abstract

The present study examined the influence of continuity of reference (i.e., discourse continuity) on children's learning of new objects labels. Four-year-old children were taught three new label/objects pairs, where the speaker's references to objects were either continuous (i.e., clusters of utterances referred to the same object) or discontinuous (i.e., no two sequential sentences referred to the same object). In two experiments, children learned new word/object mappings more successfully when object labels were accompanied by continuous references to the same object. This research reveals how discourse cues support children's encoding of new words, and in doing so, advances our understanding of the specific features of parents' language input that facilitate children's language development.

Keywords: discourse continuity; word learning; childdirected speech

## Introduction

Children are adept at analyzing the complexities of their language input in order to learn new words, but there is also substantial variability in their learning. In order to better understand these differences, researchers have examined various features of caregivers' input shown to influence vocabulary growth, including social cues (such as eye gaze and pointing; e.g., Booth, McGregor, \& Rohlfing, 2008; Brooks \& Meltzoff, 2008), structural cues (such as repetition and utterance length; Brent \& Siskind, 2001; Lew-Williams, Pelucchi, \& Saffran, 2011; Schwab \& LewWilliams, 2016), visual cues (such as the size of labeled objects in the visual field or their perceptual salience; Pereira, Smith, \& Yu, 2014; Pruden, Hirsh-Pasek, Golinkoff, \& Hennon, 2006), and auditory cues (such as intonation and pitch; e.g., Ma, Golinkoff, Houston, \& HirshPasek, 2011; Singh, Nestor, Parikh, \& Yull, 2009). Here we focus on a contextual cue of parents' speech that may also facilitate children's vocabulary development: the content or structure of the discourse exchange. Specifically, discourse continuity, or the clustering of utterances that reference the same topic, may promote children's word learning (e.g., Frank, Tenenbaum, \& Fernald, 2013). Recent research on this topic suggests that discourse continuity does promote children's in-the-moment disambiguation of word-referent mappings in noisy referential contexts (Horowitz \& Frank, 2015), but it is not yet clear whether discourse continuity also contributes to children's encoding of new words in less ambiguous contexts, i.e., when caregivers hold and talk about an object in front of children, as is common in natural communication. Thus, the present study tests whether
discourse continuity influences the learning of multiple new object labels in 4 -year-old children.

Previous research has revealed that young children are sensitive to various aspects of the discourse context and structure. For example, 24-month-olds have been shown to understand that adults pay attention to - and talk about novel aspects of an interaction (Akhtar, Carpenter, \& Tomasello, 1996). That is, children are able to learn a new word when an adult labels an object that is novel to the discourse context from only the adult's own point of view. Relatedly, two-year-olds have been shown to use speakers' speech disfluencies to predict their intended referents during object labeling (Kidd, White, \& Aslin, 2011). Finally, crosslinguistic research has revealed that children who hear more consistent referential patterns within discourse specifically, regarding the use of either null, pronominal, or lexical verb arguments - tend to produce more consistent patterns earlier, compared to children exposed to inconsistent discourse patterns (Guerriero, Oshima-Takane \& Kuriyama, 2006). Nevertheless, there is little research to date that specifically looks at children's ability to take advantage of discourse continuity, or the idea that neighboring utterances are likely to refer to the same topic (e.g., Frank, Tenenbaum, \& Fernald, 2013; Hoff-Ginsberg, 1994; Ochs \& Shieffelin, 1983). For example, if a child simply hears, "I rode a camel!", he or she might come to the incorrect conclusion that a camel is some sort of automated vehicle. If instead the child hears, "I took a trip to the desert. I rode a camel! He was so sweet and let me pet him," he or she might use the topic continuity between camel and other words in the discourse in order to discern the meaning of camel (i.e., an animal living in the desert), as well as to encode its meaning more concretely and accurately.

Most existing research on the topic of discourse continuity and children's language learning has examined the use of discourse continuity in child-caregiver interactions (Frank, Tenenbaum, \& Fernald, 2013; Rohde \& Frank, 2014). Rohde and Frank (2014) analyzed discourse continuity in parents' interactions with their children using three different methods: raw annotations of speakers' referent, the output of a computational model, and judgments made by human coders. Across the three methods, the researchers determined that many topicsignaling cues - such as pronoun use and sentence-final reference - found in adult discourse are also present in child-directed speech. They conclude that the function of these cues in child-directed speech may be to help children acquire additional referential information from their input, particularly when individual utterances are ambiguous. Hoff
(2010) revealed that children produce topic-continuing discourse themselves, particularly during certain languagerich activities such as reading. Other work suggests that speakers' discourse continuity might be relevant for supporting a key component of children's language development: the learning of new words. Frank, Tenenbaum, \& Fernald (2013) found that caregivers’ references to objects in a child-parent play session were more continuous (or "clumpy") than would be expected by chance. Moreover, computational modeling work has shown some evidence of the importance of discourse continuity for word learning. In their word-learning model, Luong, Frank, and Johnson (2013) set speakers' intended referent to be continuous across utterances. This discourse information, combined with social cues, led to some improvements in the model's word learning performance. Together, these studies suggest that discourse continuity exists in adult-child interactions and provides helpful cues to word learning, yet they are unable to conclusively determine whether or not discourse continuity improves children's word-learning abilities.

Erika Hoff (2003) began to answer this question - of whether continuity of discourse promotes children's word learning - by looking at topic-continuing replies, i.e., caregivers' utterances that continue a topic previously introduced by the child. Hoff found that the amount that mothers used topic-continuing replies predicted their children's vocabulary growth ten weeks later, suggesting that continuity in mother-child interactions may indeed promote children's language learning. Horowitz and Frank (2015) went further by testing whether children are able to use a speaker's discourse continuity as a strategy for determining object reference in ambiguous word learning situations. In their study, children ages 2-6 years completed a novel word-learning task, where the only cue to reference was the placement of a labeling event within the discourse structure of the interaction. Specifically, children heard an object label (with no associated gestural cues to the referent) flanked by descriptions of either toy A or toy B (which were accompanied by gestural cues). If children are able to use discourse continuity as a cue to reference, they should be able to determine the object/label pairing if the labeling event occurs between two descriptions of the same object (either toy A or toy B), i.e., if the labeling episode is discourse continuous. If the labeling event occurs between two descriptions of different objects (toy A and toy B), the label/object pair should be indeterminable. The results revealed that children were in fact only able to successfully determine the referent when labels were discourse continuous. Moreover, children only started showing successful disambiguation by age $3-4$, and showed even better learning through ages 5 and 6, suggesting that children's ability to use discourse information in determining object reference might develop over the course of childhood.

Discourse continuity clearly seems to be helpful for disambiguation, i.e., determining reference in uncertain
situations. However, it has not yet been determined whether discourse continuity, in addition to helping determine an accurate word/object mapping in the moment, is also helpful for children's encoding of a new word that is clearly the focus of attention. Not only is the latter common in caregiver-child interactions (e.g., Pereira, Smith, \& Yu, 2013), but so is caregivers' tendency to refer to a string of objects in sequence. As speakers rapidly shift focus from one object to the next in conversation, it is possible that providing context for each labeling episode through topic continuity helps children successfully encode and remember new object labels. In the present paper, we test this prediction in 4 -year-olds by teaching them three new words, either with or without discourse continuity. If discourse continuity does in fact promote children's word learning, we predicted that children who heard clusters of continuous reference to objects would show better learning of object labels (defined as proportion of object/label mappings correctly identified in the test phase) compared to children who heard object references distributed over the course of the learning phase.

## Experiment 1

In Experiment 1, we tested the extent to which continuity of reference influences children's learning of three new word/object pairs. In the Continuous condition, clusters of three utterances included one labeling utterance directed toward a particular object, accompanied by two additional utterances describing - but not explicitly labeling - the same object. In the Discontinuous condition, children heard the same labels for each object and the same object-directed utterances as in the Continuous condition, but the discourse was not continuous (e.g., a label for Object A might be immediately followed by commentary about features of Object B). Each label or object-directed utterance was unambiguous, i.e., it was accompanied by the speaker gazing toward and grasping the object. At test, children were presented with a two-alternative forced choice reaching task in order to measure their knowledge of each object label. If discourse continuity does in fact promote children's word-learning abilities, children should show more successful learning of correct object/label mappings in the Continuous compared to the Discontinuous condition.

## Method

Participants Participants were 40 4-year-old children ( $M=46.41$ months, $S D=3.71$, Range $=42.1-53.63$ ). Twentythree participants were male, and all participants came from monolingual English-speaking homes. Children had no history of pervasive developmental delays. Twenty children were randomly assigned to each of two experimental conditions: a Continuous or Discontinuous condition, described in detail below. Three additional participants were tested but not included due to fussiness/refusal to cooperate ( $n=2$ ) or taking an extended break halfway through test trials ( $n=1$ )

Figure 1. Schematic depicting sample trials in the learning phase for the Continuous and Discontinuous conditions in Experiment 1. Between each trial, the speaker rested both hands in her lap and smiled at the participant.

Stimuli and Design Three novel words-gazzer, cheem, and tobu-corresponded to one of three novel objects, each characterized by a different color, texture, and shape (see Figure 1). Half of participants were exposed to one set of word/object pairings, and half were exposed to a second, counterbalanced set of pairings.

In the Continuous condition, blocks of three adjacent trials in the learning phase referred to the same object. Either the first or second trial was a labeling trial, while the other two trials provided identifying visual information about the object (e.g., "This is a gazzer. / This is small and green. / This feels really spiky."). There were two blocks of trials for each novel word/object pair. Each object was referred to six times total ( 2 x per object label).

The Discontinuous condition consisted of the same exact trials as the Continuous condition, but trials within each block of the learning phase were pseudo-randomly ordered such that no two adjacent utterances referred to the same object (see Figure 1). Thus, participants heard the same number of total references to each object and the same number of object labels as in the Continuous condition, but discourse continuity was absent.

Procedure During the experiment, an experimenter sat across from the participant at a table and told him or her, "We're going to play a game together! Just watch and pay attention because I'm going to ask you some questions about these things later. Are you ready? Here we go!"

During the learning phase, the experimenter placed all three objects in a line directly in front of her on the table (in one of two counterbalanced orders). On each of 18 learning trials (approximately four seconds in duration), the experimenter began with her hands in her lap. Then she 1) smiled at the participant, 2) looked down at an object, 3) grabbed the object, raised it slightly, and tilted it up, 4) looked back at the participant and said a labeling or objectdirected sentence about the object, 5) looked back at the object and set it back down, and 6) put her hands back in her lap. Two counterbalanced trial orders were used for each condition across participants.

The test phase began immediately after the learning phase. The experimenter removed all three objects from the table and told the participant that she was now going to ask some questions. Next, the experimenter took two objects at a time, placed them in an uncovered basket, and put the basket on the table. Without looking down at the objects, the experimenter slid the basket toward the participant. Then she asked the participant to choose one of the objects and hand it to the experimenter (e.g., "Which one is the cheem? Can you give me the cheem?"). During each test trial, the experimenter maintained eye contact with the participant. If a child initially touched more than one object, the object that was finally handed to the experimenter was recorded as his or her choice. There were 12 test trials total (four trials per object/label pairing). Two counterbalanced test orders were used across participants. Across conditions, participants saw the same pairs of two novel objects, positioned on the left and right sides of the basket.

Finally, children's vocabulary was assessed using the Peabody Picture Vocabulary Test (PPVT) (Dunn \& Dunn, 2007). The PPVT is a standardized measure to assess children's receptive vocabulary by asking them to identify familiar words from a flipbook of pictures. Children were also rewarded with stickers following the test phase and again during and after the administration of the PPVT.

## Results and Discussion

Word learning was measured in terms of the proportion of word/object pairs that children correctly identified in the test phase. A two-tailed independent samples $t$-test showed that learning was significantly greater in the Continuous condition ( $M=.88, S E=.03$ ) compared to the Discontinuous condition ( $M=.77, S E=.04 ; t(34.27)=2.05, p<.05, d=.65$; see Figure 2). Additionally, between conditions, there was no significant difference in children's mean age (Continuous: $M=46.96$ months, $S D=4.13$; Discontinuous: $M=45.86$ months, $S D=3.26 ; \quad t(36.05)=.94, \quad p=.35)$ or mean standardized PPVT score (Continuous: $M=118.63$, $S D=11.96 ; \quad$ Discontinuous: $\quad M=114.21, \quad S D=15.05$; $t(34.26)=1.0, p=.32)$. Interestingly, however, learning was significantly greater than chance for both the Continuous
$(t(19)=12.28, \quad p<.001)$ and Discontinuous conditions $(t(19)=6.20, p<.001)$, suggesting that children are able to successfully learn the novel words even without discourse continuity. However, continuity of reference does seem to provide an additional word-learning boost.

Because we tested children ranging from 3.5 to 4.5 years of age, we examined a possible interaction between age and discourse continuity on children's word learning. A $2 \times 2$ factorial Analysis of Variance (ANOVA) with age and condition (Continuous or Discontinuous) as betweensubjects factors revealed a significant main effect of condition $(F(1,36)=4.31, p<.05)$, but no significant main effect of age $(F(1,36)=2.04, p=.16)$ and no significant condition x age interaction $(F(1,36)=.80, p=.38)$. Thus, across the 3.5 - to 4.5 -year range, discourse continuity supported children's word learning equivalently.

These results suggest that discourse continuity promotes word learning for 3.5- to 4.5-year-old children. Importantly, however, the "discourse" in our experiment provided relevant visual information about each object, such as its color or texture (in a similar manner to Horowitz \& Frank, 2015). Thus, it remains unclear whether topic continuity in this experiment facilitated learning due to the informative discourse that accompanied object labels, or whether simply having continuity of object reference drove the more successful learning in the Continuous condition. In particular, we wanted to determine whether continuity of uninformative discourse - i.e., discourse that provided relatively neutral information about the objects (e.g., "This is good and neat") - would promote children's word learning in a similar manner. In Experiment 2, we sought to answer this question by replicating Experiment 1, but using uninformative instead of informative discourse.

## Experiment 2

Experiment 2 sought to replicate the results of Experiment 1 using uninformative discourse. In each condition (Continuous/Uninformative and Discontinuous/ Uninformative), object labels were the same as in Experiment 1, but accompanying discourse provided no relevant information about each object. If the relevant contextual cue boosting children's performance in this task is continuity of reference more generally - and not the pairing of object labels with important visual information in the discourse - we again expected children to show more successful learning of object/label mappings in the Continuous/Uninformative condition compared to the Discontinuous/Uninformative condition.

## Method

Participants Participants were 40 4-year-old children ( $M=46.37$ months, $S D=3.36$, Range $=42.27-53.13$ ). Sixteen participants were male, and all participants came from monolingual English-speaking homes. Children had no history of pervasive developmental delays. Twenty children were randomly assigned to one of two experimental conditions: a Continuous/Uninformative or Discontinuous/

Uninformative condition, described in detail below. Two additional participants were tested but not included due to experimenter error $(n=1)$ or being bilingual (less than $85 \%$ English exposure) ( $n=1$ ).

Stimuli and Design The words and objects used were identical to Experiment 1. The Continuous/Uninformative condition was identical to the Continuous condition from Experiment 1, except that object-directed utterances provided no identifying visual information about each object (e.g., "This is a gazzer. / This is good and neat. / This is nice and cute."). Object-directed utterances in the Continuous/Uninformative condition were matched to sentences in the Continuous condition from Experiment 1 in total number of syllables. The Discontinuous/Uninformative condition consisted of the exact same trials as the Continuous/Uninformative condition, but trials within each block of the learning phase were ordered such that no two adjacent utterances referred to the same object. Thus, as in Experiment 1, participants in this condition heard the same number of total references to each object and the same number of object labels as the Continuous conditions, but there was no discourse continuity.

Procedure The procedures for the learning phase, test phase, and administration of the PPVT in Experiment 2 were identical to the procedures in Experiment 1.

## Results and Discussion

Again, word learning was measured in terms of the proportion of word/object pairs that children correctly identified in the test phase. A two-tailed independent samples $t$-test showed that learning was significantly greater in the Continuous/Uninformative condition ( $M=.88, S E=.03$ ) compared to the Discontinuous/Uninformative condition ( $M=.72, S E=.04 ; t(34.64)=2.93, p=.006, d=.92$; see Figure 2). Additionally, between conditions, there was no significant difference in children's average age (Continuous: $M=46.27$ months, $S D=3.20$; Discontinuous: $M=46.47$ months, $S D=3.60 ; \quad t(37.50)=-.18, \quad p=.86)$ or average standardized vocabulary score (Continuous: $M=119.5$, $S D=13.13$; $\quad$ Discontinuous: $\quad M=114.72, \quad S D=12.62$; $t(35.83)=1.14, p=.26)$.

Because we tested children ranging from 3.5 to 4.5 years of age, however, we again examined a possible interaction between age and discourse continuity on children's word learning. A $2 \times 2$ factorial Analysis of Variance (ANOVA) with age and condition (Continuous or Discontinuous) as between-subjects factors revealed a significant main effect of condition $(F(1,36)=8.27, p=.007)$, but no significant main effect of age $(F(1,36)=.01, p=.92)$ and no significant condition x age interaction $(F(1,36)=.62, p=.44)$. Similar to Experiment 1, across the 3.5- to 4.5-year range, discourse continuity promoted children's word learning equivalently. Additionally, similar to Experiment 1, there was significant learning compared to chance for both conditions (Continuous: $\quad t(19)=11.83, \quad p<.001 ; \quad$ Discontinuous:
$t(19)=4.95, p<.001)$, again suggesting that continuity of reference supports word learning in the absence of discourse continuity.

Comparing across Experiment 1 and Experiment 2, there was no significant difference in learning between the Continuous and Continuous/Uninformative conditions $(t(37.95)<.01, p>.99, d<.01)$, or between the Discontinuous and Discontinuous/Uninformative conditions $(t(37.99)=-.81$, $p=.42, d=.26$ ). A $2 \times 2$ mixed analysis of variance (ANOVA) with experiment ( 1 or 2 ) as a between-subjects factor and condition (Continuous or Discontinuous) as a withinsubjects factor revealed a significant main effect of condition $\left(F(1,76)=12.47, p<.001, \eta_{p}^{2}=.14\right)$, but no significant main effect of Experiment $(F(1,76)=.44, p=.51$, $\eta_{p}^{2}=.005$ ), and no significant condition x experiment interaction $\quad\left(F(1,76)=.44, \quad p=.51, \quad \eta_{p}^{2}=.005\right)$. Thus, Experiment 2 successfully replicated the results of Experiment 1 in an uninformative discourse context. Together, these results suggests that continuity of reference generally - and not just continuity of informative discourse - seems to promote children's word learning.

Figure 2: Mean proportion object/label mappings correctly identified in Experiment 1 (Continuous vs. Discontinuous conditions) and Experiment 2 (Continuous/Uninformative vs. Discontinuous/Uninformative conditions). Error bars show +/- 1 SEM across participants.

## General Discussion

In two experiments, we show that continuity of reference promotes 4 -year-old children's learning of new object labels. Moreover, the speaker's discourse does not need to provide informative content in order to promote children's word learning - simply having continuity of reference in child-directed speech seems to be sufficient to support learning. Thus, not only does discourse continuity help children determine ambiguous word/object mappings in the moment (Horowitz \& Frank, 2015), but also, it helps children encode multiple new object labels in the context of rapidly shifting adult-child interactions.

A great deal of recent research has focused on children's ability to track statistical co-occurrences in language in order to learn word-referent mappings (e.g., Smith \& Yu,
2008), but fewer studies have focused on children's ability to use information about the structure of discourse in order to learn new words. Because children have been shown to be adept at tracking object-label regularities over time, in some contexts these kinds of contextual cues may not be necessary. More likely, however, discourse cues, in addition to socio-pragmatic cues, help children encode information about word/object co-occurrences over time, presumably by increasing their salience. Relatedly, Pereira, Smith, and Yu (2013) have suggested that there are optimal visual moments for learning new word/object pairs. That is, when objects appear in a clean, stable view in front of a child while it is being labeled, that child is more likely to learn the object's label. Here, continuity of reference may provide a similarly optimal contextual moment for learning a new word/object pair, where each word and referent are clearly linked within the discourse, allowing children to attend to their features or potential functions.

The present results are convergent with findings showing that repetition of words across neighboring utterances is helpful for learning (e.g., Onnis, Waterfall, \& Edelman, 2008; Schwab \& Lew-Williams, 2016). In particular, previous research has shown that repetition of object labels in blocks of successive utterances promotes two-year-olds' encoding of new word/object pairings. Here, at least with older preschool-age children, simply referencing one object for several sentences in a row - without repeating the object label itself - may enable the learner to better encode a word/object pairing. It is possible that repetition of object labels themselves - compared to continuity of reference more generally - promote word learning differentially along the developmental continuum. For example, previous work suggests that children's ability to exploit discourse continuity to disambiguate moments of reference increases as children age, with children under 3 years not showing the ability to take advantage of discourse cues in this context (Horowitz \& Frank, 2015). In a similar manner, the need for caregivers to repeat object labels in neighboring sentences may decrease over time as children increase their proficiency in inferring information from the discourse, i.e., become better at learning from discourse continuity. Future research should aim to directly examine differences in the influence of partial repetition and discourse continuity on children's learning across a wider age range, as well as relate children's learning abilities to differences in caregivers' naturalistic use of these cues in the home.

Finally, it is not yet clear from the present results whether children's increased learning in the Continuous conditions is a facilitation or interference effect. Specifically, it may be the case that continuity of reference promotes learning, or that discontinuity in object reference interferes with learning because of rapid shifts in attention to different objects. We are currently pursuing follow-up studies to determine whether visual continuity is sufficient to support children's word learning in this experimental context, or whether visual discontinuity interferes with learning. If children learn words similarly regardless of continuous or
discontinuous visual exposure, this would suggest that continuity in a speakers' discourse in particular seems to promote children's word learning.

Overall, the present experiments reveal that discourse continuity promotes 4 -year-old children's learning of new object labels, and this seems to be true regardless of the content or informativity of the discourse. Previous research on discourse continuity has found that natural child-directed discourse tends to be "clumpy" (Frank, Tenenbaum, \& Fernald, 2013), and continuity of discourse helps children disambiguate between possible referents in the moment (Horowitz \& Frank, 2015). The present work goes further by suggesting that clusters of reference to particular objects can help children more successfully encode new words in the context of hearing sequential label/object pairings, as speakers rapidly shift focus from one object to the next. This research has implications for our understanding of how differences in caregivers' language input can influence children's vocabulary development.

## Acknowledgments

Thank you to the participating families and to Jessica
Quinter for all of her help with testing participants and coding videos. We also thank Eva Fourakis, Carolyn Mazzei, and the rest of the Princeton Baby Lab for their administrative assistance. # The Facilitatory Effect of Referent Gaze on Cognitive Load in Language Processing 

## Mirjana Sekicki (mirjana@coli.uni-saarland.de)

Maria Staudte (masta@coli.uni-saarland.de)<br>Department of Language Science and Technology; Saarland Univeristy, Germany

#### Abstract

This paper considers prediction in language processing by examining the role of the visual context, and specifically, the role of speaker referent gaze on cognitive load. We inspect the anticipatory visual attention during sentence processing together with the cognitive load induced at the points of the gaze cue, and the linguistic referent. Employing a novel measurement of cognitive load - the Index of Cognitive Activity (Marshall, 2000) allowed us to simultaneously consider both anticipatory eye-movements and cognitive load. Our results show that the gaze cue is being followed, and considered as a relevant piece of information, which subsequently reduces the cognitive load on the linguistic referent. In addition, we found that considering the gaze cue is in itself not costly, unless it cues an object mismatching with the previous linguistic context.

Keywords: Gaze; Cognitive Load; Index of Cognitive Activity; Prediction; Eye-tracking

## Introduction

A series of investigations in the visual world paradigm (VWP) have shown how listeners simultaneously combine linguistic and visual cues to predict upcoming linguistic input (for a review of the VWP see Huettig, Rommers, \& Meyer, 2011). Based on the idea that prediction is a unifying principle of the human mind, a large body of psycholinguistic research, in the VWP, as well as employing EEG, has been examining the role of prediction in language processing (see Huettig, 2015; Huettig \& Mani, 2016). Anticipatory eye-movements collected in the VWP have reliably shown that people predict upcoming referents based on the previous linguistic material (e.g. Altmann \& Kamide, 1999; Kamide, Altmann, \& Haywood, 2003), as well as based on the visually presented events (Knoeferle, Crocker, Scheepers, \& Pickering, 2005).

Our present work examines the influence of the visual modality on processing linguistic information by specifically investigating speaker gaze, as an inseparable part of the visual context in situated communication, and its influence on prediction making. We hypothesized that speaker gaze to the upcoming referent helps constrain the set of possible targets and thus, by increasing the predictability of the cued object reduces the cognitive load induced by its linguistic referent. In addition, we examined whether any cost reduction on the referent would be accompanied by a cost increase on the gaze cue, effectively spreading the cognitive load across the two modalities, namely, the gaze cue and the language.

The Gaze Cue Gaze has been shown to play an important role in situated communication. Listeners inspect objects they anticipate will be mentioned next (Altmann \& Kamide, 1999), and they fixate the mentioned object 200-300 ms after the speaker started referring to it (e.g. Tanenhaus, SpiveyKnowlton, Eberhard, \& Sedivy, 1995). Speakers also fixate
the relevant object $800-1000 \mathrm{~ms}$ before mentioning it (e.g. Griffin \& Bock, 2000). But, how does speaker's gaze add to the listener's prediction?

Previous research on gaze and language has established the gaze cue to be utilized and proven helpful while processing linguistic material (e.g. Hanna \& Brennan, 2007) even when the speaker is a robot (Staudte \& Crocker, 2011) or a virtual agent (Staudte, Crocker, Heloir, \& Kipp, 2014). The conclusions about the effects of gaze following are drawn on the basis of participants' eye-movements and responses to the task at hand. The eye-movement data give insight into the shifts of visual attention indicating whether the gaze cue was considered. In addition, the effect of considering the gaze cue on the comprehension of linguistic material is assessed by reaction times, comprehension and production tasks. Importantly however, no direct effect of speaker gaze on cognitive effort required for language processing has, to our knowledge, been examined yet. This paper sets out to investigate just that by combining eye-movement data with an online pupillary measure of cognitive load, which enabled us to measure this cost / benefit directly, and independent of a specific task.

We examined both the process of creating and (dis)confirming predictions in one and the same setting. To this end we employed a novel measurement of cognitive load - the Index of Cognitive Activity (ICA; Marshall, 2000) which allows for an experimental design that combines eyemovements, shedding light on the predictive processes, while simultaneously measuring cognitive load at different stages of sentence processing. The results revealed that referent gaze is followed and that it indeed adds to the predictability of the upcoming referent such that the spoken reference induces less cognitive load. Note that whether this effect could also be induced by arrows or other visual pointers is considered irrelevant at this point.
The Index of Cognitive Activity (ICA) The two experiments presented in this paper are conducted in the VWP. We considered the eye-movements and the cognitive load reflected in pupil size. While the traditional eye-movement analysis helps reveal any patterns of anticipation of potential target objects, the ICA allowed us to simultaneously also measure cognitive load both on the gaze cue and on the referent noun, i.e. the cognitive load induced by creating and (dis)confirming one's predictions.

Pupil dilation happens in consequence of either changes in light or cognitive activity. Two groups of muscles are responsible for pupil size: circular muscles that make the pupil contract, and radial muscles that make it dilate. Pupil size
changes due to light and due to cognitive activity employ different activation and inhibition processes, the dilation due to cognitive load being shorter and more abrupt (Beatty, 1982).

The ICA measurement disentangles the two types of change in pupil size by performing a wavelet analysis on the pupil dilation record and removing the large oscillations, while considering only the quick pupil jitter that is related to cognitive activity (Marshall, 2000). Such events of small abrupt changes in pupil size are referred to as the ICA events.

The ICA has been shown to reflect changes in cognitive load in a variety of different studies since its appearance (e.g. Marshall, 2002, 2007). However, only recently has it been examined with cognitive load induced by linguistic processing (Demberg \& Sayeed, 2016). Demberg and Sayeed present a series of seven experiments showing that the ICA indexes linguistic processing difficulty for both reading and auditory presentation of linguistic stimulus. In addition, the ICA proved to be robust with respect to eye-movements making it a valid measure of processing difficulty in the VWP.

Hence, employing the ICA in present experiments allowed for simultaneous assessment of both visual attention and cognitive load.

Current Questions and Predictions Two studies were set out to examine whether gaze is considered as part of the context determining the predictability of the subsequent referent. We examined if the gaze cue actually helps reduce the cognitive load of a linguistic referent online and whether cognitive load is in fact spread across gaze and spoken reference such that the gaze cue itself then induces higher cognitive load.

Experiment 1 made use of the gaze cue that was always fitting (the previous linguistic context) and congruent (cuing the object to be referred to linguistically). We manipulated the existence of the gaze cue in order to answer the following research questions:
a) Does the gaze cue influence the predictability of a linguistic referent?
b) If so, how does it influence the cognitive load induced by the referent?
c) Can we measure cognitive load on the gaze cue itself?

Experiment 2 also made use of congruent gaze, while manipulating the fit of the referent (thus, also the fit of the gaze cue) with the previous linguistic context. This was done in order to answer the following research questions:
a) Does the gaze cue help reduce the cognitive load on the linguistic referent even when they both do not fit the previous linguistic context?
b) Does the gaze cue to a mismatching object itself induce higher cognitive load?

We expected mismatching gaze to be surprising and thus, more costly, which would as its consequence have a reduction in cognitive load on the corresponding linguistic referent.

## Experiment 1

This study aimed to examine whether the online measure of cognitive load also supports previous findings that the gaze cue

Figure 1: A trial timeline example (from Exp.1) - referent gaze condition (left); and no-gaze condition (right).
is actively considered in language processing, by quantifying how its existence modifies the cost induced by the linguistic referent. In addition, we were interested in measuring the potential cost of gaze perception.

## Method

The study made use of $2 \times 2 \times 2$ mixed factorial design. The independent variable Gaze was a between subjects variable, i.e. half the participants were presented with the version of the experiment where all items included the gaze cue, while the rest saw the version with items never having the gaze cue. Fillers balanced the gaze conditions to the ratio of $1: 1$. In addition, four linguistic conditions were created with the two within subjects variables, Constraint and Plausibility. Constraint was manipulated by verb restrictiveness (spill vs. order), and Plausibility by noun fit (spill: water vs. ice-cream).
Participants 64 students of Saarland University took part in this study ( 45 women) and were monetarily reimbursed for their partaking. Their age ranged from 18 to 34 years old ( $M$ $=24.16$ ). Participants were all native speakers of the German language with normal or corrected to normal vision.

Materials and Design Each participant was presented with 20 items and 30 fillers, both consisting of visual and auditorily presented linguistic stimulus. In addition, visual displays included a face-like object forming the gaze cue.

Note that the gaze cue used in our studies, since being an always congruent visual pointer, is arguably not different from an arrow. This is true, but, currently irrelevant, since the differences between a visual pointer and a gaze cue are potentially to be expected in cases of manipulated congruence.

We made use of simple German sentences (Subject - Verb - Adverb - Object) that included a restrictive (spill) and a nonrestrictive (order) verb and two object nouns (water vs. icecream) of differing semantic fit in relation to the restrictive verb. The chosen nouns were controlled for frequency and two pretests have shown that in the context of order, water was more predicted (cloze probability of $13.67 \%$; plausibility rating of 1.12 on a 7 -point Likert scale ${ }^{1}$ ), than ice-cream (cloze

[^482]

Figure 2: (Exp.1) Proportion of fixations in the four linguistic conditions without the gaze cue (left) and with ref. gaze (right). The verb onset, gaze and noun onset are shown averaged across trials, and aligned to the 100 ms bins within which they fall.
probability of $0.16 \%$; plausibility rating of 2.76 ). The same adverb, neutral in meaning (gleich - ENG: soon), was used for all items and served the purpose of a spillover region.

In addition, visual displays with four concrete objects ${ }^{2}$ were presented. Two of the four objects fit the category introduced by the restrictive verb (spill: water, ice-cream), while all four fit the non-restrictive verb (order: water, ice-cream, suitcase, coat). The referent noun was always fitting with the previous linguistic context and the gaze cue was always congruent, that is, cuing the object that is about to be mentioned. The main manipulation of the study was the presence (vs. absence) of the gaze cue which was presented before the target object was referred to verbally.

Figure 1 illustrates a trial timeline. The visual scene with open eyes was presented 1000 ms prior to sentence onset. The gaze cue (or closed eyes) was introduced 300 ms after the verb, i.e. from adverb onset to sentence end. Finally, the eyes would look straight for another 1000 ms .

Fillers Fillers included the same visual setting, but differed in the structure and complexity of the linguistic stimulus and the number of objects that fit the verb category. 30 fillers were used, 25 of which had the opposite and 5 the same gaze condition as the items (ratio of 1:1 for gaze and no-gaze). 19 fillers were followed by simple yes/no comprehension questions that were answered on a key-press. The questions were related exclusively to the linguistic content. This was done in order not to inspire extensive inspection of the visual scene, but rather so that participants consider it only optionally and freely in addition to the linguistic information.

Procedure An EyeLink II head-mounted eye-tracker (SR Research, Ltd; Mississauga, Ont., Canada) was used to track

[^483]both eyes at a sampling rate of $250 \mathrm{~Hz} .{ }^{3}$ Participants were instructed to listen carefully to the sentences while looking freely at the presented objects. They would advance the experiment on a button press after each trial. Other two buttons were used to answer the comprehension questions. The experimental session was preceded by a three-trial practice session. The experiment lasted for approximately 15 minutes.

## Results

First, in order to gain insight into the patterns of prediction and visual attention we consider the proportion of fixations to the presented objects throughout a trial. Second, we analyse new inspections. Consecutive fixations to the same interest area are considered as one inspection. Since we are interested in the shift of attention inspired by a relevant stimulus, we analyse new inspections, i.e. the first inspection to an interest area that started after the linguistic or visual point of interest (as done in e.g. Staudte \& Crocker, 2011). We consider new inspections from verb onset (showing linguistic predictions) and from gaze cue onset (showing if the gaze cue influenced visual attention). Finally, the ICA events are extracted from the pupil jitter, summed over a duration of a relevant time-window and statistically analysed. For the ICA analysis, we considered the gaze time-window and the referent noun window.

Variable Coding and Data Analysis In their VWP experiment, Demberg and Sayeed (2016) establish a time-window taken 600-1200 ms from the onset of the critical word to be an appropriate window size and timing for the analysis of the ICA events. Since our critical words differ in length across items, we correct this potential confound by taking a time-window that starts from the middle of a word ${ }^{4}$, and con-

[^484]sider the following 600 ms . In addition, we analyse the gaze window: 600 ms from the gaze cue onset.

The ICA events are extracted for both eyes separately. Since there is no clear theoretical reason why differences should be expected for the two eyes, we combine the two datasets by summing the ICA events for corresponding time-windows and conduct the analyses on the combined data.

All independent variables were contrast coded for the statistical analysis. New inspections, a binary dependent variable required the use of generalized mixed effects models of binomial type. On the other hand, the analysis of the ICA, a count variable, required the use of generalized mixed effects models with Poisson distribution. All models included a maximal converging random structure for both Item and Subject. The analyses were conducted in R programming environment ( R Core Team, 2013) and using the lme4 package.

Proportion of Fixations Figure 2 illustrates the proportions of fixations to all presented objects during a trial. The first dashed line presents verb onset; second line - gaze onset (not relevant for no-gaze); the third line - referent noun onset. It is apparent that the restrictive verb (spill) shifts the focus of visual attention to one particular object (water). The less fitting object (ice-cream) is considered only upon being referred to linguistically (no-gaze), or earlier, at the point of the gaze cue (referent gaze), confirming that the visual attention is not only influenced by linguistic content but also by the gaze cue.
New Inspections We conducted a statistical analysis of new inspections to an object (water, ice-cream, distractors) from verb onset (to verb offset). In addition, we consider the new inspections to both water and ice-cream, from gaze onset (to adverb offset).

Considering the verb window, three identical models were run for the inspections to the three relevant objects. ${ }^{5}$ Looks to water: A main effect of Constraint ( $\beta=-0.361, S E=0.124$, $z=-2.904, p=0.004$ ) suggests that more new inspections to water occurred upon hearing spill (vs. order). Looks to icecream: No effect of Constraint ( $p=0.406$ ) suggests ice-cream was looked at with no significant difference in the contexts of both verbs. Looks to the distractors: A marginal effect of Constraint ( $\beta=0.153, S E=0.081, z=1.89, p=0.059$ ) suggests that there were somewhat more new inspections to the two distractors in the non-restrictive context of order.

Considering the gaze window, we analysed new inspections to both water and ice-cream together as TargetInspections and considered the effects of gaze on the looks to these two objects. ${ }^{6}$ We find a main effect of Gaze $(\beta=0.427, S E=$ $0.141, z=3.022, p=0.003$ ) confirming that the objects were more readily looked at with the gaze cueing them compared to the absence of gaze, i.e. that the gaze cue caused an immediate shift in visual attention.

[^485]

Figure 3: (Exp. 1) ICA events at the four time-windows of a sentence presented for the no-gaze (above) and the ref. gaze (below) conditions separately. (95\% CI error bars)

The Index of Cognitive Activity The analysis of the gaze time window did not yield significant results.

Considering the referent noun window ${ }^{7}$, we found a main effect of Gaze ( $\beta=-0.116, S E=0.051, z=-2.26, p=0.024$ ), suggesting that the presence of the gaze cue led to the reduction of cognitive load on the subsequent referent. Moreover, we found a significant Constraint:Plausibility interaction ( $\beta=-$ $0.184, S E=0.042, z=-4.37, p<0.001$ ), as well as a main effect of Plausibility ( $\beta=0.057, S E=0.029, z=2.01, p=$ 0.045). Further comparisons show a main effect of Plausibility in the subset of spill ( $\beta=0.152, S E=0.035, z=4.37, p$ $<0.001$ ), suggesting that spill water induced less cognitive load than spill ice-cream. No such effect was found in the non-constraining subset ( $p=0.249$ ), suggesting no difference between order water and order ice-cream. Figure 3 illustrates these findings (note: Adverb - gaze window; Object - referent window). Finally, to rule out an effect of experiment part found in the second study, experiment Half was included in the fixed effects structure. We found no Half:Gaze interaction, but a main effect of experiment Half ( $\beta=-0.047, S E=0.013$, $z=-3.57, p<0.001$ ), since the second part of the experiment induced less cognitive load.

## Discussion

The results show that the gaze cue inspired fixations to the cued object even when it was not predicted by the verb. Moreover, the presence of gaze led to the reduction of cognitive load on the referent noun in all conditions, while preserving the preference for the item that best matched the verb. Interestingly,

[^486]the existence of the gaze cue did not in itself induce additional cost on cognitive load.

Hence, we saw that the gaze cue influences predictability of the linguistic referent and subsequently reduces the cognitive load it induces. Interestingly, on the cue itself, no differences in cognitive load were induced either by its mere existence, or by whether it was cuing an object already anticipated based on the linguistic context.

## Experiment 2

The second study aimed at examining, firstly, whether the gaze cue helps reduce cognitive load on the linguistic referent even when they are both mismatching with the previous linguistic context, and, secondly, whether the cue to such an object is in itself more costly, since unexpected.

## Method

Participants 36 students of Saarland University ( 23 female) took part in the study and were monetarily reimbursed for their partaking. ${ }^{8}$ Their age ranged from 18 to 34 years $(M=23.36)$. Two students were excluded from the analysis due to technical issues, and two because their mother tongue was established to be Luxemburgish. Thus, 32 participants, German native speakers, were included in the analysis.

Materials and Design This experiment made use of $2 \times 2$ experimental design, combining Gaze (no-gaze/referent gaze) and referent noun Fit (fitting/mismatching). Only restrictive verbs were used (spill), combined with either a thematically fitting (water) or mismatching referent noun (sausage). 20 items were created, half of which were anomalous ${ }^{9}$. Note that the gaze cue was, again, always congruent (cuing the object subsequently referred to linguistically). When the referent noun did not fit the previous linguistic context, that made the gaze cue to the object in question mismatching as well. The same procedure was implemented as in Experiment 1.

Fillers The experiment included presenting 75 trials in total, 55 of which were fillers. $20 \%$ of the total number of sentences were anomalous ( 10 items, 5 fillers). The gaze cue was present in $2 / 3$ of all trials ( 10 items, 40 fillers). Only $16 \%$ of all trials included an anomalous gaze cue, i.e. gaze that was cueing a mismatching object ( 5 items, 3 fillers).

## Results

The same measures and analyses were conducted as in Experiment 1 , except for the new inspections analysis where only the gaze window was considered, due to the differing experimental design of Experiment 2.

Proportion of Fixations Figure 4 shows the proportion of fixations to all presented objects during a trial. As previously, the first dashed line presents verb onset; the second line -

[^487]

Figure 4: (Exp. 2) Proportion of fixations to presented objects in the four experimental conditions.
gaze onset (not relevant for no-gaze conditions); and the third line - referent noun onset. We see that the verb shifts the focus of visual attention to one particular object (water). The mismatching object (sausage) is considered only upon being referred to linguistically (no gaze), or earlier, at the point of the gaze cue (referent gaze). Thus, we observe the same pattern as in Experiment 1, namely, of the gaze cue shifting visual attention, on a par with the linguistic information.
New Inspections Considering the gaze window we combined the new inspections to both water and sausage together as TargetInspections and examined the effect of gaze on the looks to these two objects. ${ }^{10}$ A main effect of Gaze ( $\beta=$ $0.381, S E=0.191, z=1.995, p=0.046$ ) confirmed that the gaze was followed, as found in Experiment 1.

The Index of Cognitive Activity We first analysed the referent window ${ }^{11}$ and found a main effect of Fit ( $\beta=0.223$, SE $=0.043, z=5.21, p<0.001$ ), suggesting that the anomalous spill sausage required more cognitive load than spill water. Considering the effect of the gaze cue on the cost of the referent, a significant Gaze:Half interaction was observed ( $\beta=$ $-0.126, S E=0.062, z=-2.05, p=0.040$ ). Further analysis showed a marginal main effect of Gaze in the second half of the experiment $(\beta=-0.091, S E=0.047, z=-1.93, p=0.054)$, suggesting that the referent gaze reduced the cognitive load on the referent noun in both linguistic conditions. No such effect was found in the first half of the experiment ( $p=0.392$ ).

Since gaze affected referent processing in each experimental half differently, we considered cognitive load on the cue itself (gaze window) for each half separately. ${ }^{12}$ The first part of the experiment revealed a Gaze:Fit interaction $(\beta=0.179, S E=$

[^488]

Figure 5: (Exp.2) ICA events at the four time-windows of a sentence in the first (above) and the second (below) half of the experiment. ( $95 \%$ CI error bars)
$0.084, z=2.13, p=0.033)$. In the second half, a main effect of Gaze ( $\beta=0.099, S E=0.045, z=2.20, p=0.028$ ) suggests that the referent gaze induced higher cognitive load than the nogaze condition. The results are illustrated in Figure 5 (note: Adverb - gaze window; Object - referent window).

## Discussion

The eye-movements data showed evidence of gaze following even when it was unpredicted, or worse, also mismatching. Regarding the cost of processing the referent noun, initially, the existence of gaze did not have an effect; but the cognitive load induced by the mismatching cue itself was higher than that induced by both fitting gaze and no gaze cue. However, in the second half of the experiment, cognitive load on the referent noun was marginally reduced due to the helpful gaze cue; while the cue itself (to both fitting and mismatching object) now induced higher cognitive load. This suggests that participants gradually adapted to and started relying on the surprising gaze cue (increasing load on the cue) and started making use of its informativity (lowering load on the noun).

## Conclusions

Referent gaze is actively considered in the process of prediction making, shifting the visual attention to the cued object, and leading to the reduction of cognitive load on its linguistic referent. This holds even when the cue (and the corresponding referent) is mismatching with the verb. Gaze perception proved not to be costly unless mismatching with the verb.

Both studies included conditions with unpredicted but congruent gaze cue (Exp.1: order water, order ice-cream; Exp.2: spill sausage). Such a condition induced a higher processing cost on the gaze cue in Exp. 2, but not in Exp. 1. We argue that in Exp. 1 gaze is still processed naturally, as a gaze cue, due to its overall fit, while in Exp. 2, due to the mismatch with the verb, the cue became more salient, treated as a visual
pointer, regardless if cuing a fitting or mismatching object. We interpret this as evidence against a spread of cognitive load between gaze and linguistic reference.

In sum, the gaze cue is exploited to predict the upcoming referent such that it can be processed with less effort. If verb selectional features direct visual attention to a particular object and the gaze cue (alternatively) introduces a different object, this creates a shift in visual attention but, does not negate the existing preference. Cognitive load is reduced as an effect of the gaze cue, but only when the cue is established as informative and reliable, and regardless of its contextual fit.

# Gestural Hesitation Reveals Children's Competence on Multimodal Communication: Emergence of Disguised Adaptor 

Kazuki Sekine (kazuki.sekine@mpi.nl)<br>Radboud University/ Max Planck Institute for Psycholinguistics, Wundtlaan 1, 6526 XD Nijmegen, the Netherlands

#### Abstract

Speakers sometimes modify their gestures during the process of production into adaptors such as hair touching or eye scratching. Such disguised adaptors are evidence that the speaker can monitor their gestures. In this study, we investigated when and how disguised adaptors are first produced by children. Sixty elementary school children participated in this study. There were ten from each school year (from 7 to 12 years of age). They were instructed to remember a cartoon and retell its story to their parents. The results showed that children did not produce disguised adaptors until the age of 8. The disguised adaptors accompany fluent speech until the children are 10 years old and accompany dysfluent speech until they reach 11 or 12 years of age. These results suggest that children start to monitor their gestures when they are 9 or 10 years old. Cultural influences and cognitive changes were considered as factors to influence emergence of disguised adaptors.

Keywords: co-speech gestures; disguised adaptors; elementary school children; speech dysfluency.

## Introduction

Researchers have examined the development of gestures in children in terms of when the frequency or repertoire increases and how the relationship between a gesture and speech changes with age. The present study focused on spontaneous suppression of gesture production during speech. Analyzing when and how children try to not produce gestures would provide insight into when children become aware that their gestures are socially communicative.

The present study focuses on co-speech gestures (hereafter simply referred to as 'gestures') that spontaneously co-occur during speech and that have no standard of well-formedness, unlike sign language, but are created idiosyncratically on the fly (McNeill, 1992). A gesture typically has three phases: preparation, stroke, and retraction. In the preparation phase, the hand moves from a position of rest. The stroke phase is the central part of a gesture that conveys substantial information. The relevant meaning represented by this phase is usually expressed in the concurrent speech. Sometimes, a hold phase, where the hand is held in mid-air at the same position, occurs before and/or after the stroke phase.

As children prefer to use speech as a means of communication, the frequencies of gestures that appear around the first word and are used alone without speech, such as deictic gestures and symbolic gestures, decreases (Volterra \& Iverson, 1995). In their place, gestures that cooccur with meaningful words, called "co-speech gestures", appear around the period. Goldin-Meadow \& Butcher
(2003) observed that gestures begin synchronizing with speech both semantically and temporally in the transitional phase to the two-word speech period, at about 18 months of age. Given that gestures are not often used solely but are coproduced with speech, gestures and speech seem to form an integrated system during this period (Goldin-Meadow \& Butcher, 2003).
Previous research has shown that speech and co-speech gesture develop hand-in-hand even after two-word period. Mayberry \& Nicoladis (2000) observed that longitudinally bilingual children between 2- and 3-and-half years old produce more gestures when they speak either language that allows them produce a longer utterance, as measured by the mean number of morphemes (Mayberry \& Nicoladis, 2000). They concluded that gestures are closely related to morphosyntax level. This conclusion is indirectly supported by Fujii's (1999) study showing that the frequency of gestures does not correlate with vocabulary in the preschool period. McNeill (1992) observed that by the end of the preschool period, the frequency of gestures ascends to near adult levels. Once children start having formal education, they gradually develop the ability to create a coherent narrative by using language devices such as anaphora expressions, substitutions, ellipses and connectives (Wigglesworth, 1990). Research has shown that as children acquire spoken referential expressions for making coherent discourse, they also use gestures to mark introduced or maintained referents in the narrative (McNeill, 19992), and the number of gestures consistently increases during the elementary school period (Colletta et al., 2014; Sekine \& Furuyama, 2010). Thus, these previous studies indicate that gesture and speech develop hand-in-hand across the development. However, it is not clear if children start monitoring their gestures or become aware of gestures as information resources that their listeners can make use of.
Studies on self-repair in speech have asserted that to correct one's speech, the speaker has to monitor his or her speech process continuously, and thus, correction of speech errors is considered to reflect the speaker's ability to monitor speech (Karmiloff-Smith, 1986). Based on this assumption, it seems that determining when children start to correct their gestures would provide insight into understanding when they start monitoring their gestures. However, unlike speech in which the message is delivered by aligning linearly linguistic elements that exist independently, a gesture conveys a meaning globally at once, and any decomposition into elements is dependent on the whole (McNeill, 1992). Because of the linearity in speech, it is easier to understand where speech errors occurred and how the speaker corrected them than errors in
gestures. In contrast, gestures are mostly continuous and some of their parameters change simultaneously. This makes it difficult to determine whether and where a speaker has corrected a gesture. Considering these differences in semiotic characteristics, this study focused on a specific type of gestural correction; i.e., disguised adaptors.

Adaptors are movements that help persons to satisfy personal needs, manage emotions, and adapt to their environment such as touching one's hair or adjusting one's glasses (Ekman \& Friesen, 1969). At times it is observed that a speaker stops making a gesture in the middle of production and switches it to an adaptor to hide the gesture. Such movements may be able to say socially preferable in the situation. In this study, this kind of behavior is termed a disguised adaptor, which is defined as a gesture that is altered into an adaptor before or during the stroke phase of the gesture.

It can be observed in daily conversation that when a speaker is asked a question by the listener in the middle of her gesture and speech production, she stops producing the gesture, and puts her hand on her head or eye to scratch as if it feels itchy, like shown in Figure 1. Figure 1 indicates a scene in which the speaker on the right was retelling an episode of cartoon that she had watched to the listener on the left ((1) in Figure 1). When she was describing the figure of the drainpipe with a gesture, the listener started asking her whether one character was in the birdcage (2). At that moment, she stopped her gesture in the middle, and put her right hand on her head and scratched it until the listener finished the question (3).

Speaker (on the right side):
[soko made (1)ikitakutte, sono mado no (2)tokoro nikou'(he) (1)wants to go there, and (2)at the place where the window is, like this-'
Listener (on the left side):
[torikago (3)no naka ni haitteiruno?]
'is (he) (3)inside the cage?'
Figure 1: Halt of a gesture by listener's question.
Here, and in subsequent examples, the square brackets represent the start and end points of the motion of the speaker's hands, boldface marks the stroke phrase of the gesture phrase, underline indicates a motionless hold phase, and double underline represents the duration in which a disguised adaptor, such as touching the body or clothes. ' $\%$ ' indicates a smacking sound, '*' represents self interruption, and ' $\because$ ' in speech indicates an elongated phonation. The numbers used in figure, correspond to the numbers in the transcription, which in turn indicate the places where
gestures occurred. In the transcription, the first chunk is the original Japanese speech and the second chunk is the English translation.

Similar behaviors to the one in Figure 1 can be observed in other situations, for example when one raises his hand to catch a taxi, but misses it, or in which one is waving to her friend, and then quickly becomes aware of mistaken identity. In these situations, they often switch the hand movements to self-contact behaviors such as scratching head or eyes as if it is meant to be. Interestingly, literature on Tourette's syndrome, a chronic neurological disorder characterized by multiple involuntary movements and uncontrollable vocalizations called tics, has documented the correction of tic movements made by patients. Sottofattori and Nicolai (2007) observed that the patients can modify tics or odd movements into other movements like gestures in a natural conversation. For example, when a tic affects the right or left arm, the patient tries to move the forefinger straight with the tic as if it were a deictic gesture. All these cases suggest that when we are aware of mistake of hand movement or when we are interrupted in executing our hand movements, we often change the hand movement to a more socially acceptable movement such as scratching a body part or producing gestures.

In the light of development of gestures in children, it is important to examine whether typically developing children also are able to modify body movement into a more socially acceptable one. Because if children perform this kind of correction, it implies that they can monitor their gestures. If they already know that gestures can be seen as information resource by their listeners and they can detect errors in their gestures or speech, they may try to modify their gestures into more socially acceptable movement, such as scratching the neck.

Suppose that gesture and speech interacts in the production process (McNeill, 1992), and then gestural correction may affect or be affected by speech errors or dysfluencies. Thus, the relationship between disguised adaptors and speech errors should also be investigated. Karmiloff-Smith (1986) found that the percentage of speech repairs denoting sensitivity to the linguistic system, such as the determiner functions of articles, adjectives and possessives, increased during the elementary school period. Given these findings, it is predicated that the number of disguised adaptors also increases during this period as children acquire an ability to monitor their expressions. In addition, if disguised adaptors are due to difficulties in retrieving words, they would co-occur with filled pauses, unfilled pauses, or speech errors, rather than with intact linguistic elements, because previous studies have shown that adaptors tend to occur with speech dysfluencies while the speaker is retrieving words (Fujii, 1997; Pine, Bird, \& Kirk, 2007). However, if a disguised adaptor does not cooccur with speech dysfluencies, it might occur influenced by other factors such as cultural or cognitive factors. For instance, cognitive capacity or cultural pressure to produce or inhibit gestures may control the emergence of disguised
adaptors. Under this hypothesis, this study examined when disguised adaptors emerge during the elementary school period and how this emergence is related to speech.

## Method

## Participants

Sixty elementary school children and their parents participated in this study. There were ten children from each grade, 1 st to 6 th grade. Half were boys. In this study, each grade is referred to by their mean age, 7 - to 12 -years-olds (7-year-olds, $\mathrm{M}=7 ; 0$, Range 6;9-7;4. 8 -year-olds, $\mathrm{M}=7 ; 11$, range $7 ; 9-8 ; 10,9$-year-olds. $\mathrm{M}=9 ; 4, \mathrm{R}=9 ; 0-9 ; 6,10$-yearolds, $\mathrm{M}=10 ; 0, \mathrm{R}=9 ; 7-10 ; 5$, 11-year-olds, $\mathrm{M}=11 ; 4, \mathrm{R}=10 ; 9$ $11 ; 11, \quad 12$-year-olds, $\mathrm{M}=12 ; 0, \mathrm{R}=11 ; 5-12 ; 10$ ). All the participants were native monolingual Japanese speakers from middle-class families, and the children attended public or private elementary schools in Tokyo, Japan.

## Material and Apparatus

Each child watched a seven-minute animated color cartoon of the Tweety and Sylvester series, titled 'Canary Row' (Warner Brothers, Inc.). This cartoon was displayed on a 14-inch color computer monitor (Panasonic CF-F8). A miniDV camcorder (Sony HDR-HC9) was used to record the children's gesture and speech.

## Procedure

The experiments were conducted in a quiet room in the participant's home or a local community center. Each child was instructed to remember the cartoon story shown on the computer monitor and retell it to his or her parent as a listener in as much detail as possible. The parent was allowed to respond to the child by nodding their head or by using back channels during the child's narration. The whole session was recorded using the mini-DV camcorder on a tripod.

## Coding

Speech data. All narratives were verbatim transcribed. From the transcriptions, the mean number of clauses was then calculated. A clause was loosely defined as a combination of a noun phrase and a verb phrase). The mean number of unfilled pauses, which was defined as periods of silence longer than 200 msec . (Beattie, 1983), filled pauses, such as 'unttoo' (umm) or 'eeetto' (ehhh), and speech errors, including repetitions, replacements or false starts, were measured in order to ascertain the relationship between speech fluency and production of disguised adaptors.
Gesture data. First, co-speech gestures were identified. Hand movements were classified as gestures only when they had an identifiable beginning and a clear end and were synchronized with speech. After identifying which movements were gestures, the total number of gestures was counted. Next, disguised adaptors were identified. We coded a hand movement as a disguised adaptor if two criteria were met; 1) A gesture was altered into adaptor
before or during the stroke phase without any pause, and 2) the direction of the gesture suddenly changed when it is altered into adaptor. To analyze the temporal relationship between disguised adaptors and speech fluency, their combinations were categorized into the following six types: DA (disguised adaptor), FP (filled, pause), IS (intact speech that was completely articulated, such as Noun or Verb phrases), PR (the preparation phase of a gesture), SE (speech error), and UP (unfilled pause). The orders were as follows:

## 1. PR $\rightarrow$ IS + DA

After the preparation phase started, a disguised adaptor occurred with intact speech.
2. $\mathrm{PR} \rightarrow \mathrm{FP}+\mathrm{DA}$

After the preparation phase started, a disguised adaptor occurred with a filled pause.
3. PR $\rightarrow$ UP + DA

After the preparation phase started, a disguised adaptor occurred with an unfilled pause.
4. $\mathrm{PR} \rightarrow \mathrm{FS}+\mathrm{DA}$

After the preparation phase started, a disguised adaptor occurred with a filled pause.
5. PR $\rightarrow$ FS (FS) $\rightarrow$ IS + DA

After the preparation phase started, a false start or a number of false starts occurred. Then, a disguised adaptor occurred with intact speech.
6. $\mathrm{PR} \rightarrow \mathrm{FP}$ and/or FS $\rightarrow \mathrm{FP}+\mathrm{DA}$

After the preparation phase started, a false start and/or filled pause occurred. Then, a disguised adaptor occurred with a filled pause.

## Results

Number of gestures, clauses, pauses, and speech errors To calculate the frequency of gestures and the proportion of unfilled pauses for each age, the total number of gestures and the total amount of time spent for unfilled pauses were divided by the total speaking time. To calculate the frequency of filled pauses and speech errors, the total number of filled pauses and speech errors were each divided by the mean number of clauses (Table 1). After performing an angular transformation on the proportion of unfilled pauses in the speaking time, an ANOVA was conducted on each index (Table 1). A main effect of age group was found for the gesture frequency, $F(5,54)=3.86, p=.005$, the proportion of unfilled pauses in the speaking time, $F(5,54)$ $=2.44 p=.046$, and the proportion of speech errors in clauses, $F(5,54)=2.49, p=.042$. A post hoc comparison (Tukey, $p<.05$ ) showed that 12 -year-olds produced gestures more frequently than $7-, 9$ - and 10 -year-olds did and that the proportion of unfilled pauses during the speaking time was significantly greater for 7-year-olds ( $47 \%$ ) than for 12 -year-olds ( $33 \%$ ). There was no significant age-group difference in the total number of clauses or frequency of speech errors. These results indicate that the proportion of unfilled pauses gradually decreases during the elementary school period, whereas the frequencies of
gestures and speech errors increase in the late elementary school period.

Table 1: Number of Clauses, Gestures, Pauses, and Speech Errors.

| Age | 7 | 8 | 9 | 10 | 11 | 12 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| -Frequency of gestures | $0.12(0.06)$ | $0.14(0.09)$ | $0.10(0.09)$ | $0.09(0.06)$ | $0.19(0.13)$ | $0.27(0.17)$ |
| per second | $62.4(29.93)$ | $69(20.42)$ | $77.8(24.68)$ | $77.3(15.58)$ | $91.9(20.90)$ | $78.6(19.47)$ |
| -Total number of clauses | $6.47(0.19)$ | $0.40(0.11)$ | $0.38(0.08)$ | $0.34(0.06)$ | $0.36(0.08)$ | $0.33(0.08)$ |
| -Proportion of unfilled | $0.38(0.25)$ | $0.29(0.17)$ | $0.26(0.07)$ | $0.39(0.31)$ | $0.31(0.18)$ | $0.25(0.10)$ |
| pauses in speaking time | $0.20(0.10)$ | $0.21(0.12)$ | $0.38(0.19)$ | $0.28(0.11)$ | $0.36(0.20)$ |  |
| -Filled pauses per clause | $0.3)$ |  |  |  |  |  |
| -Speech errors per clause | $0.26(0.15)$ |  |  |  |  |  |

## Number of children who produced a disguised adaptor

In total, 22 disguised adaptors were observed. The absolute number of disguised adaptors produced by each age group was three times for 9 -year-olds, three times for 10 -yearolds, twelve times for 11-year-olds, and four times for 12-year-olds. Three 9 -year-olds, three 10 -year-olds, five 11 -year-olds, and two 12 -year-olds produced a disguised adaptor at least once during their narrations. There were no 7 - or 8-year-olds who produced disguised adaptors. A Fisher's exact test was used to examine the relationship between the age of the group and the number of children who produced disguised adaptors. There was a significant association between them (Fisher's exact test, $p=.03$ ). A residual analysis was conducted to find out where the significant differences among age groups were. The analysis indicated that 11-year-olds produced disguised adaptors more often than the other age groups did.

ntto: saisho: sono neko ga: tweety o: sagashi ni: it-te: [de mi-ta mi-ta nekotan] ttsut-te: sorede [(1)\% (2)sono ] (2.07) (3)sagashi ni it-ta tokoro wa: inu: toka neko wa dame tte iu omise de
'well, at first, the cat went to look for Tweety and (he) said "(he) saw, saw the pussy cat," then, well the place where (he) went to look for the cat was a shop where dogs and cats were not allowed'

Figure 2: A 11-year-old girl telling a story.
Figure 2 shows a typical case of a disguised adaptor in which an 11-year-old girl described the first of eight scenes, in which Sylvester the Cat goes into a building to catch Tweety Bird who lives there. Regarding the scene where Tweety said that he saw the cat, "mita mita neko tan ttutte sorede", the girl raises her right arm and puts her fingers into an O-shape ((1) in Figure 2). Given that she uses the right side of the space and a hand shape as if it is holding an object while talking about where Sylvester went to find

Tweety, the right hand movement seems to be part of the preparation phase to depict the building that Tweety is in.

However, while saying 'sono', which functions as a filled pause and also means an article "the" in English, she stopped production of the gesture's stroke and modified it into a disguised adaptor of rubbing her right eye with her right hand ((2) in Figure 2). After that, an unfilled pause, which lasted about 2 seconds, occurred until the next word started. During this pause, she retracted the disguised adaptor and described in speech the place where the cat went to find the bird. This case can be interpreted as being that she first tried to depict the building that the cat goes into by using both speech and gestures. However, because she could not remember the proper name for it, she abandoned the gesture in the middle of the production and modified it into a disguised adaptor.

Temporal relationship between speech and disguised adaptor
Each disguised adaptor could be categorized into one of six types (Table 2). The most frequent type was the cooccurrence of a disguised adaptor and intact speech (Type 1), followed by a combination of a disguised adaptor and intact speech after a false start(s) (Type 5) and synchronization of a disguised adaptor and a filled pause after a speech error and/or filled pause (Type 6).

Table 2: Number of cases categorised into temporal relationships

| Types ${ }^{1)}$ | Absolute number (\%) |
| :--- | :---: |
| 1. PREP $\rightarrow$ Intact speech + DA | $7(32)$ |
| 2. PREP $\rightarrow$ Filled pause + DA | $3(14)$ |
| 3. PREP $\rightarrow$ Unfilled pause + DA | $2(9)$ |
| 4. PREP $\rightarrow$ Speech error + DA | $1(5)$ |
| 5. PREP $\rightarrow$ Speech error ( $\rightarrow$ Speech | $5(23)$ |
| error) $\rightarrow$ Intact speech + DA | $4(18)$ |
| 6. PREP $\rightarrow$ Filled pause and/or |  |
| Speech error $\rightarrow$ Filled pause + DA <br> Total | $22(100)$ |

1) Abbreviations and notations: DA (disguised adaptor), PREP (preparation phase), $\rightarrow$ (order of temporal direction), + (synchronization of elements)

To see whether disguised adaptors were related to word searches, the six types were further classified into two
groups in terms of whether the disguised adaptor occurred with a speech error, (un)filled pause, or intact speech element. The former group is termed the dysfluent speech combination and includes Types 2, 3, 4, and 6, whereas the latter group is named the fluent speech combination and includes Types 1 and 5 . The number of children who produced each combination was counted for each age group. Three 9 -year-olds, three 10 -year-olds, three 11 -years-olds, and one 12-year-old produced fluent speech combinations. Five 11-year-olds and one 12-year-old produced dysfluent speech combinations. No children aged 9 or 10 produced dysfluent speech combinations. A Fisher's exact test was used to examine the relationship between age group and each combination. A significant association was found only in the dysfluent speech combination (Fisher's exact test, $p=$ .002). In contrast to the fluent speech combinations produced by 9 - to 12 -years-olds, dysfluent speech combinations were not produced by 9 - and 10 -year-olds, and all of 11-year-olds produced dysfluent speech combinations.

Figure 3 show a 9-year-old boy who produced a fluent speech combination. The figure shows him explaining a scene in which Sylvester got inside Tweety's apartment, but was struck by the bird's owner with an umbrella. While he was talking about the umbrella, he raised his right hand and shaped his hand as if it were holding an umbrella ((1) and (2) in Figure 3). However, without finishing the preparation as a gesture, he moved his hand to his eye to scratch it as a disguised adaptor. Unlike the girl in Figure 1, who produced a dysfluent speech combination, his speech did not contain obvious speech errors or pauses. Thus, his disguised adaptor may have been caused by other factors besides a word search (this point is taken up in the discussion section).

sorede ouchi no naka ni hait-ta $n$ dakedo sono kainu[shi no obaachan ga] dete[(1)ki-te (2)kasa de: (3)\# (4)nagurare-te: tsugi wa are ]
'and (he) got inside the house, the grandma, the owner comes out and (he) is struck with an umbrella, and the next is, umm'

Figure 3: A 9-year-old boy telling a story.

## Discussion

The present study investigated disguised adaptors as an index of a child's ability to monitor his or her own gestures by focusing on the relationship between disguised adaptors and speech flow. The results showed that the gesture frequency and the proportion of speech errors increase with age, especially in the late elementary school period, whereas
the proportion of unfilled pauses decreases with age. The increase in speech errors suggests that children tend to dedicate much effort to planning coherent narratives especially from the age of 10 . Considering pauses may reflect cognitive processes underlying speech planning including word search, syntax, conceptual and articulation planning (Schönpflug, 2008), it is considered that children gradually acquire the ability to plan speech quickly during their elementary school years.
In this study, disguised adaptors were produced by children who were more than 9 -years-old. None of the $7-$ and 8 -year-olds used disguised adaptors at all. This result indicates that children become aware of their gestures as an informational resource for listeners from the age of 9 onwards. In other words, they acquire the ability to monitor their gestures from the age of 9 .
The analysis of the temporal relationship between a disguised adaptor and speech fluency suggests that disguised adaptors are caused by not only speech dysfluency but also other factors. Children from 9- to 12 -years-old produce fluent speech combinations, but only the higher graders produced dysfluent speech combinations. This implies that disguised adaptors of 11- and 12-year-olds are partly caused by the act of searching for an adequate word or planning a sentence. In these cases, children may notice that they have to stop speaking to retrieve a word or re-plan a sentence, and accordingly they modify their gestures to a disguised adaptor in the middle of gesture production. Based on these results, I will discuss why disguised adaptors appear around the age of 9 years in terms of cultural and cognitive factors

## Cultural influence

Previous studies on the gestures of elementary-school-age children suggest a cultural influence. Some studies have reported that the frequency of gestures consistently increases during the elementary school years. These trends appear across cultures, although most of the studies were on children in Indo-European language cultures (e.g., Colletta et al., 2014). However, this study on Japanese children showed that the frequency of gestures decreases temporarily in the middle grades compared with in the lower grades or higher grades. This difference may come from their educational environment. In Japan, sometimes pupils are implicitly and explicitly warned by their teacher to avoid fidgeting or moving their hands when the teacher or another child is speaking or sometimes even when they themselves speak. In fact, speakers in Asia sometimes learn not to gesticulate (Neu, 1990). These findings suggest that Japanese children as young as 9 -years-old attempt to embody the rule about hand movement during communication. This may be related to why disguised adaptors produced by 9 - and 10 -year-olds do not synchronize dysfluences. Because they seem to start noting that their hand movements can be read by someone as symbols, even when they do not have a problem with word search, they may try to suppress their hand movements.

## Cognitive change

As a factor influencing the emergence of disguised adaptors from the age of 9 or 10 , one may consider cognitive changes occurring during this period. Piaget \& Inhelder (1969) suggested that the period is considered to be the concrete operational stage at which abstract logical thought is first applied to the physical world. Karmiloff-Smith (1986), who investigated the development of metalinguisitc awareness in 4 - and 12 -year-olds, found that many children from 9 years onwards explicitly have metalinguistic awareness. Thus, children in the middle grades of elementary school seem to develop metacognitive knowledge to notice that there are underlying rules or mechanisms in the physical world and human communication. At same time, they may also become aware that gestures are informational resources for the listener. Because children in this period are sensitive to such rules, they start monitoring their expressions to check whether the message in the expression is adequate given the communicative context. This awareness seems to result in the emergence of disguised adaptors and an increase of speech errors in children in the later years of elementary school. Ito and Tahara (1985) found that 10-year-olds had poorer usage of the postpositional particle $W A$ in comparison with other age groups. The speculated that because children in this period are just beginning to notice and attempt to grasp the multifunctional nature of language devices, their performance seems to decline temporarily. This suggests that the ages of 9 and 10 can be seen as the transitional period in which Japanese children begin noticing the communicative function of gesture and linguistic system, and monitoring them.

Examining when children suppress gestures contributes to an understanding of children's gestural development. Just as certain self repairs in speech that are spontaneously made by children during narratives reflects metalinguisitc awareness that they have acquired (Karmiloff-Smith, 1986), the emergence of disguised adaptors implies that children have an awareness of gestures. This study showed that although the production of gestures may be mostly an unconscious process (Goldin-Meadow \& Butcher, 2003), the speaker can notice that she is producing a gesture after she raises her hand for a gesture, and that this awareness begins at about 9 years of age. Future task is exmaning whther disguised adaptors are rubost phenomonen by collectiong more data from other age groups and from other cultuore groups.

# Adaptability and Neural Reuse in Minimally Cognitive Agents 

Matthew Setzler (msetzler@indiana.edu)<br>Cognitive Science Program, Indiana University Bloomington, IN 47408 USA

Eduardo J. Izquierdo (edizquie@indiana.edu)<br>Cognitive Science Program, School of Informatics and Computing, Indiana University Bloomington, IN 47408 USA

#### Abstract

Cognitive agents are continuously faced with new problems. To facilitate adaptation, emerging theories of neural reuse propose that evolution might often favor re-purposing existing brain structures for new functions. This paper presents a novel approach to the study of neural reuse based on the evolution of simulated agents in an object-categorization task. We artificially evolve populations of dynamic neural networks to perform two variants of a categorization task that alternate over evolutionary time. We find that populations become increasingly adaptive over repeated exposures to the tasks. Analysis of evolved networks reveals two types of equally-fit solutions: one that is specialized to a given task variant and does not adapt to changes easily; and another that is more general, in that it can adapt to the other task with minimal change to its structure. Interestingly, we find that populations exposed to alternating tasks spontaneously locate the latter type of structures.

Keywords: neural networks; minimally-cognitive behaviors; neural reuse; artificial evolution; evolvability

## Introduction

A central goal of cognition is adaptation. Cognitive agents are continuously faced with new problems and it is in their best interest to reuse pre-existing solutions from prior problems wherever possible. Many lines of research in cognitive science are motivated by this broad notion of adaptation. An emerging class of theories suggest neural reuse is a fundamental organizing principle of adaptation in the brain (Anderson, 2007; Gallese, 2008; Dehaene, 2005; Hurley, 2008). According to these theories, neural circuits established for one purpose are often put to different use without losing entirely their original functions. Different versions of this theory have been proposed, some that operate over the developmental timescale (Dehaene, 2005) and others over evolutionary timescales (Anderson, 2007). These theories are supported by a wealth of empirical evidence (see Anderson, 2010, for more details). However, a grounded account of how reuse might occur remains poorly understood. Computational models in this area have tended to focus on disembodied cognitive architectures (Braylan, Hollenbeck, Meyerson, \& Miikkulainen, 2016), largely detached from the increasingly accepted viewpoint that cognition is distributed over a dynamically coupled brain-body-environment system (Chiel \& Beer, 1997).

The work presented here takes a different approach to studying adaptation and neural reuse over the evolutionary timescale. We study adaptation in a computational model of dynamic embodied agents evolved to perform two variants
of a visual discrimination task. Specifically, we artificially evolve populations of dynamic neural networks to perform two closely-related variants of a visual discrimination task that alternate over evolutionary time. To the extent that adaptability is achieved, we should observe populations adapting quicker to changes in the task requirement over the course of an evolutionary run. The degree to which neural reuse occurs will be evident in the evolved neural structures, which are readily analyzable after evolution.

Our approach extends beyond the scope of other work in two important ways. First, studying reuse in a deliberately simple computational model gives us a tractable and fully transparent system which can be analyzed to yield a grounded account of how adaptability and neural reuse play out in an embodied and situated context. Secondly, unlike other computational approaches which employ evolutionary frameworks specifically designed to facilitate neural reuse (Stanley \& Miikulainen, 2002), we use a standard genetic algorithm, thus minimizing assumptions about the form of neural reuse by seeing how it might occur spontaneously as a result of implicit pressures imposed by changing task requirements.

In this paper, we aim to show adaption via neural reuse over the evolutionary timescale in an idealized computational model of dynamic, embodied agents performing two variants of a previously studied visual discrimination task (Beer, 1996, 2003). Insofar as model-agents exhibit hallmarks of cognition, this is of interest in and of itself. Additionally, insight gained in this idealized computational setting will provide a proof of principle for how reuse might occur in naturalistic (embodied/situated) settings, which will help inform the conceptual and analytical tools used to study this phenomenon in living systems.

## Methods

## Agent, Environment, and Task

In previous work (Beer, 1996, 2003), model agents were evolved that could "visually" discriminate between objects of different shapes, catching some while avoiding others. All details of the agent, environment, and task have been adapted from these previous studies.

The agent lives on the floor of a $275 \times 400$ rectangle (Figure 1A). It has a circular body with a diameter of 30 and an "eye" which consists of 7 vision rays evenly distributed over an angle of $\pi / 6$. These rays extend out from the agents body with a maximum range of 220 . There are two kinds of objects

Figure 1: Agent and environment, adapted from (Beer, 1996). [A] Agent moves horizontally while an object falls towards it from above. Object can be one of two shapes: circle or line segment. Agent's sensory apparatus consists of an array of seven distance sensors (dashed lines). [B] Neural architecture. Distance sensors (black) project to a layer of fully interconnected interneurons (gray, recurrent connections not shown), which in turn project to the two motor neurons (light gray).
in the world: circles (with a radius of 15 ) and horizontal line segments (of length 30). These objects fall from a height of 275 at some initial horizontal offset with respect to the agent. Objects fall with a constant vertical velocity of -3 and no horizontal motion. If an object intersects a ray within this range, an external input is fed to a corresponding sensory neuron. The value of the input is inversely proportional to the distance at which the intersection occurs, normalized from 0 to 10.

As depicted in Figure 1B, the agent's nervous system is a 3-layer continuous time recurrent neural network (CTRNN) with the following state equation (Beer, 1996):

$$
\begin{equation*}
\tau_{i} \frac{d y_{i}}{d t}=-y_{i}+\sum_{j=1}^{N} w_{j i} \sigma\left(y_{j}+\theta_{j}\right)+I_{i} \tag{1}
\end{equation*}
$$

where $y$ is the state of each neuron, $\tau$ is its time constant, $w_{j i}$ is the strength of the connection from the $j^{t h}$ to the $i^{t h}$ neuron, $\theta$ is a bias term, $\sigma(x)=1 /\left(1+e^{-x}\right)$ is the standard logistic activation function, and $I$ represents an external input (e.g., from a sensor). The top layer consists of 7 sensory neurons which are stimulated by the agent's vision rays as described above. These project down to a middle layer of 5 fully interconnected neurons, which in turn feed into two motor neurons. The difference in output between the motor neurons results in an instantaneous horizontal velocity which moves the agent in one direction or the other. The network is bilaterally symmetric in terms of connection weights, gains and biases, with the additional stipulations that all sensory neurons shared the same gain and biases. This makes for a total of 47 parameters. States were initialized to 0 and circuits were integrated using the forward Euler method with an integration step size of 0.1 .

The task of the agent is to visually discriminate between objects of different shapes. These experiments were designed
to produce evolved examples of categorical perception (Beer, 2003). For the purpose of our study, there are two variants of the object discrimination task. In Task A, agents must distinguish between circles and line objects by reliably moving towards the former and away from the latter. In Task B, the agents must do the opposite: move towards line objects and avoid circles. The tasks were chosen because of how closely related they are to one another.

## Evolutionary Swapping

A real-valued genetic algorithm was used to evolve CTRNN parameters: connection weights, biases, time constants, and gain. Agents were encoded as 47-dimensional vectors of real numbers varying from $[-1,1]$. Each vector element linearly mapped to a parameter of the CTRNN: interneuron and motorneuron biases $\in[-5,5]$, sensory neuron biases $\in[-4,-2]$, time-constants ranged $\in[1,2]$, and connection weights $\in[-5,5]$. Parents were selected with a rank based mechanism, with an enforced elitist fraction of 0.04 . Offspring were generated from uniform crossover of two parents (probability 0.5 ). A Gaussian distributed mutation vector was applied to each parent $\left(\mu=0, \sigma^{2}=0.01\right)$.

Fitness was calculated across 24 trials with objects dropped at horizontal offsets uniformly distributed over the range of $+/-50$. The performance measure to be maximized was: $\sum_{i=1}^{24} p_{i} / 24$, where $p_{i}=1-\left|d_{i}\right|$ for the objects that need to be caught and $p_{i}=\left|d_{i}\right|$ for the objects that need to be avoided, and $d_{i}$ is the horizontal distance between the centers of the object and the agent when their vertical separation goes to zero on the $i$ th trial. The distance $d_{i}$ is clipped to a maximum value of 45 and normalized to run between 0 and 1 .

The two tasks have inverted fitness rewards. In Task A, agents are required to catch circles and avoid line segments; in Task B agents are required to catch line segments and avoid circles. Therefore, high fitness with respect to one guarantees proportionately low fitness on the other.

We performed evolutionary runs under changing conditions. In this case, a population was initially evolved for a given task variant until the best agent reached a fitness threshold of $95 \%$. Once the fitness threshold was reached, the task was changed to the opposite task. Populations were continuously evolved in this alternating manner for 2500 generations. In addition to these, runs were performed for Task A and Task $B$ in isolation under the same evolutionary conditions.

## Results

The following sections report results obtained from 40 evolutionary swapping runs. We focus first on understanding one exemplary evolutionary run where adaptation occurs via neural reuse. That is, we show that over the course of an evolutionary run the population locates a general-purpose neural structure that enables it to quickly respond to changing task requirements. We then analyze this increase in adaptability in terms of population dynamics in parameter space and reuse of neural structure in the agents. In the last section, we look
at how well these findings generalize to the full ensemble of evolutionary runs.

## Increased adaptation over time

As most work on evolving minimally cognitive behaviors focuses on one task, we set out to test whether evidence for adaptation could be observed in populations under changing conditions. That is, does learning one task help a population adapt to new tasks over time?

Figure 2 depicts the fitness trajectory of the best agent in the population in each generation for one of the evolutionary runs. Altogether, this population achieved a total of 98 swaps in 2500 generations. The first 4 are labeled for the sake of discussion; A1 indicates the first time the population achieves fitness threshold for Task A, B1 indicates the first time population reaches threshold for Task B, etc. This trajectory shows evidence of adaptation. As can be seen, the population starts off close to random behavior (0.5) and rapidly improves performance at the first task Task A: circlecatching, line-avoidance). As soon as the best individual in the population surpasses the established fitness threshold, the task is swapped (A1), at which point fitness of the population suddenly drops. Recall that fitness measures of each task are inversions of one another, so we should expect a population with high fitness with respect to one task to have a sudden drop in fitness when tasks are swapped. The population quickly begins to make improvements in performance at the new task (task B: circle-avoidance, line-catching). As soon as the threshold is met for this task (B1), the task is swapped back to Task A, and the fitness drops again. Interestingly enough, the fitness does not drop anywhere as low as what we would expect from an agent that performs the opposite behavior, or even a random behavior. Thereafter, the population evolved to very quickly re-adapt to the new task after each new swap (Figure 2B).

The fitness trajectory of this evolutionary run shows evidence of adaptation. The trajectory is characterized by periods of ascent leading to a peak and sudden drop offs that occur due to task swaps. The time-to-adapt corresponds to the number of generations taken to reach the fitness threshold for the new task after a swap. In this study, we consider adaptability as the extent to which populations improve their time-to-adapt to changes in the fitness landscape over time. Therefore, a population shows evidence of adaptability when the time-to-adapt decreases over the course of an evolutionary run. In this example, we observe that the first time the population evolves for Task A and Task B it took around 500 generations each. After that, the time-to-adapt dropped sharply to between 1 and 30 generations. In other words, the population improved substantially its time-to-adapt by the third task swap, and maintained this ability for the duration of the evolutionary run.

## Spontaneous meta-fitness selection

How did such a dramatic increase in adaptation efficiency occur? We hypothesize that the population increases its adap-

Figure 2: Increased adaptation over time in an evolutionary run. [A] Fitness trajectory of the best individual in the population over time. Dashed vertical lines mark task swaps. Blackdotted horizontal line represents the $95 \%$ fitness threshold. The first 4 task swaps are labeled A1, B1, A2 and B2 respectively. Panel [B] shows the inset in panel [A].
tation efficiency by locating a region of meta-fitness, which we define as a region in parameter space where individuals with high fitness on both tasks exist in close proximity to one another. In other words, the proposal is that adaptability over evolutionary timescales involves a spontaneous selection for regions of parameter space that support multiple tasks over regions of parameter space that are specialized for only one of the tasks. In order to test this hypothesis, a principal component analysis (PCA) was performed on the 47-dimensional set of all genotypes in populations at points A1, B1, A2 and B2. Figure 3 shows these populations in a reduced 2D space, where the first dimension captures $73.1 \%$ of the overall variance and the second captures $1.7 \%$.

The movement of the population in parameter space during evolution shows evidence of meta-fitness selection. Figure 3 shows the structure of the evolutionary dynamics over the course of the first four task swaps. The population starts off at random in parameter space and they find a region that is adapted to Task A for the first time (A1). The task swaps to Task B, and the population moves from A1 to B1, where they find a region that is adapted to Task B, also for the first time. When Task A is presented once again, the population finds a region of parameter space that is relatively nearby (A2). The same occurs when the task swaps back to B (B2). The number of generations to adapt to each task, therefore, corresponds to the relative distances that the population moved in

Figure 3: Spontaneous meta-fitness selection. [A] Projection of populations at A1, B1, A2 and B2 in reduced 2D space obtained through PCA. [B] Fitness distributions of populations seeded around the best individual at A1 (blue) and the best individual at A2 (green). Populations were obtained by applying Gaussian perturbations within the range of $[-0.2,0.2]$ to the seeded values in each dimension.
parameter space. This suggests that the fitness landscape contained two qualitatively different kinds of adaptive regions. Although individuals in populations A1 and A2 were both equally adapted to Task A, individuals in A1 were isolated in parameter space, while individuals in A2 were in close proximity to regions of high fitness for the opposite task. What is interesting about this result is that we did not include direct selection pressure towards these regions; instead populations were guided towards them spontaneously over repeated exposure to different tasks.

What is the fundamental difference between these two types of adaptive regions? To address this question we sampled random populations in each region and evaluated their fitness distributions; results are presented in Figure 3B. Recall that each agent achieved equally high fitness with respect to Task A, but the best individual at A2 was found to be located in a region of meta-fitness whereas the best individual at A1 was not. As expected, both populations contain equally high-performing circuits. However, the fitness distribution of agents sampled around A1 (blue) is highly skewed towards high fitness values, as would be expected for a typical fitness peak. In contrast, the fitness distribution of agents sampled around A2 (green) is significantly flatter, indicating that it encompasses a greater diversity of phenotypes. This result reveals a crucial difference between meta-fitness regions and otherwise equally-fit fitness peaks.

Figure 4: Similar behavioral strategy and neural structure for opposite tasks. Behavior (left) and structure (right) of best individuals from populations A2 and B2. Left panels: Horizontal position of agents over time as object falls for all 24 trials (circle trials purple, line trials cyan). Right panels: Neurons represented by disks (opacity depicts bias parameter, where a large negative bias is white and a large positive bias is black) and connections represented by lines (excitatory grey, inhibitory black; thickness proportional to strength).

## Neural reuse in meta-fitness regions

Meta-fitness regions in parameter space have interesting implications for neural reuse. Due to linearity in the genotypephenotype map, close proximity of genomes in parameter space translates to a high degree of similarity between neural structures in corresponding phenotypes. As a result, we observe that best-agents from the same meta-fitness region share the same essential structure despite being evolved to perform different tasks. This is illustrated in Figure 4, which presents graphic depictions of the neural structures of the best agents taken from populations A2 and B2. The two structures are nearly identical, despite the fact that they ultimately support different task variants. In other words, structure evolved to perform Task A in A2 was largely reused in the subsequent evolution for Task B.

In addition to neural reuse, we observe that these two individuals utilize the same behavioral strategy for performing each task (Figure 4). In each case, the agent scans back and forth over the mid-line several times before either centering or heading away. Although not shown, this strategy is qualitatively different from the behaviors of best agents performed in isolated runs.

## Ensemble Analysis

How reliably does evolutionary swapping result in increased adaptation of populations? Of the 40 runs, 17 never reached the fitness threshold in the allotted 2500 generations. We consider these to be null cases. Of the remaining 23 runs, 9 showed evidence of increased adaptation over time. It is unclear whether or not the runs that did not demonstrate signs

Figure 5: Increased adaptability via meta-fitness. Distances between best-genomes from swapping runs (black) versus distances between best-genomes produced by successful isolated runs (grey).
of increased adaptability would have had they been allowed to run past the arbitrary 2500 generation cutoff. Regardless, the remainder of the section is concerned with the 9 runs that showed evidence of increased adaptability.

In the case study, increased adaptation was due to the evolving population locating an area of meta-fitness. Is this also the case for the rest of the populations that showed increased adaptability? We computed the set of Euclidean distances separating best genomes in successive epochs for all swapping runs and compared this with the set of distances separating best genomes coming from successful isolated runs. As depicted in Figure 5, best-agents produced in the same swapping run are usually quite closer to one another in parameter space than random opposite-task best-genomes sampled from isolated runs. This suggests that in general, adaptability is achieved via meta-fitness regions.

Given that populations in general became more adaptive by locating meta-fitness regions, it is of interest to ask whether each run located the same region or different meta-fitness regions were located by different runs. Figure 6 displays distributions of within-run distances (Euclidean distances separating the best agents of all target populations occurring within given runs) and inter-run distances (Euclidean distances separating best agents of all target populations occurring in different runs). If all swapping runs located the same meta-fitness region we would expect these two distributions to be equivalent. That within-run distances are substantially less than inter-run distances suggests that different swapping runs indeed located different meta-fitness regions.

As we observed in the case study, a region of meta-fitness in parameter space corresponds to a general-purpose neural structure. In the case study, we also observed that best-agents from the same meta-fitness region can perform opposite task variants with the same behavioral strategy. Figure 7 illustrates the generalization of these ideas to multiple meta-fitness regions. It depicts three pairs of best-agents from separate evolutionary runs. In each pair both agents have nearly-identical neural structures and qualitatively similar behavioral strategies despite performing opposite tasks. If we contrast pair

Figure 6: Different runs locate different meta-fitness regions. Distances between best-genomes of the same evolutionary run (black) versus distances between best-genomes of different evolutionary runs (grey).

A with pair B we see that they each perform the tasks with the same qualitative behavioral strategy, despite the fact that they have different neural structures. This demonstrates how a given behavioral strategy can be supported by qualitatively different neural structures. In contrast, pair C has a qualitatively different behavioral strategy from both A and B.

## Discussion

We set out to test whether evidence for adaptation and neural reuse could be observed in populations of embodied agents required to perform two variants of an object discrimination task that changed over evolutionary time. Evidence of adaptation was indeed observed: over the course of an evolutionary run populations gained the ability to more quickly adapt to changes in task requirement. In general, populations achieved this increase in evolutionary efficiency by evolving generalpurpose neural structures, which could be reused to support either task variant with minimal structural modifications. Below we discuss these results in light of continued work in neural reuse and evolvability.

Despite a growing body of empirical and theoretical support for neural reuse (Anderson, 2010), a grounded understanding of how neural reuse works in organisms remains elusive. There have been some computational efforts to this effect (Hurley, 2008; Anderson, 2010), but the present work contributes in two important ways. First, whereas other modeling work incorporates elements of reuse into the model, we see reuse spontaneously arising in our system as a result of the evolutionary pressures imposed by the varying task requirements. Secondly, in studying dynamic embodied agents, we examine neural reuse in light of the increasingly accepted viewpoint that cognition is distributed over a brain-body-environment system (Chiel \& Beer, 1997). In previous work, it was shown that the model-agents studied here offload some cognitive load to their bodies and the environment (Beer, 2003). It is likely that successful neural reuse observed in these simulations relies on features of embodiment. Ongoing work on a deeper, more thorough analysis of agents exhibiting reuse promises to bring some of these issues to light.

Figure 7: Different behavioral strategies and general-purpose neural structures are located in different evolutionary runs. Example solutions from three different evolutionary runs are shown in panels $[\mathrm{A}],[\mathrm{B}]$ and $[\mathrm{C}]$. For each evolutionary run, two solutions are shown: the best agent for line-catching and circle avoidance (i); the best agent for the opposite task obtained successively (ii). Graphics follow same coloring conventions as Fig. 4.

Work on lifetime learning and adaptation in cognitive systems parallels ongoing research on evolvability in evolutionary systems. Evolvability refers to the ability of a population to adapt to changes in its fitness landscape, and has been a hot topic in theoretical biology and evolutionary computation (Pigliucci, 2008). In order for an evolutionary system to support evolvability there must be redundancy in the fitness landscape; there must be many genomes which have high fitness in a given environment, and some of these must be more adaptable to future environmental changes than others. Typically investigations of evolvability examine the role of developmental processes indirectly linking genotype to phenotype as a mechanism for such redundancy (Pigliucci, 2008). In the present work, however, we observe signatures of evolvability in a system without any developmental scenario. While our system has a direct genotype to phenotype map, the complexity of agents introduces sufficient redundancy in the phenotype to behavior map (qualitatively different neural structures can produce the same basic behavior) and behavior to fitness map (qualitatively different behaviors can yield the same fitness) to allow for increased adaptation.

The work presented above demonstrates that evolving embodied agents for time-varying cognitive tasks is fertile ground for exploration of cognitive adaptation in general, and neural reuse more specifically. There are many ways in which efforts here can be built upon. First, given that neural reuse is most concerned with brain circuits supporting vastly different cognitive functions (Anderson, 2010), we would like to expand the repertoire of tasks to include some that are qualitatively different. As our understanding of neural reuse advances, we can extend our approach to increasingly complex interesting tasks. Secondly, we would like to analyze in more depth the operation of agents that exhibit reuse. Past work has shown that the mathematical tools of dynamical systems theory and information theory can be used to provide rich accounts of cognition exhibited in these systems (Beer \& Williams, 2015). Ultimately, we would like to provide a grounded understanding of neural reuse in embodied, situated agents capable of diverse cognitive phenomena.

#### Abstract

Different hypotheses were proposed concerning the role of talker variability in lexical learning. It remains unclear whether new phonetic categories are acquired as episodic memory traces with talkers' voice information preserved or as abstract categories. The current study investigated the role of voice similarity in perceptual learning of Cantonese tones. Six high-variability training sessions were given to 12 Mandarin speakers. Voice similarity was controlled in the training and pre-and posttests. Results indicate that the training positively transferred to both similar and dissimilar talkers. However, in the pretest, the performance was not significantly different between similar and dissimilar voices, whereas significant better performance was found in the similar voices in the posttest. These results suggest that learners retained speakers' information in the learning process and made use of such information for future perception. This implies that lexical tones are probably encoded episodically in the mental representation of Mandarin L2 learners.

Keywords: Talker similarity, high variability training, Cantonese lexical tones, Mandarin leaners of Cantonese, mental representation.

## Introduction

When presented with a word auditorily, a listener receives a lot of information. For instance, the phonological form and meaning of the word, as well as the auditory information of the speaker. There existed a great amount of acoustic differences between speakers resulted from the differences in the shape and length of vocal tract, articulatory dynamics and native dialects (Goldinger, 1998). A long-documented problem for theories is how the speech perception and spoken word recognition achieve perceptual constancy in spite of the highly variable speech signals (Bradlow, Nygaard and Pisoni, 1999).

Two different accounts had been put forward concerning how the speaker's information is encoded in the memory system during auditory lexical learning, which are called abstractionist approach (Pisoni, 1997) and episodic theory (Nygaard, Sommers, \& Pisoni, 1994). According to the speaker normalization hypothesis (Joos, 1948, as cited in

Goldinger, 1998), acoustic variances produced by different speakers were considered as redundant information or noise that was quickly forgotten after lexical access and only lexical-semantic information was encoded in long-term memory. This allows listeners to understand new speakers instantly by only following the lexical-semantic content of speech and disregarding the superficial details such as speaker's information (Goldinger, 1998). In this abstractionist approach, a speaker-specific representation which contained all the lexical and speaker's information was first modified to a relatively speaker-neutral abstract representation prior to the encoding of lexical-semantic information (Johnson, 1997). The encoded lexical-semantic information was stored as an abstract representation, which then formed a template or prototype that could be used to match with the incoming speech signals to allow lexical retrieval (Goldinger, 1998). For instance, Peterson and Barney (1952) found that listeners could correctly perceive the target vowel despite the great variation in vowel formant frequencies produced by men, women and children. Evidence was also found in the perceptual normalization in consonants and prosody (Johnson, 2005), but normalization of such categories requires further intrinsic and extrinsic cues (Johnson, 2005; Moore, 1996; Strand \& Johnson, 1996; Zhang \& Chen, 2016). In a more recent study, it was also found that newly learned words could be sufficiently lexicalized, and be abstract with respect to talker voices (Kapnoula and McMurray, 2016).

On the other hand, a growing body of research suggested another direction. Episodic theory proposed that perceptual details including speaker's information were retained in memory during lexical learning and were integrated into perception later (Goldinger, 1996; 1998). All experienced instances were defined in a perceptual category and no abstract categories or prototypes were created. In accordance with this theory, Goldinger, Pisoni and Logan (1991) found that listeners made use of speaker variability to recall individual items in multiple-speaker word list, achieving higher accuracy than that in single-speaker word list. This result suggested that speaker variability in
multiple-speaker word list facilitated word encoding and retrieval. Moreover, Bradlow, Nygaard and Pisoni (1999) presented a word list to a group of participants auditorily and asked them to judge whether they had heard the words before. They found that listeners made use of speakers' information as well as speaking rate and amplitude information in the tasks which also supported the episodic theory. In addition, Nygaard and Pisoni (1998) found that speech from familiar voices was more intelligible than from unfamiliar voices, which suggested speakers' information were related to linguistic processing at both word and sentence levels (see Souza et al., 2013 for similar findings). Altogether, these studies suggested that the talker information was stored as episodes in the long-term memory.

The two hypotheses mentioned above hold different views on the role of talker information in language processing/acquisition. Perceptual training in second language (L2) learners offers a scenario to test whether the new phonetic categories are learned as episodic memory traces with speaker's voice information preserved or as abstract categories, which is the aim of the current study.

High variability perceptual training (HVPT hereafter) was developed from the low variability training in which only one speaker was involved and very limited phonetic context was provided (Strange \& Dittman, 1984). HVPT exposes subjects to a wider range of stimuli, including sounds produced by several speakers, in multiple phonetic contexts, and at multiple syllable positions (Bradlow, 2008). Several studies have adopted this approach to improve non-native speakers' identification of consonants (Bradlow et al., 1997; Bradlow et al., 1999;), vowels (Iverson \& Evans, 2009; Iverson, Pinet \& Evans, 2012), as well as lexical tones (Wang, Jongman \& Sereno, 1999; Wang, Spence, Jongman \& Sereno, 2003; Wang, 2013). These findings confirmed that HVPT was very effective in facilitating the acquisition of non-native phonetic contrasts.

Although HVPT was found to be effective in the generalization to novel stimuli and speakers, previous studies did not control the speaker voice similarity between training and pre-/posttests. The current study aims to control the voice similarity in the training sessions and pre-and posttest, and to compare the generalization effect to novel speakers whose voice was either similar or dissimilar to those speakers during training. Via this study, the question of whether L2 speech sounds are encoded as an abstract representation or an episodic representation during L2 perceptual learning will be investigated.

The current study focuses on the L2 lexical tone learning. Like consonants and vowels, lexical tones are important in differentiating word meanings in tonal languages. Mandarin and Cantonese are both tonal languages where pitch patterns of a syllable are crucial to its lexical meaning. Tone contours are commonly shown by numbers representing the pitch register according to a scale of five, 1 being the lowest and 5 being the highest. Usually two numbers, e.g., 55, indicate the pitch at the beginning and end of a syllable respectively (Chao, 1930). Mandarin has four lexical tones:

Tone 1: high level (55); Tone 2: rising (35); Tone 3: fallingrising (214); and Tone 4: falling (51) (Norman, 1988). Cantonese has six regular tones, which are classified according to their register and contour (Bauer \& Benedict, 1997). The six distinctive tones are: Tone 1: high level (55); Tone 2: high rising (25); Tone 3: mid level (33); Tone 4: mid-low falling (21); Tone 5: mid-low rising (23); and Tone 6: mid-low level (22). These six distinctive tones were included as the stimuli of the current study.

We aim to investigate the nature of mental representation of Cantonese tones in Mandarin L2 learners by controlling voice similarity of novel speakers. This allows us to examine the two hypotheses mentioned above. If Cantonese tones were encoded as an abstract representation, Mandarin listeners would ignore speaker variability and therefore generalize to novel speakers no matter whether their voices are similar or dissimilar to those in perceptual training. If Cantonese tones were encoded as an episodic representation, listeners would make use of speakers' information in lexical retrieval and therefore demonstrate better generalization to novel speakers whose voices are similar than those whose voices are dissimilar to the speakers in the perceptual training.

## Method

## General design

A pretest-training-posttest design was employed to assess the subjects' initial ability and the effects of training. Pretests and posttests consisted of two main parts: tone category identification and discrimination. The identification and discrimination tasks were designed to test whether identification training is effective and transfers to new talkers whose voice were similar and dissimilar to the talkers used in the training sessions.

## Participants

Student participants were recruited in Hong Kong Polytechnic University (PolyU). 45 students responded to an online self-report questionnaire. 19 participants were selected based on the following criteria: (1) resided in Hong Kong for less than five months prior to the pretest session, (2) speaks Mandarin as mother tongue and did not speak any Southern dialect including Hakka and Southern Min dialect, (3) did not receive professional musical training. Seven participants withdrew from the study before the posttraining test. A total of 12 participants completed the whole program.

## Talkers and Stimuli

## Stimuli

The stimuli were 60 words contrasting six Cantonese tones (high level tone (T1)-/55/, high rising tone (T2)-/25/, mid level tone (T3)-/33/, extra low level/low falling tone (T4)$/ 21 /$, low rising tone (T5)-/23/, low level tone (T6)-/22/) on ten base syllables (/jan/, /ji/, /jau/, /jiu/, /fan/, /fu/, /ngaa/, $/ \mathrm{si} /$, /se/ and /wai/), all are meaningful in Cantonese. Each
monosyllabic target word was embedded in a carrier phrase context＂呢個係＿lei1 go3 hai6［target word］＂（this is ［target word］）．Six female and six male native Cantonese speakers recorded the stimuli．Each speaker recorded six repetitions of each target word．One token for each target word was chosen by the experimenters according to its intelligibility and tone accuracy．The carrier phrase was normalized in duration to 877 ms （mean value of all carrier phrases），and the target word was normalized to 631 ms （mean value of all target words）．The mean intensity was scaled to 70 dB using Praat．

## Voice Similarity Judgment

The voice similarity among the 12 talkers was rated by another 12 native Cantonese speakers who were blind to the purpose of the current study．One speaker for each gender （F01 and M01）were chosen as references．The other five talkers（F02，F03，F04，F05 and F06；M02，M03，M04，M05 and M06）in each gender were compared against the reference speaker in term of voice similarity．In the similarity judgment experiment，raters were asked to listen to the target words embedded in the context＂呢個係．．．lei1 go3 hai6．．．＂［This is ．．．］spoken by the reference speaker and one other speaker of the same gender．They were asked to rate the voice similarity of the speakers on a scale of 1 （very dissimilar）to 9 （very similar）．The 60 target words were included and each trial was repeated twice．

The similarity score was averaged across raters．Table 1 shows the similarity score of each talker．Three talkers who received highest similarity scores in each gender group were used in the training sessions（F02，F04 and F06；M03，M04 and M06）．The talkers with lowest similarity rating score in each gender（F03 and M05）were included in the pre－and posttests as the speakers with dissimilar voices．

Table 1：Result of similarity judgment test averaged across 12 raters．

| Female <br> talkers | Similarity <br> score |  | Male <br> talkers | Similarity <br> score |
| :---: | :---: | :---: | :---: | :---: |
| F02 | $\mathbf{7 . 4 4}$ |  | M04 | $\mathbf{7 . 4 9}$ |
| F04 | $\mathbf{7 . 2 7}$ |  | M06 | $\mathbf{7 . 7 3}$ |
| F06 | $\mathbf{6 . 0 7}$ |  | M03 | $\mathbf{7 . 3 8}$ |
| F05 | 5.90 |  | M02 | 5.91 |
| F03 | 4.70 |  | M05 | 5.30 |

## Procedure

The training programme consisted of a pretest，training，and posttest phase．All sessions were conducted in a soundproof room in PolyU．

## Training

There were six sessions of HVPT（i．e．，tone identification with feedback）．The entire course of training for each subject was completed over 1－2 weeks，and each session lasted about 1 hour．There was a different talker each session，as is typical of HVPT procedures．Female and male
stimuli were trained alternatively．Moreover，our design was different from previous studies in that the six talkers in the training sessions（ 3 female and 3 male）were similar to two of the talkers who were presented in the pre－and posttest． Although the talkers used in the training phase were judged to have similar voices，it is still a HVPT，as the subjects were exposed to a wide range of stimuli，produced by several speakers，and the tones were carried by multiple syllables．

Figure 1．An example of identification choice in the training sessions．

The 60 stimuli were repeated twice，which gave 120 basic trials in each training session．On each trail，participants were presented with a target word with the context＂呢個係 ．．．leil go3 hai6．．．＂［This is ．．．］．Six choices with minimal contrast of tones were presented on the computer screen（see an example of＂ngaa＂in Figure 1）．As can be seen in Figure 1，visual demonstration of each of the six tones were provided．The subjects were then asked to indicate the tone of the target word with the number keys 1－6 corresponding to the tones one to six．After each response，a feedback screen was presented．The feedback information includes： （1）if the response made by the participant was correct in blue text or incorrect in red text，（2）the cumulative accuracy of the current training session and（3）the correct response， its corresponding tone contour and its corresponding word written in traditional Chinese．If the response made was correct，the participant was proceeded to the next trial，if the response was incorrect，the incorrect trial was repeated until a correct response was indicated．

## Pre－and Posttest

The pretest and posttest consisted of identification and discrimination tasks．In both identification and discrimination task，there were four talkers separated in four blocks．Two talkers（female F01 and male M01）were similar to those used in the training sessions，while two talkers were of dissimilar voice to the talkers used in the training（F03 and M05）．

Tone identification．In the identification task，the 60 stimuli words were presented with the context＂呢個係．．． lei1 go3 hai6．．．＂［This is ．．．］．Each trial was repeated twice and presented randomly to the participants．Six choices with minimal contrast of tones were presented on the computer screen with the tone，its corresponding tone contour and its corresponding character in traditional Chinese as shown in Figure 1．Participants were asked to indicate the tone of the
target word by pressing the number keys 1-6 corresponding to the tones one to six. No feedback was given.

Category Discrimination. In the discrimination task, the syllable /ji/ was selected as the stimuli. Fifteen different tone pairs were presented in both directions of comparison (T1-T2, T2-T1, T1-T3, T3-T1, T1-T4, T4-T1 etc.) and then repeated twice, making up 60 "different" pairs. Six same tone pairs (T1-T1, T2-T2, T3-T3 etc.) were repeated 10 times to make up 60 "same" trials in order to balance the number of "same" and "different" trials, which gave a total of 120 trials in the discrimination test. Participants were asked to discriminate whether the two syllables were of the same or different tones by pressing the left (same) or right (different) arrow. No feedback was given.

For both discrimination and identification tasks, a short practice session was given before the first set of stimuli. Participants were allowed to take a break every 20 trials in both tasks. The responses of participants were recorded and coded. Response time was also collected.

## Results

In both discrimination and identification tasks, for the accuracy analysis, mixed-effects logistic regression models were conducted, with the response to each trial as the input, training (pretest, posttest) and voice similarity (similar, dissimilar) as two fixed effects, and subjects as a random effect. For the response time analysis, two-way repeated measures ANOVAs were conducted, with the response time as the dependent variable and training (pretest, posttest) and voice similarity (similar, dissimilar) as independent variables. Figures 2 and 3 showed the mean accuracy of all participants achieved in identification and discrimination tasks respectively, in pretest and posttest for similar and dissimilar scenarios. Figure 4 and 5 showed the mean response times of all participants in identification and discrimination task.

For the identification accuracy, mixed-effects logistic regression model revealed significant main effect of training $(\chi 2(1)=315.81, p<0.001)$, and significant two-way interaction between training and voice similarity $(\chi 2(2)=$ 5.185, $p<0.05$ ), while the effect of voice similarity alone was insignificant $(\chi 2(1)=2.267, p=0.132)$. Post-hoc tests showed that the accuracy in the posttest was significantly higher than the pretest in both similar $(z=-13.936, p<$ 0.001 ) and dissimilar voices scenarios $(z=-10.962, p<$ 0.001 ). Within the pretest, there was no significant difference between similar and dissimilar voices $(z=-0.389$, $p=0.697$ ). However, in posttest, the accuracy in the similar voices scenario was significantly higher than that in dissimilar voices scenario $(z=2.713, p<0.01)$.

For the response time in the identification task, there were significant main effects of training $(F(1,11)=20.471, p=$ $0.001)$, voice similarity $(F(1,11)=25.73, p<0.001)$, as well as significant two-way interactions between training and voice similarity $(F(1,11)=8.552, p=0.014)$. Independent sample $t$-tests were then conducted within pretest and posttest to test the effects of speaker similarity.

The results showed that in the pretest, response time in the similar voice scenario was marginally significantly longer than the dissimilar voice scenario $(t(22)=1.899, p=0.071)$, but the difference was not significant in the posttest $(t(22)=$ $0.563, p=0.579$ ), implying that training improved the response time in the similar voice condition. Within the similar speaker condition, the response time in the posttest was significantly shorter than the pretest $(t(22)=2.708, p=$ 0.013 , suggesting the effects of training. While in the dissimilar voice condition, there was no significant difference between the pretest and posttest $(t(22)=1.479, p$ $=0.153$ ), indicating that training had very little impact on the response time in the dissimilar voice scenario.

Figure 2: Mean accuracy in the identification task averaged in the pre- and post-test, under similar talker scenario and dissimilar talker scenario.

Figure 3: Mean accuracy in the discrimination task averaged in the pre- and post-test, under similar talker scenario and dissimilar talker scenario.

In discrimination tasks, mixed-effects logistic regression model revealed a significant two-way interaction between training and voice similarity $(\chi 2(2)=4.362, p<0.05)$, while the effects of training $(\chi 2(1)=2.875, p=0.090)$ and voice similarity $(\chi 2(1)=1.110, p=0.292)$ were not significant. Post hoc tests showed that accuracy in pretest was significantly higher than that in posttest ( $z=2.665, p<0.01$ ) with dissimilar voices. However, no significant difference
was found between pretest and posttest in the similar voices scenario ( $z=-0.333, p=0.740$ ). The accuracy in similar voices scenario was significantly higher than that in dissimilar voices scenario within posttest $(z=2.197, p<$ 0.05 ), while the difference in accuracy with similar and dissimilar voices was found to be insignificant within pretest ( $z=-0.809, p=0.419$ ).
For the response time in the discrimination task, no effects were significant.

Figure 4: Mean response time in the identification task averaged in the pre- and post-test, under similar talker scenario and dissimilar talker scenario.

Figure 5: Mean response time in the discrimination task averaged in the pre- and post-test, under similar talker scenario and dissimilar talker scenario.

## Discussion

The current study provided HVPT to Mandarin speakers who had minimal exposure to Cantonese prior to the study. The generalization to novel speakers who had similar and dissimilar voices to the training stimuli was investigated to explore the role of talker voice similarity in the learning of Cantonese tones and henceforth to shed light on the nature of mental representation of Cantonese tones in L2 learners. If Cantonese tones were encoded as an abstract representation, no significant difference would be found in the generalization to similar and dissimilar novel voices. On the other hand, if Cantonese tones were encoded as an
episodic representation, generalization to similar voices would be significantly better than to dissimilar voices.

We found that in the identification task, the effect of training was transferred successfully to both the similar and dissimilar voice scenarios. This finding fell in line with previous studies in that exposing the listeners to multiple talkers and phonetic contexts would enhance the phonemic categorization of the trained speech sounds. Miller, Zhang \& Nelson (2016) investigated whether adult listeners who became deaf postlingually and had cochlear implant (CI) could benefit from multiple-talker category identification training. They found that the perception performance was significantly improved for the CI listeners for the familiar talkers (i.e., talkers used in the training sessions) and also generalized to the unfamiliar talkers (i.e., talkers not included in the training sessions). There was also evidence that talker variation aids young infants' phonotactic learning (Seidl, Onishi \& Cristia, 2014). Together with these previous studies, our study provided extra evidence that the multiple-talker training was highly successful in learning to categorize speech sounds.

In both discrimination and identification posttests, the effect of voice similarity alone was significant. However, significantly better performance was found with similar voices than dissimilar voices in posttest but not in pretest and hence significant interaction between training and voice similarity was revealed. These findings echoed with previous studies that the speech from familiar voices was easier to identify than unfamiliar voices (Nygaard and Pisoni, 1998; Souza et al., 2013), supporting the hypothesis that Cantonese tones were encoded episodically in the mental representation of Mandarin L2 speakers. L2 learners retained perceptual details, speakers' voice characteristics, when encoding the tonal information into their mental representation. These perceptual details were integrated into later perception when the learner encountered with novel speakers. It is likely that the acoustic/phonetic representations are stored during the training stage, which facilitates the identification of tones in the similar voice context. In contrast, no matching representation is available in the dissimilar voice scenario, and thus the identity of the tone has to be construed from scratch.

As mentioned in the result, a significant training effect was found in identification tasks but not discrimination tasks. It is probably due to ceiling performance in discrimination tasks, for the reason that speakers without knowledge of Cantonese tones could also discriminate different tones merely by relying on psychoacoustic differences of the stimuli (Qin \& Mok, 2011). In addition, since Mandarin is a tonal language, participants already had some tonal categories in their mental representation within their L1, although it is not as complex as Cantonese categories. Therefore, participants could make use of psychoacoustic differences and their L1 knowledge to tell apart perceptually different tones in discrimination tasks even they had no knowledge of Cantonese tones. Moreover, since only the syllable / $\mathrm{ji} /$ was used in the discrimination
task, lack of syllable variability also reduced the cognitive loading of the tasks.

It should be noted that our study focused on L2 learners with limited Cantonese exposure. The episodic encoding of lexical tones might paly a role in early stage of learning, when a new speaker' voice counts as a distinct learning episode. It is unclear whether the episodic representation of L2 phonetic categories will change in late stages of learning. Future studies may include the experienced L2 learners to test the scope of the episodic learning.

## Conclusion

In the present study, perceptual trainings were given to native Mandarin speakers who had minimal exposure to Cantonese, and the voice similarity among the talkers in training and test phases was controlled. We found that the HVPT was highly effective, for the training effects generalized to both similar and dissimilar voices. However, the degree of generalization was significantly different between similar and dissimilar voices, which supported the hypothesis that learners retained speaker information during learning and made use of such information in future tone perception. This implies that newly learnt tones are encoded episodically in the mental representation of L2 learners. Future studies may explore the performance on the individual tones, so as to reveal the relationship between L1 and L2.

# A Spiking Neural Bayesian Model of Life Span Inference 

Sugandha Sharma (s72sharm@uwaterloo.ca)<br>Aaron R. Voelker (arvoelke@uwaterloo.ca)<br>Chris Eliasmith (celiasmith@uwaterloo.ca)<br>Centre for Theoretical Neuroscience, University of Waterloo<br>Waterloo, ON, Canada, N2L 3G1

#### Abstract

In this paper, we present a spiking neural model of life span inference. Through this model, we explore the biological plausibility of performing Bayesian computations in the brain. Specifically, we address the issue of representing probability distributions using neural circuits and combining them in meaningful ways to perform inference. We show that applying these methods to the life span inference task matches human performance on this task better than an ideal Bayesian model due to the use of neuron tuning curves. We also describe potential ways in which humans might be generating the priors needed for this inference. This provides an initial step towards better understanding how Bayesian computations may be implemented in a biologically plausible neural network.

Keywords: Neural Engineering Framework; biologically plausible inference; neural bayesian model; expectation maximization

## Introduction

Computations performed by the nervous system are subject to uncertainty because of the influence of sensory, cellular, and synaptic noise. At the level of cognition, the models that the brain uses to interact with its environment must necessarily cope with missing and imperfect information about the world. Behavioral studies have confirmed that humans often account for uncertainty in a way that is nearly optimal in the Bayesian sense (i.e., "Bayes optimal") (Ma, Beck, Latham, \& Pouget, 2006)). This implies that (1) neural circuits must, at least implicitly, represent probability distributions, and (2) neural circuits must be able to effectively compute with these probability distributions in order to perform Bayesian inference near-optimally.

Probabilistic models based on Bayes' rule have been widely used for understanding human cognition including inference, parameter and structure learning (Jacobs \& Kruschke, 2011), and word learning (Xu \& Tenenbaum, 2007). However, most Bayesian models lack biological plausibility because it is unclear how these computations might be realized in the brain. In particular, these models rely on sophisticated computations including high-dimensional integration, precise multiplication, and large-scale structure representation, without the use of spiking neuron models to implement these necessary computations.

A biologically plausible Bayesian approach can provide us insights into the working of the brain at multiple levels of analysis (Eliasmith, 2013). Moreover, it can also help in making more accurate normative predictions about how the perceptual system combines prior knowledge with sensory observations, enabling more accurate interpretations of data from psychological experiments (Doya, 2007). And finally, it
can point the way towards approximate Bayesian algorithms that are efficiently implemented in a neural substrate.

Griffiths, Chater, Norris, and Pouget (2012) conclude that different theoretical frameworks, such as Bayesian modeling and connectionism, have different insights to offer about human cognition, distributed across different levels of analysis. Here we make an initial attempt towards integrating these frameworks. We explore the biological plausibility of Bayesian inference by implementing a neural model of a life span prediction task using the Neural Engineering Framework (NEF; Eliasmith \& Anderson, 2003). We answer questions about how probability distributions can be represented in a connectionist framework using spiking neurons, and how the neural representations of these probability distributions can be used in meaningful ways. The next section describes the life span prediction task which we use.

## Life span prediction task

Griffiths and Tenenbaum (2006) evaluate how cognitive judgments compare with optimal statistical inference by asking people to predict human life spans. A group of 208 people were asked to predict human life spans, after being presented by a question in survey format as given below:
"Insurance agencies employ actuaries to make predictions about people's life spans - the age at which they will die based upon demographic information. If you were assessing an insurance case for an 18-year-old man, what would you predict for his life span?"

The responses were recorded and compared with the predictions made by a Bayesian model.

## Bayesian model

If $t_{\text {total }}$ indicates the total amount of time the person will live and $t$ indicates his current age, the task is to estimate $t_{\text {total }}$ from $t$. The Bayesian model computes a probability distribution over $t_{\text {total }}$ given $t$, by applying Bayes' rule:

$$
\begin{equation*}
p\left(t_{\text {total }} \mid t\right)=p\left(t \mid t_{\text {total }}\right) p\left(t_{\text {total }}\right) / p(t) \tag{1}
\end{equation*}
$$

where:

$$
\begin{equation*}
p(t)=\int_{0}^{\infty} p\left(t \mid t_{t o t a l}\right) p\left(t_{\text {total }}\right) d t_{\text {total }} \tag{2}
\end{equation*}
$$

We assume that the maximum age is 120 years. Thus, when calculating $p(t)$ in practice, the integral may be computed from 0 to 120.

Prior Griffiths and Tenenbaum (2006) use publicly available real-world data to identify the true prior distribution $p\left(t_{\text {total }}\right)$ over life spans (shown in Figure 1A).

Likelihood The likelihood $p\left(t \mid t_{\text {total }}\right)$ is the probability of encountering a person at age $t$ given that their total life span is $t_{\text {total }}$. Griffiths and Tenenbaum (2006) assume for simplicity that we are equally likely to meet a person at any point in his or her life. As a result, this probability is uniform, $p\left(t \mid t_{\text {total }}\right)=$ $1 / t_{\text {total }}$, for all $t<t_{\text {total }}$ (and 0 for $t \geq t_{t o t a l}$ ).

Prediction function Combining the prior with the likelihood according to Equation 1 yields a probability distribution $p\left(t_{\text {total }} \mid t\right)$ over all possible life spans $t_{\text {total }}$ for a person encountered at age $t$. As is standard in Bayesian prediction, Griffiths and Tenenbaum (2006) use the median of this distribution-the point at which it is equally likely that the true life span is either longer or shorter-as the estimate for $t_{t o t a l}$. This identifies a prediction function that specifies a predicted value of $t_{\text {total }}$ for each observed value of $t$.

Results Results obtained by Griffiths and Tenenbaum (2006) through this Bayesian model are shown in Figure 1B.

Figure 1: (A) Empirical distribution of the total life span $t_{\text {total }}$. (B) Participants' predicted values of $t_{\text {total }}$ for a single observed sample $t$. Black dots show the participants' median predictions for $t_{\text {total }}$. Solid line shows the optimal Bayesian predictions based on the empirical prior distribution shown in A. Dotted lines show predictions based on a fixed uninformative prior. Note: the fit between the human predictions (black dots) and Bayesian predictions (solid line) looks spot on in this figure due to the compressed y-axis, but Figure 4b shows a zoomed version revealing that this is not the case. Adapted from Griffiths and Tenenbaum (2006).

## Neural Engineering Framework

The Neural Engineering Framework (NEF) is based on three principles-representation, transformation, and dynamics-
which are used to construct large-scale neural models. The first two principles are described in the following sections. The principle of representation also describes how probability distributions can be represented using spiking neurons. The third principle is not required for this paper, and its details can be found elsewhere (Eliasmith \& Anderson, 2003).

## Principle 1 - Representation

In the NEF, information is represented as time-varying vectors of real numbers by populations of neurons. We say that a population of neurons has activities $a_{i}(\mathbf{x})$, which encode an $n$ dimensional stimulus vector, $\mathbf{x}=\left[x_{1}, x_{2}, \ldots, x_{n}\right]$, by defining the encoding:

$$
\begin{equation*}
a_{i}(\mathbf{x})=G_{i}\left[J_{i}(\mathbf{x})\right], \tag{3}
\end{equation*}
$$

where $G_{i}[\cdot]$ is the nonlinear transfer function describing the neuron's spiking response, and $J_{i}(\mathbf{x})$ is the current entering the soma of the neuron. For the purpose of our model, we have chosen $G_{i}[\cdot]$ to be the leaky integrate-and-fire (LIF) neuron model. The soma current is defined by:

$$
\begin{equation*}
J_{i}(\mathbf{x})=\alpha_{i}\left\langle\mathbf{e}_{i}, \mathbf{x}\right\rangle_{n}+J_{i}^{\text {bias }} \tag{4}
\end{equation*}
$$

where $J_{i}(\mathbf{x})$ is the current in the soma, $\alpha_{i}$ is a gain and conversion factor, $\mathbf{x}$ is the stimulus vector to be encoded, $\mathbf{e}_{i}$ is the encoding vector which corresponds to the "preferred stimulus" of the neuron-consistent with the standard idea of a preferred direction vector (Schwartz, Kettner, \& Georgopoulos, 1988)—and $J_{i}^{\text {bias }}$ is a bias current that accounts for background activity. The notation $\langle\cdot, \cdot\rangle_{n}$ indicates an $n$ dimensional dot-product.

Given this encoding, the original stimulus vector can be estimated by decoding those activities as follows:

$$
\begin{equation*}
\hat{\mathbf{x}}=\sum_{i} a_{i}(\mathbf{x}) \mathbf{d}_{i} . \tag{5}
\end{equation*}
$$

The decoding vectors $\mathbf{d}_{i}$ (also known as "representational decoders") are typically found in the NEF by least-squares optimization, which we use here (Eliasmith \& Anderson, 2003). Thus, the decoders resulting from this optimization complete the definition of a population code over a set of neurons $i$ for the representation of $\mathbf{x}$. The code is defined by the combination of nonlinear encoding in Eq. 3 and weighted linear decoding in Eq. 5.
Temporal representation The population code does not explicitly address the issue of how information is encoded over time. To do so, we can begin by considering the temporal code for each neuron in isolation by taking the neural activities to be filtered spike trains as shown in Eq. 6:

$$
\begin{equation*}
a_{i}(t)=\sum_{m} h_{i}(t) * \delta\left(t-t_{m}\right)=\sum_{m} h_{i}\left(t-t_{m}\right), \tag{6}
\end{equation*}
$$

where $\delta_{i}(\cdot)$ are the spikes at time $t_{m}$ for a given neuron $i$, generated by $G_{i}[\cdot]$ and $h_{i}(t)$ are the linear decoding filters. We can compute the optimal filters for decoding using the NEF, however to make our model biologically plausible, we
have chosen these filters $\left(h_{i}(t)\right)$ to be the postsynaptic currents (PSCs) induced in subsequent neuron by the arrival of a spike. Eliasmith and Anderson (2003) have shown that this assumption causes minimal information loss which can be further reduced by increasing the population size.

This temporal code can be combined with the population code defined before (Eqs. 3, 4, 5), to provide a general population temporal code for vectors. The encoding and decoding equations for such a code are given by Eq. 7 and Eq. 8:

$$
\begin{align*}
\delta\left(t-t_{i m}\right) & =G_{i}\left[\alpha_{i}\left\langle\mathbf{e}_{i}, \mathbf{x}\right\rangle_{n}+J_{i}^{\text {bias }}\right]  \tag{7}\\
\hat{\mathbf{x}} & =\sum_{i, m} h_{i}\left(t-t_{m}\right) \mathbf{d}_{i} . \tag{8}
\end{align*}
$$

Representing probability distributions Probability distributions are essentially functions of some parameters. Having described how to represent vectors using the NEF, we consider the relationship between vector and function representation. For any representation, we need to specify the domain of that representation. In case of vectors, the domain is the subspace of the vector space that is represented by the neurons (e.g., the $\mathbf{x}$ vector). We define the relevant function domain by parameterizing the set of represented functions by an $n$ dimensional vector of coefficients $\mathbf{k}=\left[k_{1}, k_{2}, \ldots, k_{n}\right]$. These define any function of interest over a fixed set of basis functions $\phi(v)$ as follows:

$$
\begin{equation*}
\mathbf{x}(v ; \mathbf{k})=\sum_{j=1}^{n} k_{j} \phi_{j}(v), \quad \text { for } k \sim p(\mathbf{k}) . \tag{9}
\end{equation*}
$$

Thus we define a particular probability distribution $p(\mathbf{k})$ by limiting the space spanned by the basis $\phi(v)$ to some subspace of interest depending on the application. This is also the domain over which the optimization to find the decoders in Eq. 5 is performed.

Next, we define population encoding and decoding analogous to that in Eqs 3 and 5 for functions:

$$
\begin{align*}
a_{i}(\mathbf{x}(v ; \mathbf{k}))=a_{i}(\mathbf{k}) & =G_{i}\left[\alpha_{i}\left\langle\mathbf{e}_{i}(v), \mathbf{x}(v ; \mathbf{k})\right\rangle_{n}+J_{i}^{\text {bias }}\right]  \tag{10}\\
\hat{\mathbf{x}}(v ; \mathbf{k}) & =\sum_{i} a_{i}(\mathbf{k}) \mathbf{d}_{i}(v), \tag{11}
\end{align*}
$$

where $\mathbf{e}_{i}(v)$ and $\mathbf{d}_{i}(v)$ are the encoding and decoding functions of the neurons. We project these functions onto the same basis $\phi(v)$ used to identify the function space. For simplicity, we assume that $\phi(v)$ is an orthonormal basis - an analogous derivation for a bi-orthonormal set can be found elsewhere (Eliasmith \& Martens, 2011). Hence, we get the following encoding and decoding functions:

$$
\begin{align*}
& \mathbf{e}_{i}(v)=\sum_{j=1}^{n} e_{i j} \phi_{j}(v)  \tag{12}\\
& \mathbf{d}_{i}(v)=\sum_{j=1}^{n} d_{i j} \phi_{j}(v), \tag{13}
\end{align*}
$$

where $e_{i j}$ and $d_{i j}$ identify the $n$ coefficients that represent
the encoding and decoding functions in $\phi(v)$ basis for each neuron. We now substitute these into Eq 10 :

$$
\begin{align*}
a_{i}(\mathbf{x}(v ; \mathbf{k})) & =G_{i}\left[\alpha_{i}\left(\sum_{m, n} k_{n} \phi_{n}(v) e_{i m} \phi_{m}(v)\right)+J_{i}^{\text {bias }}\right] \\
& =G_{i}\left[\alpha_{i}\left(\sum_{m, n} k_{n} e_{i m} \delta_{m n}\right)+J_{i}^{\text {bias }}\right]  \tag{14}\\
& =G_{i}\left[\alpha_{i}\left(\sum_{n} k_{n} e_{i n}\right)+J_{i}^{\text {bias }}\right] \\
& =G_{i}\left[\alpha_{i}\left\langle\mathbf{e}_{i}, \mathbf{k}\right\rangle_{n}+J_{i}^{\text {bias }}\right] .
\end{align*}
$$

This way, function encoding is expressed as vector encoding identical to Eq. 7. Similarly, function decoding can also be expressed as vector decoding as follows:

$$
\begin{equation*}
\hat{\mathbf{k}}=\sum_{i} a_{i}(\mathbf{k}) \mathbf{d}_{i} . \tag{15}
\end{equation*}
$$

To summarize, we have shown that it is mathematically equivalent to talk in terms of (finite-dimensional) function spaces or (finite-dimensional) vector spaces. Since probability distributions are most generally functions, we can approximate them as high-dimensional vectors over a fixed set of basis functions using the NEF.

## Principle 2 - Transformation

Transformations of neural representations are functions of the vector variables represented by neural populations.

To perform a transformation $f(\mathbf{x})$ in the NEF, instead of finding the representational decoders $\mathbf{d}_{i}$ to extract the originally encoded variable $\mathbf{x}$, we can re-weight the decoding to specify some function $f(\mathbf{x})$ other than identity. In other words, we can find the decoders $\mathbf{d}_{i}^{f(\mathbf{x})}$ (also known as "transformational decoders") by using least-squares optimization to minimize the difference between the decoded estimate of $f(\mathbf{x})$ and the actual $f(\mathbf{x})$, which results in the transformation:

$$
\begin{equation*}
\hat{\mathbf{x}}=\sum_{i} a_{i}(\mathbf{x}) \mathbf{d}_{i}^{f(\mathbf{x})} \tag{16}
\end{equation*}
$$

Both linear and nonlinear functions of the encoded vector variable can be computed in this manner (Eliasmith \& Anderson, 2003). In the NEF, connection weights between neurons can be defined in terms of encoders and decoders as: $\omega_{i j}=\alpha_{j} \mathbf{e}_{j} \mathbf{d}_{i}^{f(\mathbf{x})}$, where $i$ indexes the presynaptic population, $j$ indexes the postsynaptic population, and $\mathbf{d}_{i}^{f(\mathbf{x})}$ are representational or transformational decoders.

## Neural model of life span prediction

Figure 2 shows the architecture of the neural model for life span inference built using the NEF. All neural ensembles (populations of neurons; symbolically represented by five circles) are 20 dimensional and contain 200 LIF neurons each, except the Normalized Posterior ensemble which is 120 dimensional and contains 800 LIF neurons. The

Figure 2: A schematic diagram of the neural model. Here "Likelihood" and "Prior" contain 200 neurons each, "Product" network contains 4000 neurons and "Normalized Posterior" contains 800 neurons.
product network computes an element-wise product of its inputs. Though multiplication is nonlinear, it has a wellcharacterized implementation in neurons that does not require nonlinear interactions, and can be implemented accurately with the NEF (Gosmann, 2015). The product network makes use of this characterization. It has 40 neural ensembles of 100 neurons each for a total of 4,000 neurons. The entire model contains 5,200 neurons.

To represent the probability distributions (prior and likelihood) needed to perform the task, we define a basis $\phi_{20}(v)$ to span the space of each distribution. To compute the basis we sample from a family of 120 dimensional distributions and do Singular Value Decomposition to obtain a 20 dimensional basis. This basis is used to determine the encoders (as given by Eq. 12) used in the NEF simulation. The same basis is used for the optimization to find the neuron decoders (as given by Eq. 13) that are needed to perform the desired computations. Similar to the encoding and decoding functions, the 120 dimensional prior and likelihood functions are also projected to the 20 dimensional space through weights over the basis. Refer to the supplemental material for details.

The likelihood_input and prior_input are nodes that provide the named 20 dimensional inputs to the neural ensembles Likelihood and Prior respectively. The product network receives input from these ensembles and computes the posterior distribution (in the 20 dimensional space). The output connection from product network to Normalized Posterior reconstructs the posterior back to 120 dimensional space and computes the normalization function using principle 2 of the NEF. Thus, the Normalized Posterior ensemble represents the normalized posterior distribution. Next we approximate the median of this distribution on the connection between the Normalized Posterior ensemble and the Prediction node (again using principle 2). We read out the model prediction from the Prediction node.

Figure 3 shows the inference results obtained from the spiking neural network run in the Nengo (Bekolay et al., 2014) software package. Model predictions are plotted for current ages $(t)$ from 1 to 100 . The difference between the results in Direct mode and Neuron mode is due to the limited number of neurons in the Normalized Posterior ensemble. As the number of neurons in this ensemble increases, the results

Figure 3: Inference results from neural model ( $95 \%$ confidence intervals), compared to humans and Direct mode our model with computations in low-dimensional ( 20 dimensional basis) space, but without neurons.
approach the Direct mode results ( 800 neurons provide the best fit to human data). Thus, neural results match the human data better due to the approximate representation of the normalized posterior by the neurons in the Normalized Posterior ensemble. The tuning curves of the neurons in this ensemble were fit to a function space consisting of a family of distributions which have three parameters (similar to the parameters in the prior) and also depend on the current age $(t)$ (similar to the likelihood function). The three parameters: $a$ - the skewness parameter was varied from -7 to -4 , scale - used to scale the distribution was varied from 26 to 29 and $l o c$ - used to shift the distribution was varied between 49 to 101 . The current age $(t)$ was varied in the range of $+/-5$ for a given age in a trial except ages below 5 for which the range was taken to be from $[1,10]$. This provides the function space that was used to sample the encoders for Normalized Posterior ensemble.

We use the Kolmogorov-Smirnov (K-S) test to examine the goodness of fit of the neural model predictions relative to the Griffiths and Tenenbaum (2006) model. The data used for the K-S test are shown in Figure 4b. The dissimilarity of the Griffiths and Tenenbaum (2006) model relative to human predictions is 9.628 , while that of the neural model is 1.959 , indicating the much closer fit of the neural model to the human data. Figure 4a shows a comparison between the Griffiths and Tenenbaum (2006) model, the computational model (our replication of their model), and direct mode (our model with computations in a compressed 20 dimensional space, but without neurons). Since the results obtained from the direct mode are the same as the computational model, the low dimensional embedding is not losing any information. However, we expect some error due to this constraint for more complex priors (though we have not explored the minimum dimensionality for this prior).

Overall, our results suggest that the closer fit of the neural data can be solely attributed to fitting the neuron tuning

Figure 4: (a) Results from Griffiths and Tenenbaum (2006) model (only data corresponding to human data), Computational model i.e., our replication of their model, and Direct mode i.e., our model with computations in low-dimensional space, but without neurons. (b) Kolmogorov-Smirnov (K-S) test results. Dissimilarity relative to human predictions - Griffiths and Tenenbaum (2006) model: 9.628, neural model: 1.959. Neural model and human data are median predictions. Note: Griffiths and Tenenbaum (2006) model data and human data were obtained from Figure 1B through a web plot digitizer.
curves in the Normalized Posterior ensemble, where 800 neurons provide the best match to human performance. Since the low-dimensional neural implementation can be made to match the human data, this is some evidence in support of the hypothesis that human brains represent low-dimensional state spaces (low-dimensional parameterizations of highdimensional distributions fit using neural tuning curves).

## Generalized life span inference

In our neural model, we use the prior obtained empirically by Griffiths and Tenenbaum (2006). However, our neural modeling methods can further be used to explore how this prior might be learned in the human brain. Here, we lay some theoretical ground work for addressing this question, while building the complete neural model remains for future work.

We assume that priors that humans have about life spans are a result of their experiences encountering people of different ages in their daily lives. Thus the prior will be inferred from the data that comes from daily experience. We further assume that the prior is parameterized by some unknown hyperparameters ( $\alpha$ ) which are to be estimated from the observed ages of $n$ distinct people, given by $\mathbf{X}=\left\{x_{1}, \ldots, x_{n}\right\}$. Here, each random variable $x_{i}$ corresponds to a separate $t$ from the previous model. Likewise, we model each element of $\mathbf{X}$ as being drawn independently from each element of $\mathbf{Z}=\left\{z_{1}, \ldots, z_{n}\right\}$ corresponding to the (unknown or hidden) life spans of these same $n$ people. Each random variable $z_{i}$ corresponds to a separate $t_{\text {total }}$ from the previous model, which in turn is drawn from the unknown prior. We now describe two standard methods for determining a prior by obtaining an estimate $\hat{\alpha}$ of the hyperparameters.

If we do not know the actual prior, then the optimal solution can be found by trying them all. That is, we directly find the hyperparameters $\hat{\alpha}$ that maximize the marginal like-
lihood of the observed data, $L(\alpha ; \mathbf{X})$ (or equivalently the loglikelihood for numerical stability):

$$
\begin{equation*}
\hat{\alpha}=\operatorname{argmax}_{\alpha} L(\alpha ; \mathbf{X})=\operatorname{argmax}_{\alpha} \sum_{i=1}^{n} \log \sum_{z_{i}} p\left(x_{i}, z_{i} \mid \alpha\right) \tag{17}
\end{equation*}
$$

In general, however, the procedure described above is intractable, since it requires that we iterate over all combinations of $\alpha$ and $\mathbf{Z}$. This motivates near-optimal iterative procedures such as the widely-used expectation maximization algorithm (EM; Dempster, Laird, \& Rubin, 1977). Below we work out the details of the EM procedure for the case where the hyperparameters are $\alpha=\left(\mu, \sigma^{2}\right)$, i.e., the prior is assumed to be normally distributed with unknown moments. We begin by simplifying the expectation function using independence and other known facts about the model:

$$
\begin{align*}
Q\left(\boldsymbol{\alpha} \mid \boldsymbol{\alpha}^{(t)}\right) & =E_{\mathbf{Z} \mid \mathbf{X}, \boldsymbol{\alpha}^{(t)}}[\log L(\boldsymbol{\alpha} ; \mathbf{X}, \mathbf{Z})] \\
& =\sum_{i=1}^{n} E_{z_{i} \mid x_{i}, \boldsymbol{\alpha}^{(t)}}\left[\log L\left(\alpha ; x_{i}, z_{i}\right)\right]  \tag{18}\\
& =\sum_{i=1}^{n} \sum_{z_{i}} T\left(x_{i}, z_{i}\right) \log \left(p\left(z_{i} \mid \alpha\right) / z_{i}\right)
\end{align*}
$$

where we have defined $T\left(x_{i}, z_{i}\right):=p\left(z_{i} \mid x_{i}, \alpha^{(t)}\right)$ to be some fixed function with respect to $\alpha^{(t)}$. Next, we simplify the log expression using our model of the prior:

$$
\begin{align*}
& \log \left(p\left(z_{i} \mid \alpha\right) / z_{i}\right)=\log \left(\frac{1}{\sqrt{2 \sigma^{2} \pi}} e^{-\frac{\left(z_{i}-\mu\right)^{2}}{2 \sigma^{2}}}\right)-\log z_{i}  \tag{19}\\
& =-\frac{1}{2}\left(\left(z_{i}-\mu\right)^{2} / \sigma^{2}+\log \sigma^{2}+\log (2 \pi)+2 \log z_{i}\right)
\end{align*}
$$

and then differentiate this with respect to $\mu$ :

$$
\begin{equation*}
\frac{\partial \log \left(p\left(z_{i} \mid \alpha\right) / z_{i}\right)}{\partial \mu}=\left(z_{i}-\mu\right) \sigma^{2} \tag{20}
\end{equation*}
$$

and with respect to $\sigma^{2}$ :

$$
\begin{equation*}
\frac{\partial \log \left(p\left(z_{i} \mid \alpha\right) / z_{i}\right)}{\partial \sigma^{2}}=\frac{1}{2}\left(\left(z_{i}-\mu\right)^{2}-\sigma^{2}\right) / \sigma^{4} . \tag{21}
\end{equation*}
$$

By linearity of differentiation, we then know that the derivatives of $Q(\cdot)$ are zero when:

$$
\begin{align*}
\frac{\partial Q\left(\alpha \mid \alpha^{(t)}\right)}{d \mu} & =\sum_{i=1}^{n} \sum_{z_{i}} T\left(x_{i}, z_{i}\right)\left(z_{i}-\mu\right) \sigma^{2}=0 \\
\Longleftrightarrow \quad \mu & =\frac{\sum_{i=1}^{n} \sum_{z_{i}} z_{i} T\left(x_{i}, z_{i}\right)}{\sum_{i=1}^{n} \sum_{z_{i}} T\left(x_{i}, z_{i}\right)}, \quad \text { and similarly: }  \tag{22}\\
\frac{\partial Q\left(\alpha \mid \alpha^{(t)}\right)}{d \sigma^{2}} & =\sum_{i=1}^{n} \sum_{z_{i}} T\left(x_{i}, z_{i}\right) \frac{1}{2}\left(\left(z_{i}-\mu\right)^{2}-\sigma^{2}\right) / \sigma^{4}=0 \\
\Longleftrightarrow \quad \sigma^{2} & =\frac{\sum_{i=1}^{n} \sum_{z_{i}}\left(z_{i}-\mu\right)^{2} T\left(x_{i}, z_{i}\right)}{\sum_{i=1}^{n} \sum_{z_{i}} T\left(x_{i}, z_{i}\right)} \tag{23}
\end{align*}
$$

Finally, by the generalized Bayes' rule, we know:

$$
T\left(x_{i}, z_{i}\right)=p\left(z_{i} \mid x_{i}, \boldsymbol{\alpha}^{(t)}\right)=\frac{p\left(z_{i}, x_{i} \mid \boldsymbol{\alpha}^{(t)}\right)}{\sum_{z_{i}} p\left(z_{i}, x_{i} \mid \boldsymbol{\alpha}^{(t)}\right)},
$$

which we may compute via Eq. 1. We also note that since $T(\cdot)$ is a probability density function over $z_{i}$, that:

$$
\sum_{i=1}^{n} \sum_{z_{i}} T\left(x_{i}, z_{i}\right)=\sum_{i=1}^{n} 1=n
$$

Therefore, each EM iteration must make the update $\alpha^{(t+1)}=$ $\left(\mu^{(t+1)}, \sigma^{(t+1)}\right)$, where:

$$
\begin{align*}
\mu^{(t+1)} & =\frac{1}{n} \sum_{i=1}^{n} \frac{\sum_{z_{i}} z_{i} p\left(z_{i}, x_{i} \mid \alpha^{(t)}\right)}{\sum_{z_{i}} p\left(z_{i}, x_{i} \mid \alpha^{(t)}\right)}  \tag{24}\\
\boldsymbol{\sigma}^{(t+1)} & =\sqrt{\frac{1}{n} \sum_{i=1}^{n} \frac{\sum_{z_{i}}\left(z_{i}-\mu^{(t+1)}\right)^{2} p\left(z_{i}, x_{i} \mid \boldsymbol{\alpha}^{(t)}\right)}{\sum_{z_{i}} p\left(z_{i}, x_{i} \mid \boldsymbol{\alpha}^{(t)}\right)}} .
\end{align*}
$$

This converges to some locally optimal estimate of the hyperparameters. For initial $\alpha^{(0)}$ chosen sufficiently close to global optimum $\hat{\alpha}$ given by Eq. 17, this converges to the optimum.

This provides a tractable procedure for updating the prior. In particular, we begin with some initial guess at the hyperparameters, and then update them iteratively to better explain the observed data. In practice only a few iterations are required (results not shown). Once we have an estimate of the hyperparameters $(\hat{\alpha})$, we then know the prior $p\left(t_{\text {total }} \mid \hat{\alpha}\right)$. This prior can be used directly by the previously described model to provide a good prediction. In fact, it is possible to run both the prior optimization and inference at the same time, and both will become progressively more accurate over time.

## Conclusions

We have presented a spiking neural network able to effectively perform Bayesian inference in a manner that more accurately matches human behavior than an ideal Bayesian
computation. We constructed the network using the NEF to map function spaces into vector spaces and approximate the necessary computations. We suggested a means of estimating the prior for the life span task that can be implemented using these same methods.

# The Role of Causality in Temporal Binding: Evidence for an Intentional Boost 

Daniel A. Shiloh, Peter A. White \& Marc J. Buehner ([ShilohDA], [WhitePA], [BuehnerM]@Cardiff.ac.uk)<br>School of Psychology, Cardiff University, Tower Building, 70 Park Place<br>Cardiff, CF10 3AT, UK

#### Abstract

Temporal binding refers to the subjective contraction in time between an action and its consequence. Since it was reported in 2002 the effect has generated much interest, although a consensus regarding the mechanisms behind it remains elusive. While multiple theoretical accounts have been proposed, a key point of contention remains whether the effect is the result of the perception of intentionality or causality. We deployed a new apparatus to compare intentional to mechanical causation. Thirty participants reported the interval between two events in self-causal, mechanical-causal and non-causal conditions. The results of a Bayesian analysis pointed to smaller temporal estimates in the self-causal condition compared with the mechanical-causal condition, in addition to smaller estimates in the mechanicalcausal condition compared with the non-causal condition. The evidence presented here suggests that causality alone may be sufficient for temporal binding to occur, but that this effect is boosted by the presence of intentional action.

## Introduction

Temporal binding refers to the mutual attraction (in subjective time) between a causal action and its consequence, relative to two unrelated events. In a seminal paper Haggard et al (2002) found evidence for delayed awareness of the time of action and early awareness of the time of its consequence. Subsequent research has replicated this effect with a variety of paradigms, including interval estimation (Humphreys \& Buehner, 2009), stimulus anticipation (Buehner \& Humphreys, 2009) and the method of constant stimuli (Nolden, Haering \& Kiesel, 2012). The use of various interval estimation methods has demonstrated that, in addition to shifts in the perceived time of events, intentional binding also manifests as a shortening of the overall perceived interval between an action and its consequence.
Haggard et al. (2002) originally referred to the effect as intentional binding and proposed that it reflects "a general linkage through time between representation of action and effect" (p. 384), and that the subjective shortening of the interval between them may contribute to our sense of agency and motor learning through forward models. While multiple accounts of the mechanisms behind temporal binding have been proposed since then (Buehner, 2015; Moore \& Obhi, 2012; Eagleman \& Holcombe, 2002), the role of intentionality has been central to much of the work on the subject. More recently, studies have increasingly made use of temporal binding as an implicit measure of sense of agency, for example in studies of mindfulness (Jo,

Whittmann, Hinterberger \& Schmidt, 2015; Lush, Parkinson \& Dienes, 2016) narcissism (Hascalovitz \& Obhi, 2015) and Schizophrenia (Voss et al, 2010).

The focus on intentionality in the literature notwithstanding, Buehner and Humphreys (2009) have argued that temporal binding is instead driven by awareness of causality, and should be termed "causal binding": Temporal binding reflects a bi-directional interpretation of David Hume's (1739/1888) assertion that temporally contiguous events are more likely to be perceived as causally related. Specifically, because human time perception is inherently noisy and uncertain, it is subject to top-down modulation. From a Bayesian perspective it thus follows that if contiguous event pairs are likely to be causally related, then event pairings that are known to be causally linked are also likely to have occurred contiguously. Time and causality thus mutually constrain each other in subjective experience.

While there is a general consensus that a causal relationship is necessary for temporal binding to occur, there is less agreement on whether causality on its own is also sufficient (Moore \& Obhi, 2012). However, Buehner (2015) reported mutual attraction in subjective time between voluntary actions and their outcomes (i.e. the typical binding effect) as well as between involuntary, induced, causal actions and their outcomes. Furthermore, Buehner (2012) also demonstrated temporal binding between a nonbiological mechanical action (a robot arm pressing a key) and its outcome (an LED flash). While both studies revealed evidence for temporal binding in the presence of causality alone (thus demonstrating its sufficiency to result in binding), they also found a more pronounced effect when the cause was an intentional action. Thus, while causal binding appears to be rooted in causality, it seems to be subject to an intentional boost.

A limiting factor in this earlier research is that it always deployed key-presses as intentional causal actions, meaning that participants had access to precise proprioceptive feedback about the successful completion of the causal action, as well as the precise time of the start of the causal interval (i.e. the moment the key was depressed). In contrast, this type of feedback was not available in control conditions. We set out to maximize the perceptual similarity between experimental conditions. Specifically, we replaced key-presses with a continuous upwards movement made by the participant, and created a mechanical causal as well as a control condition that matched the perceptual experience. In all three conditions, participants were able to rely purely on
visual information to determine the onset of a two-event sequence, and we eliminated any tactile or auditory feedback.

Participants took part in three conditions: self-causal, mechanical-causal and non-causal control. On each trial, participants had to reproduce the interval between two sequential events (which were causally linked in the two causal conditions). Both the self-causal and mechanicalcausal conditions made use of a laser pointed at a light sensor. Upon detecting the laser beam (event 1) the light sensor responded by switching on a red LED after a randomized delay (event 2 ). In the self-causal condition participants allowed the laser to reach the light sensor manually by moving a wooden paddle out of its way, whereas in the mechanical-causal condition this was done mechanically, without input from the participant. In the noncausal control condition the laser was replaced with a small red LED which was positioned where the laser beam could be seen in the other two conditions. In this condition, the two event sequence consisted of deactivating of the small LED (simulating the perceptual experience of the laser hitting the light sensor), followed by the switching on of the red LED as in the other two conditions. This sequence was controlled by a computer.

According to the intentional binding account, temporal estimates for the two -event sequences should be smaller in the self-causal condition than in the other two (self-causal < mechanical-causal $=$ non-causal control); according to the causal binding account, temporal estimates should be larger in the non-causal control condition than in the self-causal and mechanical-causal conditions (self-causal = mechanical-causal $<$ non-causal control). Finally, if temporal binding is rooted in causality, but subject to an intentional boost temporal estimates should be lowest in the self-causal condition, followed by the mechanical-causal condition, with both being shorter than the non-causal control condition (self-causal $<$ mechanical-causal $<$ noncausal control).

## Methods

## Participants

Thirty Cardiff University students and staff (2 male, age range 18-33) participated in exchange for a payment of $£ 3$ or course credits. Participants were recruited through Cardiff University's electronic Experiment Management System and electronic noticeboard. Participants were asked to report (in writing) whether they felt they knew the purpose of the experiment prior to debriefing. Of the thirty, only three responded 'yes', and none correctly understood the purpose of the experiment.

## Apparatus

A schematic diagram of the apparatus can be seen in Figure 1. The apparatus was situated on top of a desk and placed on a platform at a height of 9.8 cm , with a gap 18.8 cm in length. The light sensor was positioned opposite the laser module,
both at a height of 14.5 cm . Between the laser and light sensor a wheel ( 21.5 cm diameter) was placed with a round 1 cm diameter hole positioned in the location through which the laser beam passed. The wheel was attached to a motor which allowed it to spin clockwise at a speed of approximately one revolution per four seconds.

Figure 1: a schematic diagram of the apparatus. $1=$ light sensor (containing a Raspberry Pi computer) connected to a red LED bulb; $2=$ wheel with 1 cm diameter perforation; $3=$ laser module; $4=$ a box housing a geared motor able to spin the wheel clockwise.

The light sensor module consisted of a $7 \times 7 \times 10 \mathrm{~cm}$ box housing a raspberry pi computer, with a 10 mm LED bulb mounted at its top and the light sensor on its front (facing the laser module). A separate, portable, 5 mm red LED bulb was also connected to the computer, but only visible to participants during the non-causal condition (see design and procedure). For the self-causal condition (see design and procedure), a rectangular wooden paddle ( 6 cm in width and 14 cm in height, with handle at its centre) with a 1 cm diameter hole was used in place of the wheel.

Participants were placed at a chin rest behind the laser module. Participant responses were recorded using a computer mouse on a separate computer. Finally, a debrief questionnaire was used to measure perceived causality using a 9-point Likert Scale (see appendix 1). For each condition, participants were presented with the question "in the condition where [condition description] did it seem like [first event] was causing [second event] ( $1=$ definitely yes, $5=$ not sure, $9=$ definitely no)?" These scores were inverted for analysis.

## Design and Procedure

After completing a consent form, participants were given safety instructions and were allowed to adjust the height of their seat. Instructions were presented verbally at the beginning of the experiment and before each trial. Throughout the experiment participants kept their head in the chin rest, ensuring that the light sensor, wheel and laser beam were visible. Participants were instructed to fixate their gaze on the laser point during the self-causal and mechanical-causal conditions, and on the 5 mm diameter LED bulb during the non-causal control condition.

Participants worked through the three conditions, with order of conditions counterbalanced between participants. Each condition consisted of 40 trials, during which
participants observed a critical two-event sequence lasting for an interval between 200 - 400ms (randomized, described below) and were asked to reproduce this interval by holding down the left mouse key for their perceived duration. Prior to each experimental block, participants worked through as many practice trials as they needed (minimum: three, regardless of performance) to understand the task. Task comprehension was assessed by the experimenter by observing the participants performing the task to ensure that participants were performing the correct movement (if any) and reporting time intervals after each trial. Probing questions were used to ensure that participants were reporting the correct time intervals and that they did not have any further questions.

The conditions were as follows (see Figure 2 for a photographs of each experimental condition):

Self-causal: Participants performed an intentional action that generated a causal consequence after a short delay. The wheel was placed with the hole aligned to the laser beam and light sensor and remained stationary throughout (i.e. the laser beam could pass through to the light sensor, when allowed through by the participant. The light sensor responded to the laser beam by switching on the 10 mm red LED at the top of the housing after a randomised delay of $200-400 \mathrm{~ms}$, and switching off after a randomised interval of $200-400 \mathrm{~ms}$, if the beam was no longer received. All randomised delays used in the experiment were drawn from a uniform distribution. Participants were told that the sensor responds to the beam after a delay, and this was demonstrated by the experimenter prior to the practice trials by using hand movements to either block the laser or allow it through. Participants were not told any additional information about these delays. Participants were instructed to place the paddle at the bottom of the apparatus, with the hole beneath the laser beam, such that the paddle blocked the beam. Participants were instructed to keep the paddle positioned adjacent to the wheel and move it upwards in front of the laser beam in each trial, such that the laser would pass through the hole. This was done to keep this condition as perceptually similar as possible to the mechanical-causal condition (see below). Participants were instructed to reproduce the time interval between the laser beam reaching the light sensor and the LED lighting up before placing the paddle back for the next trial.

Mechanical-causal: The wheel rotated continuously at a speed of approximately 4 seconds per revolution and blocked the laser beam from reaching the sensor, except when the hole came in line with it (once every 4 seconds). The light sensor was switched on and functioned in the same way as in the self-causal condition. This was demonstrated prior to the practice trials; the experimenter demonstrated that when the laser beam was blocked the light sensor did not respond at all, regardless of the position of the wheel, and that the light sensor always responded after the laser passed through the hole in the wheel. Participants were instructed to reproduce the interval between the laser reaching the sensor and the LED lighting
up as in the self-causal condition. Note that in both the selfcausal and mechanical-causal conditions, the critical causal event 1 (the laser reaching the light sensor) coincided with the perceptual experience of the laser spot (temporarily) being no longer visible against the paddle or wheel.

Non-causal control: Participants reproduced the interval between two sequential LED flashes. The wheel was positioned in the same way as in the self-causal condition. The laser module was switched off, and the 5 mm LED was placed in the hole in the wheel. At the beginning of each trial, the 5 mm LED switched on for one second before switching off, followed by the 10 mm LED at the top of the housing switching on for $200-400 \mathrm{~ms}$. Following this, participants were asked to reproduce the time interval between the 5 mm LED switching off and the 10 mm LED switching on. Participants were not told any information about the causal relationship between the two lights, but only that they turned on and off in a regular sequence. In order that the switching off of the first light would be equally predictable as the laser passing through the wheel in the mechanical-causal condition participants were informed that the first light will switch off after exactly one second on each trial. This sequence repeated automatically for the duration of the condition, with an overall trial length matching the duration of a single wheel revolution. Participants were instructed to fixate their gaze on the 5 mm LED bulb throughout.

At the end of the experiment participants were asked to fill in the debrief questionnaire, where they were asked to report whether they believed the first event in the interval they were judging caused the second event to occur, per condition. These causal ratings were taken as a manipulation check, to ensure participants correctly perceived the causal structure of the self-causal and mechanical-causal conditions (the laser beam causing the light sensor to respond) and the non-causal control condition (both lights shared a common cause). Following this participants were debriefed as to the purpose of this experiment.

Figure 2: Photographs of all experimental conditions from the participants' perspective. Self-causal condition (left): the paddle is set with the hole below the laser beam at the beginning of a trial. Mechanical-causal condition (centre): the wheel is rotating clockwise and the laser beam is obstructed. Non-causal control (right): the laser beam is
replaced with a red LED bulb positioned where the laser point can be seen in the other two conditions.

## Results

## Exclusions

Three participants were excluded for failing to follow instructions (consistently making multiple estimates per trial, or making estimates during, rather than between, trials). One further participant was excluded due to a technical error. For all other participants, individual trials for which there were two estimates and estimates which overlapped with the time of the event being judged were removed from analysis ( 8 participants with excluded trials, mean average 4.88 exclusions out of 120 trials).

## Causal estimates

A Friedman's ANOVA was used due to the ordinal nature of the causal scores. We found a significant main effect of condition on causal scores $\left(\mathrm{X}^{2}(2)=15.58, \mathrm{p}<.001\right)$. Posthoc testing using a Bonferroni correction found significantly lower scores for the non-causal control condition (median $=$ 6) compared with the self-causal condition (median $=8, \mathrm{p}<$ .05 ) and the mechanical-causal condition (median $=8, \mathrm{p}<$ .05). No significant difference was found between the selfcausal and mechanical-causal conditions ( $\mathrm{p}>.05$ ).

## Temporal estimates

Transformation A preliminary analysis of the data found significant variability in the range of reproductions between participants (see Table 1 for pre-transformation data). Additionally, a Shapiro-Wilk test found significant deviations from the normal distribution in two of the three conditions ( $\mathrm{p}<.05$ ). In order to reduce the influence of individual differences and reduce the positive skew of the data, temporal reproductions were converted to z-scores. To do this, each participant's grand mean was subtracted from each of their interval estimates. The difference from the mean of each score was divided by the standard deviation of all estimates (per participant). The mean z-score per condition for each participant was used for the temporal estimates analysis. Following transformation, the assumption of normality was met for all conditions ( $\mathrm{p}>$ $.05)$. The mean z-scores can be seen in Figure 3.

Table 1: Descriptive Statistics for raw Temporal Reproductions

| Condition | Mean | Standard deviation |
| :--- | :--- | :--- |
| Self-causal | 380.26 | 197.49 |
| Mechanical-causal | 406.8 | 134.81 |
| Non-causal Control | 501.14 | 315.39 |

Figure 3: Mean z scores of Temporal Reproductions by condition. Error bars represent the $95 \%$ confidence interval.

Analysis A one-way ANOVA found a significant main effect of condition on the z score-transformed estimates, $F(2,50)=4.46, p<.05, \eta^{2}=.15, M S E=1.57$. Planned simple contrasts were used to investigate the differences between the mechanical-causal condition and both other conditions. A significant difference was found between the mechanical-causal and self-causal conditions ( $p=.048$ ), but not between the mechanical-causal and non-causal control ( $p=.23$ ). The frequentist analysis, therefore, appears to favour the intentional binding account.

A Bayesian analysis was carried out using the BayesFactor package for R statistics (Morey, Rouder, Jamil \& Morey, 2015). A Bayesian repeated-measures ANOVA (see Rouder, Morey, Speckman \& Province, 2012 for details) found a Bayes factor of 17.23 for the unconstrained model (self-causal $\neq$ mechanical-causal $\neq$ non-causal control), indicating that the data observed is over 17 times more likely under the unconstrained model compared with the null model (intercept only). We also analysed three further models, as predicted by the intentional binding account (self-causal $<$ mechanical-causal $=$ non-causal control), the causal binding account (self-causal = mechanical-causal < non-causal control) and the 'intentional boost' account (self-causal < mechanical-causal < noncausal control). The highest Bayes factor was found for the model predicted by the intentional boost account $\left(\mathrm{BF}_{10}=\right.$ 91.82), and as such it is the preferred model compared with the models predicted by the intentional binding account $\left(\mathrm{BF}_{10}=44.57\right)$ and causal binding account $\left(\mathrm{BF}_{10}=16.22\right.$; denominator $=$ intercept only model for all Bayes factors).

## Discussion

We set out to investigate whether the perception of causality is sufficient for temporal binding to occur. We compared temporal estimates across three conditions: self-causal,
mechanical-causal and non-causal control. In contrast to the previous work on this topic, the first and second events in each sequence were equally predictable and perceived in the same modality (visual), thus eliminating possible confounding variables.

The results of the Bayesian analysis suggest that the most plausible model underlying our data is one of causal binding with an 'intentional boost'. It is noteworthy, however, that evidence of causal binding is only present in the Bayesian analysis, and cannot be seen in the frequentist planned contrasts. This apparent discrepancy may be the result of effect size; in this case there may have been a causal binding effect which was too small to be detectable under frequentist statistics, but still contributed the intentional boost model being the preferred model in the Bayesian analysis.

Our manipulation check (causal ratings) revealed higher-than-expected perceived causality between the two lights in the non-causal control condition. Although participants reported significantly weaker causal impressions in the noncausal control condition, the median score was 6 (on a 1-9 scale), indicating that 13 of the 26 participants included in the analysis perceived some causal relationship between the two lights. The causal binding view therefore would predict a reduced binding effect in those participants, due to reduced distinctiveness of the causal compared to the control conditions. .Therefore, while the manipulation has been successful in that the majority of participants reported weaker causal links between the two lights than the laser and light sensor, this may not have been sufficiently consistent across the entire sample to result in an effect size detectable by a frequentist analysis.

Although two previous studies have reported an intentional boost to causal binding (Buehner, 2015; 2012), it is still unclear how causal and intentional binding relate to each other. The causal ratings obtained here appear to rule out the possibility that participants perceived stronger causal relationships between the two events when the cause was self-initiated, so the intentional boost cannot be attributed to enhanced causal impressions following self-initiated vs mechanical causal actions. Instead, our findings suggest three possibilities. The first is that there may be two, separate causal and intentional binding effects, of differing strengths and with different roots, acting independently. This appears unlikely, however, in light of previous research suggesting that temporal binding does not occur in the absence of causality (Moore, Langado, Deal \& Haggard, 2009; Buehner \& Humphreys, 2009). Such findings indicate that the temporal binding effect is inextricably linked to perceived causality; specifically, that causality is necessary for the binding to occur.

An alternative explanation may be that causal binding and the intentional boost are a product of the same Bayesian processes, specifically, Bayesian cue integration. Humans appear to integrate information from multiple sensory cues in a manner that is statistically optimal: Ernst \& Banks (2002) found that when judging the height of a stimulus based on visual and haptic information, participants attached
more weight to the cue that has lower variance. Moore, Wegner \& Haggard (2009) suggested that Bayesian cue integration may also govern our sense of agency. Just as multiple sensory cues contribute to our judgment of physical properties such as size or shape, the perception of intentionality results from multiple cues, both internal (e.g. forward model predictions) and external (sensory cues). Applying this rationale to temporal binding, one could argue that the size of the effect depends on the noisiness of perceptual cues - specifically, the (perceived) times of the action and its consequence. One would expect that if prior expectation of the time of an effect is determined to some extent by the time of its cause, increased certainty in the time of the cause would lead to an increased weight being attached to it. Specifically, the shift in the perceived time of the effect (towards the cause) would be greater, the more certain one was about the time of the cause. While both the manual and mechanical actions were equally predictable in this experiment, participants had additional internal cues to the onset of their own action than to an observed mechanical event. It would be expected that the combination of these cues and visual feedback would lead to a more reliable and less variable percept of the time of the self-cause relative to the time of the machine-cause. As the expected time of the second event must be determined by the time of the first event (the cause is predictive of the effect), a more reliable percept of the time of the cause would lead to a more reliable prior for the time of the second event, which would be weighted more heavily against new cues to the time of the second event. This in turn would result in a greater backwards shift of the perceived time of the effect in the self-causal compared to the mechanical-causal condition. In line with this idea, Zhao et al. (2016) found greater temporal binding when participants had tactile cues to the time of the cause (key-press), compared with an action without tactile feedback (key release).

However, greater certainty in the time of the first action would also mean that it is less liable to be biased by the time of the second event. Altogether, Bayesian cue integration would thus be expected to lead to a lesser forward shift in the perceived time of the self- compared to the mechanicalcause, but a greater shift in the perceived time of the consequence towards a self- compared to a mechanicalcause. Thus, Bayesian cue integration based purely on the noisiness of the temporal cues leads to two distinct shifts in event perception working in opposite directions. We would argue that in addition to perceptual cues, the Bayesian integration process also takes into account expectations of cause-effect contiguity, in line with Hume's (1888) principles of causal inference. Crucially, that causes are predictive of their effect forms a key part of how we perceive causality; we perceive one event as causing another when it comes before it, when the second event occurs close in time to the first event and when the second event is contingent upon the first. The cause is thus more predictive of the effect than vice versa. These assumptions, however, do not necessarily accompany the perception of events
which are not causally related (e.g. a non-causal sequence of events). Furthermore, previous research (e.g. Haggard et al., 2002) has shown that outcome binding (i.e. shifts in the awareness of an outcome towards its cause) is typically greater than action binding (shifts in the awareness of a causal action towards its consequence). Therefore, the combined influence of the nature of causal relationships and the perceptual differences between self-action and mechanical actions may explain the presence of both causal binding and an intentional boost in our findings, within a single model.

More research is needed to determine what underlies the intentional boost to causal binding. The majority of research investigating the effect of agency on temporal binding to date has failed to take account of the potential role of causality: This is evidenced by failure to include adequate non-causal control conditions (e.g. Caspar, Christensen, Cleeremans \& Haggard, 2015; Zhao et al, 2016), or to obtain causal ratings as manipulation checks (e.g. Haggard et al, 2002). The present findings demonstrate the importance of control conditions in temporal binding, without which a reduced magnitude of temporal binding is indistinguishable from the absence of temporal binding. In particular, if there is indeed an intentional boost to causal binding, this calls for a reinterpretation of research suggesting there is no temporal binding effect in the absence of intentional action.

#### Abstract

Previous studies have shown that individuals often make inferences based on heuristics using recognition, fluency, or familiarity. In the present study, we propose a new heuristic called familiarity-matching, which predicts that when a decision maker is familiar (or unfamiliar) with an object in a question sentence, $s$ /he will choose the more (or less) familiar object from the two alternatives. We examined inference processes and ecological rationality regarding familiarity-matching through three studies including behavioral experiments and ecological analyses. Results showed that participants often used familiaritymatching in solving difficult binary choice problems, and that familiarity-matching could be applied in an ecologically rational manner in real-world situations. A new perspective on human cognitive processes is discussed in this study.

Keywords: binary choice task; heuristic; familiarity; familiarity-matching; ecological rationality

## Introduction

When making decisions, individuals often use simple inference strategies such as heuristics. In the field of heuristics research, many researchers initially focused on cognitive biases involved in heuristics (e.g., Tversky \& Kahneman, 1973, 1974, 1983). In contrast, recent studies have discussed the adaptive aspect of heuristics (e.g., Gigerenzer \& Goldstein, 1996; Gigerenzer \& Todd, 1999; Goldstein \& Gigerenzer, 2002). Some studies investigated human inference cues or inference strategies using binary choice tasks (e.g., Goldstein \& Gigerenzer, 2002; Hertwig, Herzog, Schooler \& Reimer, 2008; Honda, Abe, Matsuka \& Yamagishi, 2011; Honda, Matsuka \& Ueda, in press). These studies showed that subjective memory experiences, such as recognition, fluency, or familiarity of an object could be valid inference cues. For example, in the binary choice task, "Which city has a larger population, Tokyo or Chiba?" when a decision maker recognizes (or is more fluent or familiar with) Tokyo and does not recognize (or is less
fluent or familiar with) Chiba, s/he tends to choose the recognized (or the more familiar or fluent) city -as the one with a larger population size. An interesting observation is that, in many cases, this simple inference can often lead to correct inferences. Thus, a simple heuristic using subjective memory experiences can be ecologically rational (e.g., Goldstein \& Gigerenzer, 2002; Hertwig et al., 2008; Schooler \& Hertwig, 2005; Honda et al., in press).

## Choice of an object based on similarity of familiarity: Familiarity-matching

So far, previous studies have investigated the effects of subjective memory experience for finding correct alternatives in a binary choice task. However, if the familiarity of an object in alternatives can serve as a valid inference cue, it is possible that the same holds true for the familiarity of an object in a question sentence. For example, if we consider the binary choice task, "Which country is Hameln in, Germany or Liechtenstein?" A decision maker may infer it as "I have heard the name 'Hameln' and I am familiar with this city. Further, I am more familiar with Germany than Liechtenstein; therefore, Hameln should be in Germany!" In this case, the decision maker chose the more familiar alternative because the familiarity of the chosen alternative was similar to that of the object in the question sentence. Likewise, in the task, "Which country is Schellenberg in, Germany or Liechtenstein?" A decision maker may infer it as "I have never heard the name 'Schellenberg' and I am unfamiliar with the city. Further, I am less familiar with Liechtenstein than Germany; therefore, Schellenberg should be in Liechtenstein!" In this case, the decision maker chose the less familiar alternative because the two objects were similarly unfamiliar. A decision maker may thus use an inference strategy like "matching familiarity" between an object in the question sentence and another object in the alternatives. That is, a decision maker makes inferences based on similarity of familiarity between
objects. Similarity judgments are closely connected to decision making and similarities between the familiarity of an object in a question sentence and that of an object in alternatives may become an important cue for making decisions. In fact, a recent study (Hiatt \& Trafton, in press) has shown that familiarity can be one of the most important cues in similarity judgments.

Based on these considerations, we propose a new heuristic termed as familiarity-matching: If an object in a question sentence is familiar (or unfamiliar) for a decision maker, then $s /$ he will choose the more (or less) familiar object from the two alternatives in a binary choice task. The goal of this study was to examine if cognitive processes in binary choice can be explained in terms of familiaritymatching and to investigate its ecological rationality. In the following sections, we shall report on three studies. In Study 1, we conducted a behavioral experiment and examined if familiarity-matching could adequately explain inference processes. In Study 2, we examined the ecological rationality of familiarity-matching. Finally, in Study 3, we analyzed the real-world environment in terms of familiarity.

## Study 1: Examination of inference processes

The purpose of Study 1 was to investigate if individuals tend to rely on familiarity-matching in a binary choice task.

## Method

Participants Japanese under graduate students $(N=31)$ participated in this study.
Tasks, materials, and procedure We conducted the binary choice task and the measurement of familiarity.

In the binary choice task, participants answered 100 binary choice questions. All question sentences had the following format: "X is a city in, country A1 or A2?" (e.g., "Sikasso is a city in, Mali or Switzerland?"). The order of the 100 questions was randomized (see Appendix for the procedure to generate the questions). For each question, participants were also asked to rate the difficulty level in answering the question using a visual analog scale (VAS). The scale consisted of a horizontal line labeled "very easy" on the left end and "very difficult" on the right end. Participants' responses were recorded over a range of 101points (i.e., from $0=$ "very easy" to $100=$ "very difficult").

In the measurement of familiarity, participants were asked to indicate how familiar they were with each object presented in the binary choice task (i.e., 20 countries and 100 cities) using a VAS. Participants' responses were recorded over a range of 101 -points (i.e., from $0=$ "do not know at all" on the left end of the scale to $100=$ "know much" on the right end of the scale).

We conducted the above two tasks using a questionnaire. Participants completed the binary choice task followed by the measurement of familiarity.

## Results

Hereafter, the familiarity ratings for the object in the question sentence and for the two objects presented as
alternatives are expressed as "Fam(Q)," "Fam(A1)," and "Fam(A2)," respectively. In the following analyses, we excluded the questions in which $\operatorname{Fam}(\mathrm{A} 1)$ was identical to Fam(A2).
Can familiarity-matching predict inference patterns? First, we analyzed the accordance rate of observed inferences with familiarity-matching for each participant. For example, when $\operatorname{Fam}(Q)=45, \operatorname{Fam}(A 1)=30$, and $\operatorname{Fam}(\mathrm{A} 2)=80$, familiarity-matching predicts that the participant would choose A1. Figure 1 shows the accordance rate for each participant. In 29 out of the 31 participants, accordance rates were above chance level. The mean accordance rate was .88 . These results indicate that the observed choices were predicted accurately by familiarity-matching.

Figure 1: Accordance rate of observed inferences with familiarity-matching (individual data). The red line denotes chance level (.50) and the dotted line shows the mean accordance rate (.88).

Does the difficulty of a problem affect the use of familiarity-matching? Previous studies have shown that individuals do not always use heuristics but tend to rely on them for solving a difficult problem (e.g., Kahneman \& Frederick, 2005; Honda et al., in press). Therefore, we examined if experiencing difficulty in a problem affected the use of familiarity-matching. We defined a dichotomized difficulty rating, high or low difficulty, based on the difficulty ratings being above or below the median for each participant. Hereafter, a problem assigned a rating above the median is expressed as "difficult problem" and a problem assigned a rating below the median as "easy problem". We examined the use of familiarity-matching for both types of problems.

Some researchers have debated that accordance rates are not always a good indicator for examining if individuals "truly" use heuristics (e.g., Hilbig \& Richter, 2011). Thus, we used Discrimination Index (DI) (Hilbig \& Pohl, 2008) as
an indicator of the blind usage of familiarity-matching by the participants. DI was calculated using the following equation:

$$
\text { DI }=(\text { Hit })-(\text { False Alarm })
$$

where (Hit) and (False Alarm) denote the proportion in which the accordance of a heuristic results in a correct or false inference, respectively. Since DI is defined as the difference between (Hit) and (False Alarm), DI ranges from -1 to +1 . It is assumed that when a decision maker always follows a heuristic (i.e., s/he blindly uses a heuristic), DI should reach zero, as s/he uses the heuristic irrespective of its correctness, suggesting that $\mathrm{s} /$ he does not take advantage of specific knowledge relevant to the inference problem.

For each participant, we calculated DI for the two problem types. Figure 2 shows the distributions of DI for the two cases. We found that DI for the difficult problem was generally lower than DI for the easy problem. We also found that the mean DI for the difficult problem was not significantly deviated from zero (Mean $=.07, t(30)=1.23, p$ $=.23$, Median $=.06$ ), while the mean DI for the easy problem was significantly deviated from zero (Mean $=.41$, $t(30)=6.47, p<.001$, Median $=.39$ ). These results implied that individuals used memory-based simple heuristics when they experienced difficulty in solving inference problems, which was consistent with the previous finding in Honda et al. (in press).

Figure 2: DI (Discrimination Index) for the difficult problem (left) and for the easy problem (right).

## Discussion

In this behavioral experiment, the accordance rate of the prediction by familiarity-matching was sufficiently high (mean accordance rate $=.88$ ), showing that familiaritymatching predicted inference patterns effectively. Furthermore, our findings implied that participants used familiarity-matching when they experienced difficulty in problems. These results suggest that individuals take
advantage of the familiarity of objects in both question sentences and alternatives as a cue when making inferences.

In the behavioral experiment, the materials used were selected by experimenters to serve as stimuli for the binary choice task. Therefore, the question of using familiaritymatching in a binary choice task as a valid inference strategy remains open for evaluation. Thus, we examined the ecological rationality of familiarity-matching.

## Study 2: Analysis of ecological rationality

The purpose of Study 2 was to examine if familiaritymatching could serve as an ecologically rational strategy. In this study, we measured individuals' familiarity of objects and then examined whether familiarity-matching was generally a valid inference strategy in a binary choice task.

## Method

Participants Japanese under graduate students $(N=39)$ participated in the task. None of them had participated in Study 1.
Materials, tasks, and procedure We used the 50 countries with the highest population in the world and their 50 capitals as materials. We investigated the participants' familiarity with each of the 100 objects (i.e., 50 cities and 50 countries). We conducted the measurement of familiarity which was similar to the method used in Study 1.
Analysis of the validity of familiarity-matching Familiarity ratings in Study 2 were converted into z-scores for each participant and the following analyses were conducted.

We analyzed the validity of familiarity-matching in the binary choice task using the familiarity ratings for the 50 countries and their capitals collected from participants. Specifically, we calculated the accuracy rate (i.e., validity) of familiarity-matching using the following procedure:

1. A hypothetical binary choice task such as " X is a city in, A1 or A2?" was conducted and each problem "was inferred" based on $\operatorname{Fam}(\mathrm{Q})$, $\operatorname{Fam}(\mathrm{A} 1)$ and $\operatorname{Fam}(\mathrm{A} 2)$.
2. For each question, if the absolute difference between $\operatorname{Fam}(\mathrm{Q})$ and $\operatorname{Fam}(\mathrm{A} 1)$ was less than that between $\operatorname{Fam}(\mathrm{Q})$ and $\operatorname{Fam}(\mathrm{A} 2)$, then A1 was selected, and vice versa (i.e., in the same manner as the prediction by familiarity-matching in Study 1).
3. We applied the above two steps to all possible combinations ( 50 cities * 49 alternative pairs) using the familiarity ratings provided by each participant, and then calculated his/her accuracy rate.

## Results and discussion

Figure 3 shows participant accuracy rates calculated as described above $(N=39)$. The horizontal and vertical axes shows the participants (individual data) and the accuracy rate, respectively, while the red line in the graph indicates chance level (.50). Participant accuracy rates (Mean = .67) exceeded the chance level for all participants. Therefore, it is suggested that participants can accurately "make correct
inferences" by matching more familiar objects in the binary choice task, even in the real-world environment.

Figure 3: Accuracy rate of familiarity-matching by individual familiarity ratings. The red line denotes chance level (.50) and the dotted line shows the mean accuracy rate (.67).

## Study 3: Analysis of the real world

According to previous studies (e.g., Goldstein \& Gigerenzer, 2002; Honda et al., in press), if a city or country appears more frequently in the real-world environment (e.g., mentioned in media), then individuals will be more familiar with it because they are more likely to see or hear the name. Therefore, it can be estimated that familiarity-matching can be applied effectively in the binary choice task when the frequency of appearance of the name of a city is correlated with that of the name of a country in the real-world environment.

In this section, we investigated this issue using the following procedure. As an index of the frequency of appearance in the real-world environment, we used the logtransformation of the mean number of hits for each object in two online databases of Japanese newspapers ${ }^{1}$. When we searched for objects in both databases, we traced back from the oldest to latest date as possible (see footnote) on national news. We converted the log-transformed index into z-scores, which were used in this analysis.

First, we calculated the correlation coefficient between the number of hits for the 50 cities and that for the 50 countries using z-scores. This correlation coefficient was 86 ( $p<.001 ; 95 \% C I: .77 \sim .92$; Figure 4). Therefore, it was found that the frequency of appearance of a city name in the media was highly correlated with that of the country name that corresponded to the city.

[^489]

Figure 4: Correlation between the number of hits for cities and that for countries (log-transformed $z$-scores).

Although the correlation between participants' familiarity with an object and the number of appearances in the media has already been reported in previous studies (e.g., Goldstein \& Gigerenzer, 2002; Schooler \& Hertwig, 2005), we confirmed that we could replicate such a correlation in the present study. Subsequently, using $z$-scores, we calculated the correlation coefficient between participants' familiarity with each object (z-scores of the mean familiarity ratings for 39 participants in Study 2) and the number of hits for each object. This correlation coefficient was .88 ( $p<.001$; 95\% CI: . $84 \sim .92$; Figure 5). Therefore, it was found that the more often an object appeared in the media, the more familiar with the object individuals were, which was consistent with previous studies.

Figure 5: Correlation between familiarity of objects (zscores) and the number of hits for these objects (logtransformed z-scores).

The combined results of Study 2 and Study 3 suggest that familiarity-matching can be valid even in the real-world environment, as the frequency of appearance of a city name in the media is highly correlated with that of the corresponding country name, and individuals' familiarity with an object is also highly correlated with its frequency of appearance in the media. In other words, since a more frequently appearing object in the environment is likely to
be more familiar for individuals, inferences based on similarity of familiarity can be valid in a binary choice task. Therefore, familiarity-matching can be applied as an ecologically rational strategy.

## General discussion

In the present study, we proposed a new heuristic, familiarity-matching, which predicts that if an object presented in a question sentence is familiar for a decision maker, then s/he is likely to choose the more familiar object presented as alternatives in a binary choice task. The results of Study 1 showed that familiarity-matching could predict individuals' inference patterns effectively. In particular, the results implied that individuals used familiarity-matching when they experienced difficulty in inference problems. In addition, the results of Study 2 and Study 3 showed that familiarity-matching could be an ecologically valid strategy in the binary choice task, because of the high correlations between the frequency of appearance of a city name and that of a country name, and between the frequency of appearance of an object and individuals' familiarity with it.

So far, only the use of "familiarity" in making inferences has been primarily examined. Generally, in a binary choice task, "familiarity" of an object can be an informative cue (e.g., Honda et al., 2011, in press). In a binary choice task, "unfamiliarity," contrary to "familiarity," is often considered uninformative in making inferences. The present findings, however, indicate that individuals can also use "unfamiliarity" as an informative inference cue. Familiaritymatching can be applied for both, a familiar object and an unfamiliar object, in a question sentence. According to familiarity-matching, when presented with an unfamiliar object, a decision maker will infer the following: "The correct answer will also be the unfamiliar object." In this situation, the "unfamiliarity" can become an informative cue. Perhaps, in cases where a decision maker uses "unfamiliarity" as an inference cue, the cognitive processes may differ from those involved in a situation where $s / h e$ uses "familiarity" as an inference cue. The present study did not examine this issue, which, therefore, should be investigated in the future.

However, familiarity-matching still has some limitations in the practical aspect. The definition of the familiaritymatching is limited to a binary choice task. We think that familiarity-matching can be applied to a multiple-choice task, because a decision maker has only to "match" familiarity of an object in a question sentence with that of an object in alternatives, no matter how many alternatives the task contains. However, it is not clear how familiaritymatching can be extended to other more complex tasks, so we may also need to investigate this issue.

To the best of our knowledge, the present study was the first study to examine the effect of familiarity of objects in a question sentence. We believe that focusing on the relationship between objects presented as both, a main theme ("question sentence," in this study) and a supplement
("alternatives," in this study), has revealed a new perspective on human inferences.

## Appendix. Binary choice task

The binary choice task (Study 1) was generated by following the four steps listed as under:

1. For "objects presented as alternatives," we selected 20 countries (more than 2 countries from 5 regions: Asia, Europe, Africa, North America, and South America) and randomly assigned these 20 countries to 2 groups: "Alternative A1" and "Alternative A2" (each group consisted of different 10 countries).

| Alternative A1 | Alternative A2 |
| :--- | :--- |
| America | Canada |
| Sweden | Bolivia |
| Mexico | Italia |
| Columbia | Ukraine |
| Holland | Switzerland |
| Egypt | Iran |
| Turkey | Spain |
| Saudi Arabia | Kazakhstan |
| Australia | New Zealand |
| Mali | Morocco |

2. Using the groups, "Alternative A1" and "Alternative A2" described above, we created $10 * 10=100$ pairs as alternatives for the binary choice task.

|  | Alternative A1 | Alternative A2 |
| :--- | :--- | :---: |
| 1 | Holland | Iran |
| 2 | Australia | Bolivia |
| 3 | Columbia | Kazakhstan |
| 4 | Saudi Arabia | Morocco |
| $\ldots$ |  |  |
| 98 | Turkey | New Zealand |
| 99 | Mexico | Switzerland |
| 100 | America | Ukraine |

3. From each country ("objects presented as alternatives"), we selected 5 cities (total of $20 * 5=$ 100 cities) using the following criteria:
(I) Out of the 5 cities, we selected the 2 cities with the largest population size in the country.
(II) For the remaining 3 cities, we selected cities which satisfied following one (or more) of the following criteria: "is the high population size", "its
name is included in that of a historical treaty, conference, or a similar historical event," "has a world heritage site," or "has hosted the Olympic or the Paralympic Games."

| Cities | Countries |  |  |
| :--- | :--- | :---: | :---: |
| New York | America |  |  |
| Washington D.C. | America |  |  |
| Portsmouth | America |  |  |
| San Francisco | America |  |  |
| Bretton Woods | America |  |  |
| Rapallo | Italia |  |  |
| Trent | Italia |  |  |
| Roma | Italia |  |  |
| Milano | Italia |  |  |
| Genova | Italia |  |  |
| Teheran | Iran |  |  |
|  |  |  | Mali |
| Sikasso | Mexico |  |  |
| Puebla | Mexico |  |  |
| Tlatelolco | Mexico |  |  |
| Guadalajara | Mexico |  |  |
| Monterrey | Mexico |  |  |
| Villahermosa | Morocco |  |  |
| Rabat | Morocco |  |  |
| Marrakesh | Morocco |  |  |
| Tangier | Morocco |  |  |
| Fes | Morocco |  |  |
| Casablanca |  |  |  |

Note: We provided criterion (II) for two reasons: First, if all alternatives consisted of top cities in terms of population, participants might be more likely to know the answer (i.e., to use knowledge-based inference cues instead of heuristics), as it seemed that larger cities were comparatively more famous. Second, we wanted to create objects presented as question sentences (i.e., cities) that would be the only familiar element for participants (i.e., when participants are only familiar with a city, they often do not know the country it belongs to). However, even if a city satisfied criterion (I) or (II), we excluded cities whose names included the name of the country (e.g., Mexico City) or were located in several countries (e.g., Melbourne is located not only in Australia but also in America).
4. In order to make one of the two alternatives (from step 2) a correct answer, we placed a city (from step 3 ) in " $X$ " in each question sentence (" $X$ is a city in,").

|  | Alternative A1 | Alternative <br> A2 |
| :--- | :--- | :--- |
| 1. Ramsar is a city in, | Holland | Iran |
| 2. La Paz is a city in, | Australia | Bolivia |
| 3. Bogota is a city in, | Columbia | Kazakhstan |
| 4. Rabat is a city in, | Saudi Arabia | Morocco |
|  |  |  |
| 98. Ankara is a city in, |  |  |
| 99. Villahermosa is a city in, | Mexico | New Zealand |
| 100. Bretton Woods is a city in, | America | Uwitzerland |

Note: Sentences in the actual questionnaire were written in Japanese.

# Bridging a Conceptual Divide: How Peer Collaboration Facilitates Science Learning 

Andrew Shtulman (shtulman@oxy.edu)<br>Andrew Young (ayoung2@oxy.edu)<br>Department of Psychology, Occidental College<br>1600 Campus Road, Los Angeles, CA 90041

#### Abstract

Collaboration is generally an effective means of learning new information, but is collaboration productive in domains where collaborators may hold qualitatively different conceptions of the domain's causal structure? We explored this question in the domain of evolutionary biology, where previous research has shown that most individuals construe evolution as the uniform transformation of an entire population (akin to metamorphosis) rather than the selective survival and reproduction of a subset of the population. College undergraduates $(n=44)$ completed an assessment of their evolutionary reasoning by themselves (pretest), with a partner (dyad test), and several weeks later (posttest). Collaboration proved ineffective for the higherscoring partner in each dyad, as their scores generally remained unchanged from pretest to dyad test to posttest, but it proved effective for the lower-scoring partner. Not only did lowerscoring partners increase their score from pretest to dyad test, but they maintained higher scores at posttest as well. Followup analyses revealed that participants' posttest scores were predicted by their partners' pretest scores but only for lowerscoring partners, and the relation was negative: the smaller the difference between pretest score, the greater the gain from pretest to posttest for lower-scoring partners. These findings indicate that collaboration in domains characterized by conceptual change is possible, but that learning from such collaboration is asymmetric (i.e., individuals with low levels of understanding benefit more than their partners do) and unequal (i.e., individuals with low levels of understanding benefit more if their partner's understanding is only moderately higher). Thus, bridging the gap between a novice's view of a conceptually complex domain and an expert's view appears to require instruction more aligned with the former than the latter.

Keywords: collaboration, conceptual development, science learning, intuitive theories, evolutionary reasoning

## Introduction

Some ideas are more difficult to learn than others. Ideas that can be encoded in terms of preexisting concepts, like the name of an unfamiliar animal or the function of an unfamiliar artifact, are much easier to learn than ideas that require new concepts for their encoding, like the reason the seasons change or the reason projectiles fall to the ground in a parabolic path. Learning the latter requires conceptual change, or knowledge restructuring at the level of individual concepts (Carey, 2009; Chi, 1992). Conceptual change is an intrinsic part of science learning. Most domains of science entail entities, properties, and mechanisms that defy our intuitive knowledge of how the world works and can only be represented if that knowledge is reorganized and restructured (Nersessian, 1998; Vosniadou, 1994).

Conceptual change is empirically distinguishable from other forms of knowledge acquisition in that it results in systematic failures of teaching and learning. In domains
requiring conceptual change, individuals who have yet to undergo that change exhibit misconceptions about the domain's content that are internally coherent and developmentally widespread. These misconceptions are robust in the face of counterevidence or counterinstruction, and they create impasses in communication between those who have achieved conceptual change and those who have not (for reviews, see Carey, 2009; Shtulman, 2017).

Consider the domain of evolutionary biology-the domain of choice in the present study. Evolution results from differential survival and differential reproduction within a population; the traits possessed by the most reproductively successful individuals spread through the population over time. Most people, however, view evolution as the uniform transformation of an entire population, where every organism is guaranteed to have offspring more adapted to the environment than it was at birth (Bishop \& Anderson, 1990; Shtulman, 2006). This view is grounded in the commonsense assumption that all members of a species share the same inner nature, or essence, which determines their outward appearance and behavior (Gelman, 2003; Shtulman \& Schulz, 2008). Evolution is thus seen as a kind of crossgenerational metamorphosis; selection plays no role in the process. This essentialist view of evolution has been documented in people of varying ages (Berti, Toneatti, \& Rosati, 2010; Shtulman, Neal, \& Lindquist, 2016) and educational backgrounds (Coley \& Tanner, 2015; Gregory \& Ellis, 2009), and it characterizes how a person reasons about several aspects of evolution, including variation, inheritance, adaptation, domestication, speciation, and extinction (Shtulman \& Calabi, 2013).

The focus of the current study is a particular hallmark of conceptual change: impasses in communication between those who have achieved conceptual change and those who have not. Such impasses have been observed in conversations between children and adults (e.g., Carey, 1985), in conversations between science students and science teachers (e.g., Wiser \& Amin, 2001), and in conversations between scientists working within different theoretical paradigms (e.g., Kuhn, 1977). Such impasses are often encountered in the context of learning-e.g., a child learning about the properties of living things from a parent or a student learning about the properties of thermal systems from a teacher-but it is unclear how they affect learning. Achieving conceptual change requires overcoming the conceptual gap responsible for the impasse, but how and with whom?

Conceptual impasses in communication are particularly important to study in light of the finding that learning is often facilitated through collaboration. For many types of inductive problems, individuals who collaborate on those problems are
more likely to solve them-and learn from them-than individuals who work alone (Gauvain \& Rogoff, 1989; Laughlin, Vanderstoep, \& Hollingshead, 1991; Leman, Skipper, Watling, \& Rutland, 2016). Collaboration is effective for several reasons. It opens partners' eyes to ideas they would not have generated on their own, highlighting alternative approaches to the same problem (Schwarz, Neuman, \& Biezuner, 2000; Young, Alibali, \& Kalish, 2012) or alternative explanations for the same phenomenon (Ames \& Murray, 1982; Howe, 2009). It forces collaborating partners to articulate their reasons for endorsing a particular hypothesis or favoring a particular solution strategy and defend those reasons with evidence (Okada \& Simon, 1997; Teasley, 1995). And it introduces social incentives for completing the task at hand, increasing partners' motivation to persist in the face of unexpected obstacles (Butler \& Walton, 2013).

Given the pedagogical benefits of collaboration, we sought to determine whether collaboration is useful-or even possible-in domains requiring conceptual change. The answer to this question has both practical and theoretical implications. From a practical point of view, educators who instruct students on topics requiring conceptual change (e.g., evolution, microbiology, mechanics, thermodynamics, fractions) would benefit from knowing whether collaboration is an effective instructional strategy or a dead end. From a theoretical point of view, models of conceptual change would be further informed by research clarifying which kinds of input foster conceptual change and which do not. Parent-child conversation, for instance, is a form of collaboration that may help foster conceptual change (Gunderson \& Levine, 2011; Jipson \& Callanan, 2003), but it is unclear how beneficial this activity is relative to other domain-specific activities (e.g., refutation-based instruction, inquiry-based instruction, informal exploration).

Previous studies have found that collaboration in conceptually complex domains can be successful. For instance, Asterhan and Schwarz (2007) found that undergraduates who collaborated on devising evolutionary explanations for two instances of biological adaptation (mosquitos developing resistance to an insecticide, cheetahs acquiring the ability to run faster than any other mammal) provided more sophisticated (selection-based) explanations for biological adaptation from pre-collaboration to postcollaboration. Likewise, Loyens, Jones, Mikkers, and van Gog (2015) found that undergraduates who collaborated on determining the paths traced by three projectiles (a child jumping from a swing, an object falling on someone's head, a coyote falling from a cliff) drew more accurate motion paths from pre-collaboration to post-collaboration. In both the domain of evolution and the domain of motion, learning a correct, scientific view of the domain is difficult to achieve; direct (lecture-based) instruction on these topics has typically proven unsuccessful (see Shtulman, 2017, for a review).

These studies demonstrate that collaboration can facilitate learning in domains characterized by conceptual change, but they are limited in that they explored only one aspect of those
domains-explanations for adaptation in the study by Asterhan and Schwarz (2007) and trajectories of projectile motion in the study by Loyens et al. (2015). The present study explored whether collaboration is effective for learning several facets of a conceptually complex domain-namely, the phenomena of variation, inheritance, adaptation, domestication, speciation, and extinction within the domain of evolutionary biology. We chose this domain because its content is notoriously difficult to understand and because individuals who are asked to reason about domain-relevant problems would most likely hold different levels of understanding. Collaboration under these circumstances thus provides a stringent test of whether, and how, collaboration can facilitate conceptual change.

## Method

## Participants

The participants were 44 college undergraduates, recruited from introductory psychology and cognitive science courses and compensated either with extra credit in those courses or with a small stipend. They were taken from a larger dataset of 174 participants, assigned to one of 87 dyads. All participants in the larger dataset were invited to complete a posttest (for a $\$ 12$ Amazon gift card) but only 44 did. Those 44 came from 36 different dyads. Approximately half were the higher-scoring partner in their dyad $(n=25)$ and half were the lower-scoring partner $(n=19)$. In other words, approximately half collaborated with a partner who demonstrated a higher level of understanding prior to the collaboration, and half collaborated with a partner who demonstrated a lower level of understanding.

The 44 participants who completed a posttest earned similar pretest scores to those who did not complete a posttest. That is, the 19 low scorers who completed a posttest scored similarly to the 68 who did not ( $M=9.4$ vs. $M=9.7$, $t(85)=0.22, p=0.83$ ), and the 25 high scorers who completed a posttest scored similarly to the 62 who did not ( $M=17.1$ vs. $M=15.9, t(85)=1.13, p=0.26$ ). While there may be motivational differences between those who opted to complete a posttest and those who did not, there were no reliable knowledge differences between the groups (relative to participants' classification as a low scorer or a high scorer).

## Materials

Participants were assessed on their understanding of evolution using an instrument developed by Shtulman (2006). The assessment consisted of six sections, each devoted to a different biological phenomenon (inheritance, variation, adaptation, domestication, speciation, and extinction). Participants' understanding of the phenomenon was assessed with five questions or tasks designed to elicit either an essentialist interpretation or a selection-based interpretation.

With respect to inheritance, for instance, participants were asked to make predictions about parent-offspring resemblance with questions like the following: "Imagine that
biologists discover a new species of woodpecker that lives in isolation on a secluded island. These woodpeckers have, on average, a one-inch beak and their only food source is a treedwelling insect that lives, on average, one-and-a-half inches under the tree bark. Compared to its parents, the offspring of any two woodpeckers should develop: (a) a longer beak, (b) a shorter beak, or (c) either a longer beak or a shorter beak; neither is more likely." The correct response is (c), because offspring vary randomly from their parents, but most people select (a), reasoning that offspring will inherit whatever traits will help them survive-traits conferred by an underlying essence that adaptively changes in response to the species' current needs.

As another illustration, consider this task designed to probe participants' understanding of within-species variation: "During the 19th century, England's native moth species, Biston betularia, evolved darker coloration in response to the pollution produced by the Industrial Revolution. Imagine that biologists gathered a random sample of Biston betularia once every 25 years from 1800 to 1900 . What range of coloration would you expect to find at each point in time?" Participants were given a five-by-five matrix of moth outlines and instructed to shade the moths to reflect what the moths might look like at $1800,1825,1850,1875$, and 1900. The two most common response patterns are depicted in Figure 1. The pattern on the left depicts a mutation for darker coloration spreading through the population over time and is consistent with a selection-based view of evolution. The pattern on the right depicts the uniform transformation of the population, such that variation occurs between generations but not within generations, and is consistent with an essentialist view.

Figure 1: A selection-based response pattern (left) and an essentialist response pattern (right) on the moth-shading task of the evolution comprehension assessment.

The full battery of questions can be found in the Appendix of Shtulman (2006), along with criteria for scoring each question or task. Participants were assigned 1 point for every correct. selection-based response and 0 points for every incorrect, essentialist response. Responses too vague to be counted as selection-based, were also assigned 0 points. Participants' scores thus ranged from 0 to 5 per section and from 0 to 30 for the assessment as a whole.

## Procedure

The evolution comprehension assessment was administered on a computer. It took between 30 and 45 minutes to complete, and participants completed it twice by themselves (pretest and posttest) and once with a partner (dyad test). Participants were tested in pairs in a room in the Psychology Department. They completed the pretest by themselves, and they completed the dyad test together immediately following the pretest. Participants typically did not know their dyad partner, and they were given no instruction on how to coordinate their responses. They were simply asked to complete the survey as a pair, on a single computer. Their conversations were recorded and transcribed at a later date. (Data from the conversations are not reported here, for lack of space).

The posttest was administered one semester (i.e., half a year) after the dyad test. The average delay between dyad test and posttest was 7.6 months, and the delay for the high scorers was equivalent to the delay for the low scorers ( $M=$ 6.8 vs. $M=8.8, t(42)=1.13, p=.138$ ). Effects of collaboration detectable after half a year arguably represent long-term changes in understanding, as participants' memory for the episodic details of the collaboration session would likely have faded.

## Results

For the analyses below, we used linear mixed models (LMMs) with random-effects structures specified according to the procedure recommended by Bates and colleagues (Bates et al., 2015). We used likelihood ratio-test (LRT) comparisons and 95\% confidence intervals (CI) for inference.

## Evolution Scores at Pretest, Dyad Test, and Posttest

Overall assessment scores at pretest, dyad test, and posttest are shown in Figure 2 (left panel). Dyads generated higher scores than individuals at pretest, $\beta=2.16,95 \% \mathrm{CI}[.27$, 4.05]. However, individuals' posttest scores were similar to their pretest scores, $\beta=.91,95 \%$ CI $[-.98,2.80]$.

## Low- versus High-Scoring Partners

An individual's ability to profit from collaboration likely depends on both their own prior knowledge and their partner's prior knowledge. For example, individuals paired with partners that demonstrated greater conceptual knowledge of evolution at pretest might have a greater opportunity to learn from collaboration than those paired with partners with less conceptual knowledge. To explore this possibility, we categorized participants in terms of whether they were the lower or higher scoring partner in their respective dyads at pretest. Figure 2 shows pretest, dyad test, and posttest scores for lower-scoring partners (middle panel) and higher-scoring partners (right panel). There was an interaction between scoring status and test, LRT $\chi^{2}(2)=$ $20.13, p<.001$. For high-scoring partners, pretest, dyad test, and posttest scores were similar. However, for low-scoring partners, dyad tests were greater than pretests, $\beta=6.53,95 \%$

Figure 2. Mean evolution score at pretest, dyad test, and posttest for all participants, low scoring participants, and high scoring participants. Error bars represent $\pm$ SE.

CI [3.92, 9.13], and posttests were greater than pretests, $\beta=$ $3.37,95 \%$ CI [1.87, 7.08].

## Low- versus High-Scoring Partners by Section

Only 5 of the 44 participants demonstrated consistently greater or poorer pretest performance than their partner across all six sections of the assessment. Categorizing participants as low- or high-scoring by section potentially provides a more nuanced view of performance than overall pretest scores. Figure 3 shows lower- and higher-scoring partners' pretest, dyad test, and posttest scores for each of the six sections. A three way interaction between scoring status, test, and section suggested variation in low and high scorers’ learning across section, LRT $\chi^{2}(10)=19.10, p=.0317$.

Scores for Inheritance and Speciation demonstrated little pretest to posttest change for both low and high scorers. Most consistent with the overall assessment, lower scorers demonstrated pretest to posttest gains for Domestication, $\beta=$ $1.50,95 \%$ CI $[.54,2.46]$, and Extinction, $\beta=.76,95 \%$ CI [$.02,1.55]$, whereas high scorers had similar pretest and posttest scores. Low scorers again demonstrated pretest to posttest gains for the Adaptation, $\beta=1.71,95 \%$ CI $[.84$, 2.57], and Variation, $\beta=1.43,95 \%$ CI [.47, 2.38]. However, high scorers surprisingly demonstrated pretest to posttest losses for Adaptation, $\beta=-1.50$, $95 \%$ CI $[-2.26,-.74]$, and Variation, $\beta=-1.21,95 \%$ CI [-2.03, -.39$]$.

## Predicting Posttest Scores

For low scorers, collaborating with a more advanced partner yielded pretest to posttest improvement in 4 out of 6 sections. For high scorers, collaborating with a less advanced partner yielded pretest to posttest decline in 2 out of 6 sections. These results suggest that participants' posttest performance was influenced both by their own understanding of the domain and by their partner's understanding.

To explore this possibility further, we fit an LMM on posttest scores (by section) with participant pretest scores, partner pretest scores, scoring status (high vs. low within a participant's respective dyad), and their interactions as fixed effects. Participant pretest score was a positive predictor of posttest score, $\beta=.38,95 \% \mathrm{CI}[.08, .67]$, and did not interact
with scoring status. In contrast, partner pretest score interacted with scoring status, LRT $\chi^{2}(1)=3.86, p=.049$. Partner pretest scores were not predictive of posttest scores for high scorers, $\beta=.08,95 \% \mathrm{CI}[-.15, .31]$. However, partner pretest scores were negatively related to posttest scores for low scorers, $\beta=-.22,95 \%$ CI $[-.43, .00]$. Thus, it appears that low scorers learned more from partners with slightly greater knowledge than themselves at pretest compared to partners with much greater knowledge.

## Discussion

Collaboration is an effective and efficient means of devising new hypotheses (Okada \& Simon, 1997) and learning new problem-solving strategies (Schwarz et al., 2000), but is collaboration possible in domains where individuals are known to hold vastly discrepant views of the domain's causal structure? The answer appears to be yes. Individuals who collaborated on tasks within the domain of evolutionary biology-a domain characterized by qualitatively different theories of what evolution is and how evolution works (Shtulman, 2006)-demonstrated a higher level of understanding together than they did individually. This finding was far from guaranteed given the content of the task. When partners disagreed, their disagreements typically reflected fundamental differences in their understanding of the task domain. Resolving those disagreements entailed more than just recognizing who knew the answer. It entailed recognizing which of two answers-a selection-based answer and an essentialist answer-was more plausible or justifiable.

Collaboration not only facilitated more accurate responding, it also facilitated learning, though the effects were nuanced. Individuals who entered the collaboration with lower levels of understanding demonstrated increased understanding at posttest (several months later), whereas individuals who entered the collaboration with higher levels of understanding demonstrated no gains at posttest.

The learning exhibited by less-knowledgeable partners was generally robust across different sections of the assessment, as was the stasis exhibited by more-knowledgeable partners. That said, there were some sections on which the lessknowledgeable partners exhibited no gains from pretest to

Figure 3. Mean pretest, dyad test, and posttest scores for low scoring and high scoring partners by section. Error bars represent $\pm$ SE.
posttest and some sections on which the more-knowledgeable partners exhibited losses from pretest to posttest. Collaboration in conceptually complex domains may thus hinder learning for some individuals in some contexts. Still, the net benefits of collaboration were positive, which is a surprising finding given that (a) collaborators often had to communicate across a conceptual divide and (b) the collaboration itself consisted solely of discussion. There were no opportunities to generate evidence or test hypotheses, which suggests that such activities may not be necessary for learning in cases where the primary intellectual challenge is just interpreting what one's partner is saying.

Perhaps the most provocative finding was that, among participants who learned from collaboration (the low scorers), those who learned the most collaborated with partners who had moderately higher levels of understanding. Individuals who collaborated with partners with substantially higher levels of understanding benefited less, at least by posttest. This finding, though tentative, may have resulted from differential impasses in communication; the greater the discrepancy between partners' understanding of the domain, the more likely they encountered impasses in communication and the more strained their collaboration may have become. Consider, for instance, the following conversation between a participant who earned a pretest score of 19 (P1) and one who earned a pretest score of 2 (P2) about the woodpecker question presented above:

P1: Alright, for the first one I put either a shorter or longer beak because it says compared to its parents, and compared to its parents it pretty much has the same beak because it has the same genes.
P2: Okay. Hmm. I put longer beak ... because, yeah, they have to eventually evolve into the thing, but I can see what you are saying about, like, it wouldn't take one generation.

P1: Well ... the next generation would end up with a longer beak, but this one particular woodpecker would have the same [beak] as its parents, if you understand what I'm saying. The generations would get longer beaks because the ones with the shorter beaks will be killed off. [But] no matter what, the offspring are gonna have beaks pretty much the same as its parents.
P2: Okay, I see what you're saying. Yeah, I guess I just assumed that they would interbreed or they would have a woodpecker from a different... Okay, I see what you're saying.

P2 claims to understand what P1 is saying, but P2's attempts to resolve the discrepancy - by acknowledging P2's answer as correct on the assumption that "it wouldn't take one generation" or that birds with different beak lengths did not "interbreed"-do not actually address P2's point that evolutionary change occurs at the population level, not the individual level. This type of impasse may be more common in conversations between partners with discrepant levels of understanding than in conversations between partners with similar levels of understanding, though confirmation of this pattern awaits further analysis of the conversational data.

The finding that participants benefited most from collaborating with individuals who were only moderately more knowledgeable about the domain helps answer the question of how individuals are able to communicate across a gap in conceptual understanding. Communication may be possible only if the gap is not too wide; wider gaps may lead to irreconcilable differences in how partners perceive or analyze the problems at hand. We plan to test this idea directly by analyzing the dynamics of participants' conversations in relation to their score differences from pretest to dyad test and from pretest to posttest. Previous research on how domain experts converse with domain novices suggests that the experts supply novices with
specialized knowledge, in the moment, by adjusting how they label or how they describe objects of shared attention (Clark \& Schaefer, 1989; Isaacs \& Clark, 1987). However, such studies have involved domains in which the difference between a novice's knowledge and an expert's knowledge is quantitative rather than qualitative (e.g., knowledge of New York City landmarks). It remains an open question how domain novices and domain experts are able to bridge differences in knowledge, through discourse patterns, when that knowledge entails conceptual change.

# A Data Driven Approach for Making Analogies 

Mei Si (sim@rpi.edu)<br>Department of Cognitive Science, Rensselaer Polytechnic Institute Troy, NY 12180 USA<br>Craig Carlson (carlsc2@rpi.edu)<br>Department of Computer Science, Rensselaer Polytechnic Institute<br>Troy, NY 12180 USA

#### Abstract

Making analogies is an important way for people to explain and understand new concepts. Though making analogies is natural for human beings, it is not a trivial task for a dialogue agent. Making analogies requires the agent to establish a correspondence between concepts in two different domains. In this work, we explore a data-driven approach for making analogies automatically. Our proposed approach works with data represented as a flat graphical structure, which can either be designed manually or extracted from Internet data. For a given concept from the base domain, our analogy agent can automatically suggest a corresponding concept from the target domain, and a set of mappings between the relationships each concept has as supporting evidence. We demonstrate the working of this algorithm by both reproducing a classical example of analogy inference and making analogies in new domains generated from DBPedia data.

Keywords: creativity; analogy; intelligent agents

## Introduction

This work proposes a data-driven approach for dialogue agents to make analogies between concepts. Analogies describe the comparative relationships between two sets of concepts, i.e. concepts A and B are related in a similar way to how concepts C and D are related. Analogies are widely used in writings and dialogues for explaining new concepts or for making the narration more vivid and more interesting. Typically, one set of concepts is more familiar to the audience than the other. Analogies can, therefore, help the audience understand concepts in unfamiliar domains.

Though making analogies is natural for human beings, it is not a trivial task for dialogue agents. There are at least two challenges associated with this task. One is how to find out and represent what people know about a domain. The other is the computational complexity of establishing mappings between two domains. Both challenges become more significant when the domains the agent tries to make analogies with are not defined explicitly. For example, it is much harder to represent what people know about music genres than linear algebra. There is both more uncertainty and more information in the first case. In addition, there may be multiple good mappings between the concepts in the two domains. For example, one's life can both be
mapped to a tree or a road depending on the purpose of making the analogy.

Many cognitive theories have been proposed for explaining how people form analogies (Keane, 2012; Kubose, Holyoak, \& Hummel, 2002; Larkey \& Love, 2003). Structure-Mapping Theory (SMT) is one of most influential theories for analogies and has been supported by a number of empirical studies using human subjects (Falkenhainer, Forbus, \& Gentner, 1989; Gentner, 1983; Gentner \& Smith, 2012). According to SMT, an analogical mapping is created by establishing a structural alignment of relationships between two sets of concepts (in two different domains). The closer the structural match is, the more optimal the inferred analogy will be.

One of the main challenges of implementing SMT is its computational complexity. Many researchers have pointed out that the computational time of establishing the mapping is intractable. Heuristics and alternative theories have been developed to form analogies and cut down the computational time. Holyoak and Thagard's Multiconstraint Theory reduces analogy inference to a constraint satisfaction problem (1989). (Forbus \& Oblinger, 1990; Grootswagers, 2013; van Rooij, 2008; Wareham, Evans, \& van Rooij, 2011) have all worked on creating heuristics for speeding up the structural mapping process.

Another challenge comes from applying SMT or other similar theories to dialogue agents. They typically require a hierarchical relationship structure in the data. For example, the analogy between the solar system and the Rutherford model is a classic example used in computational models of analogy. Figure 1 is taken from (Falkenhainer, Forbus, and Gentner, 1989) for illustrating the solar system domain. For representing this domain, SMT prefers to know not only the relationships between the concepts, e.g. the planet revolves around the sun, the sun's mass is greater than the planet's mass, and the sun attracts the planet but also the relationships among relationships, i.e. the latter two relationships are the cause for the first one. When designing virtual characters with automatically generated or crowd-sourced dialogue content, we often do not have such hierarchical information. The alternative is to design content solely by hand, which creates a huge authoring burden. This challenge is particularly significant when we study
analogy inference not only for understanding human cognition but also for procedurally generating dialogues for virtual characters.

Figure 1: Solar System

In this work, we experiment with loosening up the constraints on input data and using a flat graphical structure for representing the agent's knowledge, i.e. our proposed algorithm only needs to know the relationships between each pair of concepts. Instead of mapping the structures of the relationships, we seek to map the type of relationships from one domain to another. This algorithm is completely data driven; there is no manually designed mapping rule. Our algorithm generates comparable results with SMT when being applied to a classical analogy inference example. We also demonstrate applying the algorithm to larger domains that were automatically generated by crawling data from DBpedia (Bizer, Lehmann, Kobilarov, Auer, Becker, Cyganiak, \& Hellmann, 2009).

The results from the analogy-making module will be integrated into an automated narrative agent we developed for making presentations using data gathered through crowdsourcing or from the Internet (Si, Battad, \& Carlson, 2016). The success of this project will contribute greatly to creating interesting dialogues and computational creativity. The analogy-making module is self-contained, and the details of the presentation agent are skipped in this paper. In the next sections, we will first describe our input data's format and example domains. Then, we will present our analogy-making algorithm, and results generated by this algorithm, followed by discussions and future work.

## Example Domains and Knowledge Representation

We want to use a knowledge representation that is both compatible with structured data, such as the results from querying DBpedia, and is intuitive enough for nontechnical authors to manually design and edit the knowledge base. We use a XML format that encodes knowledge as a directed graph. Each concept is represented
as a node with a unique ID. The nodes are linked to each other by their relationships, and thus form a directed graph.

We will demonstrate the application of our algorithm using two examples. The first one makes analogies between the solar System and the Rutherford model. This example has been discussed extensively by Gentner et al. (see (Falkenhainer, Forbus, \& Gentner, 1989; Gentner, 1983) for more detailed descriptions of the example.) Figure 2 shows the solar system represented as a knowledge graph in our system. Because we don't use hierarchical relationships in our data representation, the higher-level relationships, such as "And" and "Cause" in Figure 1 are lost. However, the relationships between each pair of concepts, such as "Attracts" and "Revolve" are kept. We created a new relationship "More massive" for representing the sun's mass is greater than the planet. Our representation does not use attributes and functions. For attributes, we converted them into a relationship the concept has with another concept, e.g. the sun has a relationship with a concept called Yellow. Currently, we don't have a corresponding encoding for SMT's concept of function in our system.

Figure 2: Solar System without Hierarchical Relationship Structure

The first example only contains about a dozen concepts. For examining how well our algorithm scales up, we created a second set of example domains which are much larger. One domain is about music genres, and the other is about programming languages. In this work, we used Wikipedia data as the base of knowledge. The two domains are generated by crawling for information from DBpedia using a tool we developed in the lab. The tool uses one or more DBpedia entries as the starting points and iteratively expanding the graph by including neighbors of the entries that are already in the graph.

Each entry in DBpedia is converted to a node in our knowledge graph and represents a unique concept. The type of link between them in DBpedia becomes the relationship link in our data. These domains are significantly larger than the ones in the first example. The music genres domain contains 999 nodes and 6418 relationships. The programming language domain contains 2589 nodes and 9952 relationships. Figure 3 shows part of the data from the music domain.

Figure 3: Music Genre Data

## Proposed Approach

In this work, our main objective is to provide a dialogue agent or a game character a tool for conducting richer and more interesting dialogues, or for making explanations for a new concept to the user. We hope to help create dialogues that are creative and innovative. Therefore, different from most existing work on analogy inference, we do not necessarily need to find the best analogy we can make given the two domains. Instead, we want to be able to make analogies that are interesting and explainable. Furthermore, the computation needs to complete in a reasonable amount of time.

Our proposed algorithm follows the same philosophy as SMT in that we want to find mappings between concepts and relationships that are supported by mappings between other concepts and relationships. In other words, we want all of the mappings to be consistent with each other. Our algorithm seeks to achieve these goals while working with large and uniformly structured data.

More specifically, instead of trying to map a relationship structure, we seek to map relationship types from one domain to another. These mappings are supported by the similarities in the concepts being linked to, and the relationships related to those concepts. Because our data is large and not manually designed, there may not be a single mapping that is better than all the alternatives. Instead, there may be multiple good candidates. Therefore, instead of looking for the best mapping for all possible hypotheses between the concepts and the relationships in the base and destination domains, we seek to find the best analogy we can make just about a single concept.

Algorithms 1-4 contain the pseudo code for our proposed algorithm. On a high level, it works in two steps: 1) computes a unique index for each concept and each relationship type. This index can be used for comparing the similarities between two concepts or two relationship types; 2) generates and evaluates the hypotheses of mapping a concept in the base domain to a concept in the target domain.

```
Algorithm 1 Index_Relationship_Type (domain):
loss, gain, same, diff, index = {} # empty dictionar-
ies
# n: concept; r: relationship; d: destination concept
of r
for each n in domain do
    for each r,d of n do
        # compare n's relationships with d's relation-
    ships
        Loss[r] += n.relationship - d.relationship
        gain[r] += d.relationship - n.relationship
        same[r] += Common(n.relationship, d.relationship)
        diff[r] += Difference(n.relationship,
                            d.relationship)
    end for
end for
for each r in domain do
    index[r] = (Jaccard_index(Loss[r], gain[r]),
        Jaccard_index(Loss[r], same[r]),
        Jaccard_index(Loss[r], diff[r]),
        Jaccard_index(gain[r], same[r]),
        Jaccard_index(gain[r], diff[r]),
        Jaccard_index(same[r], diff[r]))
end for
return index
```

Algorithm 1 creates a vector of size 6 for describing each relationship type in a domain. Inspired by the structural mapping process in SMT, here we argue two relationship types are similar if they are always used in similar contexts. Because we don't have the relational structure for providing a context, we operationally defined the context as the origin and the destination concepts linked by the relationship, and we judge the similarity of these two concepts by looking at the differences between the relationships they have and what they share in common. For example, for the relationship "Hotter than" in Figure 2, n is Sun and d is Planet. The loss set, in this case, equals to ["More massive", "Is"]. It contains all the relationships the Sun has, but the Planet does not have. If "Hotter than" also links other concepts in the knowledge base, the loss set will be appended every time this relationship is used. The gain set contains all the relationships the destination concept has, but the origin concept doesn't. The same set contains all the relationships the origin and the destination concepts have in common, and diff contains all the relationships that are either in loss or gain. Currently, we are only using the measurements that represent the results of basic set operations, i.e. complement, intersection, symmetric and difference. As part of our future work, we will be looking for other measurements that can help with differentiating the relationship types.

For each relationship type, Algorithm 1 aggregates the results from every time it is used in the domain. The second for-loop converts the information in the four sets, i.e. loss, gain, same and diff into a one-dimensional vector by calculating the Jaccard indices between them. We used Jaccard index because it can provide a numerical measurement of the similarities between two sets.

```
Algorithm 2 Get_Node_Index (n,rtype_index):
\# rtype_index: the relationship indexes computed by
Algorithm 1
\# n: concept; r: relationship
tmpv \(=(0,0,0,0,0,0)\) \# a zero vector
for each \(r\) of \(n\) do
    tmpv += rtype_index[ \(r\) ]
end for
return Normalize(tmpv)
```

Based on the relationship indices computed by Algorithm 1, Algorithm 2 returns an index for a concept. Similarly, this index will be used for computing the difference between two concepts in the knowledge network. We used a simple heuristic here: a concept's index is decided by the sum of the index values of all the relationships it has. This value is then normalized to a unit vector.

Finally, Algorithm 3 generates and tests the matching hypotheses, and Algorithm 4 creates a one-to-one mapping between all the relationships a concept $n$ has in the base domain to the relationships in the target domain. With this mapping, it is straightforward to find the concept in the target domain that has the most mapping relationships with $n$.

For establishing the mapping, Algorithm 3 generates all the possible hypotheses of mapping the relationships and destinations ( $r l, d l$ ) associated with $n$ to another pair of relationship and destination $(r 2, d 2)$ in the destination domain. For evaluating the quality of this mapping, Algorithm 3 looks at both how different the two relationships ( $r 1$ and $r 2$ ) are -- rdiff, and how different the two destinations ( $d 1$ and $d 2$ ) are $--n d i f f$. The difference here is given by the cosine similarity between the two vectors. These two difference values are combined. The smaller the overall difference is, the stronger the mapping is. The variable "hypotheses" contains the list of all the hypotheses and their strengths.

```
Algorithm 3 Generate_Hypotheses( \(n, B, T\) ):
\# B: base domain
\# \(T\) : destination domain
hypotheses = [] \# hypotheses for mapping
rtype_index = Index_Relationship_Type( \(B, T\) )
\# index for source node
svec = Get_Node_Index(n, rtype_index)
for each node \(t\) in \(T\) do
    \# index for candidate node
    cvec \(=\) Get_Node_Index(t, rtype_index)
    for each \(r 2\), \(d 2\) of \(t\) do
        for each \(r 1\), \(d 1\) of \(n\) do
            rdiff \(=\) Cosine_Similarity(rtype_index[r1],
                                    rtype_index[r2])
            d1vec = Get_Node_Index(d1, rtype_index)
            diff1 = svec - divec
            d2vec \(=\) Get_Node_Index(d2, rtype_index)
            diff2 \(=\) cvec - d2vec
            ndiff \(=\) Cosine_Similarity(diff1, diff2)
            normalized_score \(=(\) rdiff + ndiff) \(/ 2\)
            hypotheses.Append(normalized_score, r1, d1, r2, d2)
        end for
    end for
```

end for
return hypotheses

Similar to SMT, we want the mappings to be unambiguous. We used a greedy algorithm to resolve the conflicts in the hypotheses. In case there are hypotheses for both mapping $(r 1, d 1)$ to $(r 2, d 2)$, and to $(r 3, d 3)$ in the destination domain, we simply accept the best -- the mapping that has the highest score -- hypotheses first, and reject any subsequent mappings that intend to revise an existing one (Algorithm 4).

```
Algorithm 4 Map_Relationships(hypotheses):
map = {}
# sort the hypotheses based on normalized_score
hypotheses.Sort_Descending()
for each h in hypotheses do
    # ensure a one-to-one mapping
    if both h.r1 and h.r2 are not mapped then
        # map r1 in base to r2 in destination
        map[r1] = r2
    end if
end for
return map
```

## Example Results and Discussion

The proposed algorithm has been applied to making analogies in the two example scenarios described in the Example Domains and Knowledge Representation section.

## The Solar System and the Rutherford Model

For making analogies between the solar system and the Rutherford model, we obtained perfect results. Our algorithm correctly generated the mapping between the Nucleus and the Sun, and between the Electron and the Planet. Our algorithm does not produce mapping relationship structure for supporting the analogy. Instead, it produces matching pairs of relationships and destination concepts. Tables 1 and 2 list the evidence for these two mappings.

Table 1: Mappings between Nucleus and Sun

| Nucleus | Sun |
| :--- | :--- |
| (Attracts, Electron) | (Attracts, Planet) |
| (Distance, Electron) | (Distance, Planet) |
| (Has, Electric charge) | (Has, Mass) |
| (More massive than, Electron) | (Hotter than, Planet) |

In Table 1, all the mappings except the last one are straightforward. We checked the intermediate results. The last mapping was an artifact. (Hotter than, Planet) and (More massive than, Planet) received the same score, and the system did not know how to break the tie. All the mappings in Table 2 are consistent with the original example. We are quite encouraged to get this result without the need of using data with hierarchical relationships. We believe the flat concept-relationship structure we designed in Fig-
ure 2 is friendlier to both human designers and automated programs that convert data from other sources.

Table 2: Mappings between Electron and Planet

| Electron | Planet |
| :--- | :--- |
| (Attracts, Nucleus) | (Attracts, Sun) |
| (Distance, Nucleus) | (Distance, Sun) |
| (Has, Electric charge) | (Has, Mass) |
| (Revolves around, Nucleus) | (Revolves around, Sun) |

## Music Genres and Programming Languages

Making analogies between these two domains generated some interesting results, and inspired us with directions for future work. These domains are much larger than the solar system and the Rutherford model. In our evaluation, the typical running time is less than a second on a Lenovo T430 laptop. We will discuss two pieces of example results below.

Table 3: Mapping Relationships between Punk rock and

| LPC |  |
| :--- | :--- |
| Punk Rock | LPC |
| Music fusion genre | Influenced |
| Stylistic origin | Influenced by |
| Instrument | Paradigm |

In the first example, the system mapped the music genre Punk Rock to the programming language LPC. Because of space limitation, in Table 3 we only list the matching relationship types the system provided for this analogy. Two of these mappings are quite reasonable. By mapping "Stylistic origin" to "Influenced by", the system provided us supporting evidence such as "the stylistic origin of Punk Rock is Garage Rock, Glam Rock, and Surf Music, just like LPC is influenced by Lisp, Perl, and C." By mapping "Music fusion genre" to "Influenced", the system provided corresponding supporting evidence "Celtic Punk is a music fusion genre of Punk Rock, just like LPC influenced Pike." Intuitively, these two examples make sense. Music genres that are influenced by other music genres have their styles originating from those genres. The inverse works as well; if genre A is a music fusion genre for genre B , then A influenced B. The system was able to equate these relation types without any explicit help.

The mapping from "Instrument" to "Paradigm" isn't as a clear cut as the other mappings. The evidence provided is "the relationship between Punk rock and Bass guitar or Electric guitar is Instrument, just like the relationship between LPC and Procedural programming and Functional programming is Paradigm." This assertion isn't inherently wrong. However, to a human observer this mapping may not seem intuitive enough.

Interestingly, we also asked the system to make an analogy about the programming language Python, and the system responded with Hardcore Punk. Table 4 provides the matching relationships for this analogy.

Most of the relationship mappings in Table 4 are reasonable. For example, we can say "Python influenced F Sharp, Ruby, and Swift just like Black Metal, Thrash Metal, and Industrial Metal are derivatives of Hardcore Punk."

Table 4: Mapping Relationships between Python and Hardcore Punk

| Python | Hardcore Punk |
| :--- | :--- |
| Influenced | Derivative |
| Influenced by | Stylistic origin |
| Operating system | Instrument |
| Paradigm | Format |

The most interesting part of this example is the assertion that Python is influenced by Perl in the same way as the stylistic origin of Hardcore Punk is Punk Rock (and hence Hardcore Punk is influenced by Punk Rock). This goes against the previous analogy of Punk Rock being comparable to LPC, since Python is not influenced by LPC. We think this shows the weakness of our approach. Without the hierarchical relationship information which in fact provides a global structure of the data, our algorithm does not do a good job in creating analogies that are globally consistent. However, the analogies are still locally consistent for a given topic because of Algorithm 4.

Another thing to note is the difference in mapping between Instrument and Paradigm. In Table 3, "Instrument" is mapped to "Paradigm", but in Table 4, "Instrument" is mapped to "Operating system." LPC does not have a relationship of the type "Operating system", so no mapping could have been made. Table 4 indicates that "Instrument" is more analogous to "Operating system" than to "Paradigm." As mentioned before, our system cannot enforce global consistency yet. Realistically, however, it's hard to say which is truly correct in this case. A similar phenomenon can be observed with "Influenced" and "Music fusion genre" in Table 3. This time in Table 4, "Influenced" is mapped to "Derivative" because the match is better, not because Hardcore Punk lacks that relation type. In Table 4, mappings from "Influenced" to "Music fusion genre" are ignored because a one-to-one mapping of relation types is enforced by the algorithm. Currently, one-to-one mappings must be enforced in order for coherent analogies to be made. However, there are cases when using many-to-one mappings is more suitable. This is especially true when using crowd-sourced data or data from the Internet where sometimes the only real difference in relationship type is semantics (e.g. "Instrument" / "Instruments").

## Future Work

We have planned future work both in the direction of improving our algorithms for finding better mappings and discovering more creative uses of the algorithms.

First of all, we want to address the issue of the agent sometimes creating conflicted mappings between two pairs of concepts. When working with a large data set, exclusively checking all the possible conflictions would be very time-consuming. Instead, we plan to develop a greedy solution. When the agent needs to make a new analogy, it will assume all the relationship mappings it used to support its previous analogies are already true. This way, instead of asking two separate questions of "what is LPC like" and "what is Python like", we are asking the system "If LPC is like Punk Rock, what Python would be like?"

Secondly, we are looking for better ways for indexing the relationships and the concepts. Right now, the semantic information of the relationship types is rarely used. Algorithm 1 only looks at whether they are different or not. We are considering using other semantic tools for helping us to get a direct measure of how close two relationship types are, and even how close two concept descriptions are. This would solve the aforementioned problem caused by the one-to-one mapping restriction. Another consideration in the indexing process is the fact that when dealing with human authored content, there is no guarantee that different contributors will use the same relation type in the same way. Such inconsistencies could throw off the results of Algorithm 1, leading to bad analogies.

Thirdly, many benchmarks have been created for analogy inference, such as (Holyoak \& Thagard, 1989). Most of the benchmarks' formats are compatible with SMT and the algorithms derived from it. We will be looking into ways of evaluating our algorithm using a standard benchmark.

Finally, we believe this work has great potential of contributing to creating rich and vivid virtual characters, interesting and interactive stories, and computational creativity. We are interested in finding new and innovative applications of our proposed algorithms in addition to making analogies for a single concept. In particular, we are interested in exploring how these algorithms can be used in creating digital stories. As one of our next steps, we plan to experiment with using this algorithm to learn how a person tells a story or how a good story is constructed and then apply the learning results for telling new stories using data from a different domain.

## Acknowledgments

This work was supported in part by the Cognitive and Immersive Systems Laboratory -- a collaboration between the IBM Research and RPI in the IBM Cognitive Horizons Network.

#### Abstract

For decades, theories of early word learning have assumed that infants are equipped with learning biases that help them learn words at a fast pace. One of these biases, called Mutual Exclusivity, suggests that infants reject second labels for name-known objects. Our first two experiments, with children and with infants, suggest that novelty preference during Mutual Exclusivity tasks should not be taken as evidence that associations between novel labels and name-known objects have not taken place. A third experiment, supplemented with computational modeling, ruled out cascaded activation patterns as alternative explanations and, instead, confirmed that word-object associations are non-selective throughout infancy and childhood.

Keywords: Mutual exclusivity; early word learning; crosssituational statistical learning

## Introduction

Children learn words at a fascinating pace (Bloom, 2000). Researchers have suggested that infants are equipped with language learning biases that help them learn words efficiently (Markman, 1990). One such word learning bias, called Mutual Exclusivity (ME; Markman \& Wachtel, 1988), suggests that each object has only one label. Markman and Wachtel (1988) found that children selected a novel object significantly more than a name-known object when hearing a novel label. The associations formed between novel labels and novel objects through ME have been shown to be retained, as Mather and Plunkett (2011) found that children were able to match novel labels with the matching novel objects they were exposed to during a learning phase. This provided evidence that ME can indeed be used to learn words. Yet, it did not address the question of whether infants reject additional labels for name-known objects or not.

In parallel, Smith and Yu (2008) found that when only name-unknown objects are present, infants retain multiple associations between labels and objects. According to their cross-situational statistical learning account (CSL), different word-object associations are being retained and their strengths evolve along with the presentation of labels and objects. Ultimately, a hierarchy of word-object associations is established through the differing numbers of cooccurrences between words and objects. The strongest word-object associations can be seen as providing a basis
towards establishing robust patterns of word learning. This framework suggests that, contrary to ME, children are capable of forming more than one association between objects and words.

Further evidence brought a nuanced view to strict ME accounts. Learners were found to be able to overcome ME and performed above chance when forming two-to-one mappings in CSL-type experiments (Yurovsky and Yu, 2008). Kachergis, Yu and Shiffrin (2009) and Poepsel and Weiss (2014) found that although children performed better in one-to-one mapping, they readily violated ME if there was strong evidence that a new mapping was required.

Yet, Trueswell, Medina, Hafri, Gleitman (2013) found that children do not store all word-object associations. Instead, they make an initial guess and evaluate the validity of this guess in subsequent trials. If the guess is proven to be correct, then the association is strengthened. Otherwise, children will make another guess while discarding previously-made associations. This strategy was coined as a Propose-but-Verify hypothesis (PbV). In a more recent study, Stevens, Gleitman, Trueswell, and Yang (2016) refined their PbV hypothesis, and suggest that children store previous associations as references for future trials.

In our present contribution, we ask whether infants and young children accept second labels for name-known objects. To this end, we adapted a classic ME task, in which novel labels are being uttered while a name-known object and a novel object are being displayed. Strict ME accounts would suggest that children will map novel labels to novel objects, and that they will reject the formation of an association between novel labels and name-known objects.

In our adaptation, the learning phase featured two sets of ME training trials: in each set a novel label was uttered in the presence of a name-known object and of a novel object. During the testing phase, both novel objects used during training were shown together. If children were able to retain the associations learned during ME practice, they would be able to map each novel label to the matching novel object. This testing phase was aimed at verifying that ME can indeed be used to learn words, thus replicating Mather and Plunkett (2011). In another testing block, the two nameknown objects used during ME were shown together, while playing one of the novel labels used during training. According to a strict interpretation of ME, children should not display preference for either objects, since they should
have inhibited the formation of an association from the novel word to the name-known objects. In contrast, if children displayed a preference for the name-known object of the matching set, this would suggest that infants do not reject additional labels for name-known objects, and that they are non-selective when forming word-object associations. In other words, children would map the novel word with all objects present in the scene.

Thereafter, we will present three experiments aiming at refining our understanding of the formation of early wordobject associations.

## Experiment 1

## Methods

Participants 174 children were recruited in Nottingham (UK) from which only data from English monolinguals ( $N=$ 148) was analysed, as bilinguals are expected to differ from monolinguals in ME-related tasks (e.g., Byers-Heinlein \& Werker, 2009; Davidson \& Tell, 2005; Houston-Price, Caloghiris, \& Raviglione, 2010). The participants' age ranged from 4 years to 12 years ( $M=7.36$ years, $S D=$ 2.06). Among them, 65 were male and 83 were female.

Stimuli The visual stimuli (pictures of $640 \times 480$ pixel) were obtained from Frank, Sugarman, Horowitz, Lewis, \& Yurovsky (2016). The novel labels were "dax" and "modi" and both novel words and familiar words were embedded in the carrier sentence "Find the _ !". Auditory labels were recorded by a female native English-speaker in an infantdirected manner.

Procedure The experiment was carried out on an iPad. The participants had to first complete a warm-up task, where they were instructed to tap on five dots appearing in random places, followed by five smiley faces presented on the screen of the iPad. After the warm-up task, the experiment was started. There were three experimental blocks, namely a Mutual Exclusivity (ME) training, a Word Learning test and a Selectivity test (see Figure 1).

Figure 1: Example of different block types in Experiment 1.

In ME training, two sets of stimuli were used. Each of the sets consisted of one pair of images, one name-known image and one novel image, along with a novel label ("dax" and "carrot" for the first set, "modi" and "cat" for the other set). In each ME trial, one pair of images was displayed while the novel label was being played (embedded in the carrier sentence "find the __!"). We defined the target to be the novel object. Participants had the opportunity to learn two novel labels for the two novel images via ME. Each pair was repeated four times.

In the Word Learning test, both novel images (the "targets" in ME training) were displayed side-by-side while one of the corresponding novel labels used during training was played. These trials were repeated four times, such that both novel labels were uttered twice. The aim was to test whether the participant had formed an association between a novel label and the corresponding novel image; a prerequisite for word learning.

In the Selectivity test, the two name-known images (the "distractors" in ME training) were displayed side-by-side while one of the novel labels used for training was played. Target selection (i.e., tapping on the name-known image from the matching set) would provide evidence that an association between the name-known image and a second label was not inhibited during ME training. This block also consisted of four trials. The order of presentation of the Word Learning test block and the Selectivity test block was randomised across participants.

## Results and Discussion of Experiment 1

As children were required to select an image out of two presented to them, binomial tests were run to measure the proportion of accurate responses as compared to chance (.50) in the different blocks. The proportion of accurate responses for the different blocks may be seen in Table 1.

Table 1: Observed proportion of accurate responses in different blocks

| Auditory <br> stimuli | ME <br> training | Word <br> learning test | Selectivity <br> test |
| :--- | :--- | :--- | :--- |
| "dax" | $.99^{* * *}$ | $.98^{* * *}$ | $.60^{*}$ |
| "modi" | $.98^{* * *}$ | $.96^{* * *}$ | $.69^{* *}$ |
| $* p<.05 . * * p<.01 . * * * p<.001$ (1-tailed). |  |  |  |

The results obtained provided evidence for the occurrence of ME during training, where the children selected the novel image upon hearing a novel word, thus replicating classical ME results (e.g., Golinkoff, Hirsh-Pasek, Bailey, \& Wenger, 1992; Mather \& Plunkett, 2011).

Children also performed above chance in the Word Learning test, indicating that they were able to form an association between the novel images and the novel words. This also replicates previous studies (e.g., Mather \& Plunkett, 2011; Mervis \& Bertrand, 1994;), which suggest that ME can indeed be used to learn words.

Crucially, it was also found that children were able to form associations between novel words and name-known objects, suggesting that word-object associations are nonselective.

Age was not found to correlate significantly in the Selectivity test ( $r=.113, p=.171$ ), suggesting that younger infants going through a rapid expansion in their vocabulary may also be able to associate novel labels to name-known objects.

## Experiment 2

Experiment 2 aimed at establishing whether infants are also non-selective when forming word-object associations. The design of Experiment 2 was similar to the previous experiment, with the main difference that infants were tested using an eye-tracker.

## Methods

Participants Forty-three 21-month-old infants ( $M=21.01$, $S D=0.57$ ) participated in the experiment ( 25 boys). Nine additional children were tested but excluded because of fussiness (4), failed calibration (4) or software problem (1). All participants were French native speakers recruited in the canton of Geneva, Switzerland.

Stimuli Four novel labels were created for the experiment: "pogalle", "pizelle", "nidoupe" and "loutade". The novel labels were all defined to be of feminine gender, so that no disambiguation could be applied before the onset of the word itself. In addition to the novel labels, eight familiar words were used throughout the experiment. All words were embedded in the sentence "Regarde la __!" (Look at the !). All auditory stimuli were recorded by an enthusiastic French native speaker of Switzerland in a child-directed manner. Visual stimuli were photographs of objects on a light grey background which were extracted from the NOUN database (Horst \& Hout, 2016).

Procedure The procedure of Experiment 2 was similar to Experiment 1 with the exception of two changes, listed thereafter. First, Experiment 2 was conducted with an eyetracker. Thus, looking preference was analysed as opposed to target selection in Experiment 1. Second, another set of images and labels was used.

Infants sat on their caregiver's laps, in front of a flatscreen, approximately 70 cm from the screen. An SMI RED500 eye-tracker recorded infants' fixations at a sampling rate of 500 Hz . The experiment started with a 5point calibration and validation sequence. Upon successful calibration, the experiment started. The calibration procedure was repeated for infants who failed to go through all 5 points or if the validation revealed substantial deviations.

Analysis method Due to data loss in eye-tracking studies, measures typically used in intermodal preferential looking (IPL) paradigms, Preferential Target Looking (PTL) and Longest Look (LL) measures are not appropriate (Wass,

Forssman, \& Leppänen, 2014). A novel analysis was thus introduced similar to the one described by Maris and Oostenveld (2007). The approach is of the model-fitting type, whereby one does not merely compute the maximum likelihood estimates for a set of parameters; the models can also be tested whether or not they are significantly different from each other. The likelihood ratio test then provides the means for comparing the likelihood of the data under the hypothesis that infants are biased towards the target, against the likelihood of the data under the more restricted hypothesis (or null hypothesis) that infants do not have a preference for either the target or the distractor.
A binomial analysis is performed for every time step of every test trial in the post-naming phase, from 367 ms after the onset of the target word (accounting for the time it takes infants to fixate the target object, see Swingley \& Aslin, 2000) for 1500 ms . For each time step the number of infants looking at the target is counted, as well as the number of infants looking at the distractor. The binomial test can reveal if an excess of infants looking at either the distractor or the target at that moment is likely to result from a biased looking behavior (e.g., that infants tend to look more at the target) or if an observed imbalance in the number of infants looking to the target and the distractor can be attributed to mere random variations or noise.

## Results and Discussion of Experiment 2

Results Figure 2 depicts the looking preference of the 21-month-old infants when they were presented during the test phase with the two novel objects used during training (in black) and the two name-known objects used during training (in red). Vertical bars indicate the time steps for which an individual binomial test rejects the hypothesis that infants are not biased towards any object. In both test situations, hypotheses were rejected in favor of a bias towards the target.

Infants display a preference for the target and the loglikelihood that each point belongs to the distribution of unbiased simulated infants can be computed, as it corresponds to the negative square of the Mahalanobis distance (Mahalanobis, 1936). The log-likelihood $L$ that the 21-month infants is unbiased equals $L=1.891$ for the Word Learning test and $L=-44.765$ for the Selectivity test. The statistical relevance of this hypothesis can only be made from the comparison to another model; the biased model.

Log-likelihoods that the 21-month-olds belong to the distribution of simulated infants can be computed for each different bias, and one can estimate the maximum loglikelihood estimate, associated with the optimal bias; e.g., that accounts best for the data.

The maximum log-likelihood equals $L=-0.010$ for a bias towards the target when both novel objects are used during the Word Learning test and equals $L=-0.003$ for a bias towards the target for selectivity test.

Finally, the likelihood ratio test is applied. In the Word Learning test, the 21-month-old infants approach significance $(p=.053)$. On the Selectivity test, the
likelihood ration test shows that infants are significantly biased towards the target ( $p<.001$ ). In other words, they have formed a second association between a novel label and a name-known object; 21-month-old infants also seem to be non-selective when forming word-object associations.

Figure 2: Proportion of infant target looking in the Word Learning test (in black) and in the Selectivity test (in red). Vertical lines highlight significant preference for the target according to a binomial test.

## Experiment 3

In Experiment 1 and 2, children were found to be able to form associations between novel labels and name-known images. Yet, one cannot rule out that infants have formed an encyclopaedic mapping; i.e., they rely on the co-occurrence between the novel object and the name-known object to form an association between both objects. In turn, they may exploit this object-object association to select the nameknown object when hearing the novel label, through cascaded activation from the novel label to novel object (through ME) and from the novel object to the familiar object (through the encyclopaedic mapping). To test if the association between the novel word and the name-known object is lexical or encyclopaedic, a new test, referred to as the Encyclopaedic test, was created. In this test, both novel images used during training were presented side-by-side, but the labels of the name-known distractors were played instead (see Figure 3). As the novel images were never displayed in the presence of these familiar labels, we would expect children's performance to be at chance level.

## Methods

Participants 150 children were recruited at The University of Nottingham. Only data from the 124 English monolingual children ( 55 male, 69 female) was retained for analysis. Children were 3 to 12 years of age ( $M=7.31$ years, $S D=2.28$ ).

Stimuli Visual stimuli were obtained from the same source as Experiment 1. The novel labels used were "pifo" and "dofa" paired with images of a ball and a cup, respectively.

Procedure The procedure was the same as Experiment 1 except for the sequence of the tasks. In Experiment 3, there were four blocks, namely the ME training, the Selectivity test, the new Encyclopaedic test and the Word Learning test. There were four trials in both the Selectivity test and the Encyclopaedic test but only two trials in Word Learning test. The order of the Selectivity test and the Encyclopaedic test was counterbalanced whereas the Word Learning test was always administered at the end of the experiment.

In the Encyclopaedic test, novel images used during ME training were displayed side-by-side while the names of the corresponding familiar images were played (see Fig. 3).

Figure 3: Example of the Encyclopaedic test.

## Results and Discussion of Experiment 3

Binomial tests were run to measure the proportion of accurate responses as compared to chance (.50) in the different blocks. The results once more supported the presence of ME during training (all $p$ 's $<.001$ ) and that word-object associations are retained in the Word Learning test (all $p$ 's $<.001$ ).

However, and contrary to our hypothesis, children selected the target in the Encyclopaedic test (significantly above chance for "cup" ( $p=.001$ ), and approaching significance for "ball", $p=.063$ ), suggesting that infants formed an encyclopaedic mapping between all items, rather than forming multiple associations at a lexical level between a name-known object and multiple labels. The only explanation is that children display evidence of cascaded activation, from the familiar name to the corresponding name-known object, and through the novel object it was paired with.

Does cascaded activation also explain results concerning the Selectivity test? Maybe children are strictly following ME; upon hearing the novel label, they activate the representation of the matching novel object (learned during ME) and select the name-known object that co-occurred with the novel object? How can we distinguish between the cascading and the non-selectivity explanations?

Let us look at correlations between the different experimental blocks. A strict ME account would suggest that lexical associations can only be formed between the novel label and the novel object during ME training. A
stronger ME effect would translate into stronger associations between novel labels and novel objects. Through cascaded activation, novel label to novel object (ME) and from novel object to familiar object (through an encyclopaedic mapping), a strict ME account would suggest a positive correlation between performances in the ME training phase and performance in the Selectivity test.

In contrast, the hypothesis that word-object associations are non-selective (following the arguments of CSL) would predict that the novel label would also be associated with the name-known object. Accordingly, higher accuracy in the ME training block would suggest that children should spend more time on the novel object than at the name-known object, in turn leading to the formation of stronger associations between novel labels and novel objects but weaker associations between novel labels and name-known objects. Thus, if the associations between novel words and novel objects are non-selective, and that such associations take place at a lexical level, the accuracy score in ME training should correlate negatively with the accuracy score in the Selectivity test.

In our data, the accuracy score of ME training correlated positively with the Word Learning test ( $r=.232, p=.009$ ), while correlations between ME and the Encyclopaedic test were not significant ( $r=-.075, p=.406$ ), thus far consistent with both explanations. However, ME training results correlated negatively with performance during the Selectivity test ( $r=-.218, p=.015$ ). The experimental results support the hypothesis that word-object associations are non-selective, and that the formation of association between novel labels and name-known objects take place at a lexical level. Next, we further scrutinise the above reasoning by constructing two simple computational models of Experiment 3.

## Computational Models of Experiment 3

Two models were constructed, in order to compare a strict ME account with a non-selective account of the CSL type. In both models, associations are modulated based on cooccurrence of items presented simultaneously; between objects and labels, as well as between both objects. In each trial, previous association strengths define relative looking time towards each object via the application of Luce's forced choice rule (with a separation parameter of $k=8$ ). Looking time, in turn, modulate the magnitude of the association strength update, in a Hebb-like update rule (with a learning rate of 0.1 ). The associations between both objects are obtained by computing the product of the relative preference associated with each object. Similarly, indirect associations such as cascaded activation from the novel label to the novel object and the familiar object are computed through the product of the association strength between the novel label and the novel object and the association strength between the novel object and the familiar object.

The order of stimuli was identical in the model and for participants. 100 individual models were created for each
hypothesis, and had a mean novelty-preference of 0.8 , and Gaussian random variations of a standard deviation of 0.05 . In the strict ME model, associations between novel labels and name-known objects were inhibited whereas in the nonselective model, such associations were permitted. Correlations between preference for the novel object during ME training and preference for the target object in each test block were computed.

As predicted, modelling results showed that a strict ME account sustains positive correlations between ME training and the Word Learning test $(r=.89, p<.001)$ and between ME and the Selectivity test ( $r=.68, p<.001$ ). In contrast, the non-selective model displays a positive correlation between ME training and the Word Learning test $(r=.89, p$ $<.001$ ) but a negative correlation between ME and the Selectivity test ( $r=-.33, p<.001$ ). The modelling results, along with the empirical results, provide additional evidence that children are non-selective when forming word-object associations.

## General Discussion

While Mutual Exclusivity assumes that children associate only one word to one object, Cross-situation Statistical Learning accounts suggest that children maintain a hierarchy of word-object pairings established on the basis of co-occurrence of object and labels. These two theories have typically been tested using different experimental designs; while ME studies generally feature both novel and familiar objects, CSL studies typically present only novel objects. Our approach aims at testing both theories by using a Selectivity test, so as to examine whether children accept additional associations between a name-known object and a novel label.

In all three studies, we found that children tend to map the novel label to the novel object, replicating classic ME experiments, that infants tend to look at (or select) novel objects upon hearing a novel word.

We also replicated findings that associations between novel objects and novel labels are momentarily retained, thus providing a necessary basis towards the consolidation of word-object associations, and towards word learning (e.g., see Mather \& Plunkett, 2011).

Yet, we argue that evidence of ME - a preference for a novel object when hearing a novel label - should not be taken as proof that associations between novel labels and name-known objects are suppressed. Experiment 1, with school-aged children, and Experiment 2, with 21-month-old infants, provided converging evidence that word-object associations are non-selective: children may well display evidence of ME during training, but they also show evidence that associations between novel labels and nameknown objects are maintained during test blocks, and not inhibited as suggested by strict ME accounts.

Experiment 3 aimed at ruling out alternative explanations for the results observed in the first two studies. The introduction of an additional test block, the Encyclopaedic test, suggested that children displayed cascaded activation
patterns. Yet, correlation analyses between the ME training phase and the different test blocks suggested that the pattern of results can be best explained if children are non-selective when forming word-object associations. Strict ME accounts would predict a positive correlation between ME training and selectivity test as children have to rely on cascaded activation to identify the target. In contrast, non-selective learning accounts would suggest that children displaying stronger novelty preference during ME training would display weaker associations between the novel label and the name-known object, thus leading to a negative correlation between ME training and the Selectivity test. The latter pattern of results was observed experimentally.

The finding that infants are non-selective in their formation of word-object associations sits well with other recent findings that infants are flexible in their interpretation of the meaning of novel words (Ramscar, Dye, \& Klein, 2013) and that infants engage into cross-situational statistical learning with (multiple) objects in their visual field (Yu \& Smith, 2011; Yurovsky, Smith, \& Yu, 2013).

The very first stages of word learning taking place during ambiguous naming situations, such as in ME experiments or cross-situational statistical learning situations, do seem to be principled by low-level associationist mechanisms whereby multiple word-object pairings are being built. The hierarchy of word-object associations can then evolve across situations so that ultimately only relevant word-object mappings are retained. In sum, infants and children appear to be flexible when learning words and readily entertain the possibility that objects can have multiple names.

# The tortoise wins only when the race is long: How the task environment changes the behavior of Tetris models 

Catherine Sibert<br>Rensselear Polytechnic Institute, Troy, New York, United States<br>Wayne Gray<br>Rensselaer Polytechnic Institute, Latham, New York, United States

#### Abstract

Tetris can be viewed as a highly complex decision making task, and used as a paradigm for studying human expertise. We hypothesized that models capable of playing Tetris for a long time are doing so by adopting slow but steady strategies to accumulate points, while human players are much more prone to using high-risk, high-reward strategies that earn more points in a shorter time frame. This work used the MindModeling.org computational cognitive modeling platform to develop the best models capable of playing long term games and short term games, and then compared the performance of the two. The best long term model adopted the slow and steady strategy, while the best short term model displayed the higher-risk, higher-reward strategy that more closely matches behavior observed in human players. Models that "trained long" but "played short" did worse than those that both trained and played "short."

# Information density of encodings: The role of syntactic variation in comprehension 

Les Sikos (sikos@coli.uni-saarland.de), Clayton Greenberg (claytong@coli.uni-saarland.de), Heiner Drenhaus (drenhaus@coli.uni-saarland.de) and Matthew W. Crocker (crocker@coli.uni-sb.de)<br>Department of Language Science and Technology, Saarland University, 66123 Saarbrücken, Germany

#### Abstract

The Uniform Information Density (UID) hypothesis links production strategies with comprehension processes, predicting that speakers will utilize flexibility in encoding in order to increase uniformity in the rate of information transmission, as measured by surprisal (Jaeger, 2010). Evidence in support of UID comes primarily from studies focusing on word-level effects, e.g. demonstrating that surprisal predicts the omission/inclusion of optional words. Here we investigate whether comprehenders are sensitive to the information density of alternative encodings that are more syntactically complex. We manipulated the syntactic encoding of complex noun phrases in German via meaningpreserving pre-nominal and post-nominal modification in contexts that were either predictive or non-predictive. We then used the G-maze reading task to measure online comprehension during self-paced reading. Results were consistent with the UID hypothesis. In predictive contexts, post-nominal encodings elicited a more uniform distribution of processing effort. Conversely, in non-predictive contexts, more uniform effort was found for pre-nominal encodings.

Keywords: Language comprehension; surprisal; uniform information density hypothesis; G-maze; self-paced reading.

## Introduction

Levy and Jaeger's (2007) Uniform Information Density hypothesis postulates that speakers adjust their lexical and syntactic realization of a message for the benefit of comprehenders. Specifically, they suggest that there is an overarching preference to produce message encodings that distribute information as evenly as possible across the linguistic signal. This account fundamentally links encoding and decoding processes, asserting that language producers will exploit the flexibility in encoding so as to increase uniformity in the rate of information transmission, as measured by surprisal (Hale, 2001; Levy, 2008). As such, the UID hypothesis can be viewed as part of a rational theory of communication - from an information theoretic perspective - in which encoding strategies take into account resource limitations of the comprehender.

There is robust empirical evidence that surprisal accounts for cognitive load during comprehension - at least at the level of individual words in a sentence (Drieghe, Rayner \& Pollatsek, 2005; Kliegl, Grabner, Rolfs \& Engbert, 2004; Rayner, Aschby, Pollatsek \& Reichle, 2004; Rayner \& Well, 1996). However, there exists little direct online evidence that comprehenders are indeed sensitive to the surprisal and density profiles of alternative syntactic encodings - a critical assumption underlying the UID hypothesis. Furthermore, current support for UID in production is limited to relatively local encoding choices,
such as that-deletion (Jaeger, 2010; Levy \& Jaeger, 2007), contraction (Frank \& Jaeger, 2008), and the use of single word equivalents that vary in word length (chimpanzee vs. chimp; Mahowald, Fedorenko, Piantadosi \& Gibson, 2013). Although the above studies provide important and compelling support for the notion that UID modulates aspects of syntactic encoding, the generality of the findings is limited by the observation that all the phenomena are instances of highly local syntactic reduction.

The goal of the current study is to investigate whether comprehenders are sensitive to the information density of more complex alternative syntactic encodings. Consider the following examples:
(1) The journalist published...

Predictive context
The man evaluated...
Non-predictive context
a. ...[the carefully written essay].
Obj $\mathrm{NP}_{\text {adj }}$
b. ...[the essay that was carefully written].
Obj $\mathrm{NP}_{\text {rel }}$

Each object noun phrase (NP) above arguably expresses the same message, ${ }^{1}$ however (a) uses a pre-nominal adjective phrase while (b) uses a post-nominal relative clause. While the head noun (essay) is more expected in the predictive (1) than non-predictive (2) contexts, the expectation for the adjective carefully presumably does not differ across contexts. One potential encoding strategy for increasing the uniformity of information density would be to produce lowsurprisal words early in the sentence, as this may facilitate the processing of subsequent less predictable words. For instance, in the non-predictive context, the UID hypothesis predicts a processing advantage for the pre-nominal encoding because carefully written should reduce the surprisal of essay. In the predictive context, on the other hand, the pre-nominal encoding may result in a trough in information density at essay, as it is highly expected (and thus not very informative) following the verb and modifiers. In this case, the post-nominal relative clause may distribute the informational content more uniformly. The UID hypothesis therefore, predicts a greater benefit for the relative clause encoding in more predictive contexts.

We tested the above predictions using a self-paced reading design to measure online differences in cognitive load during the critical object NP.

[^490]
## Experiment

Our primary goal was to test whether comprehenders are sensitive during online processing to differences in the information density of alternative syntactically-complex encodings that nevertheless convey a similar message. The materials crossed two factors (context $\times$ encoding), as illustrated in Table 1. Because this manipulation distributes information within the critical region differently across conditions, we assessed cognitive load using a variation of self-paced reading that is less susceptible to spill-over effects than standard forms of self-paced reading. The grammaticality maze task (G-maze; Forster, Guerrera \& Elliot, 2009) can precisely identify the word at which processing time differences emerge during online comprehension (Witzel, Witzel \& Forster, 2010) and is therefore well-suited for our purposes. In this task sentences are presented word by word as a sequence of forced choices between two alternatives, only one of which continues the sentence grammatically. If the participant successfully navigates the "maze" by choosing the correct word from each pair, the selected words form a coherent sentence (Figure 1).

## Methods

Participants Twenty-seven native German speakers (age $M$ $=24, S D=2.6$ ) with normal or corrected to normal vision were recruited from the Saarland University community and were compensated $8 €$ for their participation. Participants that did not successfully navigate at least $70 \%$ of mazes in all experimental conditions were excluded $(\mathrm{n}=3)$.

Materials Forty-eight sets of sentences were constructed in German by crossing context (predictive, non-predictive) and syntactic encoding of the object NP (pre-nominal modification, post-nominal modification), resulting in four conditions per item (Table 1). In order to create the context manipulation, the same object noun (e.g., Essay, "essay") was used in all conditions, but the object was designed to be more expected in predictive contexts than non-predictive contexts. This was accomplished by choosing different subject-verb combinations for each context. Subject-verb
combinations were neutral with respect to the object noun in the non-predictive context (e.g., Der Mann bewertete, "The man evaluated"), but were semantically associated with the object in the predictive contexts (e.g., Der Journalist veröffentlichte, "The journalist published"). Importantly, however, highly expected object nouns (e.g., Artikel, "article") were avoided in order to increase the possibility of detecting surprisal differences between predictive/prenominal and predictive/post-nominal conditions.

The information density of object NPs was manipulated via pre- and post-nominal modification, affecting both the linear ordering and length (in words) of the message. Prenominal modifiers (e.g., sorgfältig verfassten, "carefully written") were shorter, containing 2 to 4 words, but positioned the head noun at the end of the NP. Post-nominal modifiers used a relative clause construction (e.g., der sorgfältig verfasst worden war, "that was carefully written") and were therefore longer, ranging from 4 to 6 words, and constrained the head noun to the beginning of the NP. To avoid having any words within the critical object NP region be sentence-final, all items ended with an adverbial phrase.

Figure 1: Example trial structure of G-maze task. Sentences (in German) were presented word by word as a sequence of forced choices between two alternatives, only one of which continued the sentence grammatically.

Table 1: Example stimulus item in four conditions with approximate English translations. The critical region of interest was the object NP. RTs were analyzed separately for the object noun (bold) and modification region (underlined).

| Context | Encoding | Example |
| :--- | :--- | :--- |
| Predictive | Post-nominal | Der Journalist veröffentlichte den Essay, der sorgfältig verfasst worden war, unter Einbeziehung des größeren Kontextes. <br> "The journalist published the essay that was carefully written, taking into account the larger context." |
| Predictive | Pre-nominal | Der Journalist veröffentlichte den sorgfältig verfassten Essay unter Einbeziehung des größeren Kontextes. <br> "The journalist published the carefully written essay, taking into account the larger context." |
| Non-predictive | Post-nominal | Der Mann bewertete den Essay, der sorgfältig verfasst worden war, unter Einbeziehung des größeren Kontextes. <br> "The man evaluated the essay that was carefully written, taking into account the larger context." |
| Non-predictive | Pre-nominal | Der Mann bewertete den sorgfälig verfassten Essay unter Einbeziehung des größeren Kontextes. <br> "The man evaluated the carefully written essay, taking into account the larger context." |

Four counterbalanced lists were constructed from these materials according to a Latin Square design such that each list contained 12 items in each condition, but no item appeared more than once in the same list. An additional 48 sentences with the same structures as above, but containing highly predictable object nouns, were constructed as fillers (e.g., Der Schneider zerschnitt den stark gemusterten Stoff am Mittwoch., "The tailor cut the heavily patterned fabric on Wednesday."). Half of the filler sentences contained prenominal modification of the object noun and the other half contained post-nominal modification. No object nouns were repeated across experimental or filler items.

Cloze probability and contextual constraint An offline Cloze completion study was conducted to confirm that object nouns were more expected following predictive than non-predictive contexts, but were not highly expected in either context. A separate group of 58 native German speakers (age $M=22.0, S D=2.9$ ) were presented with sentence fragments from the 48 experimental items described above. Fragments contained only the contexts, followed by a blank (e.g., Der Mann bewertete__ ; Der Journalist veröffentlichte___). Predictive and non-predictive contexts were counter-balanced across two lists. Participants were asked to fill in the blank with the first determinernoun combination that came to mind. Cloze probabilities were computed as the percentage of participants who provided the experimental object noun for a particular item. As expected, object nouns had low cloze probabilities in both contexts but were reliably more expected following predictive (cloze $=0.06, S D=0.18$ ) than non-predictive contexts (cloze $=0.00, S D=0.01), t(47)=-2.32, p<.05$.

The percentage of the most frequently occurring response to each sentence fragment in the cloze test was also used to assess the contextual constraint of predictive and nonpredictive contexts. As expected, the mean constraint of predictive contexts was reliably greater (51.3\%) than that of the non-predictive contexts $(21.3 \%), t(47)=-8.46, p<.001$.

Surprisal profiles To compare our response time results against a more theoretical notion of predictability, we computed surprisals for all experimental stimuli using an interpolated modified Kneser-Ney 5-gram language model trained on a 2017-01-01 dump of German Wikipedia. To obtain the corpus, we filtered the original XML dump using the tool WikiExtractor, split the corpus into sentences using the NLTK sentence splitter for German, and preprocessed the resulting dataset. ${ }^{2}$ After replacing all types occurring fewer than 15 times with <unk>, the vocabulary size was $833,734 .{ }^{3}$ We split the corpus into training, development,

[^491]and test sections with the ratio $8: 1: 1$. The resulting training section contained $666,561,150$ tokens. The model was trained using the SRILM toolkit (Stolcke, 2002) and achieved perplexities of 25 on the training section, 201 on the test section, and 1583 on our stimuli. ${ }^{4}$

Procedure Participants were randomly assigned to a stimulus list (6 per list). The G-maze task was implemented in E-prime (Schneider, Eschman, \& Zuccolotto, 2002). Each trial began with two crosses $(+)$ that remained on screen for 1000 ms , indicating where subsequent word pairs would appear. Each word in the sentence (except the first word) was then presented together with a foil word, ${ }^{5}$ which was not a grammatical continuation of the sentence. The first word in every sentence was paired with " $x-x-x$ ". The presentation side (left, right) was randomized such that the correct word appeared equally often on each side. Any punctuation (i.e., comma, period) that appeared with a word also appeared with its foil. Participants were instructed to choose as quickly and as accurately as possible the word that best continued the sentence. Participants indicated their selection by pressing the left or right button on a button box and the amount of time required for selecting the grammatical continuation was recorded as the response time (RT). If the correct word was chosen, the next pair of words appeared automatically. However, if a foil word was selected, negative feedback (Inkorrekt, "Incorrect") was displayed and the trial was aborted. Once the end of a sentence was reached, positive feedback (Korrect, "Correct") was given. Participants initiated each new trial by button press.

To confirm that participants read the sentences for meaning, a Yes/No comprehension question appeared after $1 / 3$ of the items. Half of the questions asked about the subject noun and half about the object noun. The correct answer was Yes for $50 \%$ of questions. Participants used the button box to respond. No feedback was given.

In order to familiarize participants with the task, five practice items (three with comprehension questions) were presented before the experiment began. Participants took approximately 40 minutes to complete the experiment.

[^492]
## Results and Discussion

Completed mazes Overall performance on the G-maze task was high, with participants successfully navigating $85.6 \%$ ( $S D=0.08$ ) of experimental and filler items to completion. However, because the critical region of interest was the object NP, the RT analyses reported below were conducted on all experimental items that were completed through at least the end of the critical region $(M=0.90, S D=0.06)$.

Comprehension question accuracy Performance on the comprehension questions was near ceiling ( $M=0.97, S D=$ 0.04), confirming that participants were reading the sentences for meaning during the G-maze task.

Response time RTs were analyzed with linear mixed effects models with participants and items as crossed, independent, random effects. All models included maximal random effects structures (Barr, Levy, Scheepers \& Tily, 2013). Analyses were conducted using the lmer function (lme4 library, version 1.1-10; Bates \& Sarkar, 2007) in the statistics software package $R$, version 3.2.2 ( R Development Core Team, 2013). Fixed effects were evaluated via likelihood ratio tests implemented in lmerTest (Kuznetsova, Brockhoff \& Christensen, 2015), where denominator $d f$ was estimated using the Satterthwaite method. We report estimates, standard errors, $t$ and $p$ values associated with likelihood ratio tests for significant results only.

All raw RTs that were abnormally low (below 200 ms ) or abnormally high (above 5000 ms ) were excluded ( $0.3 \%$ ), and outliers exceeding 3 standard deviations by participant were then trimmed ( $1.8 \%$ ). The remaining RTs were adjusted for word length (Ferreira \& Clifton, 1986) and punctuation using a linear mixed effects regression model with fixed effects for word length, punctuation (i.e., whether or not a comma or period was presented with the word), and their interaction. The residuals of this model, lengthadjusted RTs, served as the dependent variable in the analyses reported below. ${ }^{6}$ Because the number of words used to modify object nouns varied across items and conditions, we computed the length-adjusted RT for the modification region by averaging across modifier words.

The upper panel of Figure 2 presents the mean lengthadjusted word-by-word RTs for each condition. Differences first emerge at the subject noun, where RTs were slower for predictive than non-predictive contexts. This is not surprising as these words (e.g., journalist) are less frequent than their non-predictive counterparts (e.g., man). More relevant to the research question, all four conditions diverge within the critical object NP region (Table 2).

Object noun analysis. Length-adjusted RTs for object nouns were regressed onto a model including fixed-effect factors for context (predictive, non-predictive), encoding (pre-nominal, post-nominal), and their interaction. In order to control for task adaptation, a main effect of stimulus order was also included.

[^493]Figure 3 (left panel) shows that object nouns were read more quickly in predictive than non-predictive conditions, $\beta$ $=-161.01, S E=29.59, t(44.22)=-5.44, p<.001$. This finding replicates previous work demonstrating that expected linguistic material is easier to process than unexpected material.

Within the non-predictive conditions, pre-nominal modification clearly facilitated the processing of unexpected object nouns. Length-adjusted RTs for object nouns were faster for pre-nominal modification than for post-nominal modification, $\beta=-124.86, S E=30.42, t(23.07)=-4.104, p$ $<.001$. This result is consistent with the UID hypothesis, which predicts a processing advantage for the pre-nominal encoding: pre-modification reduces the surprisal of the unexpected word and results in a more uniform distribution of processing effort across the linguistic signal.

Within the predictive conditions, length-adjusted RTs for object nouns were also faster for pre-nominal modification than for post-nominal modification, $\beta=-51.00, S E=18.67$, $t(29.26)=-2.73, p<.05$. However, the facilitation effect was weaker for predictive conditions, resulting in a context $\times$ encoding interaction, $\beta=73.67, S E=33.02, t(53.56)=$ $2.23, p<.05$. The UID hypothesis predicts a trough in information density for words that are both highly expected and pre-modified. Figure 2 (upper panel) is compatible with this prediction. RTs drop steeply in the predictive / prenominal condition at the object noun. Note that this is true despite the fact that object nouns were selected to be lowcloze. Thus, as shown in Figure 3, the post-nominal condition distributes the informational content more uniformly, resulting in a smoother RT profile.

Modification region analysis. Length-adjusted RTs for the modification region were analyzed using the same mixed effects model as above. Figure 3 (right panel) shows that encoding influenced the processing of the modification region in a way that was complementary to its effect on object nouns (see also Table 2). Pre-nominal modification was read more slowly than post-nominal modification in both contexts, $\beta=106.04, S E=15.02, t(75.75)=7.06, p<$ .001. However the magnitude of this effect was greater in the non-predictive context, reflected in a context $\times$ encoding interaction, $\beta=-53.44, S E=18.69, t(51.68)=-2.86, p<.01$.

Table 2: Mean length-adjusted RT (ms) by condition for object noun (upper panel) and modification region (lower panel). Standard deviation in parentheses.

| Object Noun |  |  |  |
| ---: | ---: | ---: | ---: |
|  | Pre-nominal | Post-nominal | Mean |
| Predictive | $-54(77)$ | $-5(54)$ | $-30(50)$ |
| Non-predictive | $27(70)$ | $56(98)$ | $92(46)$ |
| Mean | $-13(56)$ | $76(62)$ |  |
|  |  |  |  |
| Modification Region |  |  | Pre-nominal |
| Post-nominal | Mean |  |  |
| Predictive | $54(46)$ | $2(39)$ | $28(31)$ |
| Non-predictive | $113(53)$ | $10(30)$ | $61(34)$ |
| Mean | $84(30)$ | $6(22)$ |  |

Figure 2: Upper panel: Mean length-adjusted word-by-word RTs. Lower panel: Surprisal profiles as determined by a language model trained on the German Wikipedia corpus. RTs and surprisals for the modification region were calculated by averaging across all modifiers words. Error bars represent one standard error of the mean.

Figure 3: Mean length-adjusted RTs for object nouns (left panel) and the modification region (right panel). Error bars represent one standard error of the mean.

Surprisal profiles. The lower panel of Figure 2 shows the surprisal profiles produced by the language model. Surprisals at sentence positions 1-4 patterned closely with RTs, reflected in a positive correlation within this region ( $r$ $=0.36$ ). However, the surprisal pattern differed somewhat from the pattern of RTs during the critical object NP region
( $r=-0.06$ ). There are at least two plausible explanations for this divergence. First, the predictable contexts may not have made our atypical (i.e., low cloze) object nouns statistically more predictable, given our German Wikipedia corpus. For instance, verpackte ("boxed", a verb in the predictive context) and Geschenk ("gift", the corresponding object noun) were both present in the corpus but never co-occurred in the same sentence. We assessed this possibility and found that, on average, subject nouns in predictive contexts did not substantially increase the predictability of object nouns above the general case. Verbs, however, did so by a factor of 6 . Second, the dependencies that existed in the training corpus may not have been fully captured by the language model. To test this possibility, we calculated the mean gram size used for surprisal predictions in the object NP region ( $M=1.86$ ). This finding indicates that despite being trained on 5 -grams, the model predictions in this region were based predominantly on more local statistics (i.e., bigrams), effectively modeling only the non-predictive conditions. ${ }^{7}$

Despite these caveats, the results broadly confirm our assumptions about the distribution of surprisal across prenominal and post-nominal encodings of the critical object

[^494]NP: according to the language model, the pre-nominal encodings had more uniform information densities. To capture the behavior found for reading times in the predictive conditions, either a closer domain match between training corpus and stimuli would be required, or a language model architecture that is less sensitive to word position.

## General Discussion

The UID hypothesis links production strategies with comprehension processes and predicts that speakers utilize flexibility in encoding to distribute information as evenly as possible across the linguistic signal (Jaeger, 2010; Levy \& Jaeger, 2007). While prior evidence for UID comes primarily from word-level effects (Frank \& Jaeger, 2008; Jaeger, 2010; Levy \& Jaeger, 2007; Mahowald et al., 2013), a critical assumption underlying the UID hypothesis is that comprehenders should also be sensitive to the information density of alternative syntactically-complex encodings. To our knowledge, the current study is the first to investigate this important and challenging question.

We manipulated the syntactic encoding of complex noun phrases via meaning-preserving pre-nominal and postnominal modification in contexts that were either predictive or non-predictive. The results were consistent with the UID hypothesis. In predictive contexts, post-nominal encodings elicited a more uniform distribution of processing effort than pre-nominal encodings. This makes sense because the head noun is already expected in such contexts, thus prenominal modification could lead to a trough in information density at the noun. Conversely, in non-predictive contexts, a more uniform RT profile was found for pre-nominal encodings, where pre-modification served to reduce the surprisal of the unexpected head noun. This pattern of comprehension results provides indirect support for UID as a rational strategy for producers to adopt. An important question for further investigation is whether speakers are indeed attentive to such factors when making their encoding decisions.

#### Abstract

Theories that span tasks and developmental periods require explaining how a single cognitive system can flexibly adapt across contexts yet show stable age-related improvement. Here we present a computational model that embodies a unified theory of visuospatial cognitive development. We use this model to bridge between previously disconnected domains, as diverse as infant habituation and visual working memory capacity in adults. We illustrate how the same real-time and developmental processes can account for behavior across tasks and age groups. We conclude with a discussion of the implications of a unified theory for understanding cognition and development more broadly, with an eye toward early intervention.

Keywords: visual cognition; working memory; development; infancy; neural field model

## A Unified Theory of Visuospatial Cognition

A central challenge in cognitive science is to create theories that generalize across tasks and developmental periods. Computational models provide a concrete tool to confront this challenge. We illustrate this using a dynamic neural field (DNF) model of visuospatial cognition. Our goal is to explicitly connect the processes that operate across the range of behavioral tasks used from infancy through adulthood to measure different aspects of visuospatial cognition. By demonstrating that such disparate tasks and phenomena arise through common underlying processes, we can construct a broader theory to contrast with prior theories that have been proposed to account for only a single task and age group.

The unified theory of visuospatial working memory development we espouse is implemented in a single model architecture with a single developmental mechanism to explain change from infancy to adulthood. Here we show how this model can bridge between previously disconnected domains and developmental periods. We begin by describing the basic dynamics of DNFs. Next, we present the specific architecture we have applied across tasks and age groups. We then illustrate how this model can be used to account for visual and spatial working memory processes across tasks and development. Finally, we close by discussing the implications of our unified theory for understanding cognitive development and interventions that strengthen cognition in at-risk or developmentally delayed populations.

## Dynamic Neural Fields

DNFs belong to a larger class of bi-stable attractor networks
(Amari, 1977; Wilson \& Cowan, 1972) and simulate neural population dynamics to represent a continuous dimension, such as space or color (Schöner, Spencer, \& the DFT Research Group, 2015). DNFs have a functional topographic organization such that neighboring nodes within a field representing similar features (e.g., shades of blue in color, neighboring locations in space). In DNFs, a stimulus input excites selectively-tuned neurons which then interact through local excitatory and lateral inhibitory connections to create a localized "peak" of activation (illustrated in Fig. 1 below).

A peak in a DNF represents a real-time neuronal estimate of the stimulus. With relatively weak local excitation and lateral inhibition, peaks are only present when supported by input, that is, when the stimulus is present in the environment - we refer to this as an encoding state. With stronger connectivity, peaks can persist after a stimulus disappears (i.e., input is removed), which we refer to as a working memory state. Peaks leave excitatory memory traces, a simple Hebbian-type history of activation, that facilitate the re-formation of peaks at similar values (e.g., color, location) at future points in time. For example, when presented with a blue stimulus, the model will produce a peak that estimates the specific hue. The peak will leave a memory trace that facilitates the formation of a peak for the color blue at a future point in time. We will show that this feature of DNFs has implications for behavior in working memory tasks.

Multiple DNFs can be coupled together to create more complex neural architectures that simulate neurocognitive processes of encoding, maintenance, comparison, and recognition (described further below). To use such models to understand behavior, these neural architectures can be coupled to behavioral systems to generate the particular behavioral dynamics of interest - below we describe systems to simulate looking behavior, same/different judgments, or pointing/recall responses. In the next section, we describe a three-layer architecture that we have used to simulate performance in visuospatial working memory tasks from infancy to adulthood.

## A Three-Layer Dynamic Neural Field Model

Figure 1 shows the three-layer model (reviewed by Johnson \& Simmering, 2015; referred to here as the "dynamic model" for simplicity) used for the simulations we describe. This instantiation of the model consists of a fixation and visualcognitive system. The fixation system consists of a collection of nodes that represent looking to left, right, center, and away
locations in a virtual world. The nodes compete in a winner-take-all fashion. The winner (left node in Fig.1) opens a perceptual gate and the stimulus at that location (green and red) is input to the visual-cognitive system (see green arrow from virtual world to visual-cognitive system). The visualcognitive system consists of a perceptual field (PF), which receives input from the fixation system representing the color of the stimulus. This input creates peaks representing the stimulus; connectivity in this field is set to the encoding state described above. Activation in PF supports continued fixation through reciprocal connectivity (see green arrow from PF to virtual world) and also feeds into a working memory (WM) field (see green arrow from PF to WM). These fields interact through a shared field of inhibitory nodes (Inhib). When WM activity for an item is strong, WM sends strong activity to Inhib (see red arrow from WM to Inhib). This, in turn, suppresses activity for that item in PF (see red arrow from Inhib to WM). In addition to this threelayer (PF-Inhib-WM) architecture, the dynamic model includes memory trace (MT) layers associated with PF and

Figure 1. Three-layer dynamic neural field architecture, coupled to a fixation system viewing colors in a virtual world. Green versus red arrows indicate excitatory versus inhibitory connections; horizontal dashed lines indicate the zero threshold in each field. See text for further description.

WM that accumulate activation over a longer time scale (for simplicity, only $\mathrm{MT}_{\mathrm{WM}}$ is shown in Fig.1), serving the Hebbian function described above.

Figure 1 illustrates how the dynamic model simulates encoding, maintenance, and comparison of items in WM. A critical insight gained from applying this model across tasks and development is how the same real-time processes underlying these cognitive functions can produce a range of seemingly unrelated behavioral signatures (e.g., habituation, perseveration, novelty preferences, capacity limits, dimensional attention), as described below. At the moment represented in Figure 1, WM is maintaining the colors light green and orange, which has inhibited encoding in PF (see inhibitory troughs at sites tuned to light green and orange), which released fixation from the right location (see position in virtual world). This inhibition of encoding by WM is the mechanism of recognition in the model. After fixation was released from the right location in the simulation shown in Figure 1, the model fixated the left location and is encoding a dark green and red stimulus there. This is the mechanism of novelty detection in the model - fixating and encoding items not held in WM. Notice that the model has MTs associated with the light green and orange items. This will enable the model to form robust WM peaks for those colors in the future, which can support recognition of those items as familiar.

This simulation shows the dynamic model equipped with a fixation system that looks at multiple locations, which simulates looking behavior (Perone, Simmering, \& Spencer, 2011). To simulate the behaviors required by different visuospatial working memory tasks, the model can be used to generate continuous recall responses (e.g., pointing to a remembered location or color) based on peak positions (e.g., Spencer, Smith, \& Thelen, 2001) or equipped with a same/different response system (Johnson, Spencer, Luck, \& Schöner, 2009). Critically, however, each of these different behavioral responses is driven by the same underlying cognitive processes embodied in the three-layer architecture.

In the following sections, we synthesize recent applications of the dynamic model to provide a unified explanation of visuospatial cognitive processes across previously disconnected domains and development: habituation and visual recognition during infancy, and VWM capacity limits from infancy to early childhood and adulthood.

## Common Processes Underlying Visual Working Memory from Infancy to Adulthood

In this section, we describe how this model can account for behavior and development in three domains, highlighting that a single developmental mechanism produces change in all three domains. We begin by describing how the model links infant looking at a single location to WM formation in the habituation paradigm. Next, we show how the same model looks to multiple location in a visual recognition context, the visual paired comparison task. After that, we show how the same model can once again be adapted to explain visual working memory capacity limits in children and adults.

## Habituation

Infant looking paradigms form the foundation of our understanding of the origins of human cognition. Habituation of looking behavior has been used for half a century to probe perceptual, memory, and cognitive processes during infancy. In a typical habituation task, infants are presented with a single stimulus (e.g., blue circle). Initially, they exhibit high levels of looking which decreases with repeated presentation. They typically renew looking when presented with a novel stimulus (e.g., red star). Prior theories have not considered looking behavior a central part of the learning process (Cohen, 1972) but rather as an output. However, there is evidence that how infants distribute their looking through time structures what they learn (Jankowski, Rose, \& Feldman, 2001). To explore the interplay between looking and learning, Perone and Spencer (2013) used the dynamic model with a simple fixation system that stochastically oscillated between looking at a single stimulus and looking away. As described above, when the fixation node was looking to the stimulus, it opened a perceptual gate that sent input PF. Strong activation in PF supported continued looking and led to the formation of memory representations in WM and MT. When the WM representation grew robust across presentations, encoding in PF was inhibited (as described above), and looking was released. Thus, the dynamic model showed habituation in looking time, just as infants do.

Perone and Spencer (2013) tested whether the dynamic model could account for the developmental changes infants show in habituation tasks: faster habituation rates and the ability to make finer-grained distinctions with age. To simulate development in the visual-cognitive system of the dynamic model, they implemented the Spatial Precision Hypothesis (SPH). The SPH posits that the strength of excitatory and inhibitory connectivity within and between layers increases over development (see Simmering \& Schutte, 2015, for review). Implementing the SPH in the context of the habituation task led to faster, more stable WM formation and more robust novelty detection. This led to quick habituation and improved discrimination with age, just as infants show. The dynamic model's performance highlighted the link between visual exploration and learning. For example, spontaneous long looks helped WM form, which led to fast habituation. Conversely, spontaneous short looks led to slowed memory formation. This provides an explanation for how individual differences in visual exploration can structure learning. This highlights the importance of simulating real-time behavior in a model to understand how the cognitive system functions and develops.

## Visual Paired Comparison

The visual paired comparison (VPC) paradigm is commonly used to study visual recognition and categorization processes during infancy. VPC differs from the habituation paradigm in a critical way: it introduces competition. Infants are presented with pairs of stimuli and can freely look back and forth between them. This context yields a rich set of looking
measures, including shift rate (gaze switches per second of looking), look duration (mean duration of each look), peak look (longest look), and preferences (proportion of looking to one item greater than chance). Infants' recognition memory is assessed via pairing a previously seen, familiar item with a novel item. A preference for the novel item is evidence of both (1) recognition of the familiar item and (2) discrimination between the familiar and novel items (as illustrated in Fig.1). With age, infants exhibit faster shift rates, shorter look durations, shorter peak looks, more finegrained discrimination, and stronger novelty preferences. These looking behaviors develop more slowly in at-risk populations, such as preterm infants (e.g., Rose, Feldman, \& Jankowski, 2001).

The dynamic model can adapted to VPC by equipping it with a fixation system that looks at left and right locations (see Fig.1), compared to the single item/fixation location used for habituation. The dynamics of the visual-cognitive system are otherwise identical to the model simulations of habituation from Perone and Spencer (2013). Perone and Spencer (2014) asked whether this same model and developmental mechanism could account for the range of behavioral changes infants show over development in VPC. They probed this by testing infants' looking behavior and discrimination abilities between 5 and 10 months of age, then simulating the paradigm in the dynamic model. They found that infants exhibited faster shift rates, shorter look durations, and shorter peak looks with age. They also found that infants were able to make discriminations along a continuous metrically organized dimension by 7 months of age. The model exhibited the same behavioral pattern over development for precisely the same reasons as it did in the habituation paradigm: faster, more robust memory formation.

Perone and Spencer (2014) also analyzed individual differences. In particular, individual differences in looking during the learning phase of VPC predicted their discrimination abilities during the testing phase. This pattern was found in the dynamic model's performance as well. But where did these individual differences come from? There were no parameter changes to simulate "individuals" in the model; rather, the individual differences in patterns of performance were emergent. The structure of looking behavior that builds memory representations and supports discrimination in the dynamic model emerged autonomously. This parallels the insight gained from the simulations of habituation: infants' exploratory behavior in the task influenced the formation of memory, which in turn shaped their subsequent looking behavior. Although the processes at work in the habituation and VPC are generally considered similar, what infants remember in each paradigm is different (Oakes \& Ribar, 2005). This is the first theory to formally account for how the same learning process unfolds in both contexts.

## Capacity Limits over Development

One of the hallmarks of WM is its limited capacity. Visual working memory (VWM ) in particular is limited to only three or four items in adults (Luck, 2008). The majority of
work characterizing VWM capacity limits have focused on children and adults, with the change detection task being a common approach, shown in Figure 2A. In this task, a small number of simple items (e.g., colored squares) is shown briefly, followed by a brief blank delay, then a test array in which either all of the items remained the same or one has changed. Capacity estimates from this task (using a formula proposed by Pashler, 1988) have shown a gradual increase from early childhood through adolescence (Simmering, 2016; Simmering \& Perone, 2013). Studies with infants, however, present seemingly contradictory results, with estimates of capacity reaching adult-like levels within the first year of life (e.g., Oakes, Ross-Sheehy, \& Luck, 2006; Ross-Sheehy, Oakes, \& Luck, 2003). One way to address this apparent discrepancy across tasks and age groups is through the dynamic model framework presented here.

Figure 2. Sample trials from two tasks used to estimate VWM capacity: (A) change detection used with children and adults and (B) change-preference used with infants.

The task used to estimate capacity during infancy, shown in Figure 2B, is a variant of VPC called the change preference paradigm. Infants are presented with the same number of colored squares is presented on each of two displays. The squares briefly appear and disappear repeatedly throughout each trial; across these presentations, the colors in the "nochange" display remain the same; on the other "change" display, one color changes following each blank delay. Infants' fixation is tabulated over the course of the trial, and compared to chance (i.e., equal looking to both displays). Capacity is estimated from the highest set size (i.e., number of colors per display) at which infants show a reliable preference for the "change" display. The rationale behind this interpretation is that if infants can remember the colors within a display, the "change" display will appear novel and therefore support a looking preference. Ross-Sheehy et al. (2003) estimated capacity to be only one item at 6 months, but three to four items at 10 months. Oakes et al. (2006) then showed that the capacity increase from one to three items occurred between 6 and 7 months of age.

How can the change preference task yield a VWM capacity of 3-4 items at 10 months but the change preference task only yield a capacity of 1-2 items at 3 years? Perone et al. (2011) situated the dynamic model in the change preference
paradigm and showed that the SPH could account for the agerelated changes in capacity estimates during infancy. One intriguing finding from these simulations was that a robust preference in the model did not depend on holding all of the items in memory: that is, a preference for set size three did not necessarily reflect that three items could be held in WM. Perhaps this means that the items required to be remembered to yield different estimates differs across tasks. Simmering (2016) probed this possibility by situating the dynamic model in both the change preference and change detection task. In order for the dynamic model to simulate performance in the change detection task, it must be equipped to give the "same" or "different" responses required by the task. This type of response system can be implemented by building from the mechanisms of recognition and familiarity inherent in the model's visual-cognitive system (see Fig.1): peaks in WM indicate familiar items whereas peaks in PF indicate novel items. Thus, a simple system in which activation from WM projects to a "same" decision node, and activation from PF projects to a "different" decision node, can use these signals to general a discrete response on each trial (see Johnson \& Simmering, 2015, for further discussion).

Model simulations revealed that the two tasks used to estimate capacity showed different relationships between the underlying memory representations and the behavioral measures used to estimate it (Simmering, 2016). In particular, while simulations of the infant task suggested that behavioral estimates may over-estimate the number of items held in memory (Perone et al., 2011), simulations of adults' performance in change detection indicated it under-estimated the number of items held in memory (Johnson, Simmering, \& Buss, 2014). Simmering (2016) bridged these results from infancy and adulthood by testing young children in both types of capacity tasks, then directly comparing performance across tasks and simulating results within a unified model. Simulations showed that developmental changes in both tasks could be accounted for within the same model through strengthening connectivity. Furthermore, although the tasks yielded different estimates of capacity between 3 and 5 years of age - at least six items in the looking task versus only two to three items in the change detection task - the common underlying processes were evident in correlations across tasks. Motivated by the common processes that support the detection of novelty across the two tasks in the model, Simmering (2016) found that children's preference scores in the looking task were significantly correlated with their hit rates (i.e., proportion correct on change trials) in change detection. This relationship across tasks was not evident from considering only the capacity estimates from each task, but rather depended on a systematic understanding of how cognition and behavior relate.

## Spatial Cognition and Development

The preceding sections showcased the use of the same model and developmental mechanism to adapt across contexts and development for visual (featural) memory processes. In this section, we illustrate that the same model
can be adapted to account for performance in four spatial cognition tasks- (1) perseverative reaching in the Piagetian A-not-B task, (2) A-not-B-type biases in a sandbox task, (3) reference-related biases in spatial recall and (4) similar biases in position discrimination. Moreover, we show that developmental change across all of these domains was explained with the SPH.

## A-not-B Tasks

Beginning with the A-not-B task (cf. Thelen, Schöner, Scheier, \& Smith, 2001), weaker connectivity to simulate early infancy (8-10 months) led to perseverative reaching because the peak representing the second (B) location was not strong enough to overcome the history of reaches at the first location (A). With stronger connectivity to capture development, this peak could be maintained accurately through the delay to support accurate reaching as seen in older infants (10-12 months).A similar interaction between memory for the current target and prior reaches can be seen in older children's performance in a sandbox version of the A-not-B task (e.g., Schutte, Spencer, \& Schöner, 2003; Spencer, Smith, \& Thelen, 2001). Children between the ages of 2 and 6 years show recall responses that are biased toward previously-remembered locations, with a developmental change in the spatial spread of this influence - younger children's performance is biased over larger separations than older children's (Schutte et al., 2003). This metric change in the influence of reaching history in the task has been simulated first through changes in the spread of activation within the three-layer architecture (Schutte et al., 2003) and later through changes in only the strength of connectivity (Simmering et al., 2008; see Simmering \& Schutte, 2015, for further discussion). By showing that the SPH can account for changes in infants' performance in the canonical A-not-B task as well as the metric changes during early childhood, this model architecture brought together previously disconnected age groups and tasks into a unified framework.

## Spatial Recall \& Discrimination

Young children's performance in spatial recall tasks also shows influences of the spatial structure of the space, in addition to prior history of reaches. Specifically, young children recall locations as closer to the midline symmetry axis of the task space, whereas older children and adults recall locations further from midline and the edges of the task space (see Spencer, Simmering, Schutte, \& Schöner, 2007, for review). These effects can be simulated in the same three-layer architecture through the coordination between perceptual and memory processes in the sandbox or "spaceship" tasks. As connectivity strengthens over development, the representation of information in both perception and memory lead to the transition in bias (Schutte \& Spencer, 2009, 2010). These processes operate continuously through time, and can be detected even in the brief delay of position discrimination tasks, linking together previously disconnected areas of research (Simmering \& Spencer, 2008).

## Implications and Future Directions

We presented a unified theory of working memory development that spans an impressive number of domains and periods of development. Importantly, this was only possible by using a concrete tool - a computational model to tackle the difficult challenge of explaining cognition across domains and development. There are a number of implications of this work. First, our theory indicates that cognitive processes are not domain specific. Instead, the same general visual-cognitive system can account for multiple neurocognitive processes by organizing itself differently in different contexts with different behavioral demands. These include infant habituation (looking), visual working memory capacity (same/different judgments), and spatial recall (position estimation). Second, our theory indicates that the developmental mechanisms that drive change across domains are not unique. We showed that the SPH could account for changes in performance across multiple domains and radically different periods of development. Last, our account raises the intriguing possibility that we can target basic visual-cognitive processes to strengthen early in development, which may have an impact across many domains and over a long period of time.

One long-term goal of employing such a computational framework is to make further connections across age groups and domains, and to provide a mechanistic account of how behavior emerges in specific task contexts. Such examples can already be found in the domains of executive function (e.g., Buss \& Spencer, 2014; Perone, Molitar, Buss, Spencer, \& Samuelson, 2015) and word learning (e.g., Samuelson, Schutte, \& Horst, 2009; Samuelson, Smith, Perry, \& Spencer, 2011). By connecting the same real-time processes of encoding, maintaining, and comparing visual inputs with the longer time-scale of learning in contexts that connect to verbal labels, we can test how far relatively simple cognitive mechanisms can go toward explaining complex behaviors (cf. Smith, Jones, \& Landau, 1996).

## Acknowledgments

Both authors contributed equally to this work. Thanks to Aaron T. Buss, Christian Faubel, Jeffrey S. Johnson, John Lipinski, Yulia Sandamirskaya, Sebastian Schneegans, Gregor Schöner, Anne R. Schutte, and John P. Spencer for helpful discussion and support during the development of this line of research.

#### Abstract

Risky decisions involve cognitive and emotional factors. As the primary test for the Somatic Marker Hypothesis (SMH), the Iowa Gambling Task (IGT) examines these factors. Skin conductance shows anticipatory physiological responses on the IGT supporting SMH. Pupil dilation offers an alternative physiological marker. Predictive effects of anticipatory pupillary responses to positive and negative decks on IGT performance were examined in an extended IGT. The extended Cognitive Reflection Test (CRT) examined the relationship between reflective thinking and IGT performance. Data demonstrated correlations between reflective thinking and performance from the second block onwards and that task learning continued into the additional blocks - performance was not optimized even in the final block. Regression analysis showed both anticipatory pupil dilation for disadvantageous and advantageous decks, and reflective thinking were strong predictors of IGT performance. While both emotional and reflective processes are implicated in IGT performance, analytic cognition is more important than traditionally acknowledged.

Keywords: Pupil dilation; Iowa Gambling Task; Cognitive Refection; Somatic Marker Hypothesis; Dual-process Theory.

## Introduction

Learning and decision making in uncertain situations is an important activity, and it can be challenging to find an optimal decision even for simple choices. Decisions can be driven by the desire to maximize expected utility (Quartz, 2009), but information management regarding reward utility is frequently uncertain. Cognitive and emotional influences on risky decision making were traditionally regarded as separate in nature, with emotional factors typically seen as a hindrance. However, more recent evidence indicates that there is an interplay between the two, such that cognitive functions may serve as moderators for emotion-based learning (e.g. Brevers, Bechara, Cleeremans, \& Noel, 2013; Simonovic, Stupple, Gale \& Sheffield, 2016).

Damasio (1994) developed Somatic Marker Hypothesis (SMH) arguing that emotional processes play a central role in risky decision-making. SMH postulates that decisions are guided by subjective 'gut feelings' (e.g. bodily representations) about the inherent goodness or badness of future choices. These somatic markers direct individuals towards alternatives that have been positive previously or guide them away from the negative options. Particularly in uncertain conditions, response options are marked with an emotional signal, and only those options that are marked as favorable are cognitively processed (Damasio, 1994; Bechara \& Damasio 2005). Somatic markers operate covertly, indicate arousal anticipation and are regarded as physiological markers of emotion-based learning (Bechara \& Damasio, 2005; Critchley et al., 2001).
A further theoretical framework for investigating risky decision making is Dual Process which proposes that there are two types of cognitive process: unconscious, emotional gut-feelings (Type 1) that contrast with explicit, effortful, analytic processes (Type 2) (e.g. Kahneman. 2003). This proposal has been linked with SMH; for example Type 1 processes include a range of intuitive processes such as emotional responses or gut feelings (Glockner \& Witteman 2010) that can be measured through physiological techniques. There is also evidence of a role for cool reflective processing (Brevers, Bechara, Cleeremans, \& Noel, 2013; Simonovic et al., 2016) which maps onto Type 2 processing.
The primary paradigm in evaluation of emotion-based learning is the Iowa Gambling Task (IGT, Bechara, Damasio, Damasio, \& Anderson, 1994). The IGT offers a means of testing decision preferences and performance and has become an important experimental tool in evaluation of emotion-based learning and decision making. It has been argued that IGT resembles real life decision making as it involves uncertainty and monitoring of rewards and punishments (Bechara \& Damasio, 2005). Participants are
required to choose cards from four decks ( $\mathrm{A}, \mathrm{B}, \mathrm{C}$, and D ), all of which differ in frequencies of financial rewards and punishments. Advantageous decks (C and D) offer moderate rewards and small punishments whereas disadvantageous decks (A and B) offer larger rewards but substantial penalties, which result in an overall loss.
During the IGT, participants need to learn from experience about the 'goodness' or 'badness' of decks based on the feedback of learned contingencies. Thus, while participants experience deck reward properties they also assign affective values to the decks which implicitly influence decision making. The standard IGT consists of five blocks of 20 trials and healthy participants are considered to reach ceiling performance in the final block as the disadvantageous selections have been extinguished. Optimal IGT performance rests therefore on monitoring emotional responses and impulse inhibition related to the rewards and punishments (e.g., Bechara \& Damasio, 2005).
An important finding for SMH is that anticipatory somatic markers of emotions occur before decisions are made, indicating that covert anticipatory emotions can guide decision making (e.g. Bechara, Damasio, Tranel \& Damasio, 1997). Indeed, there is evidence demonstrating anticipatory Skin Conductance Responses (aSCR) to rewards and punishments under uncertain conditions (e.g. Bechara et al., 1997; Wagar \& Dixon 2006). Furthermore, interpretation of these aSCR's highlight the primary role of emotions in guiding decision making performance (e.g. Bechara \& Damasio, 2005).

In contrast, there is also evidence that reflective evaluation of affective choices guides future decisionmaking and occurs relatively early in the decision-making processes (e.g. Bowman, Evans, \& Turnbull, 2005 Brevers et al., 2013; Simonovic et al., 2016). This evidence is consistent with an interplay between Type 1 and Type 2 processes in determining the outcome of the decision making process (cf. Kahneman, 2003). Indeed, Brevers et al. (2013) argued that anticipation of long-term consequences in uncertain condition rely on two neural systems: a 'cool' and a 'hot' systems. The 'hot' system is impulsive, laden with affective 'gut feelings' akin to intuition, while the 'cool' system is reflective and includes analytic aspects. Learning and optimal decisions depend on the integration of both systems whereby, a 'cool' reflective process can be critical in monitoring or inhibiting 'hot' processes. It has also been argued that cool reflective processes should not play a role until the deck contingencies become explicit and so there should not be a role for Type 2 processing in the early blocks. Simonovic et al., (2016), however, demonstrated that reflective processes play a role earlier than previously predicted (cf. Schiebener, Zamarian, Delazer and Brand 2011).
Evidence suggest that aSCRs represent a good example of anticipatory somatic markers or 'hot processing'. They are, however, imperfectly represented because the SCR is not sufficiently sensitive in discriminating between negative and positive valence (Dunn et al., 2006). Faster measures of
emotion feedback (e.g. heart rate and blood pressure with an electrocardiogram or pupil dilation using eye trackers) are warranted (e.g. Bradley, Codispoti, Cuthbert \& Lang, 2001). Indeed, studies that use faster physiological measurement, (e.g. eye-tracking methodology) can better capture surprised responses to unexpected stimuli (e.g. Lavin, San Martin, \& Jubal, 2014).
Recent studies have also shown pupil dilation can measure surprise such as when feedback does not meet expectation (Preuschoff, Hart, \& Einhauser, 2011), when negative feedback occurs during the gambling task (Satterthwaite et al., 2007), and as evidence of learning (Lavin et al., 2014). Moreover, there is evidence linking pupillary responses to Locus Coeruleus (LC) - norepinephrine (NE) activity in the brain stem in anticipation of a reward, suggesting memory enhancement (Tully \& Bolshakov, 2010), and consolidation of behavioural decisions (Bouret \& Sara, 2005). Some evidence indicates greater pupillary responses before selecting negative options (e.g. Bierman, 2004), or after experiencing unexpected losses (Satterthwaite et al., 2007), thus indicating that anticipatory pupillary responses can be related to negative outcomes. However, Lavin et al. (2014) argue that pupillary responses are associated with positive feedback. Thus, although anticipatory pupillary responses serve as affective physiological markers and may offer a measure of the somatic markers that moderate learning in uncertain conditions their interpretation is also not necessarily straightforward.

To our knowledge, only one study has utilised eyetracking methodology during the IGT performance in a healthy population. Lavin et al. (2014) tested IGT performance and measured pupil dilation in a sample of 10 participants and demonstrated changes in pupil dilation due to learned uncertainty. Their results suggest that changes in pupil dilation reflect learned uncertainty about future feedback conditions, thus indicating differential processing of unexpected feedback. However, a non-standard version of the IGT was used and did not differentiate between disadvantageous and advantageous deck selection. In the present study, we extend Lavin et al.'s (2014) findings, with a larger sample and an alternative approach to measuring anticipatory pupil dilation.

Our focus was on the period during the IGT where participants had hypothetically developed somatic markers but that these were not yet sufficient to extinguish particular card selection. On this basis we measured pupil dilation in the 500 ms prior to the final selection from each deck and hypothesized that there should be somatic markers indicating negative anticipation for disadvantageous decks and positive anticipation for advantageous decks. We measured anticipatory pupillary responses for the advantageous $(\mathrm{C}+\mathrm{D})$ and the disadvantageous $(\mathrm{A}+\mathrm{B})$ final options. If anticipatory somatic markers play a role in IGT performance then these should be evident prior to the final selection of each type of card.

Moreover, we included a direct measure of deliberative thinking to replicate previous findings demonstrating that
the CRT was highly predictive of IGT performance (Simonovic et al., 2016). We used the extended seven-item Cognitive Reflection Test (CRT ${ }^{1}$ ), developed to measure the ability to resist and override intuitive responses by engaging analytic ability (Toplak, West, \& Stanovich, 2014), this is a more comprehensive measure than the original three item CRT used in the Simonovic et al. (2016) study.

It was predicted that the CRT and last anticipatory pupillary responses for advantageous and disadvantageous deck picks would predict IGT performance. It was also predicted that the correlations observed by the Simonovic et al., (2016) between CRT score and disadvantageous card selections across blocks would be replicated (such that strong correlations would be found in blocks $2-4$, but no correlation would be observed in the early trials and the correlation would be reduced in the final blocks). Finally, the standard analysis of IGT performance across blocks was extended to test whether performance reached ceiling levels in the fifth block (the final block in the standard IGT) or whether performance continued to improve.

## Method

## Design

Predictor variables were: the seven-item CRT (Toplak et al., 2014) and pupillary responses averaged across the 500 ms prior to the final selection for both advantageous (C $+\mathrm{D})$ and disadvantageous $(\mathrm{A}+\mathrm{B})$ decks. The CRT was used as a measure of analytic thinking. The dependent variable was the IGT score. Performance across blocks was also examined for completeness with $(\mathrm{C}+\mathrm{D})-(\mathrm{A}+\mathrm{B})$ as the dependent variable for performance in each block

## Participants

Sixty-nine ${ }^{2}$, healthy students from the University of Derby, aged 19-29 years, received course credit for participation. Research was conducted in accordance with stipulations of the local ethics committee. Participants had normal or corrected to normal vision.

## Materials and Procedure

Participants completed Bechara et al.'s (1994) computerised version of $\mathrm{IGT}^{3}$. Scoring was derived by deducting 'good' card picks ( $\mathrm{C}+\mathrm{D}$ ) from total 'bad' picks $(\mathrm{A}+\mathrm{B})$. A positive score indicates a more optimal decisionmaking strategy.

[^495]The seven-item CRT (Toplak, West \& Stanovich, 2014) score was the total number of correct answers. Higher CRT scores indicated higher reflective ability. Cronbach's alpha was $\alpha=$. 66 .
Eye movements were recorded with the Eye-gaze binocular system Tobii-X2-30 (Inquisit 4 milliseconds plugins), with a remote binocular sampling rate of 30 Hz and an accuracy of about $0.45^{\circ}$. The X2 Eye Tracker is a stand-alone eye tracker, and it was attached to a laptop (Dell, Precision M6700, 2.70Ghz). Participants were seated approximately 70 cm from the laptop monitor. The Tobii measured 184 mm ( $7.2^{\prime}$ ') in length and enabled tracking at close distances (up to $36^{\circ}$ gaze angle). The eye-tracker used both bright and dark pupil illumination setups to calculate the optimal gaze position. Blinking periods were filtered and replaced via linear interpolation (e.g. Siegle, Steinhauer Carter, Ramel, \& Thase, 2003). The anticipatory pupil dilation (aPD) diameter was defined as the mean pupillary response generated 500 ms before card selection. A 500 ms time frame was identified a priori as a period where fixation occurs, and direction of the information search can be determined (e.g. Horstmann. Ahlgrimm, \& Glockner, 2009).

## Analytic Strategy

Initial analyses focused on participants' performance per block by using repeated measures ANOVA. Next, correlations between CRT scores and selection of disadvantageous cards for each block were calculated. Finally, regression analysis was used to examine the independent contributions of CRT scores and pupil dilations on IGT performance. Analysis was conducted using IBM SPSS 24 for Windows.

## Results

Performance across blocks was tested using a Greenhouse-Geisser adjusted repeated measures ANOVA. There was a main effect of Block condition, $\mathrm{F}(3.86,239.12)$ $=25.21, \mathrm{p}<.001, \eta_{\mathrm{p}}{ }^{2}=.29$. Bonferroni adjusted post hoc tests demonstrated that performance improved significantly through the blocks of trials (excluding Block 6). Notably the nonstandard additional blocks 6 and 7 continued to show changes in performance relative to earlier blocks such that performance dipped in Block 6 but Block 7 was significantly better than all but Block 5. Means and standard deviations are shown in Table 1.

Table 1: Mean (SD) IGT Performance as a function of Trial Block.

| Trial Block | IGT Performance |
| :--- | :--- |
|  |  |
| Block 1 | $-3.65(6.29)$ |
| Block 2 | $-.016(7.71)$ |
| Block 3 | $2.76(8.79)$ |
| Block 4 | $4.19(10.45)$ |
| Block 5 | $7.38(9.75)$ |
| Block 6 | $5.86(11.24)$ |
| Block 7 | $9.35(9.63)$ |
| Total | $26.27(46.70)$ |

Table 2: Correlations between Disadvantageous card selections and CRT score as a function of Trial Block

| Trial Block | Correlation |
| :--- | :--- |
| Block 1 | $\mathrm{r}=-.18, \mathrm{p}=.150$ |
| Block 2 | $\mathrm{r}=-.41, \mathrm{p}=.001$ |
| Block 3 | $\mathrm{r}=-.74, \mathrm{p}<.001$ |
| Block 4 | $\mathrm{r}=-.81, \mathrm{p}<.001$ |
| Block 5 | $\mathrm{r}=-.70, \mathrm{p}<.001$ |
| Block 6 | $\mathrm{r}=-.71, \mathrm{p}<.001$ |
| Block 7 | $\mathrm{r}=-.67, \mathrm{p}<.001$ |
| Total | $\mathrm{r}=-.89, \mathrm{p}<.001$ |

Correlations between CRT score and selection of disadvantageous cards across blocks were conducted (see Table 2). These demonstrated a significant negative relationship between CRT score and disadvantageous card selections in all but the first block of trials.
A multiple regression (Enter method) tested the relative predictive strength of last anticipatory pupillary responses for disadvantageous ( $\mathrm{A}+\mathrm{B}$ ) (mean, $\mathrm{SD}=3.02,0.36 \mathrm{~mm}$ ) and advantageous $(\mathrm{C}+\mathrm{D})$ (mean, $\mathrm{SD}=3.00,0.38 \mathrm{~mm}$ ) deck picks and CRT scores (mean, $\mathrm{SD}=2.13,1.76$ ) for performance on the IGT. Data indicated that the three predictors combined reliably accounted for $35 \%$ of the variability in IGT scores. The standardized beta for disadvantageous cards showed a negative correlation with pupil dilation while the advantageous cards showed a positive correlation. This indicated that increased pupil dilation on the last pick of a disadvantageous card predicted poorer overall performance in contrast with increased pupil dilation for advantageous cards which was associated with better overall performance. The CRT score was the strongest predictor with higher scores on the CRT predicting better card selections.

Table 3: Multiple Regression Analysis of CRT, Final Anticipatory Pupil Dilation for Disadvantageous (AB)

Decks, Last Pupil Dilation for Advantageous (CD) decks as predictors (standardized betas) of IGT performance

| Predictors |  |
| :--- | :--- |
| Model 'Enter.' | $\mathrm{R}^{2}=.38, \mathrm{R}^{2}{ }_{2 d j}=.35$ |
|  | $\mathrm{~F}(3,58)=12.03, \mathrm{p}=.001$ |

$\begin{array}{ll}\text { CRT scores } & \beta=.56, \mathrm{p}<.001 \\ \text { Last aPD }(\mathrm{A}+\mathrm{B}) & \beta=-.46, \mathrm{p}=.05 \\ \text { Last aPD }(\mathrm{C}+\mathrm{D}) & \beta=.52, \mathrm{p}=.03\end{array}$
Durbin Watson $=1.93$, VIF $=1.042 ; 4.965 ; 4.992$

## Discussion

Consistent with our predictions anticipatory pupillary responses and reflective thinking were reliable independent predictors of IGT performance. Importantly, pupillary responses differ according to the nature of the deck and incrementally predict performance in addition to cognitive reflection. Specifically, increased pupil dilation on the last pick of disadvantageous cards predicted poorer overall performance, whereas increased pupil dilation for the last pick of advantageous cards was associated with better overall performance. This is important because it indicates that differing somatic markers may develop for advantageous and disadvantageous decks and that these predict task performance alongside cognitive reflection.
Correlations between CRT scores and IGT broadly replicated the findings from the control group in Simonovic et al., (2016) but with stronger correlations and evidence that reflective processing is implicated even earlier in the task. Finally, block by performance analysis demonstrated that IGT performance did not reach ceiling at block 5 and significantly improved in block 7 after a (non-significant) dip in block 6, albeit it was not greater than block 5.

While our data indicate that participants' last aPD responses predict IGT performance, these somatic markers require some deciphering. Pupil dilation can be interpreted in various ways with anticipated threat, anticipated reward and general cognitive effort all potentially resulting in dilated pupils. Our data showing increased pupil dilation for advantageous deck is consistent with participants anticipating a positive outcome rather than a threat. However, it is possible that an increased level of cognitive effort may be in play (which would also be consistent with the correlations with cognitive reflection). Irrespective of the precise interpretation these data demonstrate a role for somatic markers in performance on the IGT, but allow for the possibility that these somatic markers are of cognitive effort as well as an indicator of emotional learning.

Pupillary responses data for the IGT contributes to the understanding of SMH and support a role for anticipatory physiological mechanisms in successful performance on risky decision-making tasks. These somatic markers inform explicit knowledge and facilitate learning of deck contingencies (e.g. Bechara \& Damasio, 2005). However,
our findings are incongruent with the proposition that IGT performance is primarily dependent on the development of somatic markers (Bechara et al., 1997; Wagar \& Dixon, 2006) and are instead compatible with the dual-process model where 'cool' reflective processes inhibit impulses that interfere with long-term goals. This is consistent with the proposition that integrating reflective and emotional processes is necessary to explain IGT performance and suggests that the ability to reflect on gut feelings about decisions may improve performance (Schiebener et al., 2011; Simonovic et al., 2016).

The CRT was shown to be a stronger predictor of IGT performance than the pupil dilation measures, with higher scorers clearly outperforming lower scorers. This is clear evidence that Type 2 reflective processing plays a salient role in the task and supports the view of Brevers et el. (2013) that the IGT is best understood within a dual process framework. Toplak et al.'s (2014) extended seven item version of the CRT was used and the more comprehensive nature of this measure along with the greater variability may explain the stronger correlations and greater proportion of variance explained than in Simonovic et al. (2016). The evidence from the correlations between CRT and performance across the blocks replicated findings from Simonovic et al. (2016). These data indicate a consistent role for analytic ability in determining IGT performance from the second block onwards. This is inconsistent with the view that the learning on the task is implicit until the contingencies are well established and is instead indicative of a role for explicit monitoring of deck contingencies even in the early blocks.

These CRT data nonetheless need to be interpreted with caution. There is debate as to whether the CRT is a measure of cognitive miserliness or a more general measure of analytic thinking or numerical ability as it has been correlated with both working memory (e.g., Stupple et al., 2013) and risk neutrality (Oechssler, Roider, \& Schmitz, 2009), which could impact on performance or task strategy.

Most of our participants began the task by exploring disadvantageous decks $(\mathrm{A}+\mathrm{B})$. Hence it could be argued that a reduced pupillary reaction for disadvantageous cards in relation to IGT performance occur because participants had 'unlearned' the initial preferences for big reward. This is consistent with a suggestion that during the IGT performance reversal learning, needs to be implemented to suppress learned preferences that are no longer beneficial (Dunn, Dalgleish, \& Lawrence, 2006). Lavin et al. (2014) suggest that successful performance on IGT depends on positive feedback (based on the money gain) and highlighted pupillary responses to unexpected punishments on positive decks. This proposal is consistent with as both are indicative of anticipatory effects, as both are indicative of anticipatory effects, however, the differing methodologies of the current study and Lavin et al.'s make direct comparisons difficult.

Since the SCR has a relatively slow time course, it is possible that a distinct somatic marker cannot be
distinguished by conventional SCR measurements (Newell \& Shanks, 2014). The use of an eye-tracker allows a distinction between somatic reactions on different options before a decision has been made. This is particularly important because the anticipatory SCR captured during the IGT performance may represent part of a broader response such as attentional bias, implicit learning and a risk-taking.

Steingroever et al. (2013), called for greater scrutiny of IGT performance in healthy populations to bolster the ecological validity of IGT and demonstrate that IGT scores measure real-life decision making. The validation of IGT performance in healthy population is of great importance for such a widely used clinical tool; our analyses add to this literature on healthy populations. The prominent role of cognitive reflection in IGT performance leads us to urge caution in its application in diagnosing emotional deficits in populations who may lack the working memory capacity to perform well on the CRT and, by implication the IGT.

The measures used in the present study are relatively narrow and further applications of the pupil dilation methodologies are necessary to more fully explore the utility of this measure in investigating the IGT and the SMH more broadly; in particular, extending analysis across the task to examine how pupillary responses relate to IGT performance curves may be illuminating. Moreover, alternative eye-tracking measures such as fixations on particular decks of cards offer strong potential in investigating the locus of explicit attention as learning progresses on the task.

In conclusion, our data demonstrated that a combination of anticipatory pupil dilation and reflective thinking predicted IGT performance, such that both emotional and reflective processes are implicated in IGT performance. That is, anticipatory pupil dilation may serve as learning markers particularly for individuals with higher levels of cognitive reflection. Analytic cognition, moreover, plays a more salient role than traditionally acknowledged.

# Talking Through Your Arse: Sensing Conversation with Seat Covers 

Sophie Skach (s.skach@qmul.ac.uk)<br>School of Electronic Engineering and Computer Science, Queen Mary University of London, E1 4NS<br>Patrick G. T. Healey (p.healey@qmul.ac.uk)<br>School of Electronic Engineering and Computer Science, Queen Mary University of London, E1 4NS<br>\section*{Rebecca Stewart (rebecca.stewart@qmul.ac.uk)}<br>School of Electronic Engineering and Computer Science, Queen Mary University of London, E1 4NS

#### Abstract

People move in characteristic ways during conversation and these movements correlate with their level of particpation. For example, speakers normally gesture significantly more than listeners. These visible, overt movements are normally analysed using full body video or motion capture. Here we explore the potential of a 'minimal' approach to sensing these participatory movements in part of the natural environment of everyday interactions; chair seat covers. Using custom built fabric sensors we test whether we can detect people's involvement in a conversation using only pressure changes on the seats they are sitting in. We show that even from this impoverished data we can distinguish between talking, backchanneling and laughter; each state is associated with distinctive patterns of pressure change across the surface of the chair. We speculate on the possible applications of this new, unintrusive form of social sensing for architecture, performance and augmented human interaction.

Keywords: human interaction; dialogue; non-verbal communication; social sensing; smart textiles; posture analysis; fabric sensors;

## Introduction

People make a variety of distinctive body movements during conversation. The most commonly studied of these are the gestures that speakers produce while talking. These include gestures that contribute to the content of what is said, such as iconics, metaphorics and pantomimes (McNeill, 1992; de Ruiter, 2000), as well as gestures that help to orchestrate the interaction such as beat gestures and gestures that can hold or hand over the turn to someone else (Bavelas, Chovil, Lawrie, \& Wade, 1992; Healey \& Battersby, 2009). Listener's body movements are also organised in characteristic ways. Most obviously through the production of concurrent feedback or 'backchannels' (Yngve, 1970). Although these are often produced as non-interruptive verbal acknowledgements such as a brief "aha" or "mmhm" people also frequently backchannel by nodding in response to an ongoing turn. Listeners are also distinguished from speakers by their relative lack of hand movement although they move their hands much more when a speaker requests clarification or makes repairs to their turn (Healey, Plant, Howes, \& Lavelle, 2015).

The significance of this non-verbal choreography is illustrated by how much we can infer about an interaction from
the observation of body movements alone. We can often tell just by looking at who is talking to whom, who -if anyone- is listening, who is likely to speak next, whether the interaction is hostile or friendly and so on (Kendon, 1990). These inferences from non-verbal performances can be striking; people appear to be able to make reliable estimates of the quality of someone's teaching over a whole semester from a single 5 second video of body movements alone (Ambady \& Rosenthal, 1992).

Research on non-verbal communication has tended to focus on these relatively large scale overt body movements; they are the easiest signals for participants to perceive and respond to and the most tractable for analysis (although see e.g. Ekman \& Friesen 1969). Research typically takes advantage of video and, more recently, motion capture equipment to capture and analyse these movements (e.g. Healey \& Battersby 2009; Vinciarelli et al. 2009. The rapid development of new sensor technologies and their application to social signal processing has opened an intriguing new space of possibilities for detecting patterns of interaction (Vinciarelli, Pantic, \& Bourlard, 2009). For example, it is possible to detect people's levels of interest, stress and intoxication in conversation using the speech signal alone i.e. without knowing anything about the content of what is said (B. W. Schuller \& Rigoll, 2009; B. Schuller et al., 2013). In contrast to relatively intrusive technologies such as video or automatic speech recognition, this approach makes it possible to create anonymised 'minimal' forms of social sensing by using textile technology (see also e.g. Rekimoto 2001).

Here we explore the potential of this approach for one of the most commonly used parts of the physical environment for social interaction; chairs. Even the shape and position of unoccupied, uninstrumented chairs can indicate a great deal about interaction; chairs around a small table suggest something very different from chairs in rows (see also Anderson 1996). Moreover, chair covers are often made out of stretch and soft fabric that makes the textile surface itself a potentially promising sensing material. Using metallic yarn gives a fabric conductive properties so that it can be turned into a
pressure sensitive surface. Different possibilities of using textile surfaces as sensing materials or interfaces for electronic devices have been explored in recent years, for example by turning a jacket into an interface to a mobile phone (Poupyrev et al., 2016) or by measuring biomechanical data for healthcare applications (e.g. Pacelli et al. 2006). Here we apply a similar fabrication technique to chair covers to address the basic question of whether it is possible to detect patterns of conversational interaction from movements on the chair surface alone.

## Sensing Chairs

Informal observation suggests that people frequently change the position of the torso, lower body, and feet during seated conversations. These movements necessarily cause pressure changes on the surface of the chair and are therefore potentially detectable by measuring changes in resistance. Previous work has investigated the use of chairs to classify postures through pressure sensors, creating pressure maps of both, static and dynamic postures - posture identification versus continuous tracking (Tan, Slivovsky, \& Pentland, 2001; Slivovsky \& Tan, 2000). A commercially available pressure measurement system, BPMS (Body Pressure Measurement System) by Tekscan ${ }^{1}$ has been used in some of these research projects (e.g. D'Mello et al. 2007 and Arnrich et al. 2010), which consists of a plastic mat with 64 integrated pressure sensors that allow for the creation of detailed pressure maps. The main applications for these sensing systems have been in the analysis of posture to improve seating comfort (e.g. Milivojevich et al. 2000), designs for objects involved in rehabilitation (e.g., wheelchairs) and Human-ComputerInteraction. For example, presenting chairs as novel haptic interfaces for computer games (Tan, Slivovsky, \& Pentland, 2001), or as a system to measure people's cognitive states in various situations Arnrich et al. (2010), including measuring a car driver's fatigue (Furugori, Yoshizawa, Iname, \& Miura, 2003) or identifying drivers (Riener \& Ferscha, 2008), as well as measuring boredom in students (D'Mello, Chipman, \& Graesser, 2007). However, this approach has not previously been applied to sensing aspects of social interaction. With this study, we explore what information about social behaviour can be retrieved from pressure sensor data on a chair.

## Methods

Drawing on informal observations of people's leg and torso movements in meetings we decided on a configuration of eight sensors that were integrated in the chair cover and distributed in a symmetric arrangement; four in the seat of the chair and four on the back (see Figure 1), dividing the chair into four key areas to be sensed in order to determine postures: shoulders (at the top of the back rest), waist (lower back), buttocks and thighs. These observations also laid the basis upon which initial hypotheses about different states in a conversation were built.

[^496]

Figure 1: Reverse side of the chair cover showing sensors.

## Sensor Development

The textile sensors were made from conductive fabric and resistive foam, hand sewn into soft sensor patches that were manually attached to the backside of a chair cover (which was made of jersey knit fabric). The conductive fabric, SaniSilver, was purchased from LessEMF and woven with a silver yarn showing on one side of the fabric and a cotton yarn visible on the other. The sensors are constructed such that two swatches of conductive fabric are facing the resistive foam on both sides. When pressure is applied to the conductive fabric on either side of the foam, the foam compresses and reduces the resistance between the two fabric swatches. This change in resistance is measured by the microcontroller. The sensors have the advantage of behaving like an ordinary fabric that could also be used in other wearable applications, such as garments (since, through the use of cotton fibre, the fabric retained a soft touch and remained comfortable to wear).

## Data Collection

A microcontroller (a Teensy 3.2) collected the pressure data from the sensors and stored it on micro SD cards. The sampling frequency of the sensors was 4 readings per second. Using these piezoresistive sensors, the unit of measure is Ohm $(\Omega)$. Since the aim was to investigate postural behaviour in a situation of social interaction, three chair covers were manufactured, each housing one micro controller that were placed underneath the chair. Wires were hooked into the conductive fabric and connected the sensors with the Teensy (to ground and to an assigned analog pin providing 3.3 volts to run the programme, which read analog output values from the sensors).

## Participants

Participants were recruited in groups of three friends or colleagues to ensure they all had some initial level of familiarity
with each other. We conducted 9 trials in total, collecting data from 27 participants, of which were 11 female and 16 male and between the age of 20 and 40.

## Procedure

The experiment was carried out in the Human Interaction Lab at Queen Mary University of London. Groups of three participants were asked to resolve a moral dilemma: the balloon task. This is a fictional scenario describing three people in a hot air balloon that is about to crash, if not one of the passengers jumps to their certain death. The task is then to come to an agreement of who to throw off. The participants were told that the aim of the experiment is to investigate collaborative interaction. They were seated at a round table and asked to discuss options and come to an agreement on how to resolve this dilemma. We aimed to record 15 to 20 minutes of conversation, so if not having come to an agreement after this time, participants were given the option to stop the conversation or carry on (vice versa, if they came to an agreement faster, alternative scenarios were provided to encourage further discussion). Due to the materiality of the sensors, the presence of the sensor patches was not noticed by the participants, so that the experience wasn't different to sitting on a common chair.

## Data Analysis

The interactions were captured on two cameras placed in different corners in the room. Lapel microphones were used to facilitate speaker-specific analysis of the audio for transcription. The data from the video recordings was annotated using Elan (Brugman, Russel, \& Nijmegen, 2004). Coding focused on three key behaviours with: speaking, laughter and backchannels. When determining speaking modes, periods of overt speech were coded, regardless of postural and gestural changes, or nodding. But focusing on postural movement overall, it was noticed that often, a postural or gestural change was performed immediately prior to speaking. This makes the start of an utterance ambiguous. For the purposes of this study, the beginning of utterances was defined as the onset of speaking. For laughter, responsive as well as speakers concurrent laughter was noted. Therefore, laughter is annotated for both, speakers and listeners. Backchannels were coded for all continuous verbal particles of response, as well as repair initiations. An overview of the coding scheme for these behavioural cues can be seen in Table 1.

Table 1: Coding scheme used in Elan.

| Tiers per participant | Social behaviour |
| :--- | :--- |
| speaking | verbal utterance |
| laughter | responsive and concurrent |
| backchannel | responsive, repair initiation |

Following this coding scheme, all elements that mark listening modes are created from the gaps of the annotations
for laughter, speaking and backchannels. This means that within the listening mode, any gross and subtle body movement, as well as nodding or any other conversational action is included. With the aim of distinguishing speakers from listeners, this level of detail in annotations is sufficient, although the sensitivity of the sensors allows for richer and more finegrained distinctions.

## Results

The data from all eight sensors were analysed in a General Linear Model Multivariate Regression using SPSS v.24. Talking, Laughing and Backchanneling were included as binary predictors coded as 1 or 0 for presence / absence of each behaviour. All two and three-way interactions of these three factors were included in the model. Participants were also included as a main effect to ensure individual variation was accounted for.
Since the relative changes for each participants were calculated, changes of weight had no effect on the outcome of the analysis.

Figure 2: Estimated means of all participants for TALK: thighs: left(187.513), $\operatorname{right(209.379);~butt:~left(137.721),~}$ right(175.910); waist: left(231.599), right(345.421); shoulders: left(137.810), right(195.288)

Multivariate Tests (Pillai's Trace) show all three dialogue factors reliably predict the outputs of the pressure sensors (Talk: $F_{(8,82933)}=9.68, p<0.00$; Backchannel $F_{(8,82933)}=$ $10.2, p<0.00$; Laugh: $F_{(8,82933)}=6.95, p<0.00 ;$ ). The effects are very small with Partical Eta Squared of 0.001 and observed power for Alpha $=0.05$ of 1 . The contribution of individual variation is, by contrast, much larger: Participant: $F_{(8,82933)}=6.95, p<0.00$, Partial Eta Squared $=0.71$ ).

Analysis of the contributions of each sensor show that different patterns of pressure changes across the chair are associated with the different dialogue states. The sensors most sensitive to talking were in the seat of the chair and correspond

Figure 3: Estimated means of all participants for LAUGHTER: thighs: left(118.642), $\operatorname{right}(209.379)$; butt: left(178.079), right(187.614); waist: left(229.081), $\operatorname{right}(342.121)$; shoulders: left(143.385), right(179.532)
to increased pressure from the thighs and reduced pressure from the buttocks. In contrast to this laughter corresponded to reduced pressure in the thighs and increased pressure in the buttocks with no significant changes detected in the seat back. The pattern of pressure changes for the relatively brief backchannels were distributed across both the seat and back of the chair and corresponded to increased pressure across thighs, buttocks and waist but a reduction across the shoulders. The estimated means for changes at each sensor are illustrated in Figures 2, 3 and 4 (numbers based on modified population marginal mean).

## Discussion

The results show that it is possible, in principle, to detect significant aspects of social interaction from quite limited, indirect and noisy data. The small movements detected by pressure sensors embedded in chair seats are small-scale and almost completely invisible correlates of the gross body movements that typically distinguish speakers from hearers and laughter from silence. Interestingly, even the relatively small nodding movements of the head associated with backchannels appear to create a distinguishable pressure signature on a chair.

This is the first attempt to detect significant conversational states from simple 'homemade' pressure sensors and the signal to noise ratio is low. Individual variations in movement in particular account for far more of the variance than differences in dialogue state. Further work to optimise the size and position of the sensors would doubtless improve the quality of the sensing. It is also likely that other approaches, such as training person-specific classifiers and machine learning mechanisms, would improve the accuracy and robustness of

Figure 4: Estimated means of all participants for BACKCHANNELS: thighs: left(176.345), right(199.648); butt: left(172.195), right(189.949); waist: left(246.298), $\operatorname{right}(351.819)$; shoulders: left(114.193), right(189.709)
the approach although this would also undermine the advantages of anonymity. The demonstration that even relatively crude sensors can detect minimal changes in posture, suggests that future work should explore the possibility of capturing more complex social behaviour, especially relational questions such as whether interactions are, for example: convivial or combative; autocratic or egalitarian, or whether it is possible to characterise regularities in multiparty interaction (see e.g. (Abney, Paxton, Dale, \& Kello, 2014)).

What could this form of sensing be used to do? The principle opportunities for application are in any situations where there is value in the ability to unintrusively gather information about general patterns of social interaction including levels of interest and engagement. One example is architecture where the ability to sense a building's energy performance and patterns of air flow is highly valued but currently has no social counterpart. We speculate that the ability to make simple, systematic assessments of a building's 'social performance' by instrumenting the chairs in a building could also have a significant positive impact on domestic and workplace design. A second example is in the evaluation of audience responses (e.g. continuous audience response measure, CARM, which is used by broadcast hosts to evaluate their programs). The deployment of such a sensor network in an auditorium, meeting room or a classroom could help to assess levels of engagement of students and other audiences. In addition, there are possibly applications to augmented human interaction where, for example, live feedback about how much people are dominating (or not) a conversation can have significant effects on the conduct of the interaction (Donath, 2002). If nothing else these results shed some light on Stephen Fry's (1984) advice that when delivering Shakespeare one should
"always gather from the buttocks".

## Summary

This paper presents a new sensing system using textile pressure sensors that are designed to be integrated in a chair cover and that are able to reliably distinguish speakers from listeners and detect laughter and backchannels. These fabric sensors provide a non-intrusive way to measure conversational engagement. Data about pressure changes on the seat and back rest alone make it possible to differentiate various behavioural states in a seated conversation. The ability to extract such patterns of social interaction from sensing pressure changes could replace other, more complex motion detection systems and mitigate privacy concerns, since the data collection is anonymous involves no audio or video data and does not capture any of the content of the conversation.

## Acknowledgments

We thank the EPSRC and AHRC Centre for Doctoral Training in Media and Arts Technology, who funded this research. In particular, we also thank Adan Benito Temprano for his support, as well as the Digital Catapult Centre.

# Individual Differences in Spontaneous Analogical Problem-Solving: The Reflective Mind Account 

Slavi Todorov Slavov (s.t.slavov5@gmail.com)<br>Department of Cognitive Science and Psychology, Montevideo Str. 21, Sofia, Bulgaria<br>Penka Hristova (phristova@cogs.nbu.bg)<br>Department of Cognitive Science and Psychology, Montevideo Str. 21, Sofia, Bulgaria

#### Abstract

Analogical problem-solving involves transfer of knowledge that has been obtained from a source analog and successfully applying it in the solution of a structurally similar target problem. What is usually found in the so-called hint/no-hint paradigm is that spontaneous solution to a problem is hard to achieve. This leaves the possibility for individual differences. This study searched for and found a positive correlation to exist between scores on the Cognitive Reflection Test and spontaneously solved analogical problems which, although a weak one, possibly accounts for the differences that exist between people who need a hint to solve an analogical problem, and people that do not need a hint.

Keywords: Analogy; Analogical problem-solving; Reflective Mind thinking; Cognitive Reflection Test

## Introduction

Imagine you are presented with a problem - an oil well is on fire and is consuming large amounts of petrol every minute. You know you have enough foam to put out the fire, but if you use the one large hose that is available to shoot it at the well, the fire can be extinguished, but the pressure would also destroy the machines around the well that facilitate the oil extraction, which would be an expensive cost. If you use one of the several smaller hoses that are also available, the machines will be spared, but the fire would not be extinguished. How can this problem be resolved? Now, imagine that without any external hint to relate the problem to anything, you recall a story about an exhibition designer, who has to figure out a way to illuminate a replica of a ship, that is positioned in the center of transparent tank filled with water and fish that are sensitive to light. If the designer illuminates the replica with a powerful spotlight, the fish will be disturbed, but if she uses a low-powered spotlight, the ship would not be illuminated enough. So she decides to use several low-powered spotlights to illuminate the replica from several directions, which will not disturb the fish, but the focused light would be enough to illuminate the ship. In fact, these two superficially dissimilar problems are analogous - the solution to the fire problem is to shoot the foam using many small hoses from different directions so as to spare the machines, but also to provide enough foam to extinguish the fire. How many people would spontaneously think of using the solution of the problem they know to solve the analogous one? Probably not many, given that the stories appear to be different on the surface. The successful
solver would probably need to be able to reflect on what he is processing, to suppress the irrelevant information, and set his priorities in accordance to the task at hand.
The paradigm that is used in studying analogical problemsolving requires a relevant analog known to the solver to be available, as well as the target problem that is presented to be sufficiently novel and challenging in order for the analogy to be useful (Gick \& Holyoak, 1983). The framework that is generally required for the solver to represent the analogical relationships involves first of all a story describing the problem and how it is solved to be read and understood. Once the information is represented, it can be used to generate solution to the target problem by mapping the similar relations of the two systems, employing a top-down reasoning, forming expectations, and finally using the mapping in order to generate the solution to the target problem (Gick \& Holyoak, 1980).

## The "retrieval gap" in analogical problem-solving

In order to analogously solve the problem, participants must retrieve the correct analogical relationships. The role of retrieval is usually investigated in the so-called hint/no-hint paradigm (Novick \& Holyoak, 1991). By giving a hint to the solver in one of the two experimental conditions, they are informed that the two stories are connected and the solution to one of them can be used in solving the other. If they are not given a hint in the no-hint condition, solving the target problem would indicate spontaneous analogical transfer. What is usually found is that about $75 \%$ of the people solve the Radiation problem ${ }^{1}$ using the correct analogical solution when the appropriate analog story ${ }^{2}$ had

[^497]been previously presented and they are given explicit hint to use that story for the solution (Gick \& Holyoak, 1983). However, if no base story analog is presented, only less than $10 \%$ of the participants manage to find the correct solution. What Gick and Holyoak (1983) have found when their participants read the Attack-Dispersion story as a base, disguised to be remembered for a subsequent recall, is that $30 \%$ of them arrived at the correct solution of the Radiation problem presented subsequently, without receiving any hint, i.e. spontaneously. This apparent difference in the difficulty of mapping and retrieving the correspondences of an analog are referred to as "retrieval gap" (Holyoak, 2012), and can be considered in terms of at least 3 explanations:

Structural and surface similarity Problem-solving using analogs is very much dependent on the level of structural and surface similarity between the two stories in terms of the level of facilitation of retrieval (Blanchette \& Dunbar, 2000; Holyoak \& Koh, 1987). More specifically, if the superficial features of the base story are more similar to the ones of the target problem, spontaneous retrieval of convergence solution to the Radiation problem is as high as $90 \%$, compared to about $20 \%$ if the surface features were dissimilar (Blanchette \& Dunbar, 2000). It is suggested that because an analog that is from a remote domain, it does not share many of the salient surface features of the target, which might block the spontaneous retrieval of relevant analogs, unless the solver is able to focus on aspects that are causally related for the target (Holyoak \& Koh, 1987).

The experimental paradigm Blanchette and Dunbar (2000) show in their experiments the importance of the experimental setting in which the participants reason analogically. In the so-called "reception paradigm", the participants are given base and target problems and are required to identify the relations between them. As Blanchette and Dunbar's (2000) experiment shows, this type of setting constraints the participants and prompts them to make more analogies based on superficial similarity. On the other hand, an experimental setting organized in a "production paradigm" involves participants being given the target problem and being asked to generate possible source stories, arguably resulting in analogy generation based on deep structural features. Two of the experiments in Blanchette and Dunbar's study (2000) involved analogical reasoning using production paradigm. The results clearly indicated production of more analogies that were structurally similar. Their third experiment used arguments from the previous two experiments as stimuli, but the task was arranged in a reception paradigm. The results showed domination of retrieval of superficially similar stories. The findings are explained in terms of different type of encoding in the different types of tasks. In "reception paradigm" tasks, the initial presentation of the problem is usually guised as a comprehension evaluation or measuring recall,

[^498]which arguably causes the encoding to be more superficial. Furthermore, the base representation building may not necessarily include the relevant relations for the subsequent analogical problem solving. The "production paradigm", on the other hand, involves the participants in deeper structural encoding of the problem from the beginning, possibly resulting in more structurally similar analogies.

Possibility for individual differences The previously mentioned source Radiation problem, when learned in a different context, enables problem solvers to spontaneously produce the correct analogous solution to the superficially similar Lightbulb problem for $81 \%$ of the participants even several days after the presentation of the base problem (Holyoak \& Koh, 1987). The results for the spontaneously solved problems are discussed in terms of the possible demand characteristics of the task, or in other words that the participants might suspect the two stories to somehow be related due to them being present in the same experiment (Gick and Holyoak, 1983). This might suggest the possibility of individual differences to be present, specifically that some people might be sensitive to events occurring in the same context and interpret them as connected. Day and Goldstone (2011) discuss the possibility of individual differences in intelligence or the level of engagement in the experiment to be responsible, at least to some extent, for the difference between the transfer and the reported understanding of the analogy itself. Another possibility for individual differences in spontaneous analogical problem solving can be drawn from the so called Reflective Mind (Stanovich, 2012). According to the Tripartite model (Stanovich, 2012), the Reflective Mind is able to initiate the suppression of the initial response, due to its higher cognitive level control, that is carried out by the Algorithmic mind ${ }^{3}$. The Reflective mind is tested in the socalled typical performance situations, in which participants solve tasks without overt instructions to maximize their success. Spontaneous problem solving resembles a typical performance situation, since participants in the no-hint condition are not explicitly instructed to find and use the analogy with previous problems. Moreover, the mechanisms of Reflective mind such as cognitive decoupling operation, allows a suppression of the initial response that is provided by the Autonomous mind and creating a secondary representation of the world that could be manipulated until the correct solution is reached and then applied in reality. Just like Day and Goldstone (2011) have argued that some individual differences due to intelligence (i.e. Algorithmic Mind) may explain the superior problem solving performance of some individuals, we argue that differences regarding the Reflective Mind can also be expected in analogical problem solving. Indeed, spontaneous analogies are especially interesting case for individual differences

[^499]stemming from the Reflective mind. On the one hand, the ability to create a secondary representation of the problem that may hold and manipulate the base and target problems seems to guarantee a successful analogical problem solving. On the other hand, Holyoak (2012) has argued that the difficulties which people experience in spontaneous analogical problem solving in particular indicate that analogical mapping requires a Type 2 processing.

## Correlation between Reflective mind thinking and spontaneous analogical problem solving

The main goal of this study is exploratory - given that not much is known about individual differences in spontaneous problem solving, especially with regard to the Reflective mind, the aim would be to find a correlation between these two variables. More specifically, possible individual differences might be expected in the no-hint condition, where spontaneous analogy-making depends on the correct identification of the structural similarities in the two problems, as well as the appropriate mapping, which might be reasonable to expect from people with higher rational dispositions who are arguably better at prioritizing goals and performing well without overt instructions what exactly is expected of them.

## Method

## Design

This is a correlational study, aiming to research whether a positive correlation exists between scores on the Cognitive Reflection Test and the analogical problems that are solved spontaneously. For the purposes of the research, a reception paradigm was used. The research has been approved by the ethical commission at the New Bulgarian University.

## Stimuli

Analogical stories The stimuli for the analogical problemsolving task consisted of six problems: three bases and three targets. The problems were selected so that they can be structurally identical, but superficially dissimilar.

- Red Adair \& Aquarium problems

The first set of analogous stories consisted of the Red Adair problem (Kurtz \& Loewenstein, 2007) and the Aquarium problem (Catrambone \& Holyoak, 1989). The former described a problem, in which an oil well that is burning has to be extinguished. If a big hose is used to shoot the foam into the well, the machines in the well that facilitate petrol extraction will be destroyed, even though the fire will be put out. But if one of the many smaller hoses is used, the machines will be spared, but the fire will not be extinguished. For the Aquarium problem, a replica of a ship had to be illuminated for an exhibition, without disturbing the fish swimming around it, which were sensitive to light. If one powerful spotlight was used, the fish would be disturbed and the replica illuminated, and if one less powerful spotlight was used - the fish would not be
disturbed, but the replica would not be illuminated. The solution for both problems involved "convergence of forces", or using small amounts of force from different directions (small hoses to put out the fire and low-powered spotlights to illuminate the ship). The Red Adair problem was modified so as to obtain full structural similarity with the Aquarium, by making the using of large force from one direction causing damage to peripheral elements (machines for petrol extraction in Red Adair and the fish in Aquarium).

- Garden and Marching band problems

The second set of stories were the Garden problem and the Marching band problem (Novick \& Holyoak, 1991). These were mathematical problems, involving finding how many plants a family can have in their garden, given that they had chosen the exact number of plants, which could be divided into 10,4 , and 5 kinds of plants, but there would be space for 2 more plants. Only when they divide them in 6 , they fit in without remainder. The Marching band described musicians marching in rows of 12,8 , and 3 , but having one musician march alone. Only when they march in rows of 5, there is nobody left out. The successful solution procedure for both problems is to find the lowest common multiple of the given three divisors that leave a constant remainder, then to generate multiples of that number, add the remainder to each of them, and finally find from this set the number that is divisible to the fourth number without a remainder.

- Orange and Tribe problems

The third pair of stories consisted of the story about the sisters, who were quarreling because each of them wanted one orange for herself. The problem was resolved when the mother found out that one of the sisters wanted to use the peel of one orange for baking, and the other wanted to eat the fruit, so each of them took the respective part of the whole orange (adapted from Fisher, Ury, \& Patton, 2011). An analog to this story was created, which was about two clans from the same tribe, that have recently captured an island, and each of the clans wants the whole island for themselves. So the chief of the tribe steps in and finds out that one of the clans wants the island for its territory, and the other one wants it because the people on the island pertain to their clan. The solution, then, is to divide the people from the territory, so that each side can be satisfied.
Cognitive Reflection Test The extended version of Cognitive Reflection Test (CRT) (Toplak, West \& Stanovich, 2014) was used as a measure of Reflective Mind. CRT was introduced by Frederick (2005) and measures cognitive reflection - a concept defined as "the ability or disposition to resist reporting the first response that comes to mind". Toplak et al (2014) have expanded the CRT to a total of seven questions in a study assessing people's tendency to process information miserly. Each of the seven questions presented a problem, which had an intuitive, but wrong answer immediately coming into mind, and requiring the suppression of that answer and searching for the correct one. For example, a problem describing that a bat and a ball cost 1.10 dollars in total, and the bat costs a dollar more
than the ball, asks how much the ball costs. An intuitive answer would be 10 cents, but the correct one is 5 cents.

## Participants

A total of sixty-seven participants took part in the study (18 males). All of them were native Bulgarians. They participated either for partial fulfilment for a course credit, or voluntarily. Forty-seven of the participants were students at the New Bulgarian University. The participants' age ranged from 18 to 53 years $(M=25.18, S D=8.21)$.

## Procedure

The procedure consisted in participants signing an informed written consent, and solving all six problems and the CRT individually in a single 45-50 minute session. First, the three base problems were presented one by one, with participants having 5 minutes to solve for each problem. If the participants failed to produce the correct solution, it was given to them. Then the CRT was given, with 10 minutes time to complete it. Finally, the three remaining target problems were given one at a time.

In order to control which of the target problems were solved spontaneously, the participants were given 5 minutes per problem, and if they did not produce the correct solution, they were given a hint to use one of the previously solved problems and additional 2 minutes were allowed. If again there was no correct solution, a second hint was given to use the specific analogous base problem to solve the current one, again allowing for additional 2 minutes.

The analogical problems were chosen in such a way, so as to be symmetrical, as well as structurally identical. Due to this fact, the analogical pairs were alternated with respect to being either a base or a target, with the Red Adair problem appearing half of the times as base, half of the times as target. The same applied for all six problems. The presentation of the base and target stories was balanced, with each of the stories appearing first, second or third as a base and first, second and third as a target equal amount of times. The full randomization resulted in 72 possible presentations of the problems without repetition of the presentation order. Thus, each participant was given a unique sequence of problems arrangements, with 67 out of the 72 randomized possibilities being used in the study.

## Results and discussion

## Analysis of the analogical problems

Several types of analyses were made on the obtained data. Firstly, the time to solve the base and target problems was calculated. The mean time to solve all three base problems was $198.29 \mathrm{sec}\left(\mathrm{s}^{4}=115.44\right)$, whereas the target problems were solved faster for an average of $161.88 \mathrm{sec}(\mathrm{s}=129.77)$. That difference was significant $(\mathrm{t}(66)=3.76$, $\mathrm{p}=.00)$, indicating that some facilitation due to analogical transfer may have taken place. The tasks in each analogical pair

[^500]were randomly assigned to the base or target position, thus any differences between the base and target task cannot account for the observed faster solutions of the target compared to the base problem. Moreover, only response time for correctly solved, but not for unsolved targets was faster than the base solution time: $\mathrm{F}(1,66)=38.32, \mathrm{p}=.00$ (Figure 1). Solved targets were worked out faster than solved base problems. Unsolved problems took up approximately the same amount of time, irrespective of the base-target role they have played in a given analogy. Therefore, analogy, rather than task order, may explain the obtained facilitation in solving the target tasks.

Figure 1: Time needed to solve successfully or not a base and a target problem (in seconds).

Huge differences in both response time and accuracy, however, were observed between the individual problem pairs which share analogous relational structure. The analogical pair Garden and Marching band (noted G and M, respectively) were correctly solved as bases for average of $183.43 \mathrm{sec}(\mathrm{s}=44.17)$, which took the longest amount time to be solved out of the three pairs. The Orange and Tribe pair (noted O and T, respectively) took 70.52 sec on average ( $\mathrm{s}=73.22$ ) or was fastest of the three problems to be successfully solved as bases, and the Red Adair and Aquarium problems (noted R and A, respectively) took on average $146.00 \mathrm{sec}(\mathrm{s}=90.25)$ to be solved correctly as bases (see Figure 2).

Figure 2: Time needed to correctly solve a problem from an analogical pair as a base and as a target (in seconds).
One-Way ANOVA yielded statistically significant difference with respect time to solve the bases $(\mathrm{F}(2,104)=$ $14.40, \mathrm{p}=.00$ ). Specifically, according to a Fisher LSD post
hoc test the pair O and T was solved correctly faster as a base compared to $G$ and $M(p=.001)$ and faster than $R$ and A ( $\mathrm{p}=.00$ ). The pair $G$ and $M$ did not differ from $R$ and $A(p$ $>$.05). Target problems from the analogical pair G and M were solved for $187.75 \mathrm{sec}(\mathrm{s}=72.62)$, which again was the longest amount of time out of the three problems. O and T were correctly solved for 67.18 ( $\mathrm{s}=91.88$ ), and R and $\mathrm{A}-$ for $62.18 \mathrm{sec}(s=64.43)$ (see Figure 2). There was again significant difference between time needed to solve targets from each pair $(\mathrm{F}(2,117)=4.82, \mathrm{p}=.01)$. Fisher LSD posthoc test showed that the G-M pair was correctly solved as a target for the slowest amount of time compared to O-T (p $=.004)$ and R-A ( $\mathrm{p}=.002$ ), while there was no significant difference between R-A and O-T pairs ( $\mathrm{p}>.05$ ).

Additionally, the number of spontaneously solved target analogies was calculated for each pair. The analogical pair G-M was solved spontaneously only 4 times, or by $5.97 \%$ of the people. For the pair O-T the number was 55 ( $82.01 \%$ ), and for the pair R-A it was 61 ( $91.05 \%$ ) (Figure 3). The difference between the number of spontaneously solved problems from the pair G-M was significant from that of O$\mathrm{T}\left(\chi^{2}(1, \mathrm{~N}=59)=78.76, \mathrm{p}=.00\right)$ and also from R-A $\left(\chi^{2}(1\right.$, $\mathrm{N}=65)=97.07, \mathrm{p}=.00)$. The difference between $\mathrm{O}-\mathrm{T}$ and R-A pairs was not significant. Likewise, participants reported less often that they have been aware of the analogy between the problems in the G-M, compared to the other analogous pairs: $\mathrm{F}(2,200)=39.72, \mathrm{p}=.00$.

Figure 3. Relative frequency of solved target problems for each analogical pair

In sum, the superficially dissimilar analogous problems used in that study were quite different with respect to solution time and accuracy. Some of the target problems were solved faster and more accurately (i.e. O-T and R-A) than others (i.e. G-M). The target problem itself can hardly explain that discrepancy, since both tasks in each pair were randomly assigned as base and target for each participant. The order of the three base and the three target tasks was also randomized across participants.
In this specific case, the G-M pair consisted of mathematical problems that, although analogical, might be impeding the correct mapping or retrieval that is necessary for correct solution just because of the difficulty of the problem itself. Given that mathematical expertise has been found to be an important predictor of analogical transfer (Novick \&

Holyoak, 1991), it could be reasonable to expect that for this specific analogical pair, some additional factors might have operated by impeding the transfer. The retrieval gap (Holyoak, 2012), however, seems to be wider for some analogous problems, but not for others, probably depending on the specific expertise of participants, as suggested in our study, where most participants had background in humanities ${ }^{5}$ and failed to solve the G-M problem that requires mathematical skills (Novick \& Holyoak, 1991).

## Correlational analyses: who solves problems by means of spontaneous analogies

A correlational analysis was conducted between the variables scores on the Cognitive Reflection Test and the number of analogical problems that were solved correctly without an explicit hint (i.e. spontaneously). Importantly, a Kolmogorov-Smirnov test was applied to test for normality the two variables. Both of them were not normally distributed ( $\mathrm{p}=.000$ ), which required utilizing a nonparametric correlational test, such as Spearman's rank order correlation. There was a significant positive correlation obtained between the two variables $\left(r_{s}(67)=.25, \mathrm{p}=.045\right)$. The results indicate that a high score on the CRT tends to go together with higher number of spontaneously solved analogical problems. A scatterplot summarizes the results (Figure 4).

## Correlation Chart

Figure 4: Scatter plot with jitter, showing the correlation between scores on CRT and spontaneously solved analogical problems. The x -axis represents the score on CRT, the $y$-axis represents the number of spontaneously solved analogical target problems.

## Discussion

This study demonstrates that a positive correlation exists between the score on the Cognitive Reflection Test and the number of analogical problems that are solved spontaneously. Given the rationale of the hypothesis, this result can be explained in terms of individual differences with respect to the Reflective mind (Stanovich, 2012) at least partially accounting for the analogical problems that

[^501]are solved without a hint. Although the correlation is weak, the results indicate that the goals and hypothesis of the research are in the right direction.
Generally, what was found in this investigation was that people solve different analogical problems with a different amount of speed and also different degree of success. The finding that the analogical pair $G-M$ was solved less than the other ones and for more amount of time might point to the idea that the nature of the problems themselves might play a role in how easy or how fast the solution is extracted from the base problem in order to be applied to the target one. A possible explanation remains to be looked for in expertise in solving mathematical problems (Novick \& Holyoak, 1991) In addition, the nature of the CRT itself could be questioned as to the extent it requires a certain level of expertise. Thomson and Oppenheimer (2016) have developed an alternate version of the CRT which addresses the criticisms to the original form - that it relies on mathematical sophistication to produce the correct answer.
The weak correlation that was found between scores on CRT and the spontaneously solved analogical problems needs to be compared to other similar correlations of CRT and cognitive abilities. For example, Toplak, West, \& Stanovich (2011) show significant correlations to exist between CRT and syllogistic reasoning tasks ( $\mathrm{r}=.36$ ), heuristic-and-biases tasks ( $\mathrm{r}=.42$ ), executive functions measures (. 17 to .34 ) and thinking dispositions measures (. 18 to .19). Thus, the current study seems comparable to others with respect the strength of association between CRT and tasks involving reasoning measurement.
It should be noted, however, that correlations between CRT and cognitive ability measured by Wechsler Abbreviated Scale of Intelligence has been found to exist ( $\mathrm{r}=.32$ ), suggesting some overlap between the two (Toplak et al., 2011). A possibility to search for a partial explanation of spontaneously solved analogical problems in the cognitive ability of intelligence, thus, cannot be fully overruled.

## Conclusion

The reported correlation between the Reflective Mind measure and spontaneous analogical problem solving adds a new explanation for the retrieval gap in analogical reminding. Low superficial similarity and non-compatible relational structures between the base and target problems may explain the difficulties that participants robustly demonstrate in psychological labs when analogical problem solving abilities are tested by the means of the reception paradigm. Nevertheless, generally $20 \%$ of participants find the analogous solution (Holyoak, 2012), despite the mentioned difficulties that the reception paradigm seems to impose on them. The reported correlation indicates that among the key abilities within the profile of the successful problem solver is the reflective reasoning. It presumably enables the motivated search for possible connections between the tasks, and possibly a re-representation of the relevant relations, if needed for the purposes of the analogical problem solving. Therefore, spontaneous analogy
making may benefit from the reflective reasoning, since it most probably transforms the task into an explicit task for searching the analogy, or at least boosts the motivation to cope with the task.

# Gender or Community: What Drives STEM Interest Among Middle School Students?

#### Abstract

Much attention has been given to increasing women's and girls' interest and participation in STEM fields. One way of increasing STEM interest is to target STEM-gender stereotypes by presenting students with female stereotypedisconfirming exemplars. However, the exemplar approach has had mixed effectiveness in adolescent populations. The present study examined middle school students' interest in STEM fields and their communal goal interest. Participants were given different interventions that either presented a female exemplar of a scientist or leveraged communal goals. Results found no gender differences in STEM interest, but a correlation between communal goal endorsement and a belief that STEM careers are compatible with communal goals. The intervention that leveraged communal goals effectively increased STEM interest for some students, while the exemplar interventions were ineffective. These findings suggest that with regard to STEM interest in early adolescence, endorsement of communal goals may be a more influential factor than gender category membership.

Keywords: Science, Technology Engendering and Math, Gender, Communal Goals, Adolescents

## Introduction

As the world becomes more reliant on technology, there is a growing interest in how to increase participation in science, technology, engineering and math (STEM) fields. Of particular concern is the underrepresentation of women in STEM fields. For example, in 2012, only $20 \%$ of bachelors' degrees in physics, engineering, and computer science were earned by women (National Science Foundation, 2015). The gender disparity is more pronounced at higher levels. For example, women earned $40 \%$ of bachelor's degrees in mathematics and statistics but only $20 \%$ of master's and doctoral degrees in these fields (NSF, 2015).
What explains the gender differences in levels of STEM interest and participation, and when do these differences emerge? An interesting part of the situation is the fact that there are no substantial gender differences in early mathematics and science ability (see Hill, Corbett, \& St. Rose, 2010 for discussion), but there are differences in attitudes toward mathematics and science (e,g, Ganley \&

Lubienski, 2016; Hyde, Fennema, \& Lamon, 1990). As early as elementary and middle school, girls tend to perceive themselves as less competent in mathematics than do boys (Ganley, \& Lubienski, 2016; Herbert \& Stiptik, 2005). In middle school and high school, boys are more likely to state that they are interested in math and science than girls (Cunningham, Mulvaney, \& Sparks, 2015; Hill, Corbett, \& St. Rose, 2010).

One factor that may contribute to students' attitudes toward mathematics and science is the pervasive stereotypes that scientists and mathematicians are men (Eccles, 1987; Fennema, 1985; Nosek, Banaji, \& Greenwald, 2002). Young children in the United States tend to draw men when asked to depict a scientist or mathematician (Chambers, 1983; Steele, 2003). There is evidence that gender and the strength of gender identity are correlated with preference for mathematics, mathematics identity, and math-gender stereotypes (Nosek, Banaji, \& Greenwald, 2002).

Because it is possible that gender-STEM stereotypes negatively impact women and girls participation in STEM, many interventions have been developed to break common stereotypic misconceptions by presenting stereotypedisconfirming exemplars to students. For example, reading about the successes of women in STEM and non-STEM fields has been shown to boost women's performance on math examinations (McIntyre, Paulson \& Lord, 2003).

The proposed mechanism behind these exemplars is that encountering a particular stereotype-defying example will encourage participants to expand their notion of membership in the stereotyped category. In this instance, presenting examples of women who are successful in STEM fields would prompt a change in the perceived membership of the category of "scientist" or "mathematician". By extension, presenting a highly feminine exemplar as successful in a stereotypically male domain like STEM may be effective because it forces the perceiver to include all feminine characteristics in their category definition of who may be successful in STEM fields and discourages subtyping.

Although the power of stereotypes and representation biases cannot be denied, the stereotype explanation leaves questions about gender differences in STEM participation. Women and girls continue to select out of STEM fields, even as women continue to gain representation in other high
achieving, stereotypically male disciplines like law and medicine (Snyder, Dillow, \& Hoffman 2009; Wang, Eccles \& Kenny, 2013). This suggests that other factors such as motivation and personality characteristics may be contributing to the gender disparity in STEM fields. In addition, there may be practical problems with designing STEM participation interventions based simply on expanding students' perception of STEM "membership" because these theories assume that students will see the exemplar as similar to themselves. How would characteristics such as race, socio-economic background, geographic region, and culture be appropriately included in exemplars to appeal to all students?

Indeed, despite their success with adult women, exemplars often generate mixed effects, especially among adolescents. Exposure to highly feminine exemplars actually weakens future goals to take optional math and science among adolescent girls who are disidentified with STEM fields and decreases adolescent girl's sense of efficacy and short-term expectations of success in math and science (Betz \& Sekaquaptewa, 2012). This evidence suggests that using highly feminine exemplars to influence the future career plans of adolescent girls does not target the cleanest and most effective mechanism of STEM interest and identification.

These counterintuitive effects may stem from the complicated relationship adolescent girls have with gender stereotypes. During adolescence, especially early adolescence, girls' self-perceived math ability begins to decline relative to boys' (Wigfeild, Eccles, Mac Iver, Reuman \& Midgely, 1991). In light of this intricate relationship between budding identity development and harsh cultural stereotypes, it is not surprising that interventions designed to leverage mechanisms tied to gender stereotypes yield adverse or mixed results.

Considering the baggage accompanying gender-STEM stereotypes during adolescence, it is important to explore other theories and mechanisms that could shed light on this phenomenon. One such theory is the goal congruity perspective. The goal congruity perspective posits that women highly value communal goals like intimacy, working together and helping others. This valuation is at odds with stereotypes about STEM fields portraying careers involving those fields as individualistic and isolating. In fact, compared to other high achieving careers, STEM careers are perceived as actually hindering the path to attain goals like helping others (Diekman, Brown, Johnson \& Clark, 2010). These stereotypes work to portray STEM careers as incompatible with communal goals, leading to disinterest in pursuing math and science domains for those individuals that value communal goals. Thus, the mechanism behind the goal congruity perspective attempts to increase the degree to which goal affordance beliefs, or beliefs about what actions or pursuits will best facilitate the attainment of specific goals, align STEM careers with communal goals. In this way it might be possible to increase positivity toward STEM careers among individuals
who value communal goals (Diekman, Clark, Johnston, Brown \& Steinberg, 2011).

Indeed, this idea maps well on to the difference in female representation within STEM fields. According to 2013 census data, women make up $61 \%$ of social scientists, a field that has high communal goals stereotypicallity compared to only $27 \%$ and $13 \%$ of computer workers and engineers respectively, fields with low communal goal steryotypicallity (Landivar, 2013).

## The current study

This study seeks to examine STEM interest in an adolescent population and to test several interventions designed to increase STEM interest. Specifically, we will consider the role of gender and communal goal endorsement. The use of exemplars, along with manipulations of female stereotypicality has yielded mixed results in this population, while the communal goal approach remains untested. It is predicted that adolescents will endorse communal goals and that the intervention targeting communal goals will yield the greatest increase in STEM interest, in particular a future desire to purse science and math, compared to exemplar focused interventions.

## Method

## Participants

Ninety-four seventh grade students (41 male, 53 female) at middle school in the Midwestern United States were recruited for this study. The majority ( $93 \%$ ) of the sample self identified as White. Parental consent as well as participant consent was obtained.

## Materials

The experiment included three phases: (1) measure of communal goal interest and pretest of STEM interests (2) an intervention designed to increase STEM interests and (3) posttest of STEM interest. Participants were randomly assigned to one of three conditions (feminine exemplar, neutral exemplar, or communal goals) that varied the intervention.
Interventions. Participants were exposed to either a stereotypically feminine exemplar (feminine condition), a female but stereotypically neutral exemplar (neutral condition), or a group exemplar designed to speak to communal goals (communal condition). The intervention text appears in Appendix A exactly as it was presented to participants. All exemplars were identical except for the necessary manipulations.
The material presented to participants consisted of a short paragraph written form the perspective of the exemplar detailing their hobbies and what they enjoy about their job. A picture followed this short paragraph. In the communal condition the picture included an ethnically diverse group of men and women, and in the feminine and neutral conditions the picture included an ethnically ambiguous woman.

Exemplars were portrayed as a "profile of a scientist" (feminine and neutral conditions) or the "profile of a team of scientists" (communal condition). This profile was sourced from a website that aims to connect students to female mentors working in STEM fields and can be found in full in Appendix A.
The manipulations of feminine stereotypicality (feminine and neutral conditions) were taken from Clark, Fuesting, \& Diekman, 2016. This manipulation consisted of hobbies that were independently rated as highly feminine (knitting, watching romantic comedies and yoga) or neutral on feminine stereotypicality (running, watching nature documentaries and photography). The hobbies for the communal condition were simply "working and spending time together."

Following the intervention manipulation, participants were asked to complete a writing assignment. In this task, they first read a list of daily tasks the exemplar would perform. Then they were asked to write about what they think an average day would be like if they were a scientist doing a similar job (Appendix A). This writing exercise was timed; all participants were instructed to write for five minutes. The daily tasks were manipulated to reflect or not reflect communal goals similar to the manipulation in Clark, Fuesting, \& Diekman, 2016. For the feminine and neutral conditions the daily tasks consisted mainly of solitary work and problem solving (ex: "Look up and read about past research to help you develop new experiments."). In the communal condition the daily tasks reflected working with others (ex: "Brainstorm with your fellow researchers about past research to help you develop new experiments.").

Communal Goals Scale. The nine-question communal goals scale (Clark, Fuesting, \& Diekman, 2016) was used to assess communal goal identification. Participants were asked to rate the importance to them of nine goals, like helping others, intimacy, relationships with others and working with people, on a seven-point Likert scale.

Measures of STEM Interest. Three measures were used to assess STEM interest: a measure of future goals (Betz \& Sekaquaptewa, 2012), a measure of STEM positivity and a measure of STEM goal attainment (Clark, Fuesting, \& Diekman, 2016). The measure of future goals asked participants to rate their likelihood of taking science and math classes in high school and college on a seven point Likert scale. The measure of positivity asked participants to rate how positive they feel towards a STEM career and how much they would enjoy being successful in a STEM career on a seven point Likert scale. The STEM goal attainment measure contains two questions that ask participants to rate on a seven point Likert scale the extent to which a career in STEM fields would "fulfill goals like intimacy, working with people and helping people" and to what extent such a career would fulfill their own goals of intimacy, working with people and helping people.

## Procedure

Students took part in this study as an extension of their daily math class. Participants were first administered consent forms. Participants then completed a pen and paper pre-test questionnaire consisting of the communal goals scale, the two question future goals scale, the two question STEM positivity scale, and the two question STEM goal attainment scale. Participants were also asked to list their top three favorite academic subjects.

Participants were then exposed to the exemplar intervention materials that aligned with their assigned condition (feminine, neutral or communal). Participants were then given a uniform amount of time ( 5 minutes) to complete the writing assignment corresponding to their condition: the feminine and neutral condition received the non-communal manipulation and the communal condition received the communal manipulation.

Following this writing assignment participants were administered a post-test consisting of the future goals scale, the STEM positivity scale and the goal attainment scale. Participants were then thanked and debriefed.

## Results

## Effects of gender and communal goal endorsement.

The communal goals scale, the future goals scale, the STEM positivity scale and the goal attainment scale were each assessed on a 1 (low) to 7 (high) likert scale. These four scales were averaged to yield mean scores for each participant on each measure. Eleven participants were removed from analysis. One participant was removed due to incomplete responses and ten were removed as outliers due to reporting a communal goals score or a measure of STEM interest score that was greater than 2.5 standard deviations from the mean of the entire sample.

Overall, participants reported high communal goals scores and pre-test STEM interest scores (Table 1). Eighty percent of participants reported an average communal goal score of 5 or above and only two participants reported an average communal goal score below 4. There were no gender differences on ratings of communal goals or measures of STEM interest, ANOVA with gender as a factor $F(1,80)$ s $<$ 1.52, $\mathrm{ps}>.22$.

To consider whether participants' communal goal endorsement affected STEM interest, correlations between participants' communal goals ratings and their STEM interest scores were examined. Pearson correlation found that communal goals scores were positively correlated with STEM goal attainment scores $r(82)=.35, p<.01$. Communal goals scores were not correlated with future goals scores $r(82)=.18, p>.05$ or STEM positivity scores $r(82)=.10, p>.05$.

Table 1. Mean Ratings of Communal Goal Endorsement and STEM Interest Measures. Standard deviations are in parentheses.

|  | STEM Interest Measures |  |  |  |
| :--- | :---: | :---: | :---: | :---: |
|  | Communal <br> Goal <br> Endorsement | Future <br> Goals | Positivity | Goal <br> Attainment |
| Boys | $5.67(.73)$ | $5.94(.86)$ | $5.57(1.5)$ | $5.77(.96)$ |
| Girls | $5.86(.68)$ | $6.13(.88)$ | $5.40(1.3)$ | $5.80(.93)$ |

## Effectiveness of the Interventions.

Because communal goals scores were positively correlated with goal attainment scores, it is possible that the effects of the interventions may be different for participants with high and low communal goals scores. To consider the effect of communal goal endorsement, a median split was performed based on communal goal ratings, $($ median $=5.78$ ) which resulted in $46 \%$ of participants below the median and $54 \%$ or participants at or above the median.

To examine the effectiveness of the three different interventions and possible interactions with communal goal endorsement, a 2(gender) X 2(communal goals: high, low) X 3(condition: feminine, neutral, communal) repeated measures ANOVA was conducted with pretest and posttest STEM interest (time) as the within repeated measures. There was a significant interaction of time and gender on future goals, $F(1,68)=4.04, p<.05, \eta_{p}{ }^{2}=.06$. Overall, girls' post-intervention future goals scores decreased ( $M=$ 6.13, $S D=.88$ to $M=6.03, S D=.87$ ) while boys' ratings increased $(M=5.93, S D=.86$ to $M=6.19, S D=.71)$. A significant interaction between time and communal goals emerged for goal attainment, $F(1,68)=9.05, p<.01, \eta_{p}{ }^{2}=$ .11. Goal attainment scores decreased $(M=5.96, S D=.86$; $M=5.43, S D=1.2$ ) for participants with high communal goal ratings and increased for participants with low communal goal ratings $(M=5.59, S D=.99 ; M=6.00, S D=$ .91).

There were no significant interactions with time, condition, or gender on any of the measures of STEM interest $F(2,70)$ s $<2.46, p \mathrm{~s}>.08$. However, a significant interaction between time, condition and communal goals on future goals scores was observed $F(2,69)=5.879, p<.01, \eta_{p}{ }^{2}=$ .14. This result suggests that condition produced different changes to STEM interest ratings (in particular future goals) as a function of participants' communal goal score.

To explore the interaction between time, condition, and communal goals and further investigate the effectiveness of each intervention on future goals scores, separate ANOVAs were conducted on future goals with communal goals scores as a covariate on each intervention condition. The communal condition evidenced a significant interaction between time (pretest and posttest STEM interest) and communal goals $F(2,25)=6.44, p<.01, \eta_{p}{ }^{2}=.46$. No significant effects of time, communal goals or interactions between time and communal goals were observed in the feminine or neutral conditions, $F(2,27)$ s $<2.17, p \mathrm{~s}>.08$. This suggests that only participants in the communal goal condition had significant changes in their STEM future goal ratings. In the communal condition, future goal scores for participants with low communal goal scores increased
significantly by $15 \%$, paired sample t -test $t(11)=2.40, p<$ .05. However, none of the changes in the other conditions were statistically different than $0, t \mathrm{~s}<=1.74, p \mathrm{~s}>.11$. Figure 1 presents the percent increase in future goals scores across the three conditions, split by high and low communal goals ratings.

Figure 1: The percent increase in STEM Future Goal scores by experimental intervention condition and split into high and low communal goals groups. Error bars represent standard error of the mean.

## Discussion

The goal of the present research was to examine adolescents' STEM interest and the relationships to gender as well as communal goal endorsement. Several interventions designed to increase STEM interest were tested. Previous research has suggested that girls are less interested in STEM fields than boys are, and that exposing students to examples of female scientists will increase STEM interest. However, we found no gender differences on any measure of STEM interest. Further, the interventions presenting a highly stereotypically feminine exemplar or a female but stereotypically neutral exemplar did not improve STEM interest among female or male participants.

While the interventions involving female exemplars did not increase STEM interest, the communal goals intervention did. This intervention was designed to increase recognition of the communal aspects of work in STEM fields. Participants with low communal goal scores who received this intervention increased their future goals scores, suggesting they were more likely to take optional science and math classes in high school and college. This increase in STEM interest was only observed in the low communal goals category possibly because participants in the high communal goals category reported future goals scores at ceiling on both the pre-test and post-test measures.

It was found that this sample of adolescents evidenced high average communal goal endorsement overall.

Approximately $80 \%$ of participants averaged a score at or above 5 on a seven-point scale. Communal goal endorsement was also positively correlated with goal attainment scores, or the belief that a career in STEM fields would fulfill both communal goals in general, and specifically the participants' communal goals.

These findings lend support to the goal congruity hypothesis of STEM interest. A simple, 10-minute intervention emphasizing the role of communal goals in STEM fields was able to significantly and positively affect one measure of STEM related future goals of students who did not score at ceiling on the communal goals scale. In comparison, more traditional interventions centered on exemplars and the emphasis of femininity produced no significant change in any measure of STEM interest.

Of course this is not to say that the power and influence of gender stereotypes should be discounted, certainly they do play a role in the decision to pursue a STEM career (McIntyre, Paulson \& Lord, 2003; Nosek, Banaji, \& Greenwald, 2002). However, our data suggests that during early adolescence valuing communal goals, like working with and helping others, may possibly be a more influential factor than gender category membership on STEM interest. Simply attributing STEM interest to the influence of gender stereotyping may be somewhat of an oversimplification. Thus, our data suggests that emphasizing communal goals in this population may be a more effective and practical way to increase STEM interest than more traditional interventions that emphasize stereotype-disconfirming exemplars and femininity.

There are limitations to this study. The sample was taken from one school district and was not racially diverse. In addition, our participants appeared to have high communal goal desires causing possible ceiling effects, which might have obscured other findings. Future studies should explore this finding with a larger, more diverse sample and a modified communal goals scale to attempt to combat ceiling effects.

## Feminine and Neutral Conditions.

Profile of a Scientist:
Name: Lisa Johnson
Biography:
Lisa is an electrical engineer. She enjoys yoga, watching romantic comedies and knitting (In Neutral Condition: running, watching nature documentaries and photography) Lisa Says:

I am Electrical Engineer at the NASA Glenn Research Center. I work on Power System Development for future NASA missions. Specifically, I support the development of a power processing unit for high power, high voltage electric propulsion applications and the development of a flywheel energy storage system.

Flywheel energy storage, or storing energy mechanically in a rotating wheel, offers an alternative to traditional chemical energy storage systems, such as batteries, for future missions.

Every day I work to solve problems and learn new things. I figure out how to implement new technologies all the time and I go home everyday knowing that I made a difference!
Writing Activity:
Listed below are some typical daily tasks that a scientist like Lisa would perform. Imagine you are also a scientist doing work in an environment similar to Lisa's. What do you think your average day would be like? Please write a few sentences describing what you think it would be like if you worked as a scientist like Lisa.

Daily Tasks of a Scientist:

- Check a database for updates on ongoing experiments.
- Look up and read about past research to help you develop new experiments.
- Watch videos of other scientists presenting their recent findings
- Update a lab notebook with information about the progress and status of your experiments
- Work out data analysis problems by yourself
- Make a PowerPoint presentation of your recent experimental results to email to a supervisor

## Communal Condition.

Profile of a team of Scientists:
Name: NASA Power Team
Biography:
The NASA Power Team is made up of six electrical engineers. They enjoy working and spending time together The Power Team Says:

We are a team of six Electrical Engineers at the NASA Glenn Research Center. We work closely together on Power System Development for future NASA missions. Specifically, we support the development of a power processing unit for high power, high voltage electric propulsion applications and the development of a flywheel energy storage system.

Flywheel energy storage, or storing energy mechanically in a rotating wheel, offers an alternative to traditional chemical energy storage systems, such as batteries, for future missions. This technology also has the potential to help people here on Earth in many ways.

Every day we work together to solve problems and learn new things. Together, we figure out how to implement new technologies all the time. Each of us goes home everyday knowing we made a difference!

## Writing Activity:

What do you think your average day would be like? Please write a few sentences describing what you think it would be like if you worked as a scientist like the NASA Power Team.

Daily Tasks of a Scientist:

- Talk with team members about updates on ongoing experiments.
- Brainstorm with your fellow researchers about past research to help you develop new experiments.
- Attend presentations from other scientists about their recent findings
- Update your team coordinator with information about the progress and status of your experiments
- Work out data analysis problems with your other members of your lab team.
- Present your recent experimental results to your supervisor with your team members.

# 20-month-olds Use Social-Group Membership to Make Inductive Inferences 

Megan A. Smith (msmith57@ucmerced.edu)<br>Rose M. Scott (rscott@ucmerced.edu)<br>Psychological Sciences, University of California Merced

#### Abstract

Previous research suggests that preschool children expect members of social groups to share stable, inherent characteristics (e.g., Waxman, 2013). Here we explored the origins of these social-group based inferences by examining whether infants generalize food preferences across members of an arbitrary social group. Experiment 1 demonstrated that infants expected two individuals to share food preferences when they belonged to the same social group, but not when they belonged to two different social groups. Experiment 2 replicated and extended these findings to social groups that were labeled with adjectives instead of nouns. These results suggest that by 20 months of age, infants use social-group membership to make inductive inferences about the behavior of group members.

Keywords: social groups; inductive inference; psychological reasoning; social cognition

## Introduction

Categorization is vital to human cognition. Category representations provide an efficient way of organizing our knowledge about the world, and they enable generalization of prior knowledge to novel entities and situations (Gelman, 1988; Medin, ojalehto, Waxman, \& Bang, 2015). Upon identifying that a novel entity belongs to a familiar category (e.g., dog), one can infer that it likely possesses common properties of that category (e.g., it is alive, wags its tail, etc.). Categories also aid in reasoning about kinds of people: Adults tend to assume social categories (e.g., doctors, women) capture fundamental, inherent similarities amongst collections of individuals and thus use prior knowledge about a social category to make inductive inferences about the physical, psychological, and behavioral properties of novel group members (e.g., Agerström, Björklund, Carlsson, \& Rooth, 2012).

The tendency to use social-group membership to make inductive inferences about category members is well established by the preschool years. (e.g., Bigler, Jones, \& Lobliner, 1997; Birnbaum, Deeb, Segall, Ben-Eliyahu, \& Diesendruck, 2010; Diesendruck \& HaLevi, 2006; Waxman, 2013). For example, 5-year-old children expect that members of the same social category will prefer the same activities (Diesendruck \& HaLevi, 2006) and preschoolers expect that members of the same, but not the opposite, sex will prefer the same toys (Martin, Eisenbud, \& Rose, 1995).

When and how does this tendency to make social-group based inferences emerge? As early as 3 months, infants notice visual and auditory features that are associated with social-group membership (e.g., Bar-Haim, Ziv, Lamy, \& Hodes, 2006; Howard, Henderson, Carrazza, \& Woodward, 2015; Shutts, Kinzler, McKee, \& Spelke, 2009). Evidence
for this comes primarily from tasks that assess whether infants demonstrate preferences for individuals who are similar to themselves. For example, by 3 months infants living in primarily own-race environments prefer to attend to own-race over other-race faces (Bar-Haim et al., 2006). By 19 months, infants prefer to accept toys and foods endorsed by a speaker of their native language over a speaker of a foreign language (Kinzler, Dupoux, \& Spelke, 2007; Shutts et al., 2009) and are more likely to imitate actions produced by a native-language speaker (Howard et al., 2015). By 11.5 months, infants also attend to food preferences and clothing as potential markers of group membership (Mahajan \& Wynn, 2012).

There is also some evidence that infants spontaneously categorize individuals into social groups instead of merely detecting features correlated with group membership (Powell \& Spelke, 2013; Liberman, Kinzler, \& Woodward, 2014; Liberman, Woodward, Sullivan, \& Kinzler, 2016; Rhodes, Hetherington, Brink, \& Wellman, 2015). These findings come from "third-party" tasks in which the infant is not a member of the groups in question. For example, Liberman et al. (2016) examined whether 14 -month-old infants expect individuals who affiliate to share food preferences. In a violation-of-expectation task, infants were first introduced to two actors who either affiliated with one another by smiling and saying "Hi", or disengaged from one another by turning away, crossing their arms, and saying "Hmph." Next, Actor-2 watched as Actor-1 ate one of two foods and emoted positively. In the test trial, Actor-2 ate the same food and emoted negatively, actively disagreeing with Actor-1's preference. Infants who saw the actors affiliate expected them to prefer the same food, and looked longer if they disagreed. In contrast, infants did not expect actors that had previously disengaged to share food preferences. Together with the results of several additional conditions, these findings suggested that infants can use social relationships to predict and interpret the behavior of agents.

However, it remains unclear whether infants expect that members of a social category will share stable, inherent characteristics. This is because in prior studies, such as the one just described, the target character always acted in the presence of its group members. Infants' responses may therefore have reflected an expectation that the target character would conform to social pressures or imitate group members, rather than expectations about the inherent properties and tendencies of the individual. The present research thus asked whether infants use social group membership to make inductive inferences about the properties of an individual, even when that individual is acting in the absence of other group members.

To address this question, we examined whether 20-month-old infants expected members of a social group to share food preferences. Several decades of research suggest that by this age, infants attribute preferences to agents (e.g., Woodward, 1998). Moreover, by 18 months infants assume that an agent's preference is specific to that individual unless given indication otherwise (Egyed, Király, \& Gergely, 2013). This allowed us to test whether social-group membership overrides this default assumption. We focused specifically on food preferences because foods are culturally relevant and thus likely to be shared amongst members of a social group (Cashdan, 1998; Rozin \& Siegal, 2003).

Infants were tested in a violation-of-expectation task involving arbitrary social groups, Topids and Brinkos. Arbitrary social groups were used in order to ensure infants had equal amounts of experience with the social groups being tested. The groups were identified using both shared appearance and noun labels because previous research suggests that infants might not form social categories based on physical appearance alone (e.g., Powell \& Spelke, 2013). In the familiarization trials, infants saw a member of one of the social groups (a Topid) demonstrate a preference for one of two novel foods. In the test trial, infants saw a single agent from either the same group (another Topid) or a different group (a Brinko) choose between the two foods. If infants use social group membership to make inductive inferences about food preferences, then they should expect members of the same social group to pick the same foods, and should look longer if the Topid picks a different food instead. In contrast, infants should not use the preferences of one social group to make inferences about the preferences of an individual from a different social group. Infants should thus have no expectations about what the Brinko should choose and look equally regardless of whether she chooses the same or a different food.

## Experiment 1

## Method

Participants 36 healthy term infants participated (18 female; ages 18 months, 10 days to 21 months, 18 days, $M=$ 20 months, 8 days). Another 12 infants were tested but excluded because they were fussy (8), because of parental interference (2), or because their test looking time was over 2.5 SD away from the mean of their condition (2). Half the infants were randomly assigned to the same-group condition ( $M=20$ months, 16 days) and half to the different-group condition ( $M=20$ months, 0 days).

Stimuli Stimuli consisted of digitized high-definition video recordings of actors performing a series of actions. All infants saw four familiarization trials and one test trial. A separate video was played for each trial. Each trial consisted of an initial phase followed by a final phase. The duration of the initial phase was fixed and identical for all participants. The duration of the final phase was infant-controlled. All trials are described from the infants' perspective.

Figure 1: Familiarization trial 1 of the same-group condition of Experiment 1.

Same-group familiarization trials At the start of the first familiarization trial, three female actors sat around a table (Figure 1). Two of the actors (Topid-A, Topid-B) wore bright pink turtlenecks and decorated yellow visors while the third (Brinko-A) wore a plaid shirt and a propeller hat.

All actors began the trial with their heads down. During the $10-\mathrm{s}$ initial phase of the trial, the actors looked at one another and labeled themselves: Topid-A said "Hi, I'm a Topid," Topid-B said, "Hi, I'm a Topid too," and Brinko-A said, "Hi, I'm a Brinko." As each actor labeled herself, she looked back and forth between the other two actors. When not labeling themselves, the actors looked at the speaking actor as she spoke. After all actors had labeled themselves, the actors looked down and paused. The infants viewed this paused scene until the trial ended (see Apparatus and procedure section for trial-ending criteria).

The infants then received three familiarization trials in which Topid-A demonstrated her preference for one of two foods. On each trial, Topid-A sat behind a table. In front of her were two white plates ( 18 cm in diameter) placed 25 cm apart. The plate on the right held purple pasta and the plate on the left held blue cereal. During the $10-\mathrm{s}$ initial phase of the trial, Topid-A selected one of the foods (counterbalanced across infants) and ate it while saying, "Mmm!" She then looked down at the center of the table between the two plates and paused until the trial ended. Topid-A selected the same food on all three trials, demonstrating that she preferred it to the other food.

Figure 2: Test events shown in the same-group condition of Experiment 1.

Same-group test trials The infants received either a samefood or different-food test trial (Figure 2). For ease of description, the test trials are described from the perspective of the infants who saw Topid-A choose blue cereal in the familiarization trials.

At the start of the trial, none of the actors were present. The plates of blue cereal and purple pasta again sat on the table. During the $10-\mathrm{s}$ initial phase of the trial, Topid-B entered from the left, sat down, and then selected a piece of blue cereal (same-food event) or purple pasta (different-food event), raised it to her mouth, and ate the food. After eating the food, she proceeded to say, "Mmm!" and smile, displaying positive affect and indicating she enjoyed eating the food. She then looked down at the center of the table between the two foods and paused until the trial ended.

Figure 3: Familiarization trial 1 of the different-group condition of Experiment 1

Different-group familiarization and test trials The procedure for the different-group condition was identical to that of the same-group condition with one exception: the actor who played Topid-B in the same-group condition now played Brinko-B throughout the experiment. In the first familiarization trial, she wore the same costume as BrinkoA and labeled herself as a Brinko (Figure 3). In familiarization trials 2-4, infants saw Topid-A establish her food preference, as in the same-group condition. In the test trial, the actor wore a Brinko costume, but her actions were otherwise identical to those she performed in the samegroup condition. The infants in both conditions thus saw the exact same actor in the test trial. All that differed was which costume she wore and whether she had previously labeled herself as a Brinko or a Topid. Any observed differences in looking times across conditions could therefore not be due to a preference for a particular individual.

Apparatus and procedure The infants sat on their parent's lap 91.5 cm in front of a large television screen $(68.5 \mathrm{~cm} \mathrm{x}$ 122 cm ). The room was dimly lit. A camera hidden at the base of the television (centered, 89 cm above the floor) recorded the infant's face during the experiment. Parents were instructed to close their eyes or look down to avoid biasing their infant's responses.

The television was connected to a Macintosh computer located to the left of the infant behind a sound-dampening
room divider. This computer controlled the presentation of the experimental stimuli using custom software written in Python (Peirce, 2007). The software selected the correct version of each trial based on the infant's condition and presented the video in the center of the television screen (each video measured $64 \mathrm{~cm} \times 37 \mathrm{~cm}$ on screen). The software also controlled the duration of each trial. An experimenter observed the infant on a monitor and pressed a button on the keyboard whenever the infant attended to the video. The software separately computed looking times for the fixed-duration and infant-controlled portions of each trial; looking times during the infant-controlled portion of the trial were used to determine when each trial ended. In between trials, an attention-getter (a yellow smiley face measuring $28 \mathrm{~cm} \times 20 \mathrm{~cm}$ ) was displayed on the screen for 4 seconds and a brief tone was played to attract the infant's attention back to the television screen.

At the start of the experiment, the attention-getter was presented in the center of the television screen. When the infant attended to the screen, the experimenter initiated the presentation of the stimuli on the television screen. The infants first viewed four familiarization trials appropriate for their condition. Each familiarization trial ended when the infant either (1) looked away for 2 consecutive seconds after having looked for at least 4 cumulative seconds or (2) looked for 60 cumulative seconds without looking away for at least 2 consecutive seconds.

Finally, the infants viewed the test trial that was appropriate for their condition; half the infants in each condition saw the same-food trial and half saw the differentfood trial. This trial ended when the infant either (1) looked away for .5 consecutive seconds after having looked for at least 4 cumulative seconds or (2) looked for 30 cumulative seconds without looking away for at least .5 consecutive seconds.

Coding and analysis In order to present events with trial duration contingent on the infant's attention, online coding was conducted by the experimenter (blind to condition and test trial), as described above. All infants were then coded offline from silent video by a trained coder who was naïve to the condition and test trial that the infant received; the looking times resulting from this coding were used in all analyses. For each trial, the coder indicated the infant's direction of gaze (at the stimuli or away) for each frame of the video. Another trained coder who was naïve to the infant's condition and test trial coded all sessions, and these two coder's agreed on the child's direction of gaze for $96 \%$ of video frames. Trials in which agreement was less than $90 \%(15 / 180)$ were resolved by a third naïve coder.

The infants were highly attentive during the initial phase of the familiarization trials: averaged across the four familiarization trials, the infants attended for $96 \%$ of the initial phase. The infants were also highly attentive during the initial phase of the test trial, attending for $97 \%$ of the initial phase.

Preliminary analyses of the test data indicated no
significant interactions of condition and event with sex or which food Topid-A preferred (blue vs. purple), all $F$ s $<$ 1.55 , all $p \mathrm{~s}>.22$. The data were therefore collapsed across these factors in subsequent analyses. In order to control for baseline differences in attention, all analyses were run with average looking time during the final phases of the familiarization trials as a covariate.

Figure 4: Mean looking time (sec) of the infants during the test trial of Experiments 1 and 2 as a function of condition and event. Error bars represent standard errors, and asterisks indicate a significant difference between events with a condition ( $p<.05$ ).

## Results and Discussion

The infants' looking times during the test trial (see Figure 4) were analyzed using an analysis of covariance (ANCOVA) with condition (same-group, different-group) and event (same-food, different-food) as between-subjects factors. There was a main effect of event, $F(1,31)=14.20, p=.001$, $\eta_{p}{ }^{2}=.31$, indicating that the infants who saw the differentfood event looked longer than those who saw the same-food event in the test trial. However, this effect was qualified by a significant interaction of condition and event, $F(1,31)=$ 9.03, $p=.005, \eta_{p}{ }^{2}=.23$. There was no main effect of condition, $F<1$. Planned simple effect comparisons revealed that in the same-group condition, the infants who received the different-food event $(M=17.18, S D=4.14)$ looked reliably longer than those who received the samefood event $(M=7.94, S D=2.29), F(1,31)=23.00, p<$ .001 , Cohen's $d=2.76$. In the different-group condition, the infants looked about equally whether they received the same-food event ( $M=10.81, S D=4.16$ ) or the differentfood event ( $M=12.15, S D=5.80$ ), $F<1$.

As predicted, the infants in the same-group condition looked reliably longer if they received the different-food event than if they received the same-food event. This suggests that the infants expected members of the same
social group to share food preferences, and they looked longer if members of the same social group had different food preferences. In contrast, the infants in the differentgroup condition looked equally regardless of whether members of different social groups picked the same or different foods.

However, a possible alternative explanation of these results is that when Topid-A and Topid-B wore the same outfit, the infants were unable to discriminate between them. If so, then the infants in the same-group condition might have thought that the agent in the test trial was the same agent that they had seen in the familiarization trials and hence looked longer at the different-food event because that agent appeared to suddenly change food preferences. To address this possibility, an additional group of 12 infants were tested in an actor-discrimination condition (procedure adapted from Buresh \& Woodward, 2007). Infants first saw the same familiarization trials as in the same-group condition. Infants then viewed two test trials in which either Topid-A (old-actor event) or Topid-B (new-actor event) entered and ate the same food that Topid-A had chosen during the familiarization trials (order of test events counterbalanced across infants). The infants' looking times during the test trials were analyzed using an analysis of variance (ANOVA) with test event (old-actor event, newactor event) as a within-subjects factor and event order (oldactor first, new-actor first) as a between-subjects factor. The analysis yielded a main effect of event, $F(1,10)=9.08, p=$ $.013, \eta_{p}{ }^{2}=.48$, indicating that the infants looked longer at the new-actor test event ( $M=11.44, S D=4.58$ ) than the old-actor event $(M=7.34 \mathrm{~S} D=2.24)$. No other effects were significant, all $F \mathrm{~s}<1$. If the infants had not noticed the change in actor, they would have looked equally to the newactor and old-actor events. However, the infants found the new-actor event novel, suggesting that infants were able to discriminate between the two actors.

Together, these findings provide additional evidence that infants can reason about members of a group that they themselves do not belong to (Powell \& Spelke, 2013; Liberman et al., 2016) and add to these prior findings by demonstrating that infants expect members of social groups to share inherent properties.

## Experiment 2

Experiment 2 had two goals. The primary goal was to replicate the positive findings from the same-group condition in Experiment 1 . Our secondary goal was to explore whether the noun labels in Experiment 1 were necessary for children to establish social groups with inductive potential. To investigate this question, infants were assigned to an adjective condition that was identical to the same-group condition of Experiment 1 except that the actors labeled themselves with adjectives instead of nouns. If infants require noun labels to identify social groups with inductive potential, then when the social groups are labeled with adjectives, infants will no longer generalize preferences across members of a social group. If, however,
infants can use adjectives to identify social groups with inductive potential, then infants will expect members of the same social category to pick the same foods, replicating the results of the same-group condition of Experiment 1.

## Method

Participants 30 healthy term infants participated (16 female; ages 18 months, 3 days to 21 months, 29 days, $M=$ 19 months, 16 days). Another 5 infants were tested but excluded because they were fussy (3), or because of parental interference (2). Eighteen infants were randomly assigned to the same-group condition ( $M=19$ months, 27 days) and 12 to the different-group condition ( $M=19$ months, 0 day).

Stimuli, Apparatus, and Procedure The stimuli, apparatus, and procedure were identical to Experiment 1 except that in the first familiarization trial the actors labeled themselves with adjectives instead of nouns (e.g., "Hi! I'm Topish.").

Coding and analysis As in Experiment 1, all infants were coded offline by a coder naïve to the condition and test trial that the infant received. An additional naïve coder coded all participants; agreement between the two coders was $97 \%$. Trials in which agreement was less than $90 \%(4 / 150)$ were resolved by a third naïve coder

Infants were highly attentive during the initial phase of all familiarization trials; averaged across all four trials, infants attended for $98 \%$ of the initial phase. Infants were also highly attentive during the initial phase of the test trial, attending for $98 \%$ of the initial phase.

Preliminary analyses of the test data indicated no significant interactions of condition and event with sex, or which food Topid-A preferred (blue vs. purple), all $F \mathrm{~s}<1$. The data were therefore collapsed across these factors in subsequent analyses.

## Results and Discussion

Infants' looking times during the test trial were analyzed using an ANCOVA with condition (same-group, differentgroup) and event (same-food, different-food) as betweensubjects factors, and infants' average looking times during the final phases of the familiarization trials as a covariate. Results revealed a significant interaction between condition and event $F(1,25)=4.75, p=.039, \eta_{p}{ }^{2}=.16$. There were no main effects of event or condition, both $F \mathrm{~s}<1$. Planned simple effect comparisons revealed that in the same-group condition, the infants who received the different-food event ( $M=19.90, S D=8.40$ ) looked reliably longer than those who received the same-food event ( $M=10.44, S D=3.73$ ), $F(1,25)=8.59, p=.007, d=1.46$. In the different-group condition, the infants looked about equally whether they received the same-food event $(M=14.54, S D=5.43)$ or the different-food event ( $M=12.38, S D=4.79$ ), $F<1$. These results suggest that, similar to the results of Experiment 1, infants in Experiment 2 expected members of a social group to share food preferences and looked longer when members
of the same social group had different preferences. In contrast, infants had no expectation about whether members of different social groups would share food preferences.

To investigate whether infants' looking time patterns were similar across experiments, infants' looking times to the test trial were analyzed using an ANCOVA with Experiment (1, 2), condition (same-group, different-group), and event (same-food, different-food) as between-subjects factors, and infants' average looking times during the final phases of the familiarization trials as a covariate. Results revealed a main effect of event, $F(1,57)=12.33, p<.001$, $\eta_{p}{ }^{2}=.18$. This effect was qualified by a significant interaction of condition and event, $F(1,57)=13.93, p=<$ $.001, \eta_{p}{ }^{2}=.20$. No other effects were significant, all $F \mathrm{~s}<$ $2.3, p \mathrm{~s}>.14$. The absence of any main effects or interactions involving Experiment suggests that regardless of whether the social groups were labeled with nouns or adjectives, infants expected members of the same social group to prefer the same foods.

## General Discussion

By preschool, children expect members of a social group to share characteristics and thus use social-group membership to draw inductive inferences about the properties of novel individuals. The current studies examined the origins of this social-group based reasoning in infancy. Specifically, we examined whether infants expect members of a social group to share preferences. Infants were introduced to members of two arbitrary social groups, Topids and Brinkos, and learned that a particular Topid preferred one of two foods. Infants later expected another Topid to prefer the same food and looked longer if she did not. However, infants had no expectations about whether members of different social groups (i.e. a Topid and a Brinko) would share preferences. Infants held similar expectations regardless of whether the group members labeled themselves with nouns (Topid, Brinko) or adjectives (Topish, Brinkish).

These findings expand our understanding of infants' social-group based reasoning in several key ways. First, these studies provide additional evidence that infants can categorize individuals as members of a social group, even if they themselves are not members of that group (e.g., Liberman et al., 2016; Powell \& Spelke, 2013). Second, these studies expand on prior work by providing the first empirical evidence that infants as young as 20 months use social-group membership to make inductive inferences about the likely behavior of group members, even when other group members are not present. In our experiments, only one agent was present in the test trial, and that agent did not see which food the other agent had selected during the familiarization trials. Thus, infants' expectations regarding the agent's behavior in the test trial are unlikely to have been based on social pressures or imitation. Even without the presence of other group members, infants expected members of a social group to share stable, inherent properties.

Together, the current studies begin to shed light on the
circumstances under which infants treat social group members as alike, and the age at which these expectations emerge. Future studies should further explore the precise nature of infants' social-group based inferences. For instance, we have discussed our results in terms of shared preferences: when Topid-A selects blue cereal over purple pasta, infants interpret this as signaling that Topids prefer blue cereal and hence expect another Topid to share this preference and also select blue cereal. However, perhaps infants were instead reasoning about shared avoidance of the food that Topid-A did not select - Topids do not eat purple pasta - and hence expected another Topid to avoid that food as well. Both shared preferences for and shared avoidance of specific foods exist across cultures (i.e. some cultural groups have a strong preferences for pork products, whereas other groups prohibit consuming pork). Future research should examine whether infants expect group members to like the same foods, avoid the same foods, or both. Additionally, future research should examine whether infants were reasoning specifically about foods, or whether infants could also have been reasoning about other features of the event (i.e. reaching for a particular color). Such studies will help clarify the characteristics that infants expect social-group members to share.

#### Abstract

Theories of the mental processes people use to perform physical reasoning often differ on whether they are based on simulation or on logical reasoning. Here we test how these different processes might combine in a motion-prediction task that can be solved either by simulation or by reasoning about the topology of the scene. Participants were asked to predict which of two goals a computerized ball would reach first, but in some of these scenes the ball was 'contained' in the same space as one goal but was topologically separated from the other. Even in these contained scenes, participants responded faster when they received motion information that would speed up simulation but not affect topological parsing. This suggests that simulation contributes to predicting short-range motion, even when alternate strategies are available.

Keywords: intuitive physics; simulation; topology; containers

## Introduction

A long-standing debate in physical reasoning is whether people use simulation (Shepard \& Metzler, 1971; Battaglia, Hamrick, \& Tenenbaum, 2013) or symbolic reasoning (Forbus, 1983; Davis, Marcus, \& Chen, 2013) to understand the world, and whether the mental representations that support physical reasoning are continuous or based on a qualitative analysis of the scene. Recently, models based on continuous simulation have had success explaining a range of human behaviors such as stability judgments (Battaglia et al., 2013), motion prediction (Smith \& Vul, 2013), and causality judgments (Gerstenberg, Goodman, Lagnado, \& Tenenbaum, 2012). However, others have noted that simulation is an overly cumbersome process for many instances of physical reasoning where simple logical rules could suffice - e.g., if a ball is placed in a box and shaken, it seems easier to notice the topological relationship of containment and use the rule "An object in a closed container remains in the container" than to simulate the exact trajectory of the ball (Davis \& Marcus, 2015).

In this paper we study how people make physical predictions in cases where either simulation or a logical parsing of the scene can provide an answer. As in the example of Davis and Marcus (2015), we focus on the topological relationship of containment: an object is contained in a portion of space if there exist other objects that surround it and prevent it from leaving that space. We choose to study containment for three reasons. First, Davis et al. (2013) demonstrate that topological containment can be parsed using simple rules of firstorder logic for a rapid understanding of the scene. Second, people automatically and unconsciously process certain types

Figure 1: Diagram of continuous simulation (top) versus reasoning about kinematics using a qualitative scene parsing (bottom). Noisy simulation traces potential trajectories of objects through a continuous representation of the world. Qualitative physical reasoning segments the scene by topological regions and defines motion trajectories through a graph based on connections between those regions (bottom figure from Forbus, 1983).
of containment (Strickland \& Scholl, 2015). And finally, in previous work we found that we could explain motion prediction using a model of noisy physical simulation across a wide variety of scenes, but that people made predictions more rapidly than would be expected under the simulation model in the handful of scenes where an object was topologically contained to make one outcome impossible (Smith, Dechter, Tenenbaum, \& Vul, 2013). Together, this suggested that predicting motion in contained spaces would be a good candidate task for finding traces of both simulation and logical reasoning about scene topology.

Here we test whether and when topological reasoning about a scene occurs before simulation, versus when simulation supports prediction. We use a similar paradigm to Smith et al. (2013), in which participants observe a ball bouncing around a computerized screen and predict which of two 'goals' the ball will reach first. To make predictions using simulation, people would need to form a representation of the scene then step the motion of the ball forwards in time until it reaches a goal, but do not need to recognize the combined spatial relationship of objects: e.g., that a set of walls delineates one part of the space from another. Thus the time it takes to form simulations and make a prediction should be proportional to the path length the ball travels (Moulton \&

Kosslyn, 2009), and so the amount of time to produce a response using simulation should be affected by the motion of the ball: if the ball is moving towards a goal, the relatively shorter path should require less time to simulate, whereas motion away from the goal would produce longer simulation paths and proportionally longer response times. Conversely, to predict that the ball will reach one of the two goals because it cannot reach the other requires representing the scene, logically reasoning about whether the walls form distinct regions, then deciding whether the ball rests within a region with one but not both of the goals. However, this reasoning process does not require moving the ball forward in time, and so should be insensitive to any differences in motion information.

In this experiment, we therefore asked participants to make a single prediction and measured their response times. We further varied the motion information provided: the ball could move towards the goal, away from the goal, or have no observed motion. A facilitation effect in which motion towards the goal produces faster responses is evidence that people are at least in part relying on simulation, while absence of this effect points towards topological processing. Finally, we vary the way in which the ball can be contained in order to test for the limits of topological processing.

## Experiment

## Procedure

We recruited 100 participants from Amazon Mechanical Turk using psiTurk (Gureckis et al., 2016) to take part in this experiment. The experiment lasted $\sim 10-12$ minutes, for which participants were compensated $\$ 1.20$.

On each trial of the experiment, participants would observe a scene with a ball that could move in a straight line but bounce off of walls (such as the one in Figure 2) and were asked to predict whether the ball would reach the green goal or the red goal first. The colors of the goals were randomly switched to avoid any color biases, and responses were adjusted in switched-color trials for consistency of analysis. In two thirds of the trials, participants would observe the ball in motion for 500 ms ; in the remaining third of trials, participants would observe no motion but were instructed that the ball would move in a direction not known to them until after they made their prediction.

Figure 2: Diagram of experimental trials (Left: non-topological, Right: topological). Participants would either observe the ball in motion or a static ball, and would be asked to indicate whether they believed the ball would reach the green or red goal first. The arrow was not displayed but indicates the direction of motion.

Participants registered which goal they believed the ball would reach by pushing either the ' $z$ ' or ' $m$ ' buttons on the keyboard. The mapping between the key and goal color was randomized across participants to control for any directional effects. To ensure that participants observed the full motion path and to equate for processing time, the prediction could not be registered until either the 500 ms of motion had stopped in the motion condition, or after the response buttons flashed after 500 ms in the no motion condition.

After participants registered their response, the ball would travel along its trajectory until it reached a goal, and participants would be assigned a score between 0 and 100 points, with faster reaction times (up to 300 ms ) earning more points. If participants made an incorrect prediction, they always lost 10 points. If a participant did not respond for 2500 ms , the trial would end and the participant would be awarded no points. These points were used to incentivize rapid responses and as motivation, but did not affect compensation.

On each trial we recorded both reaction time (between when a response could be indicated and when the button was pressed) ${ }^{1}$ and the goal the participant predicted the ball would reach.

## Stimuli

Participants observed 120 trials throughout the experiment. Of these trials, 96 were 'non-topological' trials that were randomly constructed such that the ball would reach a goal within 15 seconds, but were not hand designed with topological relationships. These uncontained trials were used to ensure that participants did not develop a deliberative, top-down strategy of judging topology.

The remaining 24 trials each participant saw were crafted to investigate one of four different dimensions of topological processing. There were six trial templates for each of the four dimensions (for a total of 24 templates), and each of these templates was adjusted to create three levels of containment across that dimension - each dimension started from the most contained, most simple, or smallest (level 1) and progressed to the most open, most complex, or largest (level 3). Thus there were 72 different topological trials used in the experiment, but each participant saw only one of the three levels formed from each template to avoid carry-over from similar trials. The dimensions of topological differences are described below.

Size This dimension was used to test whether topological parsing was performed by exploring the enclosed space at a constant rate, or whether topology is processed based on the configuration of the scene. If it is performed at a constant rate, then larger scenes with the same configuration should take longer to parse as topologically contained. We crafted these stimuli such that the smallest scene had dimensions that were $50 \%$ of the largest scene, while the middle scene had

[^502]

Figure 3: Sample trials from each of the topological dimensions along the three levels. The size trials (upper left) varied from small to large containers. The porousness trials (lower left) varied the size of gaps in the wall of the container. The stopper trials (upper right) varied the distance of the goal from making a seal with the rest of the container. The complexity trials (lower right) varied the internal and external structure of the containers. Balls in the "towards" condition moved in the direction indicated by the line, while balls in the "away" condition moved in the opposite direction. In all cases the ball ended at the green goal.
dimensions that were $75 \%$ as large (see Figure 3, upper left).
Porousness This dimension was used to test whether an object is topologically parsed as a container only if it is fully sealed, or whether containment is relative to the object inside. If topological processing is based solely on the container, then any gaps should prevent it from being seen as a container, whereas if it is calculated relative to the object inside, then it should still be observed as a container if gaps in its walls are smaller than the object it is holding. In the three levels along this dimension, one container was fully sealed with no breaks in its walls, one had gaps that were smaller than the ball, and the final level had gaps large enough for the ball to fit through (see Figure 3, lower left).
Stopper Forbus (1983) suggests that scene and motion descriptions also take into account what sorts of motions are allowable within the scene. If this is the case, then topological processing might also be affected by whether the path an object takes to exit a container is implausible or impossible. We therefore tested whether participants would consider the ball to be contained if there were almost no conceivable physical paths that would allow it to escape, even if there exist simple paths outside that do not account for physical motion. Level 1 along this dimension was produced with one goal forming a seal with the rest of the container. Level 2 moved the goal away from the container so that the ball could fit through, but in a physically implausible way. Level 3 moved the goal even further so that it is easily possible that the ball could exit the container without hitting the goal under plausible kinematic motion (see Figure 3, upper right).

Complexity This dimension was used to test how topology and simulation interact - even in situations where the
ball is fully contained will people use simulation if parsing the boundaries of the container is too difficult? Along this dimension, the levels included a simple configuration (e.g., the screen is split into two parts by a single wall), a moderately complex configuration with more internal and external structure, and very complex configuration (see Figure 3, lower right).

In all of the levels of all of the trials, participants would see either motion that is in the general direction of the goal within the container, motion in the opposite direction away from the goal, or no motion. To ensure each trial was novel, each participant only saw one type of motion for each trial, counterbalanced across participants. These motion conditions were tested because differences in velocity information should affect simulation but not topological judgments. If people are using simulation, we would expect that motion towards the goal should speed processing as compared to motion away, since each simulation will have a shorter distance to travel and fewer bounces before reaching the goal (Hamrick, Smith, Griffiths, \& Vul, 2015). Similarly, if people predict the outcome of no motion trials by simulating paths the ball could take in any direction, because most potential paths would be longer than the paths created with motion towards the goal, predictions should also be slowed in this case. If containment is judged by parsing the topology without using information about velocities, then changing the type of motion information provided should not change the speed of this mental process. We can therefore test for the presence of simulation by the presence of faster reaction times in the "towards" motion condition compared to the "away" or "no motion" conditions.

Figure 4: Geometric means of reaction times across topological dimensions and motion conditions. Bars indicate $95 \%$ confidence intervals bootstrapped from 500 samples. In all cases reaction times in the "towards" condition were faster than those in the other two conditions, indicating a use of simulation.

## Results

To ensure that we do not use data from participants who were not paying attention, we eliminated responses from trials where participants minimized or otherwise hid their browser screen ( $0.3 \%$ of trials) or where participants did not indicate a prediction in the allotted time ( $1.6 \%$ of trials). Finally, because participants observed the scene for 500 ms before making a response, some responses could be anticipatory. To prevent these measurements from skewing the data, we removed all responses under 10 ms ( $0.7 \%$ of all trials). For the purpose of all analyses, reaction times were log-transformed to account for long tails (Whelan, 2008) but transformed back for reporting and display.

We first test for overall differences in speed of processing across all topological dimensions, levels, and motion directions. ${ }^{2}$ This analysis suggests that motion direction plays a pivotal role in explaining reaction times $(F(2,2152)=$ $61.8, p \approx 0$ ), with "towards" ( $321 \mathrm{~ms}, 95 \% \mathrm{CI}$ : $[288,357]$ ) being faster than "away" ( $394 \mathrm{~ms}, 95 \%$ CI: [354, 439]), which in turn is faster than "no motion" ( $487 \mathrm{~ms}, 95 \%$ CI: [437, 543]) over all trial types.

The dimension of topology also affects reaction time $\left(F(3,58)=14.2, p=7.8 * 10^{-8}\right)$, with the complex trials ( $481 \mathrm{~ms}, 95 \%$ CI: $[424,546]$ ) being slower than the size trials ( $359 \mathrm{~ms}, 95 \% \mathrm{CI}:[316,407]$ ), the porous trials $(373 \mathrm{~ms}, 95 \%$ CI: [329, 423]), and the stopper trials ( $377 \mathrm{~ms}, 95 \% \mathrm{CI}$ : [333, 428]).

Finally, the level of topology had an overall effect $(F(2,58)=5.9, p=0.0046)$. Although the specific way in which trials changed with differences in level was not the same across topological dimensions, they were all ordered such that the first level was expected to produce the fastest predictions and the third the slowest. Here the simplest / most contained trials were the fastest ( $359 \mathrm{~ms}, 95 \% \mathrm{CI}$ : [319, 404]), followed by the intermediate trials (393ms, $95 \% \mathrm{CI}$ :

[^503][349, 443]), followed by the most complex / least contained (436ms, $95 \%$ CI: [387, 490]).

Nonetheless, there was no statistically reliable effect of any interaction (all Fs $<1.5$, all ps $>0.13$ ). This suggests that the amount of speed-up from observing motion does not change with the type of topological trial, which in turn suggests that simulation is used across all topological trials.

To more directly test for the use of simulation across dimensions of topology, we can compare how fast people respond in the "towards" condition as compared to the "away" and "no motion" conditions. We calculated a simulation facilitation index as the ratio of the reaction times in the "towards" condition versus the average of the other two conditions. If this index is less than one, then we have evidence that participants were using simulation to make predictions in that condition. As can be seen in Table 1, across every condition the simulation facilitation index is numerically less than one, and in most conditions ( 9 of 12) the $95 \%$ confidence intervals do not include one either.

These simulation facilitation effects are not driven by a small set of outlier trials. Across all topological trials, reaction times of participants in the "towards" condition were faster than those in the "away" condition in 52 of 72 trials (binomial test, $p=0.0002$ ), and faster than those in the "no motion" condition in 61 of 72 trials (binomial test, $p=1.6 * 10^{-9}$ ).

We also consider whether the facilitation in the "towards" condition is truly facilitation, or whether this effect is observed because "away" motion slows down processing: in some cases the ball was moving away from the correct goal and towards the incorrect goal, and simple directional motion towards a goal might speed reactions for that goal and slow reactions for the incongruent goal. However, participants were still faster in the "away" motion condition than the "no motion" condition both in average reaction time and in 49 of 72 trials (binomial test, $p=0.003$ ), so the differences in reaction time cannot be explained simply as a slowdown due to motion towards the incorrect goal.

Table 1: Simulation facilitation index for each of the topological dimensions and levels. Numbers in brackets indicate $95 \%$ confidence intervals. In all cases, there is a simulation facilitation advantage, and in all but three conditions the confidence intervals are below one. This suggests that simulation is used across all topological conditions, including the conditions with simple containers.

|  | Level 1 | Level 2 | Level 3 |
| ---: | :--- | :--- | :--- |
| Size | $0.764[0.593,0.983]$ | $0.82[0.635,1.06]$ | $0.716[0.556,0.921]$ |
| Porousness | $0.714[0.554,0.92]$ | $0.716[0.556,0.922]$ | $0.869[0.676,1.12]$ |
| Stopper | $0.592[0.46,0.761]$ | $0.704[0.548,0.904]$ | $0.681[0.529,0.877]$ |
| Complexity | $0.845[0.655,1.09]$ | $0.7[0.543,0.903]$ | $0.713[0.554,0.917]$ |

Although motion towards the goal speeds reaction times across all trial types, we can test whether participants were simply cued to respond faster in general when the ball is moving towards the goal, or whether there is evidence that these judgments are based on simulation. If people are using simulation, then as the ball travels further to reach the goal we would expect mental simulations to also travel a longer path and thus take more time to produce (Moulton \& Kosslyn, 2009). We therefore expect that reaction times should increase roughly in line with the time it takes the ball to actually reach the goal. ${ }^{3}$ As can be seen in Figure 5, there is a relationship between the actual travel time of the ball and participants' reaction time on that trial across all of the topological trials $(r=0.29, t(142)=3.5, p=0.00056)$, but we do not have evidence that this relationship differs between the "towards" and "away" conditions $(F(1,141)=0.76, p=0.38) .{ }^{4}$ This relationship suggests that simulation was in general used to produce motion predictions in this task regardless of the direction of motion.

Finally, we considered two alternate explanations that might give rise to this pattern of data by chance. First, if participants were 'guessing' more in the towards motion trials, we might expect them to respond faster but be less accurate. Second, if participants changed the speed with which they responded over time, this could be a potential confound in our analyses. However, neither of these alternate explanations hold.

If participants are using a different speed-accuracy tradeoff across motion types, we might expect that the reduction in speed is counterbalanced by higher accuracy. Among the topological trials, participants were numerically most accurate in the 'no motion' condition ( $89.0 \%$ ), followed by the 'towards' condition ( $86.7 \%$ ), then the 'away' condition ( $81.3 \%$ ). While there is an overall effect of motion direction on accuracy $\left(\chi^{2}(2)=20, p=4.5 * 10^{-5}\right)$, this is driven by the 'away' condition being less accurate than the other two (vs. 'towards', $z=2.6, p=0.024$; vs. 'no motion', $z=3.28, p=0.003$ ) rather than by a difference between the

[^504]

Figure 5: Comparison of the time it takes the ball to actually reach the end goal versus the geometric mean of participants' reaction time in that trial $(r=0.29)$. Topological trials are linked between 'towards' and 'away' motion with dashed lines.
'towards' and 'no motion' conditions $(z=0.74, p=0.74)$. Furthermore, a speed-accuracy trade-off cannot explain why people are both slower and less accurate in the 'away' condition than they are in the 'towards' motion condition. ${ }^{5}$

We also tested for changes in the speed of response throughout the experiment. There was a minuscule effect of trial order on response speed that was not statistically reliable (each additional trial was $0.08 \%$ slower, $95 \%$ confidence interval $=[-0.02 \%, 0.18 \%], F(1,151)=2.7, p=0.10)$. Therefore changes in response times over the experiment cannot explain the difference in reaction times across the different motion conditions.

## Discussion

In this study we tested for situations where reasoning about topological containment preempts physical simulation across a wide variety of trials where both topological relationships and simulations could be used. We found that participants were using simulation across all types of topological trials, including the most simple cases of containment.

But why do we find evidence of simulation when a simple topological analysis alone would suffice? We consider five

[^505]possibilities.
First, the simulation facilitation effect could arise from a mixture of individuals, some of whom use simulation and others who use topological processing. Due to the small number of topological trials each participant saw in this experiment, we cannot precisely measure whether each participant individually had a simulation facilitation effect, only that this effect is found on average. Further research is required to investigate individual differences in the use of these two processes.

Second, because the majority of the trials could not be solved with topological reasoning, if people must choose between either simulation or topological reasoning, simulation would be the more general choice. Thus if there are cognitive costs for switching between different processing strategies, participants might constantly use simulation. Future work will study whether people continue to use simulation even when it is not as frequently required.

Third, Davis and Marcus (2015) suggest that "simulation is effective for physical reasoning when the task is prediction, when complete information is available, ... and when the range of spatial or temporal scale involved is moderate" - exactly the conditions of this experiment. Perhaps simulation is automatically activated in tasks that fit this description but not in others, and we happened to use a task that relied on simulation. This might also imply that the "no motion" trials involved a separate, logic-based process as opposed to the motion trials with complete information. Indeed there is a numerical pattern in these results that would support this interpretation: in Figure 4 the "away" reaction times are always slightly slower than the "towards" reaction times, but the difference between "towards" and "no motion" is more variable across conditions. Although there was not statistical evidence for such a difference, this pattern would be consistent with people using a separate process that requires a longer and more variable amount of time in cases where no motion was observed.

Fourth, people may be using simulation to gain information about containment. Liang, Zhao, Zhu, and Zhu (2015) explain human ratings of how well one object will be contained by another by simulating how often the first object will stay inside the second when dropped into it. This might suggest that for simple tasks our perception of containment is statistical (one would not expect this object to ever leave the container) rather than logical (the topology of the container entails the object inside will not leave).

Finally, making predictions may involve multiple processes running in parallel, including both simulation and topological parsing. In many of the topological trials participants observed - especially the "towards" trials - the ball did not have to travel far to reach the goal. If both simulation and topological reasoning are active at the same time, these might be the cases where simulation provides an answer quickly and wins out over topological processing. In Figure 5, the relationship between the time the ball actually takes to reach the goal and reaction time becomes more vari-
able and flatter as the travel time takes longer. These longer trials might be cases where simulation fails to provide an answer before less continuous processes can, and so we do not see the same sort of relationship between path length and reaction time. Intriguingly, this relationship is reduced even for the non-topological trials that last this long, suggesting perhaps that simulation can only look a short time into the future, after which point we use more qualitative scene representations that could support either qualitative simulation or logical reasoning.

Although simulation appears to be active in simple tasks that require predicting the motion of objects, fully explaining human physical reasoning will require a better understanding of how simulation interacts and trades off with more qualitative methods of conceptualizing the world.

# Promoting Spontaneous Analogical Transfer: The Role of Category Status 

Sean Snoddy (ssnoddy1@binghamton.edu)<br>Kenneth J. Kurtz (kkurtz@binghamton.edu)<br>Department of Psychology, Binghamton University (SUNY) Binghamton, NY 13902 USA

#### Abstract

Analogical comparison promotes spontaneous transfer by encouraging a more abstract representation that may be easier to retrieve. The category status hypothesis states that: if knowledge is represented as a relational category, it is easier to activate as a result of categorizing (as opposed to cue-based reminding). To investigate these two pathways to analogical transfer, participants were assigned to different study conditions: 1) standard comparison of two analogs; 2) standard comparison followed by a second comparison of two new analogs; or 3) a guided category-building task based on sequential summarization. Category-building showed a reliably higher rate of spontaneous transfer during an analogical problem solving task than standard comparison (numerically higher than double-comparison). Another experiment measured spontaneous remindings to cues on the basis of matching structure. Category-building showed a reliable advantage over both comparison conditions. This supports categorization as a novel pathway to spontaneous transfer by enhancing retrieval of structurally similar information.

Keywords: concepts and categories; analogy; problem solving; comparison; transfer

## General Introduction

People are able to transfer prior knowledge to solve problems in a superficially dissimilar context. Gick and Holyoak (1980) demonstrated that individuals who encoded a base passage, which described how a general captured a fortress by dividing an army into small groups of soldiers that simultaneously attacked the fortress from various angles, were able to transfer the passage's solution to solve an isomorphic target problem about how a doctor could destroy a tumor with a ray of radiation. The prevailing cognitive account (henceforth abstraction account) explains knowledge transfer across domains (e.g., military strategy to medical treatment) in terms of analogy. According to the abstraction account, transfer involves a mapping process where distinct superficial information between analogs is filtered out (e.g., general and doctor), and similar relationships between analogs are placed into correspondence (e.g., simultaneous application) (Gentner, 1983; Gick \& Holyoak, 1980). This mapping process allows for candidate inferences from the structure of the base to fill in missing predicates of the target problem, which allows for a solution to be devised (e.g., lower intensity rays simultaneously converging on a tumor from multiple locations) (Gentner, 1983; Gick \& Holyoak, 1980).

Despite the capacity for analogical transfer, individuals often fail to spontaneously transfer knowledge from a single
base analog to solve a problem in a different domain without an explicit hint about the base's relevance (Gick \& Holyoak, 1980). This failure is known as the paradox of similarity-based retrieval: superficially similar information to the target problem (e.g., other medical problems) is favored during retrieval, even though inferences require structural overlap between the base and target (e.g., the concept of convergence) (Gentner, Ratterman \& Forbus, 1993; Holyoak \& Koh, 1987; Ross, 1987). With this paradox in mind, the key to understanding how spontaneous transfer occurs is to determine what promotes structurebased retrieval.

Some key findings of the abstraction account are that comparison is an effective way to learn (Alfieri, NokesMalach \& Schunn, 2013) and to promote spontaneous transfer (Gentner, Loewenstein \& Thompson, 2003; Gick \& Holyoak, 1983). During comparison, cases with matching structure are presented side-by-side and participants are prompted to consider the similarities between them. This facilitates a mapping process to occur during encoding that is similar to the one that occurs during transfer, which highlights commonalities between cases and promotes the formation of an abstract schema via filtering out surfacelevel mismatches (Markman \& Gentner, 2000). These abstract schemas are more accessible in memory than representations of specific cases due to a lack of superficial mismatches with targets (Forbus, Gentner \& Law, 1995; Gick \& Holyoak, 1983). The heightened accessibility of abstract schemas facilitates retrieval of structurally similar matches during the memory search triggered by an opportunity to spontaneously transfer knowledge.

While the abstraction account focuses on the role of schema abstraction in spontaneous transfer, the type of materials used in these studies can also be viewed as embodying relational categories (Gentner \& Kurtz, 2005). Categorization may provide another pathway to structurebased retrieval. The category status hypothesis predicts that when knowledge is represented in the form of a category, it is fluidly accessed and applied (Kurtz \& Honke, submitted). There are three important aspects that contribute to the development of category status. First, category intension is knowledge of the category defining structure. This may be similar to an abstract schema, and could be conferred through the comparison process (Goldwater \& Schalk, 2016). Second, category extension is knowledge of specific members and non-members of a category as well as how to differentiate between them. Third, categorization confers experience in bi-directional mapping between generic knowledge of the category and specific cases. Thus, the key
claim of the category status hypothesis is as follows: when knowledge is represented as a psychological category, construal of a target stimulus as a category member facilitates direct activation of the category-defining concept in semantic memory. The key difference is that the category status hypothesis predicts direct activation of structurally relevant matches as opposed to a filtering out of superficial mismatches followed by an evaluation for any structural similarity.

Initial support for the category status hypothesis comes from Kurtz and Honke (submitted) who had participants learn a relational principle either through category construction or a single comparison opportunity. In the category construction task, participants formed two categories out of three examples of a principle and three alignably different examples. This was compared to the standard version of the comparison task that received two cases presented side-by-side and provided a similarity rating as well as an explanation of the similarities between cases. Category construction led to a higher rate of spontaneous transfer than the comparison task, which suggested that promoting category status may provide a novel pathway to spontaneous transfer (Kurtz \& Honke, submitted).

The goals of the present work are: 1) to further evaluate the plausibility of the category status hypothesis as an alternative account of spontaneous transfer, and 2) to further explore the abstraction account. To address the first goal, a novel category building task based on the sequential summarization of cases was used to promote category status. This task is often used as a control to comparison, and does not confer the same level of abstraction-based transfer benefits (Catrambone \& Holyoak, 1989; Gentner et al., 2003; Rittle-Johnson \& Star, 2007). If sequential summarization can be combined with additional supports that promote category status, then it should become an effective way to promote transfer. The categorization supports that were integrated with the core summarization task were: 1) summarization of category-membershiprelevant aspects of multiple cases, 2) identification of each case with a shared category label, and 3) a description of the category after encountering all cases. If these supports contribute to the development of category status, a categorization-based summarization task should become an effective way to promote transfer.

The second goal of the present work sought to further understand the abstraction account. Prior analogical comparison research has largely focused on the effects of a single comparison opportunity on transfer success. The effect of an additional comparison opportunity was explored, which should improve schema abstraction by providing additional surface-level mismatches to filter out. The additional comparison opportunity also serves as a control for case exposure in the category-building condition.

## Experiment 1

Experiment 1 used the analogical transfer paradigm (Gick \& Holyoak, 1980, 1983) to assess the impact of categorization-
based summarization (category-building), the standard version of the comparison task (single comparison) (cf. Catrambone \& Holyoak, 1989; Gentner et al., 2003; Gick \& Holyoak, 1983), a standard comparison task that is repeated a second time with novel cases (double comparison), and a baseline condition on spontaneous transfer performance. Spontaneous transfer success is contingent upon being able to both spontaneously access and retrieve relevant knowledge from memory as well as apply that knowledge to devise a solution (Gick \& Holyoak, 1983). The use of both spontaneous and hint-aided transfer assessments allows for the differentiation of the relative impact that each study condition has on application ability and retrieval.

Both the abstraction account and category status hypothesis make different predictions about what type of task will improve the retrieval process that underlies successful spontaneous transfer. The predictions for spontaneous transfer are as follows: 1) all study conditions will promote transfer (i.e., result in a higher rate of transfer than baseline), 2) the category-building condition will result in a higher rate of transfer than both comparison conditions, and 3) double comparison will result in a higher rate of transfer than single comparison. Neither account makes explicit predictions about application ability, so hint-aided transfer performance is exploratory.

## Method

Participants A total of 355 undergraduate students from Binghamton University participated for course credit. Hintaided transfer data from seven participants were excluded due to a failure to complete the assessment in the allotted time.

Materials and Design The materials consisted of both study cases and the transfer problem. All materials demonstrated the principle "problem-as-a-solution": when a large-scale event causes a large amount of damage, the event can be mitigated by repeatedly causing it on a small scale and incurring minor damage each time. The study cases were all from the domain of natural disasters. The passages were a single paragraph that consisted of a description of the problem followed by the solution.

The transfer problem involved the prevention of cybercrime. It contained a similar description of the problem as the study cases. However, the solution was replaced with an open-ended question about how the threat of computer hackers could be minimized. The general formatting of the transfer problem was different from the study tasks to make the separate phases appear unrelated. The transfer problem was presented twice. It was first presented under the guise of a new experiment about problem solving (spontaneous transfer). The same problem was presented again with a hint for participants to use their knowledge from the study phase (hint-aided transfer).

Procedure Prior to the experiment, all participants were informed that they would take part in multiple experiments,
then were randomly assigned to one of the study tasks. Participants in the single comparison condition received two study cases, which were referred to as solved problems, presented side-by-side. Participants were informed that there were important ways that the solved problems were alike and were asked to consider the similarities between them. After reading the cases, participants provided a similarity rating on a five-point scale that ranged from 'not at all similar' to 'very similar'. Participants were then asked to describe the similarities and differences they considered when making their similarity judgement. The doublecomparison task was similar to single comparison, with the only difference being a second comparison opportunity for two novel cases. During this second comparison opportunity, participants were asked to consider the important ways in which all four of the solved problems were alike, provide a similarity rating for the two additional cases, and describe the similarities used to create the rating.

In the category-building condition, participants were given instructions that explicitly stated the task involved learning about a category, and then were sequentially presented with all four cases. Upon presentation of each case, participants were provided with the label to identify the case as a member of the category (e.g., "Here is an example of the Tongo category") and were asked to summarize the relevant information to category membership. After completion of the final summarization task, participants were asked to provide a description of the category they had just learned.

Following the study task, participants were told that they were beginning a new experiment on problem solving, and proceeded to the spontaneous transfer assessment. Since the baseline condition was meant to establish chance production of transfer solutions to the problem, participants in that condition only received this assessment. After completion of the spontaneous transfer assessment, participants were then given another chance to solve the problem with an explicit hint to use their knowledge from the study phase. Both of these assessments presented participants with the transfer problem, and asked them to devise a solution. For each transfer opportunity, participants were allowed to provide multiple solutions to the problem. Each of the proposed solutions was scored by the first author blind to condition. If at least one of a participant's proposed solutions demonstrated the target principle, that participant was coded as a transfer success.

## Results and Discussion

Hint-aided Transfer Hint-aided transfer performance reflects participants' ability to retain and apply the knowledge from the learning tasks. To evaluate hint-aided transfer performance, a logistic regression model (R Core Team, 2016) was built to predict hint-aided success with condition. There were no significant differences between category-building and single comparison $(\beta=0.274, S E=$ 0.313, Wald $Z=0.872, p=.383$ ) or double-comparison $(\beta=$ $-0.174, S E=0.318$, Wald $Z=-0.547, p=.585)$.

Additionally, there were no significant differences between double-comparison and single-comparison $(\beta=0.447, S E=$ 0.313 , Wald $Z=1.426, p=0.154$ ) (see Table 1).

Table 1: Hint-aided transfer performance.

| Learning Task | \% Transfer (N) |  | 95\% C.I. | N |
| :--- | :---: | :---: | :---: | :---: |
| Single-Comparison | $55 \%$ | $(47)$ | $45 \%-66 \%$ | 85 |
| Double-Comparison | $66 \%$ | $(58)$ | $55 \%-75 \%$ | 88 |
| Category-Building | $62 \%$ | (52) | $51 \%-72 \%$ | 84 |

Spontaneous Transfer Spontaneous transfer success was modelled using a logistic regression with condition as the predictor. Both the category-building ( $\beta=1.68, \mathrm{SE}=0.433$, Wald $Z=3.88, p<.001$ ) and double-comparison ( $\beta=1.1$, $S E=0.449$, Wald $Z=2.453, p=.014$ ) conditions resulted in a higher rate of transfer than baseline. However, the single comparison condition was not significantly different from baseline transfer performance $(\beta=0.407, S E=0.491$, Wald $Z=0.828, p=.408$ ) (see Table 2).

The category-building condition led to a significantly higher rate of spontaneous transfer than single comparison ( $\beta=1.274, S E=0.393$, Wald $Z=3.239, p<.01$ ). However, there was no significant difference between categorybuilding and double comparison ( $\beta=0.579, S E=0.339$, Wald $Z=0.171, p=.088$ ). There was no significant difference between double and single comparison ( $\beta=$ $0.695, S E=0.411$, Wald $Z=1.692, p=.091$ ) (see Table 2). To account for slight numeric differences in hint-aided transfer, a more conservative analysis was done that included only participants with hint-aided transfer success to clearly reflect differences in the retrieval process. The same pattern of results was observed.

Table 2: Spontaneous transfer performance.

| Learning Task | \% Transfer (N) |  | 95\% C.I. | N |
| :--- | ---: | :--- | :---: | :---: |
| Baseline | $9 \%$ | $(8)$ | $4 \%-17 \%$ | 91 |
| Single-Comparison | $13 \%$ | $(11)$ | $7 \%-21 \%$ | 87 |
| Double-Comparison | $22 \%$ | $(20)$ | $15 \%-32 \%$ | 89 |
| Category-Building | $34 \%$ | $(30)$ | $25 \%-45 \%$ | 88 |

Contrary to prior research, which demonstrated summarization was a less effective way to promote transfer than comparison (Catrambone \& Holyoak, 1989; Gentner et al., 2003), the present work found that combining summarization with categorization supports (categorybuilding condition) is an effective way to promote transfer. The category-building led to a higher rate of spontaneous transfer than single comparison, which provides support for the category status hypothesis as a viable account of transfer. The lack of a significant difference between category-building and double comparison provides limited support, since categorization supports in the categorybuilding task led to higher performance than is typically expected of a summarization task (i.e., it was not
significantly lower than double comparison). Further, the lack of differences on the hint-aided transfer assessment suggests that the category-building task's spontaneous transfer advantage cannot be attributed to a differential ability to apply knowledge, but instead results from improved structure-based retrieval. These findings support the category status hypothesis as an alternative account of transfer.

The interpretation of the comparison conditions is less clear. Prior work has demonstrated that single comparison is an effective way to promote transfer (Catrambone \& Holyoak, 1989; Gick \& Holyoak, 1983), so the lack of an advantage over baseline is puzzling. The present study used a novel stimulus set, and the observed transfer performance is appreciably lower than has been reported with the convergence materials (Catrambone \& Holyoak, 1989; Gick \& Holyoak, 1983). This stimulus set may be more difficult than commonly used materials, and a single comparison opportunity might require additional support to remain effective under more difficult circumstances.

There was no significant difference between single and double comparison on spontaneous transfer performance, which suggests that an additional comparison opportunity might not appreciably improve abstraction. If the present principle is more difficult than previous materials, an additional comparison opportunity may also be lacking in the support needed to remain effective. While singlecomparison did not promote transfer above baseline levels of performance, double-comparison did. This suggests that there may be some small benefit to engaging in the second comparison opportunity.

## Experiment 2

Experiment 2 was conducted to conceptually replicate the main findings and clarify some of the outstanding questions of Experiment 1. The same study conditions were used with the exception that a baseline condition was not included. Instead of a problem-solving assessment, a spontaneous reminding task was used. Participants were given a series of cue passages that were superficially distinct from, but contained matching structure with the study materials, and were asked what each cue reminds them of. Since participants were given completed cases as a cue, the entire relational structure of the principle guides the memory search. This is in contrast to the problem-solving transfer assessment that provides only the problem statement as a cue to initiate the memory search. Under less demanding retrieval circumstances, a double-comparison advantage might be accrued. Other modifications were made in an attempt to support the comparison conditions. Both problem-as-a-solution and convergence (Gick \& Holyoak, 1983) materials were used to test if the problem-as-asolution principle was more difficult to retrieve than convergence, since the difficulty of the principle in the first experiment may have been a barrier to comparison success. The instructions for the comparison conditions were modified to increase the symbolic juxtaposition - invitation
to compare through shared labels (Gentner, 2005) - of the cases in another attempt to enhance the comparison task.

The main prediction was that category-building will lead to more structure-based remindings than either comparison condition. Since the procedure was made less demanding in an attempt to promote comparison performance, doublecomparison was predicted to have a higher rate of reminding success than single-comparison. Given the overall low rate of transfer in the first experiment, it was predicted that cues for the convergence principle will result in a higher rate of successful remindings than the cues for the problem-as-asolution principle.

## Method

Participants A total of 104 undergraduate students from Binghamton University participated for course credit. Data from three participants were excluded due to a failure to complete the experiment in the allotted time, and another participant was excluded for failing to follow instructions.

Materials and Design The study materials consisted of both the problem-as-a-solution and convergence (Gick \& Holyoak, 1983) principles. The study cases for problem-as-a-solution were the same as in Experiment 1. The convergence cases used were as follows: The General, The Commander, Red Adair, and The Fire Chief (Gick \& Holyoak, 1983). These cases were rewritten to be comparable in length and grammatical structure to the problem-as-a-solution materials. The order of principles remained constant across participants; problem-as-asolution occurred first and convergence occurred second.

The reminding assessment consisted of six cue cases. Two cues were used that demonstrated the problem-as-asolution principle from Experiment 1. The transfer problem used in Experiment 1 was rewritten to include the solution and the other cue involved police infiltrating black markets. The Radiation Problem (Gick \& Holyoak, 1983) and The Aquarium (Catrambone \& Holyoak, 1989) were rewritten as reminding cues for the convergence principle. Two distractor cases - The Wine Merchant (Gick \& Holyoak, 1980) and The Birthday Party (Gick \& Holyoak, 1983) were also included in the reminding assessment in an attempt to disguise the true purpose of the assessment. The order of the cues was constant across participants: distractor, problem-as-a-solution, convergence, distractor, problem-as-a-solution, convergence.

Procedure The study task procedure was similar to the first experiment, with only a few differences. Participants in both comparison conditions received the same task from the first experiment, then repeated it a second time for the convergence materials. In addition, the principles were referred to as separate 'series' to connote that they reflected different principles. In double comparison, the instructions were modified to clearly connote that the first four passages shared important commonalties, and the second four passages also shared important commonalities. The
category-building condition repeated the task for the convergence principle after completion of the task for the problem-as-a-solution principle. The only other difference in the category-building condition was that the category label was replaced with "Conaway Scenario" for the first principle and "Rummel Scenario" for the second principle to clearly reflect the change in principles.

After the study phase all participants were given the reminding packet, which was introduced as a new experiment. Participants were told they would be shown a set of passages, and were supposed to write down anything that each passage reminded them of in as much detail as possible. Participants were then presented with each reminding cue sequentially and made their response. Reminding performance was scored by the first author and an undergraduate research assistant. A successful reminding on the basis of shared structure met at least one of the three following criteria: 1) used the category label or referred to solved problems, 2) referenced one of the cases from the study task, or 3) described the principle from the study task. Any remindings of another cue from within the assessment were considered non-scoring. Both raters agreed on scores for $99.8 \%$ of the reminding responses, all disagreements were resolved through discussion.

## Results and Discussion

Figure 1: Proportion of structural remindings to target cues by study task and principle. Error bars reflect 95\% binomial confidence intervals (Dorai-Raj, 2014).

Reminding performance was modelled trial-wise via a mixed-effects logistic regression (Bates et al., 2015) with the main effect of interest as a predictor and participant included as a random intercept. The predictions concern participants' responses to only the target cues that had shared structure with the study materials, so only those cues are considered. Category-building led to a higher rate of successful remindings than double-comparison ( $\beta=3.436$, $S E=1.671$, Wald $Z=2.057, p=.0399$ ) and singlecomparison ( $\beta=6.178, S E=1.649$, Wald $Z=3.746, p<$ .001). Double-comparison led to a significantly higher rate of successful remindings than single comparison $(\beta=2.741$,
$S E=1.307$, Wald $Z=2.1, p=.036$ ). Collapsing across condition, convergence cues led to a significantly higher rate of successful remindings than problem-as-a-solution cues $(\beta=1.5, S E=.622$, Wald $Z=2.41, p=.016$ ) (see Figure 1).

The category-building task led to a higher rate of structurally based remindings to target cues than either comparison condition. This suggests that category-building promotes the spontaneous access and retrieval of relevant structural matches from memory, and that this is driving the spontaneous transfer differences observed in the first experiment. These results provide further support for the category status hypothesis and a successful replication of the main finding in Experiment 1.

These results also address some of the outstanding questions from the first experiment. In contrast to the previous findings, double comparison had a significantly higher rate of structural remindings to target cues than a single comparison opportunity. This suggests that additional comparison opportunities can enhance the retrieval of structurally relevant information from memory. However, we cannot identify which changes were responsible for the observed improvements. Additionally, convergence cues led to a higher rate of successful structural remindings than problem-as-a-solution cues, which may suggest that the convergence materials result in higher rates of transfer than other materials. However, the convergence study materials were always presented after problem-as-a-solution, so future work should explore if this is the result of a practice effect.

## General Discussion

When a sequential summarization task was given additional categorization-based supports (the category-building condition), it led to better spontaneous transfer performance than the standard version of the comparison task (single comparison), but did not significantly differ from a task that controlled for case exposure (double comparison). The second experiment replicated the advantage of categorybuilding over single comparison, and found that categorybuilding led to a higher rate of structure-based remindings than double comparison. This supports the conclusion that the spontaneous analogical transfer gains in the categorybuilding condition were due to an increase in retrieval based on matching structure. Taken together, both experiments provide additional support for the category status hypothesis as a viable account of spontaneous transfer.

It is possible that the use of category labels in the category-building condition might confer symbolic juxtaposition (Gentner, 2005), which may allow for abstraction to occur in the absence of the temporal and spatial juxtaposition that is present during comparison. However, this explanation is unlikely the sole factor driving the results. The comparison conditions referred to cases as 'solved problems' to control for the use of a category label, and referred to cases from each principle as a coherent 'series'. The comparison conditions' controls for the presence of a label likely conferred some degree of
symbolic juxtaposition. If category-building benefits were due to symbolic juxtaposition promoting abstraction, it seems unlikely that a condition which has temporal, spatial, and symbolic juxtaposition (comparison conditions) would perform significantly worse.

The benefits of an additional comparison opportunity are less clear. During the analogical transfer assessment, no advantage of an additional comparison opportunity was accrued. However, in the reminding assessment, an extra comparison opportunity led to a higher rate of retrieval on the basis of shared structure. The benefits of an additional comparison opportunity may occur only under less demanding circumstances, such as being given the full structure as a retrieval cue and not needing to apply the knowledge to solve a problem.

The category status hypothesis can provide an alternative perspective about the success of double-comparison in the second experiment that is not mutually exclusive with the abstraction account. The second instance of comparison provides a chance to build extensional knowledge of the category, since participants are told that the cases are related and participants are given a chance to test hypotheses about why. Further, since some abstraction has likely occurred during the first comparison, the second comparison may afford the opportunity for a bi-directional mapping between generic knowledge of the principle and concrete knowledge of the cases. Future work should further explore the conditions required for additional comparison opportunities to promote spontaneous transfer as well as the role of the category status hypothesis in improving comparison.

There are two possibilities about why category-building and double-comparison led to better retrieval of structural information. First, promoting category status could engage the use of a different type of retrieval process. This retrieval process might occur through the mechanism of categorization as opposed to cue-based reminding. Alternatively, conferring category status might enhance or alter the cue-based reminding process described in Forbus et al. (1995). Future work should try to uncover the mechanism by which these two pathways to improved structure-based retrieval operate.

## Acknowledgments

We would like to thank Daria E. Slaby and Ian T. Goodman for their help scoring data, Garrett Honke for creation of the problem-as-a-solution stimulus set, and members of the Learning and Representation in Cognition lab.

# Geometry-based Affordances 

Sterling Somers (sterling@sterlingsomers.com)<br>Institute of Cognitive Science, Carleton University, 1125 Colonel By Drive<br>Ottawa, On., Canada

#### Abstract

A representational approach to ecological psychology is presented. This paper identifies a computational-level commonality in ecological psychology research related to passability of apertures. It is argued that a cognitive mechanism capable of comparing the geometric properties of an environment and the geometric properties of the agent can be used to support judgments for action in space.

Keywords: affordances; ecological psychology; spatial representation.

## Introduction

Two of the most central proposals in ecological psychology are the concept of affordances and the theory of direct perception. Gibson describes an affordance as properties that objects offer to animals that have the capacity to perceive it (Gibson, 1986). This position, shared with Michaels and Carello (Michaels \& Carello, 1981), maintains that the semantics of an action, by which I mean how an agent knows what actions can be performed given the objects in its environment, are properties of that object. Because the action semantics are encoded in the environment, they are claimed to be directly perceived.

Chemero \& Turvey (2007) divide ecological psychologists into two camps: Gibsonian and representationalist. Gibsonians maintain that affordances are directly perceived, while representationalists (e.g. Vera \& Simon, 1993) maintain that affordances (the actions an object affords) are inferred. This paper presents a representationalist position that is inspired by affordance research. However, the representations proposed in both theory and model are non-static and do not include semantically-laden representations of the environment. An example of a semantically-laden representation, with respect to action, is to label a feature of the environment as a 'doorway', such that doorways are features of the environment that can be passed-through.

The representationalist approach presented here is not necessarily inconsistent with a Gibsonian approach. The aim of the theory presented is to leverage the appropriate framework to make use of the computational cognitive architecture, ACT-R (Anderson \& Lebiere, 1998), in order to identify a plausible set of information processing steps involved in an aperture-passage affordance.

## Gibsonian Positions

There are two main theoretical positions in favor of direct perception. The first, Gibson's own theory, has already been described above. Although I will provide no argument against this position here, I agree with Chemero (2003), that

Gibson's position represents a non-standard ontology, in which the environment is not simply made up of physical properties but also semantic properties. I will assume that this alternative ontology is sufficient to reject Gibson's position for the purposes of this paper. For an argument against Gibson's position and related affordance-as-property positions, I refer the reader to Chemero (2003).

The second Gibsonian position is that action semantics are emergent properties which arise from the interaction between an animal and its environment (Chemero, 2003; Chemero \& Turvey, 2007; Stoffregen, 2003). While Chemero (2003) differs slightly in the terms he uses (relations instead of properties, to avoid certain philosophical problems), neither author's version addresses how the emergent properties or semantic-laden relations arise.

The theory presented here, the theory of geometric affordances, is inspired by research on aperture passage but also attempts to be commensurate with traditional representationalist views popular in the cognitive sciences. Briefly, this paper proposes that one of the mechanisms which can inform action properties (such as passability) is a geometric comparison between the features of the environment and current or possible future geometric properties of the body.

The aim of this paper is to illustrate, by way of example, how a represenationalist approach, which posits cognitive mechanisms, leaves open the possibility to develop unifying theories about different experimental findings within the affordance literature. The research reviewed in the following section is ecological psychology research regarding the affordance of passability of an aperture. The purpose of this brief review is to illustrate how a representationalist approach can posit a cognitive mechanism that compares the geometric properties of an environment with the geometric properties of the agent. I term these affordances, geometry-based affordances. I maintain that geometry-based affordances are only one class of possibly many types of affordances.

## Aperture Passability Research

Research into the passability of apertures, such as doorways, has shown that there is a body-size/aperture-width ratio at which apertures are judged to be passable (Fath \& Fajen, 2011; Higuchi, Seya, \& Imanaka, 2012; Wagman \& Taylor, 2005; Warren \& Whang, 1987). With different degrees of commitment, the central aim of that research is to show that a passability affordance can be directly perceived.

In Warren and Whang (1987), for example, they show that people judge apertures as passable only when the ratio
between the aperture width and body width is greater than 1 . Warren and Whang argue that we perceive the width of apertures in units of body width. The theory they propose is that we see the width of the doorway in units of eye-height. Since eye-height is in a constant proportion to shoulder width, we are effectively perceiving in units of shoulderwidth. Instead of seeing a doorway, estimating its width, estimating body width, and making a determination regarding passability; we simply perceive apertures as either passable or impassible.

In a related study by Fath and Fajen (2011), participants view simulated environments while wearing a headset. In a set of experiments, Fath and Fajen modified the visual properties available to the participants. For example, they eliminate the ground plane, making the estimate of eyeheight implausible. They argue that the visual properties related to body-width-scaled units are not the only properties that can be used to make passability judgments. They propose that visual information related to head-sway and stride length (both while walking towards the aperture) can be calibrated to body-width and used in lieu of eyeheight, to directly perceive passability.

Other studies such as those by Higuchi, Seya, and Imanaka (2012) and Wagman and Taylor (2005) have participants holding objects. Chang, Wade, and Stoffergen (2009), furthermore, studied passability for people grouped in dyads. Higuchi, Takada, and Matsuur ( 2004), finally, studied passability for novel wheelchair users.

When taken together, it is not clear whether a direct perception account can extend to situations such as dyads. Judging aperture passage for yourself plus another individual seems to require the building of a representation of the total width of yourself and your compatriot. Especially considering the methodology in Chang et al. (2009), where participants are paired with different people during the course of the experiment. Because the optical information from the environment does not change, then another source of information seems modulate judgment. Regardless of the source, it seems as though two pieces of information are used to make a passability judgment: optical information and some-as-yet-to-be-determined source. It is unclear how the ecological psychologist can maintain that the judgment is direct.

A second, perhaps more important, aspect to consider is the methodology used in, for example, Warren and Whang (1987) and Higuchi et al. (2012). The experiments in these studies include a methodology where participants walk through the apertures of various sizes, rotating their shoulders as needed. In Warren and Whang there is also a condition where participants judge whether they can pass through apertures, without rotating their shoulders. In all of these cases what the participant seems to be doing is making a judgment about passibility with respect to a future configuration of their body. Judgment in these cases does not seem to be based upon their current body width but, rather, the width of their body after they have rotated their shoulders. If that is the case, then it is not clear that
passability can be directly perceived in these cases. Instead, it seems as if the passability judgment is based upon a representation of the future state of the body. Such a representation can be plausibly drawn from memory or the result of a simulation.

## A Representation-Based Theory

The theory being presented is an information processing theory about the steps involved in passability judgments of the kind exhibited in previous aperture passage research. At a functional level the theory of geometric affordances posits a geometric comparison process that compares the geometric properties (width, depth, height) of an aperture against a current or stored body posture. The geometric comparison is used both when judging whether an aperture is passable as well as a top-down metric to control shoulder rotation during passage.

The information relevant to body postures is derived from body schemas. Although previous affordances research have rejected the notion of body schemas (e.g. Carello, Grosofsky, Reichel, Solomon, \& Turvey, 1989) there reasonable evidence for their existence and their role in motor planning and performance.

## Evidence for Body-Schemas

Schwoebel and Coslett (2005) identify three types of body representations: body schemas that represent the positions of the body parts and is used to plan motor movements, the body structure that is a topological map of body part locations, and a body image which is a lexical-semantic representation of the body detailing body part names, their function, and their relationship to related artifacts. Since body schemas are central to the information processing theory being proposed, a brief summary of evidence for the existence of body schemas will be presented in this subsection.

Neural evidence provides support for the functional role of body schemas as real-time representations of the body. Firing-rates in parietal area 5 of primates supports the idea of encoding arm postures both when the arm is occluded and when a realistic, fake arm is visible, suggesting both somatosensory and visual input is used to create body schemas (Graziano, Cooke, \& Taylor, 2000).

There is strong evidence for the use of body schemas in motor simulation. For example, the hand laterality paradigm has been used to study the link between imagined movement and actual movement (e.g. Parsons, 1987). There are two aspects of the laterality paradigm. The first involves making judgements of laterality (left vs. right) and the second involves simulating arm orientations. The reaction time for both tasks was relative to orientation differences between the participant's arm and the target arm. Simulated movements were strongly correlated with actual movements.

There is also evidence of a physiological overlap between imagined and actual movements (Decety, 1996; Lotze et al., 1999). The fMRI work by Lotze et al. (1999) also supports
the view that the main difference between imagined and actual motor movements is inhibitory signals from cortical motor areas to cerebral regions, inhibiting actual movements. Sirigu et al. (1996) also show that only patients with parietal damage do not show a correlation between the times for actual and imagined finger movements.

Finally, Schwoebel, Coslett and Buxbaum (Coslett, Buxbaum, \& Schwoebel, 2008; Schwoebel, Coslett, \& Buxbaum, 2001) provide evidence for Forward Modeling. Forward Models have been theorized to be used to develop representations of body schemas based partially from efferent copies of planned motor movements. What is particularly interesting in their work is the dissociation exhibited by a patient (JD) between body schemas due to purposeful movement and body schemas for passive movement. JD had accurate reach and pointing ability when moving her hand to a target in both occluded-hand and nonoccluded hand conditions, suggesting that she had an accurate representation of the position of her arm and hand. However, JD's pointing and reaching ability were impaired when her arm was moved by an experimenter (passive movement), suggesting that, in those cases, she did not build an accurate representation of her arm posture. As pointed out by Schwoebel and Cosslett (2005), this dissociation suggests that JD had an intact ability to generate posture representations from an internal model based on predicated movements (Forward Model).

The above findings in combination imply that humans have representations of the biomechanical constraints of our bodies. If reaction times for imagined movements mimics reaction times for actual movement, then this suggests that the simulated movement has similar kinematic and biomechanical properties as real movements. The fact that there is a strong neurological overlap between simulation areas and areas responsible for actual movements suggests that motor movements are encoded in the same format for simulation as they are for actual movements. It can be inferred that some form of biomechanical representation has to exist to support biomechanically-accurate simulations. This offers compelling evidence that the biomechanical constraints of the body are also likely represented (in order to support simulation). It stands to reason that simulation can produce predictions of body posture in simulated motor planning in much the same was as forward modeling does for active motor behavior.

The theory being forwarded here assumes that we store body schemas of biomechanical constraints. This would be useful for motor planning because it would reduce the complexity of choosing a goal posture. For example, shoulder rotation would require only three representations: a body schema for relaxed, non-rotated posture; and a body schema for full rotation to the left; and full rotation to the right. Although the body is capable of rotating any angle between constraints, it would be costly to store them all. Instead, biomechanical constraints can provide sufficient conditions for an action (fully rotated shoulders might be sufficient for passing through an aperture), which is suitable
for planning. Online motor control during action could then be used to control and produce only the necessary motor movements to carry out the action for a particular circumstance.

## Information Processing Theory

It is useful to divide the processes proposed in this theory into two phases: the judgment phase and the performance phase. In the judgment phase, we first determine if we can pass through an aperture at all. The performance phase occurs once we have judged an aperture as passable and begin to walk through it. The performance phase can be subdivided further into three sub-phases: rotation initiation, rotation, and rotation termination. The following section will outline how body schemas are used in the passability judgment.

## Judgment Phase

Although it is discussed very little in the previous aperturepassage literature, before we ever attempt to pass through an aperture, we must first make a judgment of whether passage is at all plausible. Anecdotally, this must be the case because we simple do not often find ourselves trying to squeeze through apertures smaller than our bodies. This process has to be more complex than the direct perception theory proposes because passage cannot be judged purely on current posture. That is, optical information tuned to a nonrotated posture can only inform passibility judgments where no postural change is required. However, in order to judge passability in the condition where some degree of shoulder rotation is required, the optical information would somehow have to be tuned to a future state of the shoulders. It is unclear how a direct perception approach could account for this.

Geometric affordance theory proposes that a positive passability judgment results from two possible cases. In the first case, body geometry is estimated from a body schema of the current body posture. This information can then be used top-down in a visual search to find apertures of an appropriate size. If the vision system is able to return a feature in the environment that meets those constraints, the returned apertures are considered passable. In this case, the agent can simply walk through the aperture. If no environmental feature is returned by the vision system, the second case proceeds. Note that the representations used in this phase are non-static: they are current (based on current body posture) and can include other sources of information including visual or proprioceptive (such as estimates of body size while carrying objects, or in a dyad).

In the second case, a potential series of memory requests are made for stored body schemas that closely match the current body posture (e.g. standing) and current action capabilities (e.g. supportive of walking action) but are relaxed on an increasing number of postural details (e.g. no need to match with respect to the upper-half of the body). In the case of a simple doorway-like aperture, a reasonable memory request would be for a posture that affords walking
(e.g. a standing posture) but allows for variation in torso posture (such as shoulder rotation). As discussed in the previous subsection, storing only the biomechanical constraints vastly reduces the search space for a suitable posture. If a suitable schema is returned, the geometric properties of that schema are used to filter visual results in the same manner described above for the for the first case. In the second case, the retrieved body schema functions as a goal state for the motor system during the rotation phase. That is, the motor system will try to achieve the posture at the biomechanical constraint (e.g. shoulders fully rotated) regardless if that posture is necessary for the desired action.

## Rotation Phase

Another aspect of aperture passage with no known discussion in the affordances literate is the need for some trigger that starts the rotation. One possibility is that the agent plans to rotate at some specific point and initiates rotation upon arrival. A second possibility, and the one explored here, is that there is a bottom-up environment trigger that is responsible for initiating the rotation. The theory proposed here is that the visual system performs bottom-up obstacle avoidance and that the presence of the edges of the aperture triggers the rotation. When the edges of the aperture are within a multiple of the agent's rotation radius, the vision system pushes information into the visual buffer, and the agent can respond by carrying out the motor plan.

Recall that during the judgment phase a stored body schema memory may be recalled and used as a goal state for the motor system to achieve the affordance. In Warren and Whang's (1987) first experiment there is a multi-second delay between what I am describing as the judgment phase and the rotation phase (while the participants walks to the aperture). It is proposed that once a body schema is retrieved it is maintained in working memory. When the presence of the obstacle (aperture edges) is pushed in to the visual buffer, combined with the presence of a body schema in memory, the agent can then carry out the motor rotation plan. Note that for shoulder rotation, the goal state will be a biomechanical constraint, e.g. fully-rotated shoulders. However, we know from Warren and Whang (and intuitively) that we do not rotate our shoulders to maximum rotation every time we rotate. Instead the theory assumes that rotation completion is controlled by a vision-action loop in the dorsal visual stream (Milner \& Goodale, 2008).

## Rotation Completion Monitoring

In their Two Visual Streams Hypothesis, Milner and Goodale propose a functional distinction between the dorsal visual stream and the ventral visual stream (Goodale \& Milner, 1992; Milner \& Goodale, 2008). They propose that the ventral stream composes what they call vision-forperception and that the dorsal stream composes what they call vision-for-action. While the ventral stream is used for planning action and carrying out unpracticed action, the dorsal stream is used for moment-to-moment visual
updating of actions that are comparatively more automatized.
The theory proposes that a moment-to-moment visual updating can occur through rapid repetition of the original top-down visual filter process described above (i.e. the current body schema is used in a top-down visual search to determine if there are any environmental features that meet those constraints). This moment-to-moment visual updating continues until (in this case) the shoulders have rotated enough to produce a match between the body-width of the agent and the width of the aperture. Although a biomechanical constraint was originally retrieved in the judgment phase, the agent need not always rotate the shoulders maximally. This process ends once the shoulders have rotated sufficiently to pass through the aperture. In other words, the goal state of the motor system was to fully rotate the shoulders, but a moment-to-moment visual update limits the total rotation by comparing the geometric properties of the current body schema (rotated shoulder in this example) to the geometric properties of the aperture. If an aperture is found as a result of the visual search, that means an aperture with sufficient geometric constraints has been found (for whatever posture the body is currently in). In this way, there can be a limited number of stored biomechanical constraints but a large variance in intermediate postural change (a large variance in shoulder rotation). Note these processing steps are the exact same steps used in the judgment phase.

## Computational Model Support

A computational model of the shoulder rotation experiments in Warren and Whang (1987) and in Higuchi et al. (2012) was developed as an initial test of the overall theory. The model was modeled in an extension to Python ACT-R called ACT-R 3D (Somers, 2016). At a high-level, the model follows the information processing description described above. Importantly, with respect to affordance research, the model is not semantically informed about the aperture in its environment.

It would not be atypical for an ACT-R model to be semantically informed. It is fairly customary for a model to use what is termed a 'visual icon' with a chunk identifying to the programmer what visual information the agent is 'seeing.' Although semantic information is not contained in the visual icon, it would not be atypical for a production to be pre-programmed to respond to the contents of the chunk in the visual icon.

The visual system in ACT-R 3D is slightly less informed. There is, in the agent's 3D environment, nothing labeled as an aperture. In fact, an aperture is negative space between environment features (such as walls) and cannot in fact be labelled in ACT-R 3D. Although the walls in the 3D environment are labelled, the agent has no access to those labels.

Instead, the agent has a goal to walk forward and in order to carry out this goal, it looks for obstacles. Upon finding an obstacle (the wall), the agent then uses a top-down visual
search for features that might be passable in the manner described in previous sections. Put simply, the agent does a visual search for empty space in front of it that meets the geometric constraints of the agent's body (or an achievable body posture). In this way the agent does not in fact represent the aperture as an aperture. Importantly, this also means that agents of different sizes will make different passability judgments.

The task the model must perform is to walk through an aperture, rotating the shoulders as needed, or avoid walking to apertures that it thinks it cannot pass through. As described above, if the agent does perform shoulder rotation, a moment-to-moment visual update occurs to determine if the agent should stop rotating. A single model is used for both small and large agents in slow and fast walking conditions, walking through apertures of various sizes, modeling experiments in Warren and Whang (1987); as well agents holding bars of various lengths and walking through apertures of various sizes in Higuchi et al. (2012).

The measure of fit to Warren and Whang was with respect to total rotation which is influenced partially by the number of agents who decide to pass through an aperture of a given size, rotation speed, and walking speed. There were four conditions to fit: 2 (size: small vs. large) x 2 (speed: slow vs. fast); with Pearson correlations ranging from 0.91 and 0.98 . The same model was then given bars of different sizes and performed the experimental conditions given in Higuchi et al. (2012). Although the fit was not as good in this case, as it showed a strong over-rotation in one condition; the fit was still reasonable, especially with the exclusion of the results for the over-rotated condition. The measure was rotation angle as well as the safety margin made between the end of the bar and the edge of the aperture, producing a Pearson's correlation of 0.84 for absolute rotation and 0.89 with respect to safety margin.

The success of the model is encouraging, given that the accuracy of the results are dependent on the timing involved, which is a product of the information processing steps (in the form of productions) that the agent carries out.

## Discussion

There was a number of difficulties pointed out in the first section that affordances based upon direct perception has to contend with. This section will address those difficulties but will also describe an interesting fallout from using an affordance-based approach.

## Addressing Difficulties with Direct Perception

The first difficulty pointed out in the first section that direct perception has to contend with is a person-plus-other system. In cases like these, there is no invariant property of the body that can act as units to directly perceive: there are measures beyond the body that affect the judgment. The theory presented in this paper also has to be extended to account for situations like these. When an agent is part of a person-plus-other system, the theory proposes that the agent could combine representations, including body schemas, to
make a estimation of the total geometric properties. Currently neither the theory nor the model define processes for including accompanying objects (in the bar experiments, the agent has special access to the dimensions of the bar). However, the advantage with the model is that there is a clear question that can be incorporated into a unified theory in the future.

In the same manner the model (and theory) also assumes that the geometric properties of the environment can be suitably perceived. The details of this process are not yet modeled, however, we can assume that aspects such as eyeheight, head-sway, and stride-length, can all be combined to creates a representation of the aperture width. In that respect, the model would be very much in line with findings from the aperture-passage literature.

The model can also help answer questions about representational content. The model presented here is part of a series of models that address whether A/S ratio or spatial margin (between edges of the agent and edges of the aperture) might be used as a metric for aperture passage. The model presented here implement an analog of spatial margin to judge the fit between aperture width and body width, supporting Higuchi et al. (2012).

The model also helps explain over rotation evident in Warren and Whang (1987) and Higuchi et al. (2012). Because the processes during the rotation completion monitoring affect timing, they also introduce a degree of variance in the rotation. The model does not rotate perfectly each time and exhibits similar over rotation to human performance.

## Extensions

The proposed processing description given above could easily be extended to include other affordances as well. For example, Stefanucci and Geuss (2010) researched aperture passage that required a ducking action. There is no principled reason why the same model could not be used to model those experiments as well. Since the problem is largely geometric, followed by a postural change, there is no principled reason why that postural change could not be for a ducking action. The same process could also be used for any situation that requires a postural change in order to accommodate the size of the body.

Secondly, not all affordances are purely geometric but could involve a geometric comparison process. Grasping, for example, has a number of elements, one of which could involve a judgment of whether the target object would fit in a grasp.

## Conclusion

The term 'affordance', though convenient, does not come without certain theoretical baggage. The aim of this paper is not to dismiss or discredit ecological psychology or the notion of direct perception but, rather, to compliment it with an information processing description. The term, 'representation', need not carry the kind of baggage that it may have historically. The representations used in the model
are, for the most part, not static and semantically-laden. For example, each agent learns their own body schemas before experiments by performing 'exercises', storing and updating new representations for biomechanical constraints. Furthermore, the environment is not labelled in any way. Agents in the simulation have to determine what apertures are passible individually.

Adapting affordance research to a representationalist framework opens some doors for research. This work is mainly philosophical, arguing for the need to unify research in a way that is falsifiable. The theory here presented relies on a cognitive mechanism capable of comparing the geometric properties of an environment with the geometric properties of an agent or agent-plus-object systems. This high-level presentation of the theory does, admittedly, offer very little detail about the working of the mechanism but does so in the hope of inciting research into the area.

# Acquiring pitch associations across modalities: the role of experience 

Laura Speed<br>Radboud University, Nijmegen, Netherlands<br>Ilja Croijmans<br>Radboud University, Nijmegen, The Netherlands<br>Sarah Dolscheid<br>University of Cologne, Cologne, NRW, Germany<br>Asifa Majid<br>Radboud University, The Netherlands, Max Planck Institute for Psycholinguistics, Nijmegen, Netherlands.

#### Abstract

When interpreting our perceptual world, information from multiple perceptual modalities is often associated. Such crossmodal associations can arise from innate structural connections in the brain, statistical correlations in the environment, or through language. In a large group of participants across a wide age range and language background, we tested crossmodal associations between pitch and 7 dimensions in comparison modalities. We found evidence supporting the existence of all 7 types of associations, but the strength of association varied by dimension. Pitch-angularity and pitch-weight judgments were the most robust associations. In general, strength of associations increased with age, with significant associations occurring in the oldest age group (age 19+), consistent with experiential accounts of crossmodal associations.

# Theory of Mind and Valuation during Cooperation 

Michael Spezio<br>Scripps College, Claremont, California, USA<br>Tessa Rusch<br>Institute for Systems Neuroscience, University Medical Center Hamburg-Eppendorf Hamburg, Germany<br>Yuqing Lei<br>Psychology \& Neuroscience, Scripps College, 1030 Columbia Avenue Claremont, CA 91711<br>Vanessa Hayes<br>Neuroscience, Scripps College, 1030 Columbia Avenue Claremont, CA 91711<br>Jan Glaescher<br>Institute for Systems Neuroscience, University Medical Center Hamburg-Eppendorf Hamburg, Germany

#### Abstract

Societal progress requires humans to excel at cooperation over time. To sustain successful cooperation, people coordinate, especially about who is in the best position at any given moment to make the best decision or to take the best action for the team as a whole. We used a novel cooperation task between involving dynamic assignment of Teacher and a Learner under conditions of uncertainty both about reward and about who is the expert at any given time. The task is similar to Theory of Mind tasks but actually gives the participants a stake in the outcome. We found evidence for effortful representation of the preferences of others, and that successful prediction fosters cooperative success. Neural components and putative sources signaled changes in the role of expert in the task. Further, the task design allows novel applications of computational models to the cognitive dynamics and associated neural systems for cooperation.

# Fake News and False Corroboration: Interactivity in Rumor Networks 

Michael J. Spivey (spivey@ucmerced.edu)<br>Cognitive and Information Sciences<br>University of California, Merced<br>Merced, CA 95340 USA

#### Abstract

Rumors inundate every social network. Some of them are true, but many of them are false. On rare occasions, a false rumor is exposed as the lie that it is. But more commonly, false rumors have a habit of obtaining apparent verification, by corroboration from what seems to be a second independent source. However, in complex social networks, the connectivity is such that a putative second source is almost never actually independent of the original source. In the present work, rumor network simulations demonstrate how remarkably easy it is for a node in the network to be fooled into thinking it has received independent verification of a false rumor, when in fact that "second source" can be traced back to the original source. By developing a theoretical understanding of the circumstances under which the spread of false rumors, "alternative facts," and fake news can be controlled, perhaps the field can help prevent them from ruining elections and ruining entire nations.

Keywords: Networks, Social Networks, Interaction

## Introduction

The interactivity that exists among the subsystems that form a cognitive system has powerful and lasting consequences. In the human brain, the interactivity among the neural subsystems that form the language comprehension network is what allows phonetics to influence syntactic processing (Farmer, Christiansen, \& Monaghan, 2006) and semantics to influence speech perception (Gow \& Olson, 2015; Spivey, 2016). In the human brain, the interactivity among the neural subsystems that form the visual perception network is what allows depth perception to influence motion discrimination (Trueswell \& Hayhoe, 1995) and attention to influence visual perception (Gandhi, Heeger, \& Boynton, 1999; Spivey \& Spirn, 2000). In the human brain, the interactivity between the language comprehension network and the visual perception network is what allows visual context to influence spoken word recognition (Allopenna, Magnuson \& Tanenhaus, 1998; Spivey-Knowlton, 1996), and linguistic input to influence visual perception (Lupyan \& Spivey, 2010; Lupyan \& Ward, 2013). These examples form just a tiny subset of the many consequences of interactivity in the human brain.

Outside the human brain, interactivity in a social network has powerful consequences for group behavior. When two people cooperate on a shared task, or even just have a conversation, they often exhibit real-time motor coordination in their postural sway (Shockley, Santana, \&

Fowler, 2003; M. Richardson, Marsh \& Schmidt, 2005), their eye movements (D. Richardson, Dale \& Kirkham, 2007), their gestures (Paxton \& Dale, 2013), and their language use (Louwerse, Dale, Bard, \& Jeuniaux, 2012). It has even been shown that behavioral and neural responses of two participants cooperating on a task exhibit the signatures of competition between the two subtasks, even though each person is in charge of only one of those subtasks (Sebanz, Knoblich, Prinz, \& Wascher, 2006). Essentially, each person is doing some of the thinking for the other person. When these mechanisms of coordination are optimized between two people, they can even perform a joint perceptual task at a level that is better than either of them alone (Fusaroli et al., 2012).

When people share information with each other, they tend to self-organize into a larger cognitive system (Goldstone \& Gureckis, 2009). Much like how cognition may be an emergent property of billions of neurons interacting with one another in a brain (Kello, Beltz, Holden \& Van Orden, 2007), group cognition may also be an emergent property of multiple people interacting with one another in a shared context (Thiener, Allen, \& Goldstone, 2010). Due to the continuous fluid flow of information throughout the network, every node (be it a neuron or person) is richly interdependent with every other node, at least indirectly. Not only can positive influences spread throughout such a network, as when two brains show improved performance on a shared perceptual task (Fusaroli et al., 2012), but negative influences can also spread throughout the network and infect nearly every component. Network simulations of rumor-spreading have recently begun to analyze this process of false information infecting a social network (Roshani and Naimi, 2012).

Traditional studies of rumor transmission tended to focus on linear sequential transfer of a rumor, and how the content can often become accidentally modified after several transmissions (Allport \& Postman, 1947). Sometimes this is referred to as the "telephone game." However, more recent studies of rumor transmission have used network theory to examine how non-linear transmission of rumors happens in complex social networks that are richly interconnected (Del Vicario et al., 2016). For example, when the network has islands of homogeneity, tight-knit like-minded enclaves that connect mostly just to their own group, these subnetworks can become "echo chambers" that reinforce false narratives and conspiracy theories within their walls. Alternatively, when the
connectivity of a social network is scale-free (neither random nor homogenous) - much like the brain's connectivity (Kello, 2013; Sporns, 2010) - then almost any rumor can be expected to spread throughout the entire network, irrespective of whether it is true or false (Nekovee, Moreno, Bianconi, Marsili, 2007). What has not been explored yet in this small cottage industry of research is how easily a false rumor can obtain independent verification via an apparent second source, even when that "second source" actually has the original source as its origin.

When an interactive system (be it a brain or a group of people) spends any amount of time sending signals back and forth among its subcomponents, it quickly becomes difficult to trace the source of a signal and determine whether a given signal is afferent (recently coming from an external source) or efferent (better described as generated endogenously). Under these circumstances, following the trail of a rumor in a social network is extremely difficult. The journalistic practice of "corroborating the story" can become quite complicated. A common method of fact-checking is to find a second source for the same story. If the second source is independent of the first source, and says essentially the same thing, then it adds veracity to the report. Even naïve experimental participants tend to use this tactic (Kim et al., 2008). However, in an interconnected network of people sharing information, almost no one is actually independent of anyone else. Frequently, an apparent second source, which gets used as verification of the rumor, actually acquired its information indirectly from the original source.

One concrete real-world example of such false corroboration is the U.S. Pentagon's case for Saddam Hussein stockpiling weapons of mass destruction (WMD) at the beginning of the $21^{\text {st }}$ century. It has now been wellestablished that U.S. leaders were proactively seeking justification for a pre-existing plan to invade Iraq and depose its leader (Dreyfuss \& Vest, 2004; Ryan, 2006). It turned out to be all too easy for information gatherers to fool themselves into thinking they had corroborated reports of WMD, when in fact the corroboration was actually a duplicate of the original false rumor. The CIA, British intelligence services, and the New York Times all collected reports of WMD in Iraq, and carefully sought independent verification. Each of these entities received fallacious reports from the same Iraqi defector, codenamed "Curveball" by the CIA. And what's more, each of them used un-sourced reports from one another as corroboration of their own report. What they each did not realize at the time was that the "second source" to corroborate their report from Curveball was actually just someone else's report from Curveball (Bamford, 2005; Prados, 2004).

False rumors, "alternative facts," and fake news have become an everyday occurrence recently, where too many people obtain their news reports on social network sites and blogs, where "news" is provided that has not been vetted by policies of ethical journalism. For example, in January of 2016, journalist and author, Fareed Zakaria, was "trolled" on the internet with a fake report of him calling for "jihad
rape of white women to depopulate the white race." Some people believed this false rumor so strongly that they made threats on Zakaria's life, and frightening phone calls to his daughters in the middle of the night (Zakaria, 2016).

Similarly, in the fall of 2016, fake news reports were disseminated widely on Facebook about presidential candidate Hillary Clinton being involved in a child sextrafficking ring based at a particular pizza shop in Washington, D. C. One man believed that false rumor so strongly that he felt compelled to travel across state lines to visit that pizza shop with an assault rifle in his hands and fire a shot to let them know he was there to save the children. The U. S. Department of National Intelligence has recently determined that many such fake news stories about Hillary Clinton were fabricated and disseminated via social networks specifically with the intent of influencing the results of the 2016 U. S. election (DNI Report, 2017).

In Del Vicario et al.'s (2016) computational analysis of conspiracy theories on the internet, they concluded that, "many mechanisms cause false information to gain acceptance, which in turn generates false beliefs that, once adopted by an individual, are highly resistant to correction." In the following rumor network simulations, the results suggest that false corroboration may be one of those many mechanisms.

## Random Rumor-Net Simulations

In this first group of simulations, a 100 -node network was constructed and given random placement of bidirectional connections, excluding self-connections. In one set of 100 simulations, the network was given $10 \%$ connectivity, such that each node on average was connected to about 10 of the possible 99 other nodes (i.e., average node degree $=10$ ). The average clustering coefficient for this network (which shows how interconnected each node's friends are) was .10. Another set of 100 simulations used a clustering coefficient of .33 , and Figure 1 shows an example degree distribution from one of those networks. Another set of 100 simulations used a clustering coefficient of .5 , and a fourth set used a clustering coefficient of .67 .

Figure 1: Degree distribution from a 100 -node random network in which, on average, most nodes are connected to about 33 other nodes.

To begin a simulation, node \#1 was infected with a rumor by flipping its state from zero to 1.0 . This is the one-and-only origination of the rumor in this network. It could be true or false, but for the purpose of testing its evolution into "fake news," the rumor is treated as false. For every instance of transmitting the rumor, a randomly chosen infected node would select randomly among its connections to spread the rumor with one other node. After spreading, that bidirectional connection was erased in the network to prevent it from being used again in the future. (The simulation assumes that if the same rumor were shared again between the same two people, it would not count as a transmission.) For that very first transmission, this obviously involved node \#1 sharing the rumor with one of the nodes connected to it. At which point there would then be two nodes that have been exposed to the rumor. Then one of those nodes was randomly selected to spread the rumor again. After 100 transmissions of the false rumor, some of the nodes had still never been exposed, some had been exposed once, and some had heard the rumor from two or more different connections. This latter case counts as people who had heard the rumor corroborated by what would seem to be a second source. However, the simulation actually has only one source of the rumor: node \#1. For example, node \#1 might spread the rumor to node \#47, who then spreads the rumor to node $\# 23$. Next, node \#47 might share the rumor again, this time with node $\# 87$, who shares it with node $\# 18$, who then shares the rumor with node \#23. In that scenario, node \#23 could easily be fooled into believing that it had received independent corroboration (from node \#18) of the rumor it first heard from node \#47.

In this first group of simulations, the number of nodes that received this false corroboration was recorded for low-, medium-, high- and very high-connectivity networks (i.e., clustering coefficients of $.1, .33, .5$, and .67). Interestingly, after 100 transmissions of the rumor, there were no differences across these four different types of random networks (results averaged across the 100 simulations in each case). In all simulations, irrespective of how densely interconnected the network was, around 26 of the 100 nodes had heard the rumor from two or more sources (Table 1). This insensitivity to network density is likely due to the fact that a rumor-spreader is randomly selected each time (among nodes that know the rumor), and its relative likelihood of spreading the rumor to a knowing node or an unknowing node is unchanged by how well-connected it is.

Table 1: Random networks with different numbers of connections show about the same number of nodes hearing false corroboration of the rumor ( $2+$ times).

| Avg Node <br> Degree | Clustering <br> Coefficient | Never <br> Heard | Heard <br> Once | Heard 2+ <br> times |
| :---: | :---: | :---: | :---: | :---: |
| 10 | .10 | 33.6 | 40.1 | 26.3 |
| 33 | .33 | 34.6 | 38.8 | 26.6 |
| 50 | .50 | 34.8 | 38.4 | 26.8 |
| 67 | .67 | 34.9 | 38.4 | 26.7 |

With 200 nodes and 200 rumor transmissions (or 500 nodes and 500 rumor transmissions), again about onequarter of the nodes obtain false corroboration - irrespective of how densely or sparsely connected the network is. With half as many transmissions as there are nodes, about $10 \%$ of the nodes obtain false corroboration. And with twice as many transmissions as nodes, about $60 \%$ of the nodes obtain false corroboration. Based on these initial simulations, it appears that false corroboration of a rumor may be remarkably easy to obtain in a social network.

## Scale-Free Rumor-Net Simulations

Most real-world networks, including social networks, are not at all random in their connectivity. Instead, social networks tend to have a scale-free pattern of connectivity, meaning that most nodes have a smallish number of connections (node degree), while a few nodes have a very large number of connections. Using a version of Barabasi and Albert's (1999) preferential attachment process, a group of scale-free rumor networks were designed that show a power-law in their degree distribution (Figure 2).

Figure 2: (A) Degree distribution from a 100 -node scale-free network where the mean number of connections per node is 33 , but most nodes have $<25$ connections and a few nodes have $>75$ connections. (B) On log-log coordinates, the degree distribution forms a relatively straight line with a slope of -1.3 .

By contrast to a scale-free network, in a random network the proportion of connections each node has generally corresponds to the clustering coefficient as well. That is, if each node in a random network has about $10 \%$ of the possible connections, then the clustering coefficient (showing what proportion of each node's friends are connected to each other) will also tend to be around .10 . However, in a scale-free network, the clustering coefficient (.62, in Figure 2) tends to be substantially higher than the average proportion of connections the nodes have (.33, in Figure 2). That is, in a scale-free network, most nodes have relatively few friends, but a sizeable proportion of those friends know each other.

In these next simulations, a hundred 100 -node scalefree networks were designed that had an average of 10 connections per node, along with another hundred networks that had an average of 17 connections per node, then another hundred with 25 , and another hundred with 33 connections per node. (In a scale-free network, when the average number of connections approaches $50 \%$ of the possible connections, its degree distribution can become bimodal and no longer adheres to a scale-free power law. Therefore, the highest node degree used here was 33.)

Each rumor-spreading simulation with these scale-free networks was carried out in a fashion similar to those with the random networks, except that the first rumor-infected node could not be an arbitrary choice because some nodes were substantially more connected than others. To test the limiting case, the least-connected node in each scale-free network was selected as the first node to spread the rumor. After that starting point, 100 transmissions of the rumor took place exactly as it did with the random networks.

Table 2: Scale-free networks with different numbers of connections show about the same number of nodes hearing false corroboration of the rumor ( $2+$ times).

| Node <br> Degree | Cluster <br> Coeff. | loglog <br> slope | Never <br> Heard | Heard <br> Once | Heard <br> $2+$ times |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 10 | .22 | -0.71 | 40.1 | 34.6 | 25.3 |
| 17 | .39 | -1.05 | 40.4 | 34.3 | 25.3 |
| 25 | .56 | -1.25 | 40.8 | 33.9 | 25.3 |
| 33 | .68 | -1.27 | 40.8 | 33.6 | 25.6 |

In these scale-free rumor networks, a slightly larger proportion of the people never hear the rumor (about 40\%) compared to that in the random networks (about $35 \%$ ). However, remarkably, approximately the same number of false corroborations is observed $(\sim 25)$ as that seen with the random networks (compare Tables $1 \& 2$ ). As was tested with the random networks, this $25 \%$ false corroboration rate replicates for scale-free networks with 200 nodes and 200 rumor-transmissions. When there are 3-4 times as many transmissions as nodes, almost every node will have heard the rumor, and about $3 / 4$ of them will have heard it more than once (irrespective of network density). Not surprisingly, in these scale-free networks, it is usually the well-connected nodes that first obtain these false corroborations.

## When a False Rumor Becomes Fake News

Based on all these simulations, when there are as many rumor-transmissions as there are nodes, then almost $2 / 3$ of them will hear the rumor, and about $1 / 4$ of them will obtain a false corroboration of the rumor - even though it never actually had any independent secondary source. This is true for both random rumor networks and for scale-free rumor networks. However, when one of the people in the network is a reporter for a news agency, who will broadcast the story to everyone if they obtain apparent corroboration, then it turns out that the type of connectivity does, in fact, matter. If one assumes that the reporter is among the most widelyconnected people in the network, then the different degree distributions for random networks and for scale-free networks (Figures 1 and 2) make for substantially different reporters. In a random network, the most-connected node (i.e., the reporter) will have a number of connections that is greatly influenced by the density of the network's connectivity (its average node degree). However, in a scalefree network, the most-connected node is often connected to $>85 \%$ of the other nodes, irrespective of the average node degree. Therefore, a reporter in a random network will only occasionally obtain a false corroboration, and thus publish the story (Table 3). However, in a scale-free network, a reporter (who is massively well-connected) will almost always obtain false corroboration, and therefore publish the rumor (Table 4). If that rumor is false, then its publication qualifies as fake news.

Table 3: In random rumor-nets, false corroboration sometimes leads to the publication of fake news.

| Node Degree | Clustering <br> Coefficient | Reporter-node <br> Publishes Fake News |
| :---: | :---: | :---: |
| 10 | .10 | $58 \%$ |
| 33 | .33 | $42 \%$ |
| 50 | .50 | $38 \%$ |
| 67 | .67 | $35 \%$ |

Table 4: In scale-free rumor-nets, false corroboration almost always leads to the publication of fake news.

| Node <br> Degree | Clustering <br> Coefficient | loglog <br> slope | Reporter-node <br> Publishes Fake News |
| :---: | :---: | :---: | :---: |
| 10 | .22 | -.071 | $92 \%$ |
| 17 | .39 | -1.05 | $93 \%$ |
| 25 | .56 | -1.25 | $93 \%$ |
| 33 | .68 | -1.27 | $87 \%$ |

Surprisingly, with random networks, denser connectivity leads to a reduced likelihood of the reporternode obtaining false corroboration and publishing the rumor. Upon closer examination, this makes sense given the parameters of the simulation. In a random network with a small average node degree (sparse connectivity), whenever a rumor-infected node is about to spread the rumor, it has a small number of friends to choose among. If
one of them happens to be the reporter, which is somewhat likely since the reporter is the most connected node, then the reporter might hear the rumor. And if that happens a second time, then a (false) corroboration has taken place, and the story gets broadcasted. By contrast, in a random network with a large average node degree (dense connectivity), whenever a rumor-infected node is about to spread the rumor, it has a large number of friends to choose among. One of them is probably the reporter, but a random selection of to whom the rumor will be spread leaves the reporter with a slim chance. In many of these random rumor-net simulations, the reporter never even heard the rumor once.

The situation is very different in a scale-free network. In a scale-free rumor-net, most nodes have fewer connections than they would in a comparable random network. Therefore, when a rumor-infected node is randomly selected to spread the rumor, it is usually one that has a smallish number of friends to choose among, and one of them is almost certainly the well-connected reporter (see also Doerr, Fouz, \& Friedrich, 2012). Thus, almost every time the rumor is transmitted, the reporter has a reasonable chance of being its recipient. As a result, the reporter-node in such a network is highly likely to hear the rumor, and also highly likely to obtain a false corroboration of this rumor, even though the rumor actually has only one source.

## Conclusion

Interactivity in a network is usually a good thing. Ambiguities or uncertainties present in one part of the network will often be resolved by strongly biasing information present in another part of the network (e.g., Kawamoto, 1993; MacDonald, Pearlmutter, and Seidenberg, 1994; McRae, Spivey-Knowlton, \& Tanenhaus, 1998). However, when that strongly biasing information is objectively false, the interactivity within a network can compromise its ability to align itself with reality.

The present network simulations do not specifically distinguish between objectively false rumors and true rumors, but a recent analysis of 330 rumor threads on Twitter does. For a false rumor, the time between rumor onset and debunking can be as much as seven times longer than the time between rumor onset and verification for a true rumor (Zubiaga, Liakata, Procter, Hoi, \& Tolmie, 2016). That is, it takes much longer to debunk a false rumor than it does to verify a true rumor. Therefore, if a longstanding uncertain rumor has not been verified as true, then the odds are steadily increasing every day that it is a false rumor (that just hasn't been debunked yet). Most true rumors get verified very quickly.

However, the nature of this verification process comes into question when considering the present rumor simulations. If the apparent verification comes in the form of a seemingly independent source that corroborates the original rumor, it may be illusory. The interactivity inherent in social networks can all too easily make a false corroboration (i.e., an echo from the echo chamber) appear as genuine independent corroboration.

One potential solution to this problem is for reporters to make better efforts at tracing the lineage of a report, so that two reports from the same source might be identified as such. A more reliable solution would be for journalism practices to avoid using secondary-source corroboration on its own as sufficient evidence to disseminate a story. These rumor network simulations demonstrate that it is simply too easy to obtain such corroboration in a fraudulent manner. Instead, the criterion for publication of a story might ought to include evidence that cannot easily be faked, such as photos, video, audio recordings, and documents whose source can be reliably determined. For example, if the report is that a public figure made sexist comments, or mocked a disabled person, or told the public a brazen lie, simply relying on two seemingly-independent sources to publish such a story may be insufficient. If the comments or mocking are evident in a video clip of the public figure, or if the lie is present in a verifiably-sourced tweet from the public figure, then those pieces of evidence should be what are repeatedly disseminated in reporting the story. Reports without such concrete evidence should be taken with a grain of salt, or perhaps not published in the first place.

It has been proven time and time again in everyday life, as well as in high-stakes politics, that the dissemination of false rumors can ruin lives, ruin elections, and even ruin entire nations. Understanding the mechanisms that allow, and exacerbate, the spread of misinformation in a social network of any kind may help with efforts to curtail and minimize the damage that can be done. The present simulations of a false rumor spreading throughout a network show convincingly that, even in a sparsely connected network, the "apparent corroboration" of a story often comes from a source whose own source can be traced back to the originator of the story, and thus should not actually count as independent corroboration. To quote Fareed Zakaria, "No matter how passionate people are, no matter how cleverly they can blog or tweet or troll, no matter how viral things get, lies are still lies."

#### Abstract

Speakers involved in a communicative exchange construct an internal model of their addressees and draw upon the model to craft utterances that are likely to be understood. In many realworld situations (e.g., when talking to a non-expert, non-native speaker, or a child), this process of audience design involves identifying gaps in the lexical-semantic knowledge of the listener and selecting alternative expressions. We examine speaker adaptation to a listener with incomplete lexical knowledge in the spatial domain, specifically a failure to comprehend the basic terms left/right. Experimental and modeling results provide evidence of rapid adaptation that is modulated by the availability of alternative spatial terms. We consider how our approach relates to recent work in computational pragmatics, and suggest that adaptation to the lexical knowledge of the addressee is an important but relatively understudied topic for future research.

Keywords: language adaptation; audience design; spatial language; lexical semantics; computational pragmatics

## Introduction

Speakers choose referring expressions on the basis of several factors, including their beliefs about the linguistic and conceptual knowledge of addressees (e.g., Pate \& Goldwater, 2015; Brennan \& Clark, 1996). For example, speakers tend to avoid or supplement proper names that, in their judgment, listeners do not know (e.g., Isaacs \& Clark, 1987; Fussell \& Krauss, 1992; Wu \& Keysar, 2007; Kutlak et al., 2016). This is part of a more general pattern of audience design (Clark \& Murphy, 1982) in which speakers construct internal models of specific addresses and use these models to facilitate communication. Another example of audience design is the formation of partner-specific conceptual pacts during a conversation. Speakers also show some ability to adapt their descriptions to a listener's viewing perspective when it is different from their own, presumably making it easier for the listener to identify intended referents in a scene (e.g., Schober, 2009). These adjustments to the needs of particular listeners in specific circumstances are analogous to the wellknown Lombard effect, in which people tend to talk louder in the presence of ambient noise (Lombard, 1911), suggesting that audience design is a fundamental phenomenon that occurs at many linguistic and conceptual levels.

Empirical and computational work on audience design has largely adopted the assumption that discourse participants share knowledge of basic vocabulary items. For example, the Rational Speech Acts framework (Frank \& Goodman, 2012) assumes that speakers and addressees have the same literal meanings for lexical expressions, and derives pragmatic usage from literal semantics through iterated probabilistic inference. However, the assumption of common word knowledge is not completely valid for many real-world scenarios. In the same way that experts addressing novices should avoid overly technical jargon, speech tailored to nonnative or child listeners must regularly work around basic lexical-semantic gaps.

Recently, Ferrara et al. (2016) closely investigated the linguistic choices that parents made when communicating spatial information to their 3-4yo. children. The language used by parents to describe the location of items in simple spatial arrays differed significantly from that of adults addressing other adults in the same task. Most notably, parents avoided the horizontal axis terms left/right-terms that are known to be acquired relatively late by children in general, and that were not reliably understood by many of the particular children in the study-while they used many other spatial terms (e.g., the vertical axis terms above/below) in essentially the same way that adults do when taking to one another. These findings support the claim that parents have well-tuned internal models of their children's lexicalsemantic knowledge and can design utterances for them by circumventing their lexical gaps.

In this study, we investigated whether adaptation to gaps in spatial language would occur in a minimal communicative setting. The parents in Ferrara et al.'s study had developed internal models of their children through extensive interaction with them. Here we sought to determine whether calibration to the addressee's lexical knowledge could develop much more rapidly, perhaps after only a few instances of communicative breakdown. Furthermore, parents presumably have access to a variety of top-down and bottom-up cues to gaps in children's spatial lexicons (e.g., general experience with child spatial language, instances where children explicitly ask for clarification of spatial descriptions). Here we sharply restricted the interaction
among interlocutors, providing only ambiguous, bottom-up cues to the addressee's knowledge of the spatial lexicon.

Following Ferrara et al. (2016), our study took the form of a referential communication task. Participants provided spatial descriptions to a listener who had either full knowledge of lexical-semantics or full knowledge except for a gap in the horizontal terms left/right. This is the same gap observed in young children, and indeed comprehension of left/right can be demanding even for typical adults (Sholl \& Egeth, 1981). If audience design is operative in this setting, participants should more often supplement or employ alternatives to the basic horizontal terms when addressing the listener who does not accurately comprehend them.

We further investigated whether and how accommodation of the listener's lexical gap was modulated by the stimulus array. For example, in describing the location of the object marked by the arrow in Fig 1A, alternatives other than left/right may not be obvious to the speaker. Contrast this with the arrangements of Fig 1B and 1C, in each of which a non-horizontal spatial relation is available to identify the target (i.e., inside the box, below a triangle). For arrangements such as Fig 1C, speakers might even prefer to refer to the vertical axis independently of any particular addressee (e.g., Logan, 1995; Ferrara et al., 2016).

Figure 1: Examples of array types used in the spatial communication task

Finally, we were interested in whether the adaptation found experimentally could be accounted for with a simple inhibitory mechanism: one that penalizes the use of terms that have resulted in communication errors, leaving unchanged all other aspects of the speaker's system for generating referring expressions. We formalize this mechanism in a high-level computational model of referential communication, show that it matches the detailed pattern of spatial language with minimal free parameters, and discuss how it relates to and extends previous work in computational pragmatics. The detailed empirical findings presented here contribute to the understanding of the form and limitations of lexical audience design, and our model delineates a way by which previous computational models may be augmented to account for lexical differences among interlocutors.

## Spatial communication experiment

Our experiment involved communication between speakers (the participants) and a simulated listener. In each trial, the
speaker described the spatial location of a target object in a visual array (see examples in Fig 1). The listener responded by selecting one of the objects, and the participant was then shown the listener's choice alongside the original display. Apart from this minimal communicative interaction, participants were provided no information about or feedback from the listener.

There were two conditions that differed by listener type. In the Full knowledge condition, the listener comprehended all English spatial expressions without error. In the Partial knowledge condition, the listener was identical except that comprehension of left/right and minor variants of those terms was at chance. We varied the spatial arrangements across the stimulus arrays to elicit a range of linguistic expressions and, most importantly, to provide varying opportunities for adaptation in the Partial condition. We were further interested in whether adaptation would involve primarily avoiding left/right or supplementing those terms with other spatial information, as well as in the coarse-grained time course of adaptation. Rapid avoidance of the lexical-semantic gap would provide evidence of an adaptation mechanism that is quite sensitive to bottom-up feedback and that inhibits expressions that have resulted in communication errors.

## Participants

This experiment was part of a series conducted online using Amazon's Mechanical Turk service. There were 48 participants $\left(\mathrm{M}_{\text {age }}=33.9\right.$ years, 25 males $), 24$ in each condition (Full vs. Partial knowledge). Individuals received a small monetary compensation for participating.

## Materials

The stimuli consisted of 32 spatial arrays similar to those of Ferrara et al. (2016). Target objects, marked by red arrows in the display, could not be uniquely identified by intrinsic properties such as shape and color. For example, yellow circle would not be a uniquely identifying description of the target in Fig 1C, but yellow circle on the bottom or yellow circle below a triangle would both be sufficient.

In all stimuli, the target could be identified by its position on the horizontal axis (e.g., yellow circle on the right). This maximized the potential contrast between participants in the Full condition, who could in principle describe all targets with left/right, and those in the Partial condition, who would have to employ other terms to communicate successfully.

The arrays varied in the alternative spatial descriptions that they afforded. In the Horiz type (10 items), the target could be identified only by its relative position on the horizontal axis (Fig 1A). Under the assumption that left/right are generally the most accessible or preferred terms for horizontal position, these arrays would be expected to provide the greatest challenge for adaptation.

All other array types contained alternative spatial relations that could be used in identifying descriptions: proximity of the target to another object; containment of the target within a bounding box (see Fig 1B); internal vertical or horizontal orientation of the target (e.g., a pencil pointing up or down);
or a vertical relation between the target and another object. We grouped the proximity, containment, and vertical/ horizontal orientation arrays into a single type called Horiz+Other (18 total items). For such arrays, adaptation could involve using horizontal terms other than left/right or, perhaps more simply, reference to the other spatial relation (e.g., circle in the box instead of circle on the left).

The Horiz+Vert array type (4 items; see Fig 1C) was separated from the others on the basis of extensive evidence that reference to the vertical axis is both linguistically and non-linguistically privileged relative to the horizontal axis (e.g., Logan, 1995; Carlson-Radvansky \& Logan, 1997; Fitneva \& Song, 2009). Speakers could prefer vertical terms for these arrays, not because of any specific beliefs about the experimental addressee, but as a reflection of this general privilege (as was observed in Ferrara et al., 2016). Adaptation would then be difficult to measure for these arrays, as left/right may be independently dispreferred by participants in both the Full and Partial knowledge conditions.

Figure 2: Proportion of responses using left/right only (i.e., without any additional spatial expression) produced by participants and predicted by the adaptation model.

Errors bars show standard error of the mean.

## Procedure

In each trial, the participant was presented with a single spatial array and asked to describe the target so that it could be uniquely identified by the listener. Participant descriptions were typed into a text box; no restrictions were placed on the terms used (i.e., responses were completely free). Following a brief delay, participants were provided feedback about the object selected by the listener (marked with a blue arrow in a copy of the array): this was either the target or the distractor object of the same shape and color.

In the Full knowledge condition, the simulated listener selected the target whenever the description contained at least one word from a large list of spatial expressions (determined through pilot testing). While participants in this condition could in principle have communicated "successfully" by using spatial terms that did not pick out the target, as we
report below the vast majority of responses were felicitous and identifying. In the rare instance that a description contained no spatial term, the Full knowledge listener selected the target or the distractor with equal probability.

The simulated listener in the Partial knowledge condition behaved identically except when the description contained left/right (or variants such as leftmost/rightmost) without any other spatial terms. For such responses, the listener randomly selected the target or matched distractor with equal probability (i.e., the listener responded as if no spatial term was present in the description).

Three practice trials at the beginning of the experiment emphasized the goal of providing complete, unambiguous descriptions (e.g., yellow circle at the bottom instead of simply circle or yellow circle for Fig 1C). Each stimulus array was repeated 4 times over the course of the experiment, resulting in 128 trials per participant. The order in which the arrays appeared was pseudo-randomized by participant, with the constraint that there were an equal number of Horiz trials in each half of the experiment ( 20 per half). This ensured that a participant who consistently used left/right for this array type would receive, on average, at least ten instances of negative feedback during the first half of the experiment.

## Results

Descriptions tended to be brief, containing a single spatial expression (average number of words per utterance: 2.83 in the Full condition, 3.13 in the Partial condition). Two manual coders determined that more than $95 \%$ of the responses across both conditions were sufficient to uniquely identify the target (given complete knowledge of spatial terms). The rare insufficient responses were produced sporadically across participants (i.e., not concentrated on any particular speaker).

Statistical analysis was performed on the sufficient descriptions. For these, communication errors could occur only in the Partial condition and only when left/right was used without any other spatial term. Accordingly, we focused on the way in which the rate of 'left/right-only' descriptions (i.e., left/right alone or combined with only shape or color terms) varied across conditions and array types (see Fig 2).

A mixed-effects logistic regression was performed with left/right-only as the dependent variable and fixed factors of condition (Full vs. Partial), array type (Horiz, Horiz+Other, Horiz+Vert), and three experimental 'phases' (with approximately one-third of the total trials in each phase). Phase was included as a rough estimate of the time course of adaptation, which we informally gauged to occur quite rapidly (i.e., after only a few instances of negative feedback). All fixed effects were weighted sum-coded, and the model included random intercepts for participants and stimuli. In light of the number of comparisons involved and the relative novelty of our research question and design, a conservative level for significance was chosen $(p<.01)$.

As anticipated earlier, the left/right-only rate was higher overall for the Horiz array type ( $\beta=2.24, p=.006$ ), with the rate for the Horiz+Other type effectively equal to the mean across all types $(\beta=0.05, p>.8)$. Note that this implies a
much lower rate for the Horiz+Vert arrays (as expected from the vertical bias discussed earlier). There were no significant main effects of experimental condition or of phase. However, condition and array type interacted significantly, reflecting the fact that the difference in left/right-only rate for Horiz vs. Horiz+Other was much larger in the Partial condition (Condition $\times$ Horiz: $\beta=-0.28, p<.01$; Condition $\times$ Horiz+Other: $\beta=0.39, p=.01$ ). In the Full condition, the rate of left/right-only descriptions was high for both Horiz and Horiz+Other. The Partial condition showed adaptation to the listener for the Horiz+Other array type that did not fully generalize to the Horiz arrays.

Finally, condition and phase interacted significantly (Condition $\times$ Phase1: $\beta=-0.5, p<.01$ ). This accords with the numerical finding that left/right-only rate increased slightly across phases in the Full condition (phase1: 69\%, phase2: $71 \%$, phase3: 73\%) but decreased across the first two phases in the Partial condition (phase1: 57\%, phase2: $47 \%$, phase3: $42 \%$ ). The small increase in the Full condition may be due to the sufficiency of left/right for all arrays: implicit selfpriming may have elevated the frequency of these terms, or participants may have explicitly realized that there was little need to generate alternative expressions. The decline after the first phase in the Partial condition, and indeed the difference in the first phase across the two conditions, indicates that adaptation to the listener occurred rapidly (i.e., within approximately 43 trials, after an average of 12 instances of unsuccessful communication).

In summary, we observed fine-grained adaptation to the addressee with a lexical-semantic gap in the spatial domain. There was little opportunity to find adaptation in the case of Horiz+Vert arrays, given the general bias to use vertical expressions. But for Horiz+Other arrays, participants in the Partial knowledge condition began to avoid left/right-only descriptions, responding to listener errors and performing differently than participants in the Full knowledge condition, within the first third of the experiment. Adaptation in the Partial condition was significantly lower for the Horiz arrays, which did not provide an alternative spatial relation that could be used to identify the target.

The preceding analysis does not reveal whether participants in the Partial condition attempted to avoid using left/right altogether, or continued to use the problematic terms but supplemented them with additional spatial expressions. For the Horiz+Other arrays, we found that avoidance was the primary strategy. For the Horiz+Vert arrays, we observed more of a tendency to produce redundant descriptions (e.g., top right or bottom left). However, this tendency was observed in both the Full and Partial conditions, suggesting that it may reflect lexicalization o spatial collocations rather than any adaptation strategy.

A major remaining issue is why the Partial condition participants found it relatively difficult to avoid (or supplement) left/right for the Horiz arrays. Replicating Ferrara et al. (2016), we found that when participants did switch to alternative expressions these were mostly ordinal terms such as first/second/last. Ordinals would in fact have
been sufficient to identify the target in all of the array types, making their relative infrequency as alternatives to left/right all the more striking. One hypothesis is that, when exposed to errors on left/right, participants (implicitly) concluded that the listener has imperfect understanding of reference to the horizontal axis in general. If correct, this hypothesis would imply that adaptation occurred at the level of spatial relations or axes rather than at the level of spatial expressions.

An alternative hypothesis is that ordinals-in contrast to proximity, containment, etc. terms-are strongly dispreferred relative to left/right for the purpose of describing our stimulus items. Under this hypothesis, the difficulty of adaptation for the Horiz arrays in the Partial condition should be mirrored by avoidance of ordinals in the Full condition. More generally, the probability of switching from left/right to another spatial expression in the Partial condition may closely track independently-established relative frequencies of terms used to describe our arrays. We formalized this hypothesis in the computational model of spatial language use and adaptation developed below.

## Computational model of adaptation

The model has two main components: baseline (or preadaptation) preferences for spatial term usage, and a mechanism for modifying the preferences in response to errors made by the listener. Our goal in this paper is not to explain the baseline preferences, but rather to estimate them from empirical usage frequencies. The estimates take the form of numerical (dis)preferences (or 'weights') assigned to various spatial and non-spatial term types (or 'attributes'). Once the baseline has been established, we show that a single inhibition parameter (i.e., a penalty for using left/right) suffices to closely match the detailed adaptation pattern of the experiment. A uniform penalty for left/right has different effects across the array types because the viable alternative attributes for each type vary independently in their weights.

## Baseline preferences

The baseline model assigns probabilities to a large set of array-specific sufficient descriptions. Each description contains one or more binary-coded attributes indicating the presence of spatial and other terms. Specifically, the spatial attributes we considered are horizontal (horiz: left/right), vertical (vert: above/below/up/down/top/bottom), proximity (prox: close to/next to/near/far/beside), containment (cont: inside /outside/within), vertical orientation (v.o.: pointing up/down, facing up/down), horizontal orientation (h.o.: facing towards/ away from), and ordinal (ord: first/second/last). The non-spatial attributes are shape (circle/pencil) and color (yellow/green) and. This coding abstracts away from minor syntactic permutations (e.g., circle to the right vs. right circle) and lexical variation (e.g., the circle on the right vs. rightmost circle). The set of sufficient descriptions for each array was formed by considering the spatial relations that could be used to identify the target and fully crossing these with one another and all
possible shape and color combinations (e.g., Table 1 lists the relations that are relevant for the Horiz+Other arrays).

Relative frequencies of the sufficient descriptions for each array were determined, in part, from the results of the Full knowledge condition above. However, because all targets in that condition could be successfully identified with left/right, it is plausible that this data overestimates the frequency of horiz (e.g., due to participant self-priming). More generally, we were concerned that Full condition data may provide a somewhat skewed estimate of the relative accessibility of different sufficient descriptions. Therefore, we conducted an additional experiment in which each participant provided up to five descriptions of an array. This experiment was performed by 19 undergraduates at the Johns Hopkins University, each completing 32 trials (one per array) for a small amount of course credit. The total frequency of a description for a given array was equal to the sum of its frequencies in the Full condition and in this experiment.

A conditional log-linear (or maximum entropy) probability distribution over descriptions was defined by assigning a weight $w_{i}$ to each binary attribute $f_{i}$ (e.g., Jurafsky \& Martin, 2009). The conditioning information was the array, which determines the set of alternative sufficient descriptions. Weights were tied across array types and fit by maximum likelihood to the array-specific description frequencies. The resulting weights were as follows: horiz (-1.14), vert ( -0.43 ), prox (-2.73), cont (-2.3), v.o. (-2.57), h.o. (-5.78), ord (3.06), shape (1.0) and color ( -0.68 ), where a higher weight indicates a greater preference for the attribute. Note that the model assumes independence of attributes, an idealization that we show to be largely effective but which is not inherent to the maximum entropy formalism.

## Modeling adaptation

Prior to experience with the listener, participants in the Partial condition should have the baseline attribute weights. After failed instances of communication with left/right, the weights could in principle be modified in various ways (e.g., by large changes after single errors, or much more gradually over the course of the entire experiment). Given the rapid adaptation found in the experiment, and in order to restrict the number of free parameters, we implemented adaptation as a single array- and speaker- independent decrease in the weight of horiz subsequent to the first listener error.

The error-driven penalty against horiz was fit by maximum likelihood to the Partial data, with the weights of all other attributes fixed at their baseline values. The best-fitting penalty $(\approx-0.70)$ was sufficient to make alternative spatial expressions more probable than left/right in the Horiz+Other arrays. However, left/right remained the most probable expression for Horiz arrays. Because the penalty was uniform across all array types, this and other asymmetries must reflect the relative frequencies of alternative spatial expressions in the baseline data. In this sense, the model derives the nuanced pattern of audience design in the Partial condition from independently-established usage patterns and a minimal assumption about the mechanism of adaptation (see Fig 2).

## Detailed results

We examined the predictions of the model in more detail for the four subtypes of Horiz+Other arrays. Using the weights and horiz penalty above, we generated predicted frequencies of the sufficient descriptions for each subtype by sampling responses for 24 simulated participants.

Collapsed over shape and color, the predicted frequencies of the various spatial attributes were highly correlated with the actual frequencies across the subtypes ( $r=0.96$ ). In particular, for the Horiz+Other arrays offering containment, proximity and vertical orientation as alternatives to the horizontal relation, the experiment revealed that participants adapted by switching to these alternatives in the Partial condition, thereby increasing the frequencies of these features over the horizontal. However, in the arrays where horizontal orientation of the target was available as an alternative, participants continued to use left/right for identifying the target. Table 1 shows that the model captured this difference and other variations in attribute frequency.

Table 1: Proportion of responses containing each relevant spatial attribute (in bold) produced by participants in the Partial knowledge condition, and predicted by the adapted model (in parentheses), for the Horiz+Other array subtypes.

| Proximity |  | containment |  |
| :--- | ---: | :--- | :--- |
| horiz | $.48 \pm .08(.53)$ | horiz | $.44 \pm .08(.39)$ |
| ord | $.20 \pm .08(.21)$ | ord | $.13 \pm .06(.16)$ |
| prox | $.21 \pm .06(.20)$ | cont | $.26 \pm .06(.34)$ |
| vertical orientation |  | horizontal orientation |  |
| horiz | $.33 \pm .09(.45)$ | horiz | $.73 \pm .08(.69)$ |
| ord | $.17 \pm .07(.19)$ | ord | $.23 \pm .08(.25)$ |
| v.o. | $.36 \pm .09(.28)$ | h.o. | .00 |

## Model limitations

While highly successful relative to our original goals, the model contains a number of simplifications that could be addressed in future iterations. The attribute weights and horiz penalty were assumed to be identical for all participants (and trials), but there may be substantial individual (or even triallevel) variation in preferences for referential descriptions. The assumption of independent attribute weights was for the most part viable, but some form of interaction is required to account for frequent vert+horiz collocations (e.g., top right). Our focus was on spatial expressions, but use of shape and color terms would also be of interest, especially when these are used redundantly. The assumption that the inhibition of horiz applies after the first communication error, rather than coming into effect more gradually, was also an idealization.

Finally, no attempt was made to predict the baseline preferences for spatial terms or attributes (e.g., the strong preference for left/right over first/last in the Full knowledge condition). This raises the more general question of what cognitive representations and processes lead speakers to select particular utterances from a set of sufficient referential
descriptions, only some aspects of which are due to audience design.

## General discussion

In this paper, we experimentally tested whether speakers adapt their language to listeners with a lexical-semantic gap. Such situations may arise commonly, both when experts talk to novices and when adult speakers of a language address second language learners or children. Inspired by previous work with children, we focused on the case in which the listener commands all spatial terms other than left/right.

We found that participants were able to rapidly identify the listener's lexical gap, and to avoid it in cases where other alternatives were readily available. Specifically, when the target object could be identified with another spatial relation, participants mostly switched to using that relation. However, adaptation occurred to a lesser extent when the target could only be identified by its horizontal relation. This pattern of results suggests that spatial language elicited in the experiment was shaped by audience design, but that other factors prevented complete adaptation to the listener.

We formalized those factors with a computational model that assigns probabilities to sufficient descriptions with independent attribute weights. The weights were fit to utterances from the Full knowledge condition, supplemented by data in which participants provided multiple descriptions of each array. This model may reflect the endpoint of iterative pragmatic reasoning, as in the RSA framework (Frank \& Goodman, 2012), but is closer in practice to the approach of Monroe \& Potts (2015), who remedy limitations of that framework by setting attribute weights empirically. Adaptation was then modeled in a simple form, as an errordriven inhibition of left/right that applied uniformly to all array types (and participants). Despite its simplicity, the model correctly predicted the different types and degrees of adaptation observed across arrays in the experiment.

While some previous models have addressed adaptation from bottom-up information about the listener (e.g., Janarthanam et al., 2010), none have considered gaps in basic lexical knowledge. Indeed, much work in theoretical and computational pragmatics assumes a generic addressee with the same lexical semantics as the speaker. The model developed here could be applied to other cases in which listeners have idiosyncratic gaps in technical or non-technical vocabulary. Adaptation to the lexical knowledge of the listener is an important aspect of cooperative communication.

# Children's use of lexical flexibility to structure new noun categories 

Mahesh Srinivasan (srinivasan@berkeley.edu) \& Catherine Berner (catherineberner@berkeley.edu)<br>Department of Psychology, University of California, Berkeley<br>Berkeley, CA 94704 USA<br>Hugh Rabagliati (hugh.rabagliati@ed.ac.uk)<br>Department of Psychology, The University of Edinburgh<br>Edinburgh, EH8 9JZ UK

#### Abstract

Because most common words have multiple meanings, children are often learning new senses of existing words, rather than entirely new words. Here, we explore whether children can use their knowledge of an existing word sense to constrain their interpretation of a new word meaning. Across two studies, we teach 3- and 4 -year-olds and adults novel words for materials, and manipulate whether those words are also used flexibly, to label objects made from those materials. We find that participants of all ages assign markedly different interpretations to the object labels when they have a prior, material meaning: Rather than extending them to other objects of similar shapes, they extend them on the basis of shared material, thus overriding the well-documented shape bias. These findings suggest that language learners can use a word's prior meaning to learn about the structure of its new meaning.

Keywords: polysemy; lexical flexibility; word extension; word learning; shape bias

## Introduction

A great deal of evidence in language development suggests that children constrain their guesses about the referents and extensions of new words through a variety of heuristics and biases (Clark, 1990; Markman, 1990). For instance, if children are told that a novel object is called a dax, they typically infer that dax will also refer to objects that are similarly shaped (Landau, Smith \& Jones, 1988). This socalled shape bias arises early in acquisition, and is thought to play an important role in lexical development.

Of course, the shape bias is not sufficient for acquiring adult-like meanings for words, since the extension of many words meanings goes beyond shape. A single word can often apply to multiple items that vary in shape, but that share an underlying essence (e.g., natural kind terms like bird; e.g., Gelman \& Markman, 1986), intended function (artifact terms like chair; e.g., Bloom, 1996), or substance (e.g., for mass nouns like bread). Consistent with this, in order to develop adult-like meanings for words, children are thought to draw on a variety of different cues - such as animacy, background knowledge, or functional affordances - to override the shape bias, and structure their new word meanings (Booth \& Waxman, 2002; Jones \& Smith, 1988; Kemler Nelson, 1995).

While previous studies have investigated how children learn the meanings of entirely new words, they have yet to address the fact that many of the new word meanings that
children have to acquire are not associated with novel word forms, but instead with word forms they are already familiar with. This is because most words are not unambiguous, but are instead flexible: Most common words are polysemous and denote a variety of different senses of meaning (Nerlich, Todd, Herman \& Clarke, 2003). The word glass, for instance, refers to both a transparent material and a drinking vessel made from that material. This phenomenon, which we refer to as lexical flexibility, is common both within languages and across languages. Further, lexical flexibility follows systematic patterns in English and in other languages: Multiple English words, for example, can label materials and objects made from those materials (glass, tin, etc.), animals and their meat (chicken, lamb, etc.), tools and functional uses of those tools (hammer, saw, etc.), and more (see Srinivasan \& Rabagliati, 2015).

In the present studies, we investigate how children's biases about word meanings interact with lexical flexibility: How does a word's first-acquired meaning influence children's guesses about the extension of new, additional senses of the word? In particular, are additional word senses learned in isolation, or does a word's first meaning bias the application of constraints like the shape bias?

Consistent with the idea that the extension of new word senses is constrained by knowledge of other word senses, many historically-derived senses of words appear to be partially influenced by their historically-primary sense. This can be observed with the word glass, whose extended drinking vessel sense is defined by a combination of shape, function and material (and whose meaning thus differs from words like cup, which are defined by shape and function alone). Lending support to the idea that children's interpretation of new word senses could be constrained by their understanding of existing, already-learned senses, a recent body of work in language development indicates that even preschool-aged children understand the semantic relations that license lexical flexibility in their language. For example, children expect words to label animals and their meat, but not other thematically-related items (Srinivasan \& Snedeker, 2014), and generalize patterns of lexical flexibility to new words (e.g., such that they expect new words to label tools and their functional uses; Srinivasan, Al-Mughairy, Foushee \& Barner, 2017).

Given these facts, it seems plausible that if children know one sense of a word, then they might use that knowledge to constrain their guesses about how that word should be
extended. This could cause them to override the shape bias in some cases, and extend new word senses according to other criteria. Some preliminary evidence for this idea comes from a study by Yoshida and Smith (2003), who showed that the shape bias was increased if a novel object was labeled with a familiar name that was strongly associated with a characteristic shape (e.g., ball), compared to a familiar name that was associated with a substance. However, subjects in this previous study were learning novel exemplars for existing words - as opposed to novel senses of existing words - thus leaving open the role of lexical flexibility in structuring new semantic categories.

In the present studies, children and adults were first taught a novel name for a material. They were then presented a novel object made from the same material, and either learned that the object name was the same as the material name (both were called gup) or was labeled using a new, distinct word (the material was called zev and the object called $g u p$ ). Our studies tested whether this manipulation of lexical flexibility affected participants' guesses about the extension of the object name - e.g., by making them more likely to privilege shared material as basis for extension in the flexibility conditions - using a forced-choice task (Study $1)$ and a more open-ended sorting task (Study 2).

## Experiment 1

Adults and 3- and 4 -year-olds participated one of three conditions: In the flexibility condition, the novel material and novel object were given the same label, and in the unambiguous condition they were given different labels. A final material $v s$. object condition tested whether participants learn distinct material and object senses of a flexible word, or instead a single vague meaning encompassing both objects and materials.

## Methods

## Participants

This study included 100 3- and 4-year-olds from the Berkeley area (Range: 3;0-4;11; Mean age $=4 ; 0$ ), split roughly evenly among the three conditions. 48 adults were also recruited from the UC Berkeley campus community, with 16 participating in each condition. English was the primary language spoken by all participants. Children were tested in lab, and at local preschools and museums; Adults were tested in lab or at designated locations on the UC campus. Children were given a small gift for participating, and adults were given either course credit or a small gift. 16 additional children participated but were excluded for failing catch trials administered at the end of the task (described below; $n=12$ ), parental interference ( $n=3$ ), or experimenter error $(\mathrm{n}=1)$. Three adults were also excluded due to experimenter error. All participants were tested individually by a female experimenter.

Warm-up trials Participants completed three warm-up trials to ensure that they understood the task. The stimuli consisted of three sets of toy animals: two identical animals
and one contrasting animal (e.g. two bears and a horse). In each warm-up trial, the experimenter placed one of the duplicate animals on the table, and named it (e.g. "Here is a bear!"), and then placed the remaining two animals and asked the participant to point to the other matching animal (e.g. "I want another bear. Can you point to a bear?").

Test Trials Participants completed four test trials. The trials varied depending on which of the three conditions the participant was in.

The stimuli consisted of four sets of novel objects. Each set included (1) a jar of small pieces of a novel material and a wooden spoon, (2) a standard object made out of the novel material, (3) a material-match test object that was made out the novel material, but was of a different shape than the standard, and (4) a shape-match test object that was the same shape as the standard, but was made out of a different material.

## Material

This stuff is called
"gup" [flexibility] / "zev" [unambiguous]

Standard Object
This thing is called "a gup."

Figure 1: Example test trial from the polysemy and unambiguous conditions of Experiment 1. The novel material and standard object were given the same word in the polysemy condition and different novel words in the unambiguous condition.

In each test trial (Fig. 1), the experimenter brought out a jar of novel material and a wooden spoon. The experimenter labeled the material with a novel word, using mass syntax (e.g. "This stuff is called gup. This stuff is called gup. I have half a jar of gup here.") and then stirred the material with the spoon and scooped some of it out of the jar to emphasize that it was a material. The name given to the material varied depending on the condition: The material was labeled with the same novel word (e.g. gup) that was later used to label the standard object in the flexibility condition, and was given a different name (e.g. zev) in the uanmbiguous condition (Fig. 1).

Next, the experimenter brought out the standard object and named it (e.g. "Now look at this thing! This thing is called a gup."), and illustrated that it was an object by using count syntax and attributing a vague function to it ("I have two gups and I use them in my garage."). Then, the experimenter brought out the two test objects - the material-
match object and the shape-match object (in the flexibility and unambiguous conditions) - and asked the participant to extend the label for the standard object to one of the two test objects, using count noun syntax ("I want another gup. Can you point to a gup?"; Fig. 1). We expected that if participants use a prior sense of the word to constrain their interpretation of a new word sense, they should be more likely to override a shape bias-which typically arises when a count noun labels a rigid object (Landau et al., 1988)-and choose the material-match object in the flexibility condition.

The material vs. object condition was conducted to test whether participants who learned that the material and object were given the same word (e.g., when both were labeled $g u p$ ) in fact learned two distinct senses of the word (as opposed to a single word that can label both materials and objects). To test this, at test participants were asked to choose between the material-match object and a pile of the material. We reasoned that if subjects had learned a novel object sense of the critical word, they would choose the material-match more often than the pile of material, since the request at test employed count syntax (Can you point to a gup?), and thus a request for an individual.

Catch trials Finally, participants completed three catch trials at the end of the task to ensure that they had sustained their attention throughout the study. In these trials, the experimenter labeled a novel object with a novel word, and then asked participants to point to which of two subsequent objects could be labeled by the word. One of the choice objects was identical, and the other differed in shape and material. Participants who failed to correctly respond on at least two out of the three catch trials were excluded.

## Results

Our results are consistent with the idea that the meaning of one word sense guides children's guesses about subsequent senses. As indicated in Figure 2, children in the flexibility condition extended the name of the standard object to the material-match object ( $70 \%$ of trials; $S E=4 \%$ ), and were more likely to do so than children in the unambiguous condition ( $27 \%$ of trials; $S E=4 \%$ ), as revealed by a linear model ( $\beta=-1.86, S E=0.27, z=-6.79, p<.001$ ). Thus, while children in the unambiguous condition exhibited the robust shape bias documented in prior work (Landau, Smith, \& Jones, 1988), children in the flexibility condition overcame this bias and extended the new word sense according to material, rather than shape. ${ }^{1}$ This tendency to select the material-match object could not be explained by a failure to learn distinct senses of the flexible word (i.e., to learn both a material and object sense of the word), as children in the material vs. object control condition reliably selected the material-match object over the pile of material on $83 \%$ of trials ( $S E=3 \%$ ) of the time. This suggests that

[^506]children understood that the experimenter was requesting an object using the object sense of the novel word at test, as opposed to simply re-using the material word they had first been trained on.

Figure 2: Percentage of trials in Experiment 1 in which children chose the material-match object across conditions. Error bars show +/- 1 SE. Dashed line shows $50 \%$ mark.

Figure 3: Percentage of trials that adults chose the material-match object across the conditions of Experiment 1. Error bars show $+/-1$ SE. Dashed line shows $50 \%$ mark.

Adults (Fig. 3) showed a similar pattern of word extension choices to children in the flexibility condition, and extended the name of the standard object to the material-match object on $89 \%$ of trials ( $S E=4 \%$ ), significantly more than they did in the unambiguous condition ( $2 \%$ of trials, $S E=2 \% ; \beta=-6.24, S E=1.08, z=$ $-5.76, p<.001$ ). Unexpectedly, however, adults did not show the same pattern of choices as children in the material vs. object condition, and only chose the material-match object on $56 \%$ of trials ( $S E=6 \%$ ). This surprising result leaves open whether adults differentiated between the two senses of the word as clearly as children.

## Discussion

Experiment 1 showed that lexical flexibility allows children to override semantic heuristics like the shape bias: When a label for an object had previously also been used to label a material, then children's guesses about the further extension
of that object label were less reliant on shape, compared to a condition in which different labels were given to the object and material. Importantly, the additional material versus object control condition provided evidence that children did not simply conflate the "object" and "material" senses of this novel word into a single vague meaning: When asked to choose "a gup" from an object and a pile of material, children consistently chose the object. Thus suggests that children understood that while one sense of the word gup referred to a kind of material, another sense of the word (identified with count syntax) referred to an object. Surprisingly, adults behaved a chance in this condition, and we return to this result in the General Discussion.

What, then, is the status of the shape bias when children learn an additional sense under these conditions? In particular, did the participants believe that shape was entirely irrelevant to the meaning of the second sense, or did they simply privilege material when they were forced to choose between an item that matched in material (but not shape) and an item that matched in shape (but not material)? One possibility left open by the results of Experiment 1 is whether children in the flexibility condition might have chosen to extend the novel label for the object only to other items that matched in both material and shape, had they not been forced to choose between a material match and shape match (a limitation of the 2-alternative-forced-choice task used in Experiment 1).

## Experiment 2

Here, we employed a more open-ended task, giving participants more choice in how they determined the extension of the newly-learned words. 4-year-olds and adults were taught a label for a novel material and a label for a novel standard object, just as in the flexibility and unambiguous conditions of Experiment 1. Then, participants were shown an array of new objects that varied in shape, material, and size from the standard object, and were asked to classify which of these additional objects could be labeled by the same word as the word for the standard object (Fig. 4). As in Experiment 1, we varied whether the newlylearned object and newly-learned material shared a label. Using this method, we were interested in whether participants in the flexibility condition would restrict word extension to only items of the same shape and material as the standard.

## Methods

## Participants

Participants were recruited from the Berkeley area as described in Experiment 1. Experiment 2 included 32 4-year-olds (Range: 4;0-4;11; Mean age $=4 ; 6$ ), divided evenly between the flexibility and unambiguous conditions. 33 adults also participated (17 in the flexibility condition; 16 in the unambiguous condition). English was the primary language spoken by all participants. Three additional children participated, but were excluded for failing the
initial warm-up trials ( $\mathrm{n}=2$ ), or due to parental interference ( $\mathrm{n}=1$ ). All participants were tested individually by a female experimenter either at a children's museum or at designated locations on the UC Berkeley campus.

## Materials and procedure

Warm-up trials Participants completed three warm-up trials. Participants who failed on two or more of these trials were excluded. The stimuli consisted of three sets of toy animals. Each set included three animals from a single category and two animals from contrasting categories (e.g. three horses, a cat, and a fish). In each trial, the experimenter brought out a toy animal and told the participant what is was (e.g. "Here is a horse!"). The experimenter then put the animal into a plastic box and told the participant that the box was for the target animals (e.g. horses). The experimenter then placed the animal on the table with the other four animals and asked the participant to sort all of the animals (e.g. horses) into the box and all the animals that were not in that category, into a plastic bowl.

## Material

This stuff is called "kiv" [flexibility] /
"lof" [unambiguous]

## Standard Object

This thing is
called "a kiv"

## Sorting Test

Can you put all of the "kivs" into this box and all of the other things into this bowl?

Figure 4: An example test trial from Experiment 2. Participants sorted five objects as belonging to the target category or not. The novel material and standard object either received the same label (flexibility condition) or different labels (unambiguous condition).

Test Trials In each of the four test trials (Fig. 4), participants were first introduced to a novel material (but instead of pieces of a solid material, novel non-solid materials were used). As before, participants were then shown a standard object that was made out of the same novel material. Then, participants were asked to sort a set of five objects (four test objects plus the standard object itself) as either belonging to the target category or not. The four test objects varied in whether they matched the standard object in material and shape. In total, participants were asked to sort: (1) a +Material/-Shape Object that was made
out the same material, but was a different shape than the standard, (2) a -Material/+Shape Object that was the same shape as the standard, but was made out of a different material, (3) a +Material/+Shape object that shared the same material and shape as the standard, but was smaller, (4) a -Material/-Shape object that contrasted with the standard in both shape and material, and finally (5) the Standard Object itself.

In each test trial, the experimenter took out a jar of novel material. The experimenter told the participant the material's name (e.g. "This stuff is called kiv.") and then stirred the material with the spoon and then scooped and/or stretched the material, and took some material out of the jar (This was to underscore fact that the novel material was indeed a material). The name of the material varied depending on the condition, as before: In the flexibility condition, the material was labeled with the same novel word that was later used to label the standard object, and in the unambiguous condition was given a different name.

Next, the experimenter brought out the standard object and named it, using count syntax (e.g. "This thing is called a kiv."). The experimenter then brought out the four test objects and said "Some of these are kivs and some are not kivs." and then asked the participant "Can you put all of the kivs into this box and all of the other things into this bowl?"

## Results

The results from the more open-ended task of Experiment 2 paralleled those of Experiment 1. In particular, participants were more likely to privilege material in their extensions in the flexibility than in the unambiguous condition. Consistent with this, children in the flexibility condition were more likely to sort the + Material/-Shape object $(61 \%, S E=6 \%)$ as a member of the target category than children in the unambiguous condition ( $14 \%, S E=4 \% ; \beta=-2.25, S E=$ $0.44, z=-5.11, p<.001)$. In contrast, children in the unambiguous condition were more likely to show a shape bias, and sort the - Material/+Shape object $(88 \%, S E=4 \%)$ as a member of the target category than children in the flexibility condition $(38 \%, S E=6 \% ; \beta=2.46, S E=0.46, z$ $=5.37, p<.001)$. Meanwhile, children in both the flexibility and unambiguous conditions almost always sorted the Standard Object (Flexibility: 98\%, $S E=2 \%$; Unambiguous: $100 \%$ ) and +Material/+Shape Object (Flexibility: 98\%, $S E=$ $2 \%$; Unambiguous: $100 \%$ ) as members of the target category, and almost never sorted the -Material/-Shape Object as a category member (Flexibility: $2 \%, S E=2 \%$; Unambiguous: 0\%).

To examine whether individual children were internally consistent in their sorting, we coded the data in terms of their categorization strategies. Strategies were defined using a $75 \%$ cut-off: Participants who used the same strategy for 3 or 4 of the test trials were classified as having that categorization strategy, but were otherwise coded as other. As indicated in Figure 5, children in the flexibility condition more often sorted objects using a material-based strategy (i.e., sorting all three of the objects that matched in
material as being part of the target category), than children in the unambiguous condition. In contrast, a shape-based strategy (i.e., sorting all three of the objects that matched in shape as part of the target category) was more prevalent in the unambiguous condition.

Figure 5: Categorization strategies of children in the flexibility condition (left) and unambiguous condition (right).

Adults showed a similar pattern of choices to children. Participants in the flexibility condition were more likely to sort the + Material/-Shape object $(74 \%, S E=5 \%)$, as a member of the target category than adults in the unambiguous condition $(5 \%, S E=3 \% ; \beta=-4.03, S E=$ $0.65, z=-6.19, p<.001)$. In contrast, adults in the unambiguous condition were more likely to show a shape bias, and sort the -Material/+Shape object $(81 \%, S E=5 \%)$ as a member of the target category than adults in the flexibility condition ( $19 \%, S E=5 \% ; \beta=2.91, S E=0.44, z$ $=6.54, p<.001$ ). No adults in either condition sorted the -Material/-Shape as a member of the target category, and all but one participant sorted the Standard object and +Material/+Shape object as a member of the target category.

Figure 6: Categorization strategies of adults in the flexibility condition (left) and unambiguous condition (right).

Finally, similar to the children, most adult participants in the flexibility condition sorted objects using a materialbased strategy, while most in the unambiguous condition used a shape-based strategy. Only three adults (1 in the flexibility condition, 2 in the unambiguous condition) employed a material- and shape-based strategy, constraining the target category to only the standard object and the + Material $/+$ Shape object. Note that this third, more conservative strategy was never used by children.

## Discussion

While Experiment 1 showed how lexical flexibility can reduce reliance on the shape bias, Experiment 2 explored the nature of that reduction. We found that, in the presence of lexical flexibility, both children and adults tended to extend new meanings based on a single feature - material rather than through a combination of multiple features, such as shape and material (only 1 out of 16 adults in the flexibility condition used the shape \& material strategy), even though the task of Experiment 2 was open-ended enough to allow this strategy to emerge.

This reliance on material when extending the object labels in some ways conflicts with how flexible material words are used in languages. For instance, although the object senses of words like glass and tin are defined partially by material (a wooden box is not a "tin"), they label specific kinds of objects that are defined by shape and function (not all artifacts made of tin can be called "tins"). One reason that children and adults in the flexibility condition may not have used shape in their strategies is because we did not provide specific information about the functions of the standard objects; Such information could constrain hypotheses about the likely shapes - and functional affordances - of kind members (Kemler Nelson, 1995).

## General Discussion

How do children make inferences about the structure of new lexical categories? Guided by the fact that most common words are polysemous, our studies explored whether children's understanding of one meaning of a word would affect how they interpreted a subsequent meaning for that word. Two experiments demonstrated that, after children and adults learned that a substance name could also be used to label an object, they were less likely to extend that name according to shape, and instead privileged material.

These findings are consistent with a recent proposal (Srinivasan \& Rabagliati, 2015) that lexical flexibility plays an important functional role in language development, in facilitating the acquisition of the lexicon. By this account, it may be more difficult for children to learn an unambiguous lexicon in which each meaning has its own word, compared to one in which words label multiple meanings in predictable ways. Consistent with this idea, the present studies show that children's knowledge of an initial word sense can facilitate their learning of a second word sense.

Our findings also raise a host of interesting questions for future research. Some questions concern the precise meanings that children learned in our task. For instance, when children learned that gup could label both a material and an object, did they actually learn separate and conventionalized senses? Or did they simply realize that it was possible to "coerce" the meaning of gup from a material sense to a portioned object sense (cf. ordering two coffees, Frisson \& Frazier, 2005). Experiment 2 provides some evidence for the latter account, as children (and adults) were willing to extend the newly learned object name to any other object made of the material, regardless of its shape. This might also help make sense of why adults were at chance in
choosing between the material-match object and pile of material in Experiment 1: Adults may have thought that the flexible "object" label could apply to any individual made of the material, and may have been more flexible than children in construing a pile of material as an individual.

Although we have only explored our hypothesis in the context of materials and objects, our results hold implications for how lexical flexibility might shape conceptual development more broadly. While prior research has focused on how children use labels as 'invitations' to group items into common categories, our findings show that children understand that labels can pick out items from distinct, but related categories. In particular, by attending to lexical flexibility, children could use naming practices to draw inductive inferences about the structure of the world. For instance, just as hammers are used for hammering and shovels for shoveling children could reason that something called a dax that supports daxing is probably designed for that function, and that all daxes should support this function.

# Rationalizing subjective probability distortions 

Nisheeth Srivastava

IIT Kanpur

## Ed Vul

UCSD Psychology

#### Abstract

You cannot know the contents of a memory until after you have actually retrieved it. This paper considers the implications of this straightforward observation upon the psychological process of preference construction. We show that this constraint renders observers with random access memory susceptible to tail risks. We show that this difficulty can be rectified by permitting observers to weight memory retrieval for such observations, that outcome utility cannot be used for this purpose, but information-theoretic surprise can serve as a useful proxy for it. Using two novel experiments, we present evidence in support of our account. With the first, we show that humans find surprising experiences easier to remember. With the second, we show that surprising experiences in the past have a greater influence on future decisions than is statistically warranted. This twofold demonstration substantiates a psychologically plausible account for the origin of subjective probability distortions.

# Memory of relative magnitude judgments informs absolute identification 

Nisheeth Srivastava

IIT Kanpur

#### Abstract

The question of whether people store absolute magnitude information or relative local comparisons of magnitudes has remained unanswered despite persistent efforts over the last three decades to resolve it. Absolute identification is one of the most rigorous experimental benchmarks for evaluating theories of magnitude representation. We characterize difficulties with both absolute and relative accounts of magnitude representation and propose an alternative account that potentially resolves these difficulties. We postulate that people store neither long-term internal referents for stimuli, not binary comparisons of size between successive stimuli. Rather, they obtain probabilistic judgments of size differences between successive stimuli and encode these for future use, within the course of identification trials. We set up a Bayesian ideal observer model for the identification task using this representation of magnitude and propose a memory-sampling based approximation for solving it. Simulations suggest that the model adequately captures human behavior patterns in absolute identification.

# Exploration and Skill Acquisition in a Major Online Game

#### Abstract

Using data from a major commercial online game, Destiny, we track the development of player skill across time. From over 20,000 player record we identify 3475 players who have played on 50 or more days. Our focus is on how variability in elements of play affect subsequent skill development. After validating the persistent influence of differences in initial performance between players, we test how practice spacing, social play, play mode variability and a direct measure of game-world exploration affect learning rate. These latter two factors do not affect learning rate. Players who space their practice more learn faster, in line with our expectations, whereas players who coordinate more with other players learn slower, which contradicts our initial hypothesis. We conclude that not all forms of practice variety expedite skill acquisition. Online game telemetry is a rich domain for exploring theories of optimal skill acquisition.

Keywords: learning; games; skill acquisition; expertise; game analytics

## Introduction

Computer games afford a rich data set for the investigation of skill acquisition. Players invest tens, hundreds or even thousands of hours on individual games, and unlike offline domains of expertise - details of every action during practice can be unobtrusively recorded. The present analysis uses data from the online shooter video game Destiny, which has over 30 million active users as of 2016 (Nunneley, 2016). Using data on players' performance we trace their skill acquisition over time and relate it to their practice habits. Specifically we are interested in how variability in practice relates to learning.

The power law of learning is justly well-known in cognitive science (A. Newell \& Rosenbloom, 1981; Ritter \& Schooler, 2001), both for being a dependable regularity in skill acquisition data (Rosenbaum et al., 2001) and for expressing a truth we know from personal experience: when we first begin learning something new progress is often rapid, but later it slows or stalls. Nonetheless the presentation of Power Law learning curves based on averages masks the variability that occurs both within and between individuals (Gallistel et al., 2004; Gray \& Lindstedt, 2016). This is important for two reasons. Firstly because individual variability is interesting as an outcome. We wish to know why some individuals learn more rapidly, and achieve greater eventual levels of performance (and why some individuals are hindered in
their learning). Secondly, variability is interesting as a driver of learning. Previously it has been suggested that greater initial variability in practice may drive higher subsequent performance (Stafford et al., 2012; Stafford \& Dewar, 2014), a result which accords with computational accounts of how learning must balance exploration and exploitation of options (Sutton \& Barto, 1998; Humphries et al., 2012).

In addition to looking at how a skill is practised, there are also results which suggest an effect on skill acquisition of when a skill is practised - the issue of practice spacing (Stafford \& Haasnoot, 2017; Delaney et al., 2010; Cepeda et al., 2008) - as well as an effect of variability in how different components are practised (Magill \& Hall, 1990). From this perspective, variability is as much an engine of learning as consistency (Schmidt, 1975; Van Rossum, 1990; K. M. Newell \& McDonald, 1992; Ranganathan \& Newell, 2010). This raises the question of exactly which kinds of variability, and in what quantities, support optimal skill acquisition.

Previous work has looked at skill learning in a simple online game (Stafford \& Dewar, 2014; Stafford \& Haasnoot, 2017), with the emphasis that even a simple online game contains many fundamental cognitive processes perceptual, decision making and action implementation. Others have looked at skill development in more complex games (Thompson et al., 2017, 2013), and here we use the opportunity to analyse data from one such game, Destiny, to explore issues of how playing style, and particularly variability within play, affects skill development.

Destiny is a science-fiction themed, massively multiplayer, online game where players need to defend the Earth from various alien threats, taking on the role of Guardians. Players journey to different planets, complete missions, daily events, and perform a variety of different tasks to build up their characters. Destiny is a hybrid digital game that blends features from a number of traditional game genres including role-playing games and massively multi-player online games but which is first and foremost a shooter (Tammasia et al., 2016). The main components of the gameplay is focused on tactical single-player or small-team combat against players or artificial agents (Drachen et al., 2016).

Thousands of behavioural or performance-based metrics are tracked and stored by Bungie, the developer of Destiny, which in aggregate provides a detailed record of the behavioural history of Destiny players.

The metrics that can be calculated based on such datasets varies, and previous research in game analytics and other domains have seen such behavioural data being used for a variety of purposes (Tammasia et al., 2016; Rattinger et al., 2016; Drachen et al., 2016). For Destiny, a number of these metrics are of key interest in relation to evaluation of player skill and skill evolution.

- Playtime: Playtime in the current context simply refers to the amount of time a player spends playing the game per day, across either a single or all characters.
- Kills, Assists, Deaths: the shooter-heavy gameplay of Destiny means that traditional skill indicators from shooter games such as Kill/Death Ratio (KDR) form an important means for evaluating player skill.
For Destiny, a variant of KDR, the Kill-Assists/Death Ratio (KADR) is also used. An assist is a common term in esports signifying that a player helped another player take down a specific enemy (or in other ways help another player), without scoring the killing shot/hit on that enemy.
KADR is thus a more nuanced aggregate measure of performance than KDR. We use KADR-KDR as a measure of a players' propensity for 'social play'.
- Combat Rating: The Combat Rating (CR) is a game metric designed to reflect a players' overall skill. How CR is based on the TrueSkill system (Herbrich \& Graepel, 2006), a Bayesian model used for player/team ranking. TrueSkill and CR both serve a similar functionality to ELO (Charness, 2005). While the algorithm is confidential, it broadly works by initialising a player at CR 100. If the player is part of a team that wins a match, their CR goes up, more if there is a large difference in the CR between the two teams. Conversely, if they lose, the CR goes down, again in relation to the gap in CR between the two teams. CR is used by the Destiny matchmaking system to configure players into teams and balancing opponents. This means that players will be playing with and against players with similar CR (i.e. they are matched against players of simialr skill-levels).
- Grimoire Score: A Grimoire in Destiny is a record of a players experience - new cards are awarded the first time a specific action is taken or challenge overcome. In essence, the Grimoire score is an expression of the degree to which a player has explored the world and content of Destiny.

Working with very large datasets introduces some new opportunities for the cognitive scientist (Goldstone \&

Lupyan, 2016; Stafford \& Haasnoot, 2017). Observational studies, however large, necessarily have reduced power of causal inference compared to experimental studies. Large numbers mean that the data can be 'sliced' to explore if and how potential effects play out throughout the population, as well as allowing matching of individuals on various properties which might confound any effect. With enough data any observable difference can be 'statistically significant'. In experimental studies effort is expended in achieving enough power to make convincing inferences. With large data set it is more important to invest effort in exploring possible confounds and putting observable differences in the context of other effects via calculation of effect sizes.

Our hypothesis is that early variability will be associated with faster skill acquisition. This assumes that players have a tendency to under-explore the space of possible actions, and so, due to this reliance on habit, will be learning sub-optimally. We will test this hypothesis against different indices of variability in early practice: spacing of play, social play, world knowledge (grimoire score), and distribution of play across game modes (event entropy). These metrics are defined further below.

## Data and method

Our data comprise low level daily metrics indicating performance and meta information for over 20,000 randomly selected Destiny players. The behavioral telemetry was provided by Bungie.

For each player the data consists of a unique player ID and character IDs for each character the player has. A player is allowed to have at most three characters per account. For each character, the dataset contains daily aggregate player behavior such as number of deaths, completed objectives, weapon usage and average life span, and importantly playtime, each across the six game modes - or ways to play the game.

Our analytic strategy is first to split the data into a development (8682 players) and validation set (12861 players). All exploratory analysis was finalised on the development set, before being run on the validation set to produce the figures presented here. All conclusions presented are unaffected by the minor differences between the development and validation set results. This affords us some protection against discovering false patterns in our data that result from researcher degrees of freedom in analysis. It is inappropriate to make inferences from hypothesis testing p-values for an exploratory analysis such as this, but we report them for completeness where we have done standard analyses. Our main focus is on measures of effect size and confidence estimates around those measures.

Analysis scripts, player summary data, and full reports of both development and validation set results are available at https://osf.io/c59n9/. For commercial con-
fidentiality reasons the full raw dataset is not available at the point of writing.

## Analysis

First, we seek to confirm that players improve with practice. Following the method of (Stafford \& Dewar, 2014), we first select only players who play some minimum number of games (50). This produces a data set of 3475 longer term players (in the validation set; 1984 in the development set) and then divide by ranking all players according to the average of their three all time best ratings (in terms of CR). Figure 1 shows the average score per game for those who scored in the top third, middle third and lowest third of the high score table. This shows that the learning curve exists for averaged data, and that - in line with (Stafford \& Dewar, 2014) - players who end up with the highest scores begin the game with performance already above that of lower scorers (compare (Stafford \& Dewar, 2014) Figure 2).

Figure 1: Average performance rating as a function of game number and ranking based on players' highest three ratings. Error bars show +/- 1 standard error.

Note that our learning curves show performance, rather than speed, on the x -axis, and so are inverted relative to the classic 'Power Law of Learning'. None the less they reflect the expected decelerating function of learning with practice amount. Our investigation of other factors must take account this fundamental pattern in how player performance changes over time, as well as the stratification that we observe between players of differing initial performance. To do this, we fit a linear regression for each player's performance against game number. Because this regression produces a slope and an intercept, we are able to subsequently analyse player differences in both level of initial performance and subsequent change in performance (i.e. rate of learning). Henceforth when we refer to "learning rate" we mean the slope of this regression for each player. In order to explore which variables might be related to player learning rate we first visualise players split on some candidate variables against mean combatRating against prac-
tice amount (game number).

## Variation in practice timing - spacing

In order to compare practice timing, we calculate the time range over which players recorded their first 25 days of play (obviously this has a minimum of 25 days, and no theoretical maximum). This range correlates positively (Pearson's $\mathrm{r}=0.18,99 \%$ confidence interval $0.14,0.22$ ) with learning rate and negatively (Pearson's $\mathrm{r}=-0.09$, $99 \%$ confidence interval $-0.14,-0.05$ ) with initial performance.

In order to visualise the effect of greater or less spacing, we select players in the top quartile for spacing their first 25 games ('spacers') and those in the bottom quartile for spacing their first 25 games ('groupers') and plot the average performance against game for the two groups. This is shown in Figure 2.

Figure 2: Average score as a function of game number and high and low spacers. Error bars show +/- 1 standard error.

## Variation in practice type

Playing style - social play For each player we have a game by game measure of their 'assists', which are kills made by teammates which they are near to. Variation on this measure allows us to rate players according to a propensity for social play, i.e. a higher rate of assists will reflect a player who coordinates their actions with their team.

This measure correlates negatively (Pearson's $\mathrm{r}=$ $-0.16,99 \%$ confidence interval $-0.20,-0.12$ ) with learning rate and positively (Pearson's $\mathrm{r}=0.50,99 \%$ confidence interval $-0.47,0.54$ ) with initial performance.

Figure 3 shows the learning curve for players split on the average of their assists over their first 25 games, as an index of players' propensity for "social play". Those in the top quartile of the distribution of assists we term 'social players'. Those in the bottom quartile we term 'lone wolves'.

Figure 3: Social play and skill acquisition. Error bars show +/- 1 standard error.

World knowledge - Grimoire score For each player we are able to see the complete history of their Destiny playing, including how many games they play in total. Each player also has a 'grimoire' score, which is a count of the items they have encountered in the world. Obviously this is higher for players who have played more games, but there is considerable between-player variability, suggesting that some players focus on exploring the world, completing actions and collecting items, whereas others aren't focused on this aspect of the game. In order to compare grimoire scores between players who have complete different numbers of games, we calculate a normalised $(Z)$ score for each player based on the distribution of grimoire scores among players who have completed the same number of games.

This measure does not correlate with learning rate (Pearson's $\mathrm{r}=0.04,99 \%$ confidence interval $0.00,0.09$ ) and correlates positively, but weakly (Pearson's $\mathrm{r}=0.13$, $99 \%$ confidence interval $0.10,0.18$ ) with initial performance.

Figure 4 shows the average score, in terms of CR, against game for players whose grimoire Z scores are in the top and bottom quartiles of the distribution.

Playing style - mode entropy The play modes in Destiny are:

- Strikes: 3 player cooperative events.
- Raid: 6 player cooperative missions, requiring high level skills to complete.
- Story: the main single-player game mode, which can be played cooperatively by up to 3 players.
- Patrol: a single-player exploration mode.
- $P v P$ : all the player-vs-player ( PvP ) game modes of Destiny

Note that due to the aggregation into daily sets, it is possible for players to have played multiple sessions of Destiny within the same 24 hour cycle. Because Destiny

Figure 4: Average score by games for players with high and low grimoire count. Error bars show +/- 1 standard error.
has six different main game modes, it is of interest to evaluate how a player spends his or her time across those game modes. In order to quantify the measure of heterogeneity in terms of how a player splits their time between game modes, we use Shannon's entropy [see e.g. (Lessne, 2014; Algoet \& Cover, 1988)] which is defined as:

$$
\begin{equation*}
H=-\sum_{i} p_{i} \log _{2}\left(p_{i}\right) \tag{1}
\end{equation*}
$$

where $p_{i}$ denotes the probability of the player's activity across game modes $i$. For game mode $p_{i}$ is calculated as the amount of time spent in specific game mode $i$ divided by the total time spent playing all game modes that day.

Event entropy over the first 25 games for each player does not correlate with learning rate (Pearson's $\mathrm{r}=$ $-0.02,99 \%$ confidence interval $-0.06,0.03$ ) and correlates positively (Pearson's $r=0.22$, $99 \%$ confidence interval $0.17,0.26$ ) with initial performance.

Figure 5 shows performance against game for those in the top and bottom quartiles for event entropy calculated over the first 25 games.
Statistical model Hitherto, we have explored our data using visualisation of different groups and reported bivariate correlations. By entering all factors into a regression model we can check whether how all factors combine to explain variation in the learning rate. This is an essential complement to the visualisation. It allows us to confirm that patterns visible in the data are statistically significant. As well as the four measures described above - spacing, social play, grimoire score and event entropy - we include maximum numbers of games a player plays as a measure of overall motivation. The results of the regression of our five factors against the learning rate are shown in shown in Table 1.

Figure 5: Play mode entropy and skill acquisition. Error bars show +/- 1 standard error.

Table 1: Regression of player behaviours on player learning rate

| Factor | $B$ | $T$ | $p$ |
| :--- | :--- | :--- | :--- |
| Games played | 0.044 | 1.99 | 0.0465 |
| Spacing | 0.199 | 10.90 | 0.0001 |
| Assists | -0.172 | 10.04 | 0.0001 |
| Grimoire | 0.003 | 0.16 | 0.872 |
| Event entropy | 0.011 | 0.62 | 0.537 |
| $\mathrm{R}^{2}=0.063, F(5,3287)=44.47, p<0.0001$ |  |  |  |

Note that only spacing and assists, our measure of social play, are significant. Figure 6 shows the standardised regression coefficients (beta weights) when our five factors are used to predict learning rate (slope) and for the initial performance (intercept) of individual learning functions.

## Discussion

Using a complex online game we show that changes in player's performance can be tracked and related to aspects of how they play. We validate the separation of learning curves by initial performance shown by

Figure 6: Beta weights for players factors used to predict slope (learning rate) and intercept of individuals' learning functions. Standard error bars shown.)
(Stafford \& Dewar, 2014). As with that previous result, players who achieve the eventual highest levels of performance also perform better on their first game. Further, the difference between those with high and low initial performance only grows as more practice is completed.

Two other factors influence rate of learning - spacing, and social play. The effect of spacing matches that found in experimental studies of skill acquisition, as well as previous analysis of a different, simpler, game (Stafford \& Haasnoot, 2017). The differences between players who space their practice and those who don't is striking, such that the high-spacing players, on average, perform less well initially, but because they learn at a faster rate their average rating exceeds that of the low-spacing players by game 50 . The effect of social play was not predicted: those who play more socially, as measured by their assist rate, learn slower - perhaps because the demands of team coordination distract from skill honing. Two other direct measures of exploration are not found to relate to rate of learning, in contrast to earlier results (Stafford et al., 2012; Stafford \& Dewar, 2014). This suggest that curiosity alone is not sufficient to enhance skill acquisition.

Destiny, and online games in general, represent a rich test-bed for theories of skill acquisition. Games are played for reasons of intrinsic motivation and so represent an important contrast to lab studies which are completed for financial incentives or as part of a course requirement. In addition they represent an opportunity to collect large data sets, which allow confidence in the estimates of the effects of the factors analysed. Overcoming statistical uncertainty allows researchers to move swiftly to wrestling with interpretative uncertainty.

In this case, although variability in practice timing - spacing - enhances skill acquisition, we failed to demonstrate that our measures of other kinds of practice variability can be related to enhanced skill acquisition. This leaves open the possibility that the exploration which supports skill acquisition is not captured by our measures, or that more complex skills, such as Destiny playing, require an equal match of habitual practice and exploratory variability.

# Biases and labeling in iterative pragmatic reasoning 

Jon Scott Stevens (stevens.400@osu.edu)<br>Department of Linguistics, The Ohio State University<br>Columbus, OH 43210 USA

#### Abstract

This paper presents a series of reference game experiments (Frank and Goodman, 2012) and fits the results to a number of Bayesian computational models in order to explore the role of linguistic and perceptual bias in iterative pragmatic reasoning. We first discuss the modeling choices made by Franke and Jäger (2016) and others who have used similar frameworks to model reference game tasks. We introduce a space of different plausible Bayesian models based on this work, and compare models' fit to new experimental data to replicate the basic findings of Franke and Jäger (2016) regarding the strong role for perceptual salience (e.g., the primacy of color over shape as a differentiating property for possible referents) and linguistic category (e.g., a preference for nouns over adjectives) in pragmatic reference resolution. We then uncover an additional possible effect of what we call labeling, whereby a hearer may simply ignore non-salient, non-differentiating semantic properties, in a manner similar to how an incremental algorithm (Reiter and Dale, 1992) might ignore certain semantic properties when generating referring expressions. Keywords: Iterative pragmatic reasoning; probabilistic pragmatics; reference games; computational modeling; perceptual bias; reference resolution

## Introduction

When someone says, "hold up your finger," you are most likely inclined, without much thought, to hold up your index finger. This may seem unsurprising, as your index finger is particularly salient for a number of reasons. But, as Franke and Degen (2016) point out, further reflection raises the question of why the thumb-which is technically a finger, and which we might expect to be even more salient than the index finger-is never a candidate for reference. The thumb is a prime example of a pragmatic 'blocking' effect: though it is indeed a finger, the existence of the more specific word "thumb" tends to block it from reference by the word "finger". Hence, there is a tension between salience and pragmatic blocking in resolving the referent of "your finger".

This paper presents an exploration of this kind of tension using reference games (Frank and Goodman, 2012; Franke and Degen, 2016, and others). Reference games are communicative tasks where subjects are asked to either produce or interpret short utterances, which are potentially ambiguous in the context, to describe shapes on a screen. Reference games are used as a test of models of iterative pragmatic reasoning, whereby certain potential referents of an utterance are blocked by the existence of a better, more informative alternative utterance available to the speaker.

We further probe work begun in Franke and Jäger (2016) and Stevens (2016) by setting up reference games that favor strong biases toward particular visually salient referents. We test a range of different variants of the Rational Speech Act (RSA) model of Frank and Goodman (2012) on our results. We come to two conclusions:

- We replicate the basic findings of Franke and Jäger (2016), while improving their implementation of RSA by reducing the number of free parameters required from four to one.
- We examine variation between items and uncover a possible effect of what we call labeling-an independently motivated mechanism for assigning possibly incomplete semantic labels to potential referents based on salient preferred properties. We show that by introducing labeling into the model, the fit between model predictions and empirical results is improved.
Before diving into these results, we review prior work on reference games, RSA models and bias in reference resolution.

## Prior work

A recent movement toward probabilistic pragmatics-the use of Bayesian, game-theoretic and other similar methods to model how non-literal meaning is conveyed by utterances in context- has been accompanied by an emphasis on using computational models of pragmatic reasoning to explain empirical results (see Franke and Jäger, 2016, for a summary). This includes the rational speech act (RSA) model (Frank and Goodman, 2012; Franke and Jäger, 2016; Bergen et al., 2016, among many others) and its variants, as well as game-theoretic and decision-theoretic models (see e.g. Franke, 2009; Stevens, 2016). These frameworks all tell a similar story at their core: pragmatic phenomena are largely a byproduct of iterated reasoning of the form, 'I expect that she expects that I will say $\phi$ in context $C$,' or some variant.

Reference games A reference game task (Frank and Goodman, 2012) is a simple experiment which is designed to elicit iterative pragmatic reasoning behavior. A speaker and a hearer are presented with an array of colored and/or patterned shapes like the one seen in Fig.1. The speaker is assigned one of the shapes and is tasked with choosing a single word to convey to the hearer which shape she has been assigned. For Fig. 1 the choices would be "circle," "triangle," "blue" and "red." The hearer receives one of these words from the speaker and tries to guess correctly what was meant. A simple game-theoretic model of Gricean pragmatic reasoning, such as Franke's (2009) iterated best response (IBR) model, makes categorical predictions about the interpretation of ambiguous-in-context words ("triangle" and "blue" in this case). Quite simply, the hearer should assume that the speaker would have used an unambiguous word if she could have, i.e. "red" for the red triangle and "circle" for the blue circle, which leads to the conclusion that either "blue" or "triangle" alone should be taken to refer to the blue triangle. But such categorical models

Figure 1: Simple three-image setup for a reference game task.
are typically meant to be normative, and do not aim to reflect the probabilistic nature of how people actually behave. The RSA approach, which builds a Bayesian probabilistic component into a bounded IBR-style reasoning model (Frank and Goodman, 2012; Franke and Jäger, 2016) allows for computational models that more closely match experimental results.

Rational speech acts The rational speech act (RSA) approach to modeling pragmatic reasoning computes the probability of a hearer choosing a referent $r$ given a description $d$ via Bayes' rule assuming the speaker chose their utterance rationally, which in this case means the speaker attempted to maximize the chance of successful communication. We begin with a function encoding likelihood of referential success of a description $d$ given intended referent $r$ assuming a naive hearer-a hearer who randomly selects a referent consistent with $d$ 's denotation. Let's call this function $\mathcal{H}_{0}$.

$$
\begin{equation*}
\mathcal{H}_{0}(r \mid d)=\frac{1}{|\llbracket d \rrbracket|} \text { if } r \in \llbracket d \rrbracket \text {, else } 0 \tag{1}
\end{equation*}
$$

The probability of a rational speaker producing description $d$ to describe intended referent $r$ is taken to be a function of $\mathcal{H}_{0}$, namely a soft max function, which has the effect of approximately maximizing $\mathcal{H}_{0}$ by introducing a rationality parameter, $\lambda$. The rationality parameter encodes the degree to which speakers behave as perfect reasoners. As the value of $\lambda$ increases, this production probability-which we'll call $S_{1}$ asymptotically approaches an $\arg$ max of $\mathcal{H}_{0}$. Similarly to Franke and Jäger (2016), we also posit that a bias function, $\beta(d, r)$ is added to $\mathcal{H}_{0}$, which encodes possible prior bias toward certain types of descriptions over others (e.g., a preference for nouns over adjectives, empirically determined for our models). We'll return to the exact nature of the bias function in the next section.

$$
\begin{equation*}
S_{1}(d \mid r)=\frac{e^{\lambda \mathcal{H}_{0}(r \mid d)+\beta(d, r)}}{\sum_{d^{\prime}} e^{\lambda \mathcal{H}_{0}\left(r \mid d^{\prime}\right)+\beta\left(d^{\prime}, r\right)}} \tag{2}
\end{equation*}
$$

Finally, the production probability $\mathcal{S}_{1}(d \mid r)$ can be plugged in to Bayes' rule, where $P(r)$ is the prior probability of referent $r$ being referred to, to obtain a pragmatically motivated probability function for the hearer, which we will call $\mathcal{H}_{2}$.

$$
\begin{equation*}
\mathcal{H}_{2}(r \mid d)=\frac{S_{1}(d \mid r) \times P(r)}{\sum_{r^{\prime}} S_{1}\left(d \mid r^{\prime}\right) \times P\left(r^{\prime}\right)} \tag{3}
\end{equation*}
$$

We will use $S_{1}$ to make predictions about production probability and $\mathcal{H}_{2}$ to make predictions about interpretation probability. We use empirically determined values of $P(r)$.

Franke and Degen (2016) also implement a variant of RSA that starts the iteration with the speaker instead of the hearer. That variant begins with a 'literal speaker', which we could call $S_{0}$, who randomly selects from among appropriate descriptions. Then $\mathcal{H}_{1}$ selects referents that maximize the probability of having been referred to by $\mathcal{S}_{0}$ 's utterance, and then a pragmatic speaker $S_{2}$ chooses descriptions via Bayes' rule taking $\mathcal{H}_{1}$ into account. We implement this variant as well.

Biases and salience Cognitively oriented pragmatic models like RSA must take into account the prior biases that interlocutors bring to the table. Two such biases factor into Franke and Jäger's model of reference games. Firstly, the authors use data from a prior elicitation task to show that hearers have a prior bias toward picking referents that are more visually salient. For example, there is expected to be a bias toward the red triangle in Fig. 1 due to the pop-out effect that its unique color creates. Secondly, the authors use production experiment data to show that there is a prior bias toward using shape nouns rather than color-denoting adjectives to describe an intended object. These biases are built into their probabilistic model, the former being encoded in the prior probability distribution over speaker intentions, and the latter being encoded as the bias parameter $\beta$ which boosts production probability for shape terms. This allows a closer fit to experimental results when compared to more purely Gricean models.

Investigating perceptual bias in the visual domain can shed light on the role of salience in iterative pragmatic reasoning more generally, given that parallels have been found between visual salience and e.g., the use of definite referring expressions (Duan et al., 2013). In this study we find evidence that visual salience affects how hearers assign their own internal semantic labels to the potential referents in a scene. Namely, behavior on certain experimental items suggests that hearers selectively consider properties of potential referents (i.e., the object's color, shape, pattern, etc.) which serve to differentiate them from their competitors. More specifically, we suggest that hearers can generate sets of expected linguistic descriptions for each object using something like an incremental algorithm (Reiter and Dale, 1992; Krahmer and Van Deemter, 2012), which has been used to generate referring expressions in a psychologically plausible way. This algorithm is informally sketched in Fig.2. To illustrate, consider the picture in Fig.1. Imagine that the most salient property type is COLOR. To label the red triangle, the algorithm takes its value for COLOR-'red'-and checks whether there is at least one member of the distractor set (the blue triangle and the blue circle) which is not red. There is, and so 'red' gets added to the label set, and both of the non-red items are removed from the distractor set. This leaves an empty distractor set, and so the algorithm halts on the singleton set of labels, \{'red'\}. The same algorithm will generate $\{$ 'blue', 'triangle'\} for the

- Given an object $O$ in a set of objects $\Omega$, let $L$ be $O$ 's label-a set of semantic properties (e.g., \{'red', 'triangle'\}) to describe $O$. Let $P^{*}$ be an ordered sequence of property types which are ordered by salience (e.g. 〈COLOR, SHAPE〉, if color is more salient than shape). Let $D$ be the set of distractors, i.e., $\Omega \backslash O$
- Initialize $L$ to $\}$
- For $P$ in $P^{*}$ :

1. Let $V$ be the value that $O$ has for property $P$
2. Let $\Omega_{\neg V}$ be the set of objects that have a different value for $P$ than $V$
3. If $D \cap \Omega_{\neg V} \neq\{ \}$, then add $V$ to $L$ and remove all members of $\Omega_{\neg V}$ from $D$
4. If $D=\{ \}$, return $L$

Figure 2: An informal presentation of an incremental algorithm for generating salient and informative semantic labels for referents.
blue triangle and \{'blue', 'circle'\} for the blue circle. The red triangle is simply labeled as the red thing, because 'red' is a preferred property that uniquely differentiates it, while the other two shapes are labeled according to both color and shape.

## Computational models

We implement a variety of models centered around the RSA implementation of Franke and Jäger (2016), though we reduce the number of free parameters from four to one. The first reduction comes from the choice to use a single value of the rationality parameter $\lambda$ to predict both speaker and hearer behavior, where Franke and Jäger (2016) fit two $\lambda$ values separately. The second reduction comes from the use of empirical data to determine values of $\beta(d, r)$-the observed bias toward nouns in production-where Franke and Jäger (2016) use a pair of fixed values that were tweaked for best performance. Using a speaker norming task, as described in the next section, we obtain a prior probability of noun vs. adjective for each experimental item we want to model. We then set $\beta(d, r)$ to be proportional to this prior probability.

$$
\begin{equation*}
\beta(d, r)=\frac{P(d)}{\sum_{d^{\prime} \mid r \in \llbracket d^{\prime} \rrbracket} P\left(d^{\prime}\right)} \text { if } r \in \llbracket d \rrbracket \text {, else } 0 \tag{4}
\end{equation*}
$$

We now have a single-parameter RSA model that will make predictions about both production and interpretation rates in a reference game task, taking biases into account.

We implement a number of variants of this model to allow us to assess some of the modeling choices we and others have made. In particular, we want to answer the following three questions about our modeling choices:

1. Bias vs. no bias: Do we really need the $\beta(d, r)$ term?
2. Naive hearer vs. literal speaker: Should we really start with a naive hearer $\mathcal{H}_{0}$, as opposed to with a literal speaker $\mathcal{S}_{0}$ à la the variant in Franke and Degen (2016)?
3. Uniform level-0 prior vs. empirical level-0 prior: Should the naive hearer and/or literal speaker select randomly from

among semantically appropriate actions, as opposed to selecting proportionally to the empirically determined prior?
There are a total of $2^{3}=8$ possible combinations of yes/no answers to these three questions, each corresponding to a different model variant. The variant we have described, based on Franke and Jäger (2016), is the "yes/yes/yes" model. That means that bias is implemented, we follow the trajectory $\mathcal{H}_{0} \rightarrow \mathcal{S}_{1} \rightarrow \mathcal{H}_{2}$ rather than starting with a non-rational speaker, and $\mathcal{H}_{0}$ chooses a random semantically compatible meaning, ignoring the prior probability $P(r)$. Table 1 lays out the possibilities and points to examples of a few of the models from the RSA literature.

We implemented all models with integer $\lambda$ values between one and ten ${ }^{1}$ and used root mean square error (RMSE) as a measure of overall difference between model predictions and experimentally determined values.

## Experiments

Participants and materials We conducted four experiments via Amazon Mechanical Turk, two experiments to determine prior probabilities for referents and descriptions, and two reference game tasks, one where the Turker played the part of the speaker and one where they played the part of the hearer. For each experiment, 100 Turkers were assigned to one of two lists containing nine experimental items, for a total of 18 items. Each item was an array of three images similar to Fig.1, where one image was distinguished from the other two by its shape, another image was distinguished by another salient attribute, and the third image was not distinguished along any dimension. The order of item presentation was randomized, as was the order in which the shapes were presented on the screen. Items fell into one of three categories based on which salient distinguishing attribute was used, with 6 items in each category:

1. Color: Red vs. blue, as in Fig. 1
2. Pattern: Striped vs. solid (one striped and two solid)
3. Size: One shape bigger than the other two

Native language was assessed as part of a post-task questionnaire. Subjects were paid $\$ 0.70$ for about 5 minutes of their time. If any subject's responses were incomplete, or if the

[^507]subject was not a native speaker of English, the data from that subject was excluded from analysis.

Experiment 1: Eliciting hearer priors Following Frank and Goodman (2012) and others, we use empirically determined values for the prior probabilities in our model. The prior probability $P(r)$ of choosing a referent $r$ is taken to be a measure of the salience or 'newsworthiness' of a referent, i.e., a general measure of how likely $r$ is to be talked about. To elicit this experimentally, we asked subjects to select an image to describe, giving them no guidance on which images to select, and then type a description of it. The point of this experiment was not what the descriptions were, but rather which shapes they chose to talk about. We took this as a proxy for the salience of the referent, and thus its prior probability of being referred to. We asked them to type descriptions as a secondary task in order to situate the shape selection within a natural communicative setting. We used data from 97 subjects after exclusions.

For the color items we obtained similar results to Franke and Jäger (2016), where the red shape was picked much more often (probability 0.5 ) than either of the blue shapes, and where the distinguished blue shape (e.g., the circle in Fig.1) was picked more often (0.33) than the non-distinguished blue shape (0.17). For the size items, we found that the distinguished smaller shape had a high prior probability ( 0.5 vs . 0.26 and 0.24 for the large and small competitors, respectively), and for the pattern items, the priors were closer to equal for the striped and distinguished solid shapes ( 0.36 and 0.40 , respectively), and lowest for the non-distinguished shape (0.24).

Experiment 2: Eliciting speaker priors To empirically determine whether and to what extent speakers are biased toward nouns like 'circle' over adjectives like 'red', we ran an experiment just like Experiment 1, but with two important differences: (i) subjects were assigned one of the three images to describe, rather than being asked to pick one themselves (image assignments were counterbalanced across lists so that shape-distinguished, attribute-distinguished and nondistinguished items were equally represented), and (ii) subjects were told to limit their descriptions to a single word, in order to bring the task more in line with a reference game task. To discourage any kind of pragmatic reasoning, subjects were asked to use the 'first word that came to mind' and not to overthink it. We analyzed data from 84 subjects after exclusions, and only looked at items where either a shape-denoting noun or relevant attribute-denoting adjective was used (very few did not fall into this category). The words were input as free text, and thus we hand-tokenized the responses to account for spelling mistakes and superficial lexical differences (e.g., 'big' vs. 'large'). We found an overwhelming prior bias toward nouns.Overall, shape terms were used two-thirds of the time. There is evidence that this task successfully elicited prior linguistic biases and limited the amount of pragmatic

Table 2: Production of $d$ given $r$ (on the left, sum horizontally to 1 ) / selection of $r$ given $d$ (on the right in bold, sum vertically to 1 ) in Experiments 3 and 4. Subscripts $D$ and $N$ mean 'distinguishing' and 'non-distinguishing', respectively, and ATTR stands for 'attribute'.
reasoning being used to determine descriptions. For example, for the items where an attribute term would uniquely distinguish the intended referent, shape terms nonetheless comprised $60 \%$ of responses, more than double the shape-term response rate for Experiment 3, which was designed to elicit pragmatic reasoning.

Experiment 3: Reference game, speaker role Experiments 3 and 4 instantiate the canonical reference game task described in the second section. Experiment 3 asks subjects to play the role of the speaker in a reference game. Similarly to Experiment 2, subjects are assigned one of the three images and asked to give a one-word description. But for this experiment, they are explicitly told to select from a list of the relevant words (e.g., "red", "blue", "triangle", "circle"). And unlike Experiment 2, the task is framed as a game. Subjects are told they are sending a message, and to assume that a "receiver" will receive these descriptions and make a guess as to which image was assigned. The goal, they are told, is for the receiver to guess correctly as often as possible. Data from 79 subjects was used.

Experiment 4: Reference game, hearer role Experiment 4 asks subjects to play the role of the hearer, or the "receiver". For each item, a single word is displayed at the top of the screen, which the subjects are told has been carefully selected and sent to them by a sender who wants them to correctly guess an image from a one-word description. Word selection was counterbalanced across both lists. The subjects were required to select a single image for each item. Data from 91 subjects was used.

Results Our reference game experiment results are in line with other reference game results in the literature, and are summarized in Table 2. Like Franke and Jäger (2016), we find that the expected propensity toward interpreting ambiguous shape and attribute words (like "triangle" and "blue" in Fig.1) as referring to the non-distinguished shape (like the blue triangle) is dampened for the shape words, likely reflecting hearer knowledge of speakers' prior noun bias, where the prior noun bias makes a shape term like "triangle" a less reliable signal that the non-distinguished referent is intended.

Table 3: RMSE for speaker predictions (left) / hearer predictions (right). Best-case $\lambda$ value used for each reported RMSE. Best model results are in bold.

Table 3 shows how our model variants line up with the empirical results in terms of the root mean square error (RMSE), which is a measure of overall difference between predicted and observed values obtained by calculating the mean of the square of the difference between each predicted vs. observed value and taking the square root. We used the difference in predicted vs. observed subject means for each experimental item (i.e., each array of images) to determine RMSE. Not only is our refinement of Franke and Jäger (2016) the best model to predict these data, but our best-case value of the $\lambda$ parameters $(\lambda=4)$ is the best-case value for both the speaker and hearer model independently. That is to say, we would not do a lot better by allowing for separate $\lambda$ values for speaker and hearer. We take this to be a nice replication of the basic finding of Franke and Jäger (2016), obtained using only one free parameter that was only broadly tweaked. ${ }^{2}$

The numbers in Table 2 are somewhat closely replicated, with every value being within three percentage points of the real value. A plot of predicted vs. actual results from Table 2 is given in Fig.3. However, the numbers in Table 2 are averaged over all items, and tell us nothing about the range of variation of responses for different kinds of images. RMSE gives us an overall assessment of error taking into account error at the level of each individual item. What the RMSE values in Table 3 tell us is that the speaker model fits considerably better than the hearer model.

Why is the hearer model so noisy? Given the proximity of predicted to actual results on average in Fig.3, the source of the noisiness must be coming from differences between item types. An item-level investigation of the source of the higher-than-expected RMSE will lead us to posit that when there are highly perceptually salient options, as in these experiments, hearers are inclined to label their options in a way that is similar to the output of an incremental algorithm (Fig.2).

## Labeling

We now break down by-item behavior further, looking not only at whether the image array was shape- color- or sizedistinguished, but also at which word was sent to the hearer. We find that the predicted qualitative pattern-that ambiguous descriptions (and only ambiguous descriptions) should prompt a plurality of guesses of the non-distinguished

[^508]

Figure 3: Hearer predictions vs. observed values, averaged over subjects and items.
image-holds in all but two cases. These two cases are depicted in Fig.4, where we see a deviation for (i) color items when the hearer is sent an ambiguous color term and (ii) size items when the hearer is sent an ambiguous shape term. There is a pattern to these deviations. The pattern is that we see a shift away from the non-distinguished image only in cases where the semantically ruled out referent (e.g., the red thing if the description is "blue") has a high prior (in both cases, $\sim 50 \%$ ). Let's break down what this means for the three item types. First, when the hearer receives "blue" for an item like Fig.1, we find higher-than-expected selection of the unique shape (the circle in Fig.1). This is the item type for which the attribute-distinguished image (the red triangle) is maximally salient according to Experiment 1. Second, when a hearer receives an ambiguous shape term for a size-distinguished item, we find higher-than-expected selection of the uniquely large referent. This is the item type for which the shapedistinguished image is maximally salient according Experiment 1. Finally, the pattern-distinguished items fall entirely in line with what we expect, and those are the items where the priors for shape- and attribute-distinguished images are much closer to each other.

Qualitatively speaking, we would expect this if the referents were labeled according to salient distinguishing properties along the lines of Fig.2, a well-established algorithm for generating referring expressions, which we adapt for generating hearer-internal labels for possible referents. Consider Fig. 1 one more time: for the $\sim 50 \%$ of subjects in Experiment 1 who chose the red triangle, we can assume that COLOR would be their primary salient property type for purposes of Fig.2. This would generate the labels \{ 'blue circle', 'blue triangle', 'red'\}. Assuming these same priors for Experiment 4 (as we have been) we could posit that on $\sim 50 \%$ of trials, the subject has this same labeling. In that case, upon hearing the description "blue", the subject would be at chance between the two blue shapes, because under this labeling, the speaker could have used 'triangle' to uniquely describe the blue triangle and 'circle' to uniquely describe the blue circle, leaving no principled way to interpret "blue" other than to guess.

Labeling could explain the qualitative deviations, and even though the numbers are not perfect, it does indeed improve model fit to add a labeling component to the model. We can do this by substituting a new $\mathcal{S}_{1}$ function $\mathcal{S}_{1}^{\prime}$ into the $\mathcal{H}_{2}$ equa-

Figure 4: Predicted (left) and actual (right) referent selection for two combinations of item type and description type.
tion which takes labeling into account. Letting $\mathcal{L}$ be the set of labels for each possible referent, $S_{1}^{\prime}$ can be defined as follows:

$$
\begin{equation*}
\mathcal{S}_{1}^{\prime}(d \mid r)=\sum_{\mathcal{L}} P(\mathcal{L}) \times \frac{e^{\lambda \mathcal{H}_{0}(r \mid d, \mathcal{L})+\beta(d, r)}}{\sum_{d^{\prime}} e^{\lambda \mathcal{H}_{0}\left(r \mid d^{\prime}, \mathcal{L}\right)+\beta\left(d^{\prime}, r\right)}} \tag{5}
\end{equation*}
$$

We introduce no new free parameters if we simply take $P(\mathcal{L})$ to be the prior probability of the shape-distinguished referent for the $\mathcal{L}$ obtained when shape is primary, the prior of the attribute-distinguished referent for the $\mathcal{L}$ obtained when attribute is primary, and the prior of the non-distinguished shape for the 'full' $\mathcal{L}$, which omits no information. Doing this, we can reduce the RMSE from 0.18 to 0.15 , and could perhaps reduce it further if we could independently assess how primary salient properties are chosen. Using multinomial choice probabilities to determine log likelihood, we can show that the data from Experiment 4 are significantly more likely under the model with labeling. ${ }^{3}$

## Conclusion

Using a variety of models and experimental items and tasks, we have replicated existing results regarding behavior in reference games, and potentially found a new one, an effect of labeling under conditions where certain referents have highly salient properties. That it might matter how people internally label possible referents is not really a new idea, and is in fact in line with game-theoretic literature on coordination (see e.g., Sugden, 1995). But it provides somewhat of a paradox. On the one hand, this and other studies find that speakers exhibit a bias toward noun descriptions in reference games, across the board, and yet it seems as if hearers are assigning labels to potential referents that in some cases would lead them to expect the opposite (e.g., to expect "red" to describe the red triangle in Fig.1). Thus further work is warranted to probe whether such a mismatch between speaker behavior and hearer expectations is generally observable.

[^509]Further work must also be done to probe the details of exactly how labeling works in reference games, and what the implications are for iterative pragmatic reasoning more generally. For example, it remains to be seen whether labeling should be seen as part of a rational process of pragmatic reasoning, or as something that competes with it, as Stevens (2016) would suggest. Finally, future work will use online measures to probe the mechanisms that give rise to the probabilities in our models. This would take us beyond computational-level models, using such models only as a starting point to guide us toward a more fine-grained understanding of this behavior (see Yang, to appear).

# Actions that Modify Schedules of Reinforcement 

Mac Strelioff (mstrelio@uci.edu)<br>Mimi Liljeholm (m.liljeholm@uci.edu)<br>Department of Cognitive Sciences, University of California Irvine<br>Irvine, CA 92697-5100 USA

#### Abstract

Many everyday activities involve the use of one action to modify the effects of another: When driving, shifting gears modifies the influence of pressing the gas pedal on acceleration; when cooking, the rate of adding a particular ingredient modifies the influence of stirring on viscosity. Here, we investigate a general ability to learn how to use actions to control schedules of reinforcement. In Experiment 1, participants quickly discovered the optimal rate of responding on an action that controlled the rate of reward contingent on performing a different action. In Experiment 2, when the modifying action was itself rewarded, participants failed to discover the optimal rate. Implications for formal theories of instrumental behavior are discussed.

Keywords: Schedules of reinforcement; reward learning; instrumental contingencies.

## Introduction

Since the early $20^{\text {th }}$ century, researchers have investigated the influence of various reward schedules on the rate and selection of instrumental responses. For example, ratio schedules, in which reward delivery depends on the number of responses since the last reward, produce higher rates of responding than do interval schedules, in which reward delivery depends on the time elapsed since the last reward (Fester \& Skinner, 1957). When two or more action alternatives are available, that which yields the greatest, most immediate, or most certain reward is, all other things being equal, generally that most frequently selected (e.g., Rachlin et al., 1991). However, in the real world, many responses serve only to modulate the effects of other actions: The rate and pattern of pressing strings on a guitar does not itself yield music, but profoundly impacts the sounds produced by strumming. Here, we assess a domain-general capacity for learning about actions that control schedules of reinforcement on other actions.

Formally, the relationship between a particular action and its outcome has been modeled as a complex associative structure (Dickinson \& Balleine, 1993), as the difference between probabilities of reward given the presence versus absence of the action (Hammond, 1980), as the probability and subjective utility of the outcome given the action (Savage, 1954), or as a cached value assigned to the action based on its reinforcement history (Watkins, 1989). What these diverse approaches have in common is that they address the identity and/or
latency of a single action at a time, ignoring situations in which multiple actions are performed in concert and potentially interact. In our paradigm, an intermediate rate of responding on one action maximizes the reward contingent on performing a different, concurrently available, action.

## Experiment 1

## Methods

Participants Thirty undergraduates at the University of California, Irvine ( 22 females; mean age $=20 \pm 2.17$ ) participated in the study for course credit. All participants gave informed consent and the study was approved by the Institutional Review Board of the University of California, Irvine.

Task \& Procedure The task is illustrated in Figure 1. We used a free operant paradigm in which participants were allowed to respond at will on either or both of two concurrently available actions, graphically represented on the computer screen, by pressing the corresponding keys on the computer keyboard. Whenever a response was made a selection square appeared around the chosen action for 300 ms . If the response was rewarded, an image of a quarter appeared center screen for 500 ms and a count of the cumulative monetary earning, continuously displayed above the quarter image location, would increment by $+\$ 0.25$. The task was comprised of ten 2-minute blocks separated by brief rest periods. All monetary earnings were fictitious.

In the "Modify" group ( $\mathrm{n}=15$ ), the rate of responding on a "modifying" action influenced the probability that the concurrently available "modified" action would produce a reward. When the modifying action was performed at an "optimal" rate of 1.25 to 2.75 presses per second, the probability of reward given a response on the modified action was 0.9 . When response rates on the modifying action were outside of the 1.25 to 2.75 range, the probability of reward given the modified action was 0 . The modifying action did not itself produce any reward. Response rates on the modifying action were tracked using a differential equation that increased by an impulse of 1 at the time of a response and decayed each impulse at a linear rate of 0.2 per second, so that each impulse from a response decayed to zero after 5 seconds.

Specifically, for an impulse $\left(a_{i}\right)$, which was 1 if an action were taken during the current iteration of the program and 0 otherwise, a decay rate of 0.2 , a counter for the number of responses that occurred within the last 5 seconds $\left(N_{5}\right)$ and the difference in time between the current iteration of the program and the previous iteration $(d t)$, the response rate variable $(R)$ was updated on each iteration $i$ by:

$$
R_{i} \leftarrow R_{i-1}+a_{i}-0.2 N_{5} d t
$$

This method adjusts more quickly to changes in response rate than the commonly used approach of dividing the number of responses in a time window by the length of the window (e.g., Soto et al., 2006). The probability of reward on the modified action was set to 0.9 whenever the response rate variable, $R$, was in the optimal, 1.25 to 2.75 , range and 0.0 otherwise.

Note that the optimal rate of responding on the modifying action was intermediate; this was done to rule out the contribution of systematic biases of either very high or very low responding. On the other hand, an intermediate rate might represent an average towards which most responders converge in free operant tasks. To address this possibility, a second, "Yoked", group was included ( $\mathrm{n}=15$ ), in which the rate of responding on the modifying action had no influence, while the probability of reward on the modified action was yoked to that of a participant in the Modify group. We predicted that, by the end of the session, participants in the Modify group would respond on the modifying action at a rate falling within the optimal range, while those in yoked group would not.

Figure 1: Task Illustration, see text for details.

## Results

We divided the number of responses on the modifying action in each 5 -second bin of task performance with 5 (i.e., responses per second), and computed the distance of this response rate from the bounds of the optimal range, for the first and last 5 seconds of the task. We then used a mixed analysis of variance (ANOVA) with "group" as the between-subject factor and "bin" as the within-subject factor to assess a change in optimal responding between the first and last bins. There was no main effect of bin, $\mathrm{F}(1,28)=3.19, p=0.09$, but a main effect of group, $\mathrm{F}(1,28)=6.53, p<0.05$, and, critically, a
bin-by-group interaction, $\mathrm{F}(1,28)=5.78, \quad p<0.05$. Planned comparisons revealed that while the two groups did not differ with respect to optimal responding on the modifying action in the first bin, $\mathrm{t}(28)=0.13, p=0.89$, by the last bin, participants in the Modify group were significantly closer to the optimal response rate than were participants in the Yoked group, $\mathrm{t}(28)=3.61$, $p<0.01$. As can be seen in Figure 2, while the mean deviation from the optimal rate significantly decreased from the first to the last bin in the Modify group, $\mathrm{t}(14)=2.69, p<0.05$, they remained unchanged across bins in the Yoked group, $\mathrm{t}(14)=0.05, p=0.63$. The apparent absence of a change in optimal responding by Yoked participants reflects a tendency to either increase or decrease responding on the modifying action across blocks, resulting in no net change for the group; in contrast participants in the Modify group coherently converged towards the optimal rate.

Figure 2: Mean deviation of response rates on the modifying action from the optimal range in the first and last 5 seconds of task performance, for subjects in the Modify (black) and Yoked (blue) groups, and for the single group of Experiment 2, in which the modifying action was rewarded (red). Error bars=SEM.

We also assessed performance in terms of the proportion of bins with optimal response rates, early and late in the task. Bins were scored as optimal if the windowed (5 seconds) response rate was in the optimal range of 1.25 to 2.75 responses per second. For each subject, we assessed the number of optimal 5 -second bins in the first and last 30 seconds of the task. (We used 30 seconds, rather than the full 2 -minute blocks, to ensure that the index of early learning did not include already asymptotic performance.) The results using this metric were consistent with those described above: The groups did not differ in the first 30 -second block, $\mathrm{t}(28)=1.12$, $p=0.24$, but by the last 30 -second block, the mean proportion of optimal bins was significantly greater for the Modify group than for the Yoked group, $\mathrm{t}(28)=6.93$, $p<0.01$. Indeed, while the proportion of optimal bins increased significantly from the first to the last block in
the Modify group, $\mathrm{t}(14)=3.60, p<0.01$, it decreased, albeit with marginal significance, $\mathfrak{t}(14)=2.09, p=0.06$, in the Yoked group. The mean proportion of optimal bins in each 30 -second block throughout the task is shown in Figure 3.

Figure 3: Mean proportion of bins with an optimal response rate on the modifying action in each 30 -second block of the task for the Modify (black) and Yoked (blue) groups of Experiment 1, and for the Reward group of Experiment 2 (red). Shading=SEM.
With respect to the modified action, response rates were, overall, higher than those on the modifying action, for both the Modify, $\mathrm{t}(14)=3.10, p<0.05$, and Yoked, $\mathrm{t}(14)=6.76, p<0.05$, groups. This likely reflects the fact that, while the probability of reward given the modified action was either a function of (Modify) or independent of (Yoked) responding on the modifying action, the actual delivery of reward was contingent only on performing the modified action.

## Experiment 2

A well-studied phenomenon closely related to our query is that of "melioration" - a tendency to select an action alternative that produces a greater immediate pay-off, but that, when selected repeatedly, lowers the overall rate of reward (Herrnstein, 1991). Such tendencies are commonly attributed to impulsivity (Herrnstein, 1991; Otto, Markman, \& Love, 2012), but have also been described as rational choices under uncertainty (Gureckis \& Love, 2009a, 2009b; Sims et al., 2013). Other related paradigms, such as delay discounting (Ainslie, 1975; Johnson \& Bickel, 2002) and differential reinforcement of low response rates (Wilson \& Keller, 1953; Carter \& MacGrady, 1966), have convincingly demonstrated the interfering influence of salient reward on rational decision-making (Ainslie, 1975; Van den Broek, Bradshaw, \& Szabadi, 1987).

In Experiment 2, we assess whether the lure of an immediate reward results in a failure to suppress responding on the modifying action, thus interfering
with the ability to control the schedule of reinforcement on the modified action.

## Methods

Participants Fifteen undergraduates at the University of California, Irvine ( 10 females; mean age $=19.7 \pm 1.1$ ) participated in the study for course credit. All participants gave informed consent and the study was approved by the Institutional Review Board of the University of California, Irvine.

Task \& Procedure Participants performed a task that was identical to that of the Modify group in Experiment 1, with one exception: In addition to modulating the schedule of reinforcement on the modified action, the modifying action was itself rewarded by $\$ 0.25$, with a probability of 0.2 . Note that, since this reward probability is much lower than the conditional, 0.9 , probability of reward on the modified action, maintaining an optimal, intermediate, response rate on the modifying action dramatically increases the average reward rate.

## Results

We computed the same measures of optimal responding as those used in Experiment 1. Comparing the first and last 5 seconds of performance, there was no change in the deviation of response rates on the modifying action from the bounds of the optimal rate, $\mathrm{t}(14)=0.48, p=0.64$ (see Figure 2). Likewise, the proportion of optimal bins did not differ between the first and last 30 -second blocks of the task, $\mathrm{t}(14)=0.00, p=1.00$. In the absence of random assignment, we refrain from making any statistical comparisons between the results of this experiment and those obtained in Experiment 1. Nonetheless, it is worth noting that, as illustrated in Figures 2 and 3, when the modifying action was itself rewarded, the rate of responding on the modifying action was apparently closer to that in the Yoked group than in the Modify group. Finally, although, overall, response rates were again higher on the modified than the modifying action, unlike for the groups in Experiment 1, this difference was only marginally significant, $\mathrm{t}(14)=2.09, p=0.06$, presumably reflecting the fact that, in Experiment 2, reward delivery was potentially contingent on performing either action.

## General Discussion

In two experiments, we assessed the discovery and performance of an action that controlled the schedule of reinforcement on another, concurrently available, action. In Experiment 1, participants quickly discovered and implemented an optimal, intermediate, response rate on a modifying action that, while not producing any rewards itself, modulated the reward contingent on a distinct, concurrently available, action. Response rates
in a yoked control group confirmed that convergence to the optimal rate was due to the influence of the modifying action on the reward schedule of the modified action. In Experiment 2, consistent with a large literature on the failure to suppress inappropriate responding in the face of immediate reward (Ainslie, 1975; Carter \& MacGrady, 1966; Van den Broek et al., 1987; Wilson \& Keller, 1953), reinforcement of the modifying action apparently prevented discovery of the optimal response rate. The focus in the existing literature on the disruptive effects of immediate reward has largely overshadowed the question raised here of whether, and how, agents learn about actions that modify schedules of reinforcement. Our results suggest that, in the absence of interfering or competing reward contingencies, increasing levels of instrumental control can be achieved by incorporating information about dependencies between actions.

In a model-free reinforcement learning account of free operant responding, Niv et al. (2007) proposed that, for each decision, the agent selects both the latency and the identity of the to-be-executed action, based on the relative degree to which that action increases the average reward rate. Although it is possible that participants in the Modify group of Experiment 1 similarly learned about the modifying action based on its reinforcement history, several aspects of our task depart from the specification of Niv et al. (2007). Most notably, participants in our task would have to include a representation of the modified action in their state space when updating the value of the modifying action - that is, assess the value of a particular latency of the modifying action given that the modified action is simultaneously ${ }^{1}$ or proximally performed - since the modifying action is never itself rewarded. Likewise, the value of the modified action has to be specified conditional on the performance of the modifying action, since the probability of reward on the former is zero whenever responding on the latter falls outside the optimal range. It is of course possible to specify a model-free learner that has enough conditionals built into its state-representation to identify the combination of responding on modifying and modified actions that maximizes reward ${ }^{2}$.

An alternative, model-based, approach is for the agent to create a graphical probabilistic model representing

[^510]the dependencies between actions, states and rewards (e.g., Acuna \& Schrater, 2010). Although initially ignorant of the nature of these dependencies, a Bayesian reinforcement learner generates beliefs over a set of possible dependency structures and updates those beliefs, after each observation, using Bayesian inference. For example, a learner in our task might postulate two possible worlds: one in which the latency to respond on an action can modulate the probability of reward given that same, or some other, action, and one in which response latencies have no influence on schedules of reinforcement. The former possibility must of course be further partitioned into several putative structures, each with a particular set of links (e.g., an action modifying its own probability of reward vs. that of a different action) and associated parameters. The learner then updates the belief distribution over structures based on sequences of actions, latencies and rewards.

Critically, the approach sketched in the previous paragraph, to address model-based inferences regarding action dependencies, can also be used to explain some of the most basic aspects of instrumental behavior, such as the distinction between interval and ratio schedules Recall that, whereas on interval schedules a response is rewarded based on the amount of time elapsed since the last reward, on ratio schedules a response is rewarded based on the number of responses since the last reward. These qualitatively different schedules produce distinct response profiles (Fester \& Skinner, 1957), suggesting some, implicit or explicit, discrimination by the agent. Notably, the interval schedule can be conceptualized as a case in which the rate of performing an action modifies the schedule of reinforcement, rather than just the rate of reward: Specifically, on a given interval schedule, any response rate greater than "one per the required interval" will decrease the probability of reward conditional on that action. Other wellestablished schedules, such as differential reinforcement of high or low responding (Van den Broek, et al., 1987) can also be characterized as actions modifying schedules of reinforcement, as can the "seeking" component of seeking-taking schedules (Balleine, Garner, Gonzalez, \& Dickinson, 1995). Thus, the framework proposed here potentially applies to a wide range of instrumental phenomena.

At the neural level, model-free and model-based RL approaches have been mapped to dissociable neural substrates, with the ventral striatum, posterior putamen and premotor cortex being implicated in model-free responding (Glascher et al., 2010; Lee et al., 2014; Tricomi et al., 2009; de Wit et al., 2012), and the caudate, ventromedial prefrontal cortex and inferior parietal lobule in model-based computations (de Wit et al., 2012; Liljeholm et al., 2011, 2013, 2015; Lee et al., 2014). It should be noted, however, that, with some exceptions (e.g., Liljeholm et al., 2013), the work
identifying such dissociations has focused on relatively simple model-based processes, such as the encoding of individual action-outcome contingencies or sensitivity to changes in an outcomes utility. In contrast, the model-based learner postulated here engages in complex reasoning regarding how actions may be used to control action-outcome relationships. Such processes may warrant the involvement of brain regions known to support relational and inductive reasoning, including the rostolateral and dorsolateral prefrontal cortex (e.g., Krawczyk et al., 2011).

Finally, an important point regarding action dependencies such as those addressed here is how they relate to the actual representations of actions. In our task, the instructions and materials clearly defined and distinguished between action alternatives (see Figure 1), so that there could be little doubt about how many, and exactly what, actions were available. It is interesting to consider how inferences and performance might have differed had the grouping of elements into discrete action alternatives been more ambiguous. One possibility is that increasing ambiguity would afford a more rapid acquisition of relevant dependencies (Pezzulo, Rigoli, \& Friston, 2015) and, further, that those inferred dependencies might serve to configure action elements into more clearly delineated action representations based on reinforcement learning principles (e.g. Reynolds, \& O’Reilly, 2009).

In conclusion, we have demonstrated a domaingeneral ability to learn about, and take advantage of, an action that modifies the schedule of reinforcement on a different action. We have also sketched a model that, by making inferences about dependencies between response latencies and conditional reward probabilities, might account for behavior across a wide range of instrumental schedules. Future work will focus on extensions of our experimental paradigm, further development of formal accounts, and investigations of mediating neural substrates.

# Shaping the Dynamics of Category Learning in Infants and Adults by Varying Learning Context 

Jelena Sucevic (jelena.sucevic@psy.ox.ac.uk)<br>Department of Experimental Psychology, University of Oxford, 9 South Parks Road Oxford, United Kingdom<br>Nadja Althaus (nadja.althaus@psy.ox.ac.uk)<br>School of Psychology, University of East Anglia, Norwich Research Park<br>Norwich, United Kingdom<br>Department of Experimental Psychology, University of Oxford, 9 South Parks Road Oxford, United Kingdom<br>Kim Plunkett (kim.plunkett@psy.ox.ac.uk)<br>Department of Experimental Psychology, University of Oxford, 9 South Parks Road Oxford, United Kingdom

#### Abstract

During the first year of life, infants develop a remarkable ability to group objects based on their similarities and differences. This ability of category formation represents one of the main mechanisms underlying the organisation of the semantic system. Early categories are formed spontaneously, in a non-supervised fashion and this type of category acquisition remains present even when more sophisticated forms of supervised category learning emerge. Even though there are various models of categorisation mechanisms across the lifespan, there is a gap in the research investigating implicit categorisation at different stages of cognitive development. Therefore, the aim of the current study was to compare processes of spontaneous concept formation in infants and adults using an experimental paradigm based on novelty preference. We discovered that both infants and adults show evidence of category learning (Experiment 1), though with different amount of training being needed to achieve the task. Adults successfully categorised objects already after a single block of training. Infants reached a level comparable to that of adults after twice the amount of training. As these tasks inevitably pose different cognitive and sensory demands to the two groups, in Experiments 2 and 3 we explored how varying parameters of the learning context affect dynamics of category formation. Decreasing memory demands of the task resulted in an acceleration of infants' category formation (Experiment 2), whereas posing memory load in an implicit category learning task decelerated adults' dynamics of category formation (Experiment $3)$.

## Introduction

The ability to group objects based on their similarities and differences represents one of the main mechanisms underlying the organisation of the semantic system. Concepts "embody much of our knowledge of the world telling us what things there are and what properties they have" (Murphy, 2002, p. 1). Therefore, categorisation
ability is considered to be critical for the organisation and stability of cognition (Mareshal \& Quinn, 2001). The ability to detect regularities in the environment and form categories emerges early in development. At the age of 3-4 months, infants already demonstrate the ability to differentiate categories of dogs and cats (Eimas \& Quinn, 1994), but also to form abstract perceptual categories (Bomba \& Siqueland, 1983). This ability becomes even more refined around ten months of age when infants become able to shape categories based on statistical regularities of category members (Younger \& Cohen, 1986).

In the domain of infant research, novelty preference is a standard method employed to explore categorisation processes. Typically, a familiarisation phase consisting of a set of training items (for instance members of two categories), is followed with a test phase where infants are presented with two novel items, one belonging to the familiarised category and one coming from a different category. Under the assumption of novelty preference, i.e. that infants look longer at the object that is perceived as less familiar, differences in looking times are interpreted as an index of category formation (e.g. Eimas \& Quinn, 1994). For instance, in a study exploring how infants form categories based on correlational feature structure, two test items are presented, one of them depicting an average of all presented items and the second object representing a subcategory average of one of two categories that could be formed (e.g. Plunkett et al., 2008). Infants who formed two categories demonstrated preference for the novel out-ofcategory overall average.

Despite the fact that processes of implicit, non-supervised category formation have been extensively studied in adults as well as in different patient populations (Reed, Squire, Patalano, Smith, \& Jonides, 1999), there have been few attempts to directly compare category learning processes in infants and adults. One recent computational model of categorisation offered an integrative account for infant and adult category learning (the SUSTAIN model, Gureckis \&

Love, 2004). Initially developed as a model of adult categorisation, the model proposes that mechanisms underlying infant and adult categorisation are not substantially different and assumes a continuous trajectory of conceptual development. Two explanations are offered to account for developmental differences - memory limitations and stimulus encoding limitations (Gureckis \& Love, 2004). In order to empirically test these assumptions, in the present study we developed an experimental paradigm for adults providing similar learning conditions as employed in the infant study. We aimed to address the question whether there are shared mechanisms of spontaneous conceptual organisation across the lifespan.

To parallel the visual familiarisation procedure used with infants, we designed a task to explore implicit category learning in adults where preferential looking was used as an index of category learning, and which provided similar learning conditions as those encountered in the infant study. As infants were merely presented with a set of objects, adults did not receive any explicit training or feedback on category formation. The adult task was also designed to tap into implicit, unsupervised category learning. As in the infant experiment, we presented adults with a series of objects as part of the familiarisation phase, followed by a test phase in which two test objects were presented and looking preferences were measured. Several studies using visual paired-comparison procedure with adults have shown that novelty preference can be used as an index of visual recognition in adults (Richmond, Colombo \& Hayne, 2007). As the magnitude of novelty preference increases with familiarisation time in object recognition (Richmond et al., 2007), we propose that the same effect can be interpreted as an index of category formation.

Even though the same type of experimental task was used with both infants and adults, there are inevitable differences in the demands to the two groups of participants this task poses. Task difficulty and memory demands might lead to differences in performance. One recent study has demonstrated the importance of learning conditions in altering categorisation in adult participants. Carvalho and Goldstone (2014) showed that category structure influences how efficiently category representations will be formed, and that this effect is tied to the way in which category members are presented. The authors conclude that there is categoryspecific attention allocation - simultaneous presentation promotes attention to commonalities among objects, while sequential presentation emphasizes differences among objects. These studies suggest that categorisation cannot be seen only as an extraction of abstract rules or computation of feature statistics, but emphasize that the dynamics of learning have an important role in category formation.

After discovering that adults and infants both showed categorisation, but at different rates (Experiment 1), we conducted Experiments 2 and 3 to investigate further which factors are relevant for categorsation in these cases. In order to explore how the context of learning affects category learning, we varied the task difficulty and investigated its
effects on categorisation in infants and adults. Our hypothesis was that decreasing the task demands will accelerate category formation in infants (Experiment 2), whereas adding an additional cognitive load to the task will delay category formation even in adults (Experiment 3).

## Experiment 1

The aim of the first experiment was to compare implicit category learning processes in infants and adults. In addition, we were interested in exploring the effects of the amount of training on forming categories based on statistical regularities, i.e. features correlations. Thus, three training blocks were interleaved with three blocks in which category formation was tested.

## Participants

Thirty-two 10-month-old infants took part in this study (two participants were excluded due to fussiness and refusal to look at the screen). Participants were recruited at the local maternity ward and all were full-term babies with no known health conditions. All participants came from homes where English was the only language spoken.

In addition, 24 adults took part in the experiment (mean age $=23.67$ years $(\mathrm{SD}=3.08)$ ). Two participants were excluded from the analyses (one due to calibration failure and one due to eye-tracker track loss).

## Stimuli

A set of novel objects was designed for the purposes of this study. Coloured and textured 3D looking objects represented novel creatures (called Sukis). As illustrated in Figure 1, each Suki consisted of four features: body, antennae, hands and legs. Each feature varied systematically on a scale of seven dimensions (body shape, number of antennae, hand size, length of legs), (see table 1). A set of 24 Sukis was designed in a way to resemble the structure of objects used in several categorisation studies (Younger \& Cohen, 1986; Plunkett et al., 2008; Mather \& Plunkett, 2011). Values of one feature were predictive for values on other dimensions, thus inviting participants to form two categories (defined as the narrow condition in Plunkett et al., 2008). However, the range of potential dimensions each feature can take was extended, thus instead of a range of 5 dimensions used in above mentioned studies, we introduced 7 potential variations of each feature.

Figure 1. Examples of the Sukis: Subcategory average objects

The reason for increasing the variability of the stimuli set is to have the possibility to create test items made of completely novel dimensions that have not been presented in any instance during the familiarisation phase. Four additional Sukis were designed to be presented as test items: an overall average object (consisting of mean values on each dimension, i.e. 4444), two subcategory averages (2222 and 6666). In addition, completely novel, out-of-category objects which comprised of the same features as all objects, but organized in a completely different manner were presented in the final trials of the test phase. All objects were depicted against a 5\% grey background.

Table 1: Stimulus structure (first familiarisation set)

| Stimulus | Category | Antenna | Hand | Body | Legs |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | 1 | 1 | 1 | 3 | 3 |
| 2 | 1 | 1 | 3 | 1 | 3 |
| 3 | 1 | 3 | 1 | 3 | 1 |
| 4 | 1 | 3 | 3 | 1 | 1 |
| 5 | 2 | 5 | 5 | 7 | 7 |
| 6 | 2 | 5 | 7 | 5 | 7 |
| 7 | 2 | 7 | 5 | 7 | 5 |
| 8 | 2 | 7 | 7 | 5 | 5 |

## Procedure

Infants After written consent was obtained from a carer, an infant was seated on a carer's lap approximately 50 cm from a $1920 \times 1080$ inch screen in a sound-proof experimental booth. The parent was asked to keep their eyes closed for the duration of the experiment. Data was recorded using a Tobii TX300 Eye Tracker with a 120 Hz sampling frequency and four point calibration. The study was run with a custom Matlab stimuli presentation software PresentMate based on the Psychophysics Toolbox. Infants' behaviour was monitored via a centrally-located camera above the screen. Trials were initiated by the experimenter when the infant was attending the screen. Each familiarisation block consisted of eight trials. Each trial started with a presentation of an animated star in the central location of the screen accompanied by a chiming sound for the duration of 2000 ms . Following this, one stimulus ( 500 x 500 pixels) was presented in the central location for 6000 ms . As a previous study has shown that the order in which stimuli are presented may affect category formation (Mather \& Plunkett, 2011), we calculated mean Euclidean distance (as an average of seven distances between consecutive objects) for all possible stimuli sequences (40320 sequences) and selected sequences that fall within the range between the 40 th and 60 th percentile ( 8112 sequences). Then, for each participant a particular sequence from this pool was randomly selected. Three test blocks were interleaved with learning blocks. In each test, after an attention getter was presented for 2000 ms , two test objects were presented simultaneously for 10000 ms . The first two
trials were category formation test trials in which the overall category average (object 4444) and a subcategory average object ( 2222 or 6666 ) were presented. The positions of the two objects were counterbalanced across the two trials. The third test trial was always a novelty preference test in which one of the learning items from the previous learning phase was presented along with the novel, previously unseen out-of-category object. The purpose of this trial was to check whether infants were engaging in the task and expressing the expected novelty preference. The choice of the subcategory average object ( 2222 or 6666 ) presented in a particular test block was balanced across test blocks. The third test block was identical to the first test block for half of the participants, whereas others saw identical items as in the second test block. Which subcategory average object was presented first was counterbalanced across participants.

Adults Participants were instructed they would take part in a free viewing task so their only task would be to look at the objects presented on the screen. After written consent was obtained, participants were seated in front of the eye-tracker and their eye-movements were recorded using 120 Hz tracking frequency. Upon completion of the experiment, none of the participants reported they were aware what the purpose of the experiment was. The experimental design was kept as similar as possible to the infant version. Participants were presented with 3 blocks of training, each consisting of 8 trials. Each trial started with a centrally presented fixation cross for 500 ms followed by a presentation of a training items for the duration of 2000 ms . Training blocks were interleaved with test blocks. Analogous to the infant version, each test consisted of two categorisation test trials and a novelty preference trial. After the fixation cross was presented for 500 ms , test trials were presented on screen for 3000 ms .

## Results: Infants

Category Formation Test For category formation test trials, preference scores were calculated for all trials by dividing looking at the overall average object by total looking time to the overall and modal object. A repeatedmeasures ANOVA with factors Block (1, 2 and 3 ) and Test (1 and 2) showed no significant effects (all $\mathrm{ps}>0.05$ ) ${ }^{1}$. Planned comparisons against chance were performed for each test. Infants expressed a preference for the overall average object in the second trial of the second test block $(\mathrm{t}(25)=1.99, \mathrm{p}<0.05)$, (Figure 2).

Novelty Preference Test To validate that infants' behaviour was driven by novelty preference, infants were presented with the novelty preference test after each category formation test block. Infants' looking to the novel object was divided by the total looking time and a one-way

[^511]ANOVA with Block as a within-subjects factor revealed no effect of Block. Planned comparisons showed that infants' preference for the novel object differed from chance only in the second block $(\mathrm{t}(26)=2.58, \mathrm{p}<0.05)$.

Figure 2: Looking preferences in test

## Results: Adults

Category Formation Test Looking preference scores were calculated in the same way as for infants. The proportion of looking toward the overall average object was divided by the total looking time to both overall and modal objects. A repeated measures ANOVA with the within-subject factors Block and Trial revealed a significant main effect of Block ( $\mathrm{F}(2,44)=3.07, \mathrm{p}=0.05)$. Planned comparisons against chance revealed that preference towards overall average was significant only in the first block $(\mathrm{t}(22)=2.07, \mathrm{p}=0.05)$, whereas in the remaining does not significantly differ from chance ( $\mathrm{p}>0.05$; Table 2).

Novelty Preference Test Participants exhibited preference for the out-of-category object in all three novelty preferences tests (no difference was found between 3 novelty preference trials).

Table 2: Mean looking preferences on test (Experiment 1, Adults, SDs provided in brackets)

| Block | Test | Novelty |
| :---: | :---: | :---: |
| 1 | $0.55(0.17)^{*}$ | $0.67(0.22)^{*}$ |
| 2 | $0.51(0.13)$ | $0.67(0.18)^{*}$ |
| 3 | $0.47(0.17)$ | $0.61(0.20)^{*}$ |

## Experiment 1: Discussion

Results of Experiment 1 have shown that both infants and adults show evidence of category formation based on feature correlations in a free viewing task. In addition, this experiment revealed that paradigms based on novelty preference might be a useful tool in studying non-supervised category learning in adults. The results also showed that infants were slower in forming categories requiring a greater amount of familiarization to demonstrate similar level of
performance as adults. The observed differences in the performance might be due to various factors related to developmental differences. We hypothesize that one of the main factors driving these differences are memory demands. In order to compare an item presented during familiarisation with a previously presented one, information about the former items needs to be kept active in the working memory for comparison with the currently presented item. This might result in slower category formation in infants as it takes more resources to perform in this task due to limited memory abilities.

In order to test this hypothesis, we conducted the second experiment in which we decreased memory demands of the task by presenting familiarisation items in pairs. We hypothesized that, if memory load is reduced, infants will be faster in extracting category information.

## Experiment 2

## Participants

Twenty-eight 10 -months old infants took part in this study (two infants were excluded from the later analyses due to failing to reach minimum amount of looking time during familiarisation).

## Stimuli and procedure

The stimuli set used in this experiment was identical to the one in Experiment 1. As opposed to sequential presentation in the first experiment, familiarisation items were presented in pairs. A total of four trials were presented in each learning block. Following the presentation of an attention getter, two objects were presented simultaneously for 12 000 ms . Pairs of objects were selected based on sequences used in the sequential condition. Namely, each sequence used in Experiment 1 had a corresponding paired sequence in Experiment 2. It is important to note that despite the difference in the number of trials in each learning block, the total duration of learning blocks was identical across the two experiments.

## Results

Category Formation Test For category formation test trials, preference scores were calculated for all trials by dividing looking at the overall average object by total looking time to the overall and sub-category average object. A repeated measures ANOVA with factors Block (1, 2 and 3 ) and Test (1 and 2) revealed a main effect of Block ( $\mathrm{F}(2$, 36 ) $=3.15, \mathrm{p}<0.05$ ) (only participants who contributed to all trials were included in this analysis, $\mathrm{N}=19$ ). As there was no main effect of Trial, we averaged performance in the two test of the same block and performed planned comparisons. Performance in each block was compared against chance and we found that preference for the overall average object was significantly above the chance in the first block
$(\mathrm{t}(25)=2.91, \mathrm{p}<0.01)$, whereas in the remaining two blocks preference did not significantly differ from chance (mean preference values and dispersion are depicted in Table 3).

Novelty Preference Test To validate that infants' behaviour in test trials was driven by novelty preference, following each category formation test block, infants were presented with the novelty preference test. A one-way ANOVA with Block as a within-subjects factor revealed a near significant effect of Block (Greenhouse-Geiser $\mathrm{F}(2,38)=0.76$, $\mathrm{p}=0.06$ ). Planned comparisons revealed that infants' preference for the novel object differed from chance only in the first block (Wilcox signed rank test: $\mathrm{V}=242, \mathrm{p}<0.05$ ).

Table 3: Mean looking preferences on test (Experiment 2,

| SDs provided in brackets). |  |  |
| :--- | :--- | :--- |
| Block | Test | Novelty |
| 1 | $0.57(0.12)^{*}$ | $0.63(0.26)^{*}$ |
| 2 | $0.46(0.18)$ | $0.48(0.29)$ |
| 3 | $0.49(0.14)$ | $0.60(0.27)$ |

## Experiment 2: Discussion

Experiment 2 revealed that the dynamics of infants' category formation can be shaped by varying the parameters of the learning context. Decreasing memory demands in the task leads to a boost in extracting category relevant information. Infants' faster learning was also resembled in the fact that they demonstrated novelty preference already in the first test. Diminished novelty preference in the following tests and well as a larger attrition rate suggests that infants learned faster and then disengaged from the task. We conducted Experiment 3 to investigate whether increasing memory demands would lead to a decrease in the speed of category formation in adult participants. For the purpose of investigating implicit category learning in adults we adapted the N-back task, which is typically used in studies of working memory. Infants in the sequential condition were presented with one object at a time and had to mentally compare objects that were presented. Thus, we used a 1back version of the task and investigated whether participants spontaneously form categories under higher cognitive load conditions. If this incidental categorisation occurs, we expect that participants will judge betweencategories pairs faster than they would judge withincategory comparisons. Having perceptual similarity and semantic distance between to-be-compared items controlled, we predict that differences in the discrimination speed might reflect processes of categorisation.

## Experiment 3

## Participants

Twenty-four participants, students at Oxford University took part in this study (mean age $=23$ years $(\mathrm{SD}=2.54)$ ).

All participants were right handed and had normal or corrected-to-normal vision. Prior to taking part in the experiment, all participants signed an informed consent and upon experiment completion received course credits for their participation.

## Stimuli and Procedure

An identical stimuli set to the one in Experiments 1 and 2 was used in this study. The experiment consisted of seven blocks. Each block had two parts. A total of 36 learning trials were presented in the first part, and 10 test trials in the second part of each block. The order of presentation was pseudorandomised within each block. In order to balance the number of "identical" and "different" responses, participants were instructed to give a response only for probed trials, where a red dot would appear in the centre of the screen. In the learning part, there were 16 "different" comparisons (and an equal number of "identical"), half of which were within category, whereas the other half crossed the category boundary. In the test part, there were four "identical" and four "different" comparisons. While visual similarity and semantic distance (expressed through Euclidean distance) between the two compared objects was identical, some pairs crossed the category boundary (33335555), one pair was on the boundary (4444-6666) and some pairs were within the same category (1111-3333, 55557777).

## Results

In order to explore whether there is a difference in reaction times for between and within category judgments during the course of the experiment, growth curve analysis (Mirman, 2014) was used. Mean reaction times in each test block are presented in the Figure 3. The reaction time in mismatch trials were modeled using a linear growth curve model with a fixed effect of mismatch type (within-category and between-categories comparison) on the intercept and slope terms and random effects of participants on the intercept and slope to model individual differences in initial speed and rate of change. The fixed effect was added to the base model and its' effect on model fit was evaluated using model comparisons. All analyses were carried out in R version 3.3.1 using the lme4 package (version 1.1-12). There was a significant effect of mismatch type on the intercept $\left(\chi^{2}(1)=4.13, p<0.05\right)$ suggesting that participants responded faster when comparing items from different categories as opposed to performing within-category comparisons. This result suggests that participants organised items into two separate categories which resulted in making members of the same category look more similar than items belonging to different categories, even though perceptual similarity for both types of comparisons was identical.

Figure 3. Mean reaction time across 7 test blocks

## General Discussion

Taken together, the results of the experiments reported in this paper demonstrate how changing parameters of the learning context affect the dynamics of category learning in infants and adults. Experiment 1 provided evidence that both infants and adults can form categories in a free-viewing task, though it takes a different amount of exposure to succeed. Infants showed evidence of category formation after two blocks of familiarisation, whereas adults reached a similar level already after one training block. In addition, this experiment suggests that experimental paradigms based on novelty preference, the standard approach in infant research, can be used to explore non-supervised category learning in adult population as well.

Findings obtained in the second and the third experiment suggest that changing the task difficulty can accelerate (Experiment 2) or decelerate (Experiment 3) the process of extracting category relevant information for infants and adults, respectively. That the task structure can modulate infants' learning is further confirmed by the significant interaction between Experiment (1 and 2) and Block (1, 2 and 3 ) in a combined analysis $(F(2,66)=4.518, \mathrm{p}<0.05)$. The finding that paired presentation leads to faster category formation in infants is consistent with existing literature suggesting positive effects of comparison on learning and memory (Oakes \& Ribar, 2005). In addition, the results of Experiment 3 with adults also suggest that increasing the load impedes category formation. Initially developed to explain cross-modal effects of labels on categorisation, the perceptual load hypothesis can also offer a way of interpreting the obtained results (Plunkett, 2010). This hypothesis assumes that extraction of statistical information during category formation is also dependent on the perceptual load required to process individual stimuli and not exclusively on the feature correlations alone. Paired presentation may represent an optimal amount of available information for category formation in infants. Alternatively, it might be the case that the invitation to compare stimuli is contributing to the modulations of category learning. Future research needs to explore does manipulating load in other ways would result in a similar modulations of learning timecourse.

# Early produced signs are iconic: Evidence from Turkish Sign Language 

Beyza Sümer (bsumer@ku.edu.tr)<br>Koç University, Turkey<br>\author{ Clara Grabitz (c.grabitz@student.ru.nl)<br><br>Donders Institute for Brain, Cognition, and Behaviour, Radboud University Nijmegen, The Netherlands }

#### Abstract

Motivated form-meaning mappings are pervasive in sign languages, and iconicity has recently been shown to facilitate sign learning from early on. This study investigated the role of iconicity for language acquisition in Turkish Sign Language (TID). Participants were 43 signing children (aged 10 to 45 months) of deaf parents. Sign production ability was recorded using the adapted version of MacArthur Bates Communicative Developmental Inventory (CDI) consisting of 500 items for TID. Iconicity and familiarity ratings for a subset of 104 signs were available. Our results revealed that the iconicity of a sign was positively correlated with the percentage of children producing a sign and that iconicity significantly predicted the percentage of children producing a sign, independent of familiarity or phonological complexity. Our results are consistent with previous findings on sign language acquisition and provide further support for the facilitating effect of iconic form-meaning mappings in sign learning.

Keywords: Iconicity, language acquisition, sign language

## Introduction

Arbitrariness, lack of a motivated link between a linguistic form and its meaning, has long been considered as a design feature of human language (de Saussure, 1915, 1983; Hockett, 1960). However, recent evidence has shown that iconicity, resemblance between form and its referent, is a more pervasive feature of language than previously thought (e.g., Perniss, Thompson, \& Vigliocco, 2010; Dingemanse, Blasi, Lupyan, Christiansen, \& Monaghan, 2015). For example, ideophones are used to express a wide range of features such as manner of movement, color, shape, size of an object, or emotional and psychological states (e.g., Japanese words 'korokoro' to refer to a light object rolling repeatedly and 'gorogoro' to a heavy object rolling repeatedly) or onomatopoeic words, which use the sound of a word to depict the sound of its referent (e.g., "moo" to refer to a cow) (e.g., Imai \& Kita, 2014). Compared to spoken languages, the use of visual-spatial modality makes iconicity a more prominent feature in sign languages (e.g., Taub, 2001). Signers can, for example, use a curved handshape to refer to a cup or use the signing space in front of them to show the location of different objects in relation with each other.
Pervasive existence of iconic forms in languages has intrigued many researchers about its role in language development. Accumulating evidence has shown that iconicity has a facilitating effect for early language
development. Imai, Kita, Nagumo, \& Okada (2008) reported an advantage for 3-year-old Japanese acquiring children in learning action words when these words are sound-symbolic compared to those which are arbitrarily linked to the sound of the action. In another study, 2.5-year-old children showed a tendency to match the words with rounded vowels to rounded shapes and words with unrounded vowels to pointed shapes (Mauer, Pathman, \& Mondloch, 2006). Onomatopoeic words constitute a substantial portion of early acquired vocabulary by German speaking children (Laing, 2014). Also, early acquired words in English and Spanish were rated more iconic than the ones acquired later (Perry, Perlman, \& Lupyan, 2015; Massaro \& Perlman, 2017).
The potential effects of iconicity have also been explored in the context of sign language acquisition research although in fewer studies compared to spoken language research. To understand the role of iconic nature of linguistic forms in sign languages, Orlansky \& Bonvillian (1984) analyzed whether the first signs learned by signing children were more iconic, but their initial analyses did not find an overrepresentation of such signs in the first 10 words and beyond. In their data, only about a third of words were iconic, which was in line with the overall proportion of iconic signs in American sign Language (ASL). In contrast, Lloyd, Loeding, \& Doherty (1985) reanalyzed the data based on a broader definition of iconicity and found an over-representation of iconic signs in early acquired signs. Since then it has become clear that iconicity is a more complex property rather than being a holistic concept, and it is now common to rate the iconicity of signs on a scalar scale of 1 (not at all iconic) to 7 (highly iconic) (e.g., Vinson, Cormier, Denmark, Schembri, \& Vigliocco, 2008 for BSL norms). However, iconicity of signs can also differ qualitatively in meaningful ways: for example, signs can represent actions or perceptual qualities of their referents (see Thompson et al., 2011; Ortega, Sümer, \& Özyürek, 2016). Under this new view of iconicity, recent studies with signing children have shown that iconicity has a predictive power in early sign learning, i.e., iconic signs are acquired earlier than non-iconic signs (Thompson, Vinson, Woll, \& Vigliocco, 2012; Caselli \& Pyers, in press). Thompson and colleagues (2012) explored the relationship between iconicity and sign language acquisition using a mixed cross-sectional, longitudinal design on productive and comprehensive vocabulary size of British Sign Language (BSL) acquiring deaf children
of deaf parents administering the MacArthur Bates Communicative Developmental Inventory (CDI). The CDI is a parental report in which parents indicate vocabulary learning by ticking items on a list of words if their child produces or understands them (Fenson, Dale, Reznick, Bates, Thal, \& Pethick, 1994). They collected data from 31 deaf children aged between 8 and 30 months and found that iconicity facilitates sign learning from early development on, but particularly in children older than 21 months. They argue that the advantage seen in older children could be due to more cognitive capacity or more environmental experience which children can use to understand and establish such iconic links between meaning and form.
It has also been proposed that other properties of a sign may be as or even more important than iconicity such as lexical frequency (i.e., familiarity), neighborhood density (i.e., the number of lexical items that are phonologically related to a target), or phonological complexity (Caselli \& Pyers, in press; Thompson et al., 2012). Phonological complexity in sign language is based on motoric subunits and seems to be a crucial factor because children learning a sign language show phonological reductions and substitutions of features that are marked less - similar to children learning a spoken language (e.g., Meier et al., 2008). To what extent these factors are influential on early sign learning is also controversial since Thompson et al. (2012)'s results indicate iconicity to be a more powerful predictor than other factors such as familiarity or phonological complexity, while Caselli and Pyers (in press) argue that neighborhood density and lexical frequency (familiarity) are also as strong contributors as iconicity in early sign development.
Studies with signing and speaking children provide converging evidence on the facilitating role of iconic form-meaning mappings in early lexical development regardless of the language modality. Investigating the effects of iconicity in sign language acquisition provides further evidence for this "modality-free" role of iconic forms in this domain of language development and contributes to our understanding on to what extent general principles of conceptual development influence the language development in signing children - a less studied population compared to speaking children.

## The Present Study

The aim of the current study was to add to the growing literature on the role of iconicity in sign language acquisition by studying children acquiring TID, which has been studied less than many Western sign languages such as ASL or BSL. Analyzing data from other sign languages is crucial, because conflicting views on the role of iconicity in sign language acquisition still exist (e.g. Thompson et al., 2011). Based on Thompson et al. (2012) and Caselli \& Pyers' (in press) findings, we assumed that the visual-spatial modality of sign language, which is rich in iconic form-meaning mappings, would modulate language acquisition and that iconicity could present a potential advantage in early
language development for TID acquiring children. We hypothesized that the iconicity of a sign would be correlated with the percentage of children producing the sign. We further expected iconicity to be a significant predictor of the percentage of children producing a sign, even if after controlling for familiarity and sign complexity.

## Method

## Design

The experiment was realized with a correlational design. Simultaneous multiple regression was used to test whether different sign characteristics (iconicity, familiarity and phonological complexity) were good predictors for the percentage of children producing a sign.

## Participants

Data were collected for 27 deaf children of deaf parents and 16 hearing children of deaf parents (i.e., CODAs), thus for a total of 43 children (female 28) born to deaf families and exposed to TID from birth. Where possible, parents participated in data collection at two separate time points, with a 3-month interval, thus increasing our data set to a total of 57 . Although CDI typically tracks vocabulary development in children between 8-36 months of age, the age of the children in the current study ranges between $10-45$ months ( $M=25.98, S D=10.23$ ) to increase sample size. The majority of children were from families with a middle or upper socio economic status, meaning that at least one parent works in a paid job and completed high-school education.

## Procedure

Data were elicited from a version of the MacArthur Bates Communicative Developmental Inventory (CDI) adapted for TID. In this version, three source tests were taken into consideration to account for modality and cultural specific issues: ASL CDI (Anderson \& Reilly, 2002), BSL CDI (Woolfe, Herman, Roy, \& Woll, 2009) and Turkish CDI (TIGE, Aksu-Koç, Küntay, Acarlar, Maviş, Sofu, Topbaş, \& Turan, 2009). As a result, TID CDI consists of 500 items grouped into 18 categories such as "animals", "toys" and "actions".
Although previous CDIs, both for sign and spoken languages, were administered in a pen-and-paper format, considering low reading abilities of deaf people (e.g., Bloomquist Traxler, 2000), we presented TID CDI in a web-based format where parents themselves logged onto the system to see videos of signs one after each other and decided whether their children produced the sign in the video. This procedure was preceded by a training session in which they saw instruction videos in TID and asked any clarification questions to a deaf assistant, who was also online during entire training session. Only sign production data was collected since a small pilot study with a group of deaf parents showed that it was often confusing to differentiate comprehension versus production of a sign for them. They also expressed that they were less sure about their answers regarding
comprehension since they cannot see comprehension but only production of the signs.
As part of another study (Taşçı \& Sumer, in prep), 4 deaf signers of TID $\left(\mathrm{M}_{\text {age }}=32.3\right)$ were shown a total of 328 signs on a computer screen and asked how iconic they think these signs are. Here, the iconicity was defined as the similarity between the linguistic form (i.e., sign) and the entity that it refers to, including both the perceptual and/or action-based properties. In another session, 5 deaf signers ( $\mathrm{M}_{\mathrm{age}}=33.4$ ), were asked how familiar they think these signs are. Both iconicity and familiarity ratings were on a scale of 1 (not at all iconic/familiar) to 7 (highly iconic/familiar) (e.g. see Vinson et al., 2008 for norms in BSL for comparison). We additionally included phonological complexity ratings following Mann, Marshall, Mason, \& Morgan (2010), in which three main phonological parameters of signs (i.e., handshape, location, movement) were assigned a complexity value. For example, unmarked handshapes in TID, as determined by Kubus (2008), were rated less complex than other handshapes.

## Results

We excluded data points with unrealistic productive sign scores aged 10 to 20 months, if they were outside the Mean plus Standard Deviation found for ASL norms (Anderson \& Reilly, 2002) for the child's age range. These sign scores can be attributed to a misunderstanding during data collection. Exceptionally high sign scores were not excluded for children aged older than 20 months, as high variability is a key component of language acquisition. Thus, we included a total of 51 data points in our analyses. The productive sign score for the subsample of 104 signs was $(M=51.27, S D=32$ ) (Table $1)$.

Table 1. General descriptive statistics after excluding outliers ( $N=51$ )

| Age | Total Productive <br> sign score | Subset Productive <br> sign score |
| :---: | :---: | :---: |
| $10-45$ | $1-500$ | $0-104$ |
| $M=27.45$ | $M=215.49$ | $M=51.27$ |
| $S D=9.74$ | $S D=154.56$ | $S D=32$ |

$N=$ Sample size, $M=$ Mean, $S D=$ Standard deviation
Each sign was on average produced by $44 \%$ of children ( $M=0.44, S D=0.18$ ). Spearman's correlation between age and subset productive sign score was significant ( $r_{s}$ $=.54, p<.001$ ).

Figure 1. Spearman's correlation between subset productive sign score and age in months. Linear trend lines included.

Iconicity, familiarity and complexity scores of 104 signs were available and used for further analyses (Table 2).

Table 2. Sign ratings and descriptive statistics for the subset of 104 signs

| Iconicit <br> $\mathbf{y}$ | Familiarit <br> $\mathbf{y}$ | Complexit <br> $\mathbf{y}$ | Mean Age <br> $\mathbf{o f}$ <br> Productio <br> $\mathbf{n}$ | PerPro <br> $\mathbf{d}$ |
| :---: | :---: | :---: | :---: | :---: |
| $1-7$ | $2-7$ | $0-2$ | $4-27$ | $.11-.84$ |
| $M=5.15$ | $M=6.16$ | $M=.64$ | $M=15.13$ | $M=.44$ |
| $S D=$ <br> 1.89 | $S D=.91$ | $S D=.67$ | $S D=5.84$ | $S D=.18$ |

$M=$ Mean, $S D=$ Standard deviation, Mean Age of Production = mean age of children capable of producing a sign, PerProd $=$ percent of children capable of producing a sign

Spearman's correlations were carried out to clarify the relationship between the main variables in the study (Table 3). Mean Age of Production and Percentage Producing were highly positively correlated and therefore only percentage of production was used for further regression analyses. Iconicity $r_{s}=.38, p<.001$ and familiarity ratings $r_{s}=.32, p=.001$ were both significantly positively correlated with Mean Age of Production and Percentage Producing. However, iconicity and familiarity ratings were not correlated. Phonological complexity was not correlated with Mean Age of Production and Percentage Producing and was also unrelated to iconicity and familiarity ratings.

Table 3. Spearman's correlations between the main variables in the study

|  | PerProd | Icon | Fam | Complexity |
| :--- | :--- | :--- | :--- | :--- |
| Mean Age of <br> Production | $1^{* *}$ | $.39^{*}$ | $.32^{*}$ | -.13 |
|  |  | $*$ | $*$ |  |
| Percentage <br> Producing |  | $.38^{*}$ | $.32^{*}$ | -.13 |
| Iconicity |  |  | .13 | -.18 |
| Familiarity |  |  |  |  |
| Complexity |  |  |  |  |
| $\leq .005$, PerProd = Percentage of children capable of |  |  |  |  |
|  |  |  |  |  |

Figure 2. Spearman's correlation between iconicity ratings and percentage of children producing a sign. Linear trend line included. $r_{s}=.38, p<.001$.

Figure 3. Spearman's correlation between familiarity ratings and percentage of children producing a sign. Linear trend line included. $r_{s}=.32, p=.001$.

The data were entered into simultaneous multiple regression analysis, using the percentage of children producing a sign as dependent variable and iconicity, familiarity and complexity as predictors. The results for the model indicate that the predictors explained $17 \% R^{2}=$ $.17, F(3,100)=7.84, p<.001$. Both iconicity $\beta=.31$, $t(100)=3.38, p=.001$ and familiarity $\beta=.25, t(100)=$ $2.78, p=.006$ significantly predicted the percentage of children producing a sign. Phonological complexity was not a significant predictor. Adjusted R Squared values were used in the analysis.

## Discussion and Conclusion

We investigated the role of iconicity in the acquisition of Turkish Sign Language (TID) by signing children of deaf parents and found that the iconicity of a sign was positively correlated with the percentage of children producing a sign. In addition to iconicity, familiarity, but not phonological complexity, seems to be influential in early sign learning. We thus provide further evidence regarding the facilitating role of iconicity in early sign learning by signing children.

Our results converge with what previous studies with signing children have found so far (Thompson et al., 2012; Caselli \& Pyers, in press). There is robust evidence showing that early acquired signs are iconic, which suggests that resemblance between form and meaning in sign languages bootstraps word learning in sign languages. Moreover, analyzing parental input to BSL signing children aged between $25-51$ months, Perniss, Lu , Morgan, \& Vigliocco (2017) suggest that deaf parents exploit iconicity while communicating with their children. These studies also show that iconicity seems to be more advantageous for sign language acquiring children when they are at around 30 -months of age although this age group is called "older" in Thompson et al. (2012) and "younger" in Caselli \& Pyers (in press). This seems to be related to increasing cognitive skills or more experience with environment that enables establishing the link between linguistic form and meaning (Thompson et al., 2012).
Further evidence from spoken languages, which are less rich in iconic forms than sign languages (Taub, 2001), has been presented about the facilitating role of iconicity, as well (e.g., Imai \& Kita, 2014; Imai et al., 2008; Laing, 2014; Perry et al., 2015; Massaro \& Perlman, 2017). The effect of iconicity in early word acquisition in spoken languages seems to be more prominent earlier compared to what studies with signing children report. Studying expressive and receptive vocabulary development in the first four years of English acquiring children (6-47 months of age), Massaro and Perlman (2017) show that iconicity is more prevalent early in acquisition and decreases with increasing age and vocabulary size. There might be a difference in the role of iconicity throughout development due to different modalities of sign and spoken languages: sign languages are rich in iconic forms and signing children are more likely to encounter iconic forms - not only at the lexical level but also at the level of morphology (e.g., classifiers) and syntax (e.g., expressing spatial relations in signing space) than speaking children whose lexicon gets enriched with less iconic words (more arbitrary forms) as they get older. Therefore, iconicity seems to help children in their early word learning, but its role might change as children acquiring languages in different modalities advance in their language development.
Our results regarding other factors than iconicity such as familiarity and phonological complexity are partially in line with Thompson et al. (2012), who found iconicity to be a stronger predictor of early sign acquisition than others. The current study, on the other hand, reveals the role of familiarity as important as iconicity, which is in line with Caselli \& Pyers (in press). The findings regarding the role of phonological complexity do not suggest that it predicts early sign learning - as opposed to Caselli \& Pyers (in press). The difference might come from different definition of complexity since Caselli \& Pyers (in press) focused on neighborhood density (the number of lexical items that are phonologically related to a target) rather than a complexity rating system as used in the current study. Thompson et al. (2012) also
observed an effect of phonological complexity, but this effect was restricted to younger children (11-20 months of age) only while Caselli \& Pyers (in press) found the neighborhood density effect across all age groups (8-35 months of age). This might be still a result of different approaches taken to the analysis of phonological complexity in different studies.
However, one needs to be careful when interpreting our findings as the sample size was small and we had to exclude multiple outliers for the main analyses. Furthermore, only production scores were collected. Since comprehension scores are less prone to phonological and motor constraints, drawing conclusions from production scores only may underestimate the role of iconicity, especially for younger children who produce substitution errors while producing signs (e.g., Lu, Jones, \& Morgan, 2016).
It is also important to note that iconicity and familiarity ratings were mostly available for nouns which could have further skewed our sample as some of the first words were "come" or "kiss". Perry et al (2015)'s results from English and Spanish suggest that adjectives are rated as more iconic than nouns and function words, and verbs as more iconic than nouns and function words in English. Perniss et al. (2017), however, found that signs for objects and actions are rated more iconic than those for properties (e.g., blue, fast). This might be the result of modality difference between sign and spoken languages and underlines the importance of including different lexical categories in such an analysis.
Additionally, the current study is clearly limited by the correlational approach taken. With sufficient resources a Bayesian modelling approach similar to Thompson et al. (2012) or a mixed-effect logistic regression modelling approach will be more powerful as one can simultaneously account for child-specific and itemspecific variability while controlling for factors such as familiarity or phonological complexity. The current data set could be used as a basis for further analyses, but it will also be beneficial to collect iconicity and familiarity ratings for more signs, in particular for signs that are action related and represent a wider range of familiarity ratings.
Finally, the present study is clearly limited by the use of parental reports - spontaneous production sessions that target sign and speech output and/or recordings of the children that are scored will be useful to further qualify results, particularly in regard to underlying mechanisms and driving forces. Innovative approaches towards testing are needed, such as Perniss et al. (2017) who analyzed child directed signing using only the parents in an experimental setting and showed that child-directed signing exploits iconicity, especially when referents are not present. Such studies will further qualify the input that signing children receive and might be decisive in determining the real importance of iconicity for language acquisition.
Our study represents a further step on the way exploring iconicity in relation to sign language acquisition. While we do not agree with the notion that only cognitive
development drives language acquisition based on our results, iconicity cannot explain all aspects of early sign language acquisition. Acquisition of these signs is likely to be driven by contextual factors such as use of frequency (with both adults and children) or neighborhood density (Caselli \& Pyers, in press).
In summary, language acquisition is likely to be facilitated by iconicity. Considering the potential benefit of meaningfully motivated form-meaning for language acquisition in general, both iconicity and arbitrariness should be re-evaluated as general properties of a language (Perniss et al., 2010), although more studies are needed to further support this claim and its relevance for all languages.

## Acknowledgments

This work has been supported by Tubitak 2236 (Cofunded Brain Circulation Scheme) awarded to the first author. We thank deaf families who kindly agreed to participate in the study and our deaf assistants Sevinç Akın for her help with data collecting.

# A Minimal Neural Network Model of The Gambler's Fallacy 

Yanlong Sun (ysun@tamhsc.edu)

Hongbin Wang (hwang@tamhsc.edu)<br>Center for Biomedical Informatics, Texas A\&M University Health Science Center Houston, TX 77030 USA

#### Abstract

The gambler's fallacy has been a notorious showcase of human irrationality in probabilistic reasoning. Recent studies suggest the neural basis of this fallacy might have originated from the predictive learning by neuron populations over the latent temporal structures of random sequences, particularly due to the statistics of pattern times and the precedence odds between patterns. Here we present a biologically-motivated minimal neural network model with only eight neurons. Through unsupervised training, the model naturally develops a bias toward alternation patterns over repetition patterns, even when both patterns are equally likely presented to the model. Our analyses suggest that the way the neocortex integrates information over time makes the neuron populations not only sensitive to the frequency signals but also relational structures embedded over time. Moreover, we offer an explanation for how higher-level cognitive biases may have an early start at the level of sensory processing.

Keywords: gambler's fallacy; alternation bias; waiting time; temporal integration; predictive learning.

## Introduction

The gambler's fallacy-a belief that chance is a self-correcting process where a deviation in one direction would induce a deviation in the opposite direction-has been a notorious showcase of human irrationality in probabilistic reasoning (Tversky \& Kahneman, 1974). For decades, this fallacy is thought to have originated from a cognitive bias called the "representativeness heuristic", which is attributed to the belief of the "law of small numbers" that small samples are highly representative of the populations from which they are drawn (Gilovich, Vallone, \& Tversky, 1985; Tversky \& Kahneman, 1974).

Recent development in neuroscience and computational models suggests that the human mind develops structured probabilistic representations about the world and performs nearoptimal Bayesian inferences (Pouget, Beck, Ma, \& Latham, 2013; Tenenbaum, Kemp, Griffiths, \& Goodman, 2011). For example, representativeness has been defined with a Bayesian belief-updating structure in which different hypotheses are evaluated based on different sets of the input data (Gigerenzer \& Hoffrage, 1995; Griffiths \& Tenenbaum, 2001). However, it remains elusive how the structured hypothesis space has originated in the first place, and how cognitive biases can arise from normative probabilistic models.

On the topic of randomness perception, there has been a growing speculation that people's intuition about random process, also known as the subjective randomness, is biased by the statistical structures in the learning environment (Budescu, 1987; Falk \& Konold, 1997; Hahn \& Warren, 2009; Lopes \& Oden, 1987; Nickerson, 2002; Oppenheimer \& Monin, 2009; Oskarsson, Van Boven, McClelland, \& Hastie, 2009; Sun,

Tweney, \& Wang, 2010). Particularly, we have argued that without a predefined hypothesis structure, biases underpinning the gambler's fallacy can emerge by simply capturing the temporal relations between patterns as a random process unfolds over time (Sun \& Wang, 2010a, 2010b, 2012, 2015). With a biologically realistic simple recurrent model that learns to reencode sequential binary data through unsupervised learning, we show that dissociation of random patterns can naturally emerge as the consequence of inhibitory competition between overlapped representations (Sun et al., 2015). Our findings indicate that cognitive biases in overt behavior can emerge early and locally at the level of sensory processing, and neurons' sensitivity to the temporal structures in the learning environment is the key in bridging the gap between neurons and behavior.

In the following, we first introduce some basic normative measures on the time of random patterns. Then, based on the neural model we reported earlier, we present a minimal neural network model with only eight units. We will show that this minimal model can mostly replicate our previous findings and provide new insights regarding the neural encodings of sequential patterns.

## Temporal Distance between Patterns

In sequences generated by a random process, there can be fundamentally different types of statistical structures regarding how often a pattern occurs and when a pattern is to occur. Our previous works have been focusing on the distinction between the mean time statistic that measures how often the pattern occurs in a global sequence, and the waiting time statistic that measures when a pattern will first occur since the beginning of the observation. Here we introduce a more compact yet more comprehensive framework that incorporates not only both types of statistics for individual patterns but also the statistics depicting the relational structures between different patterns.

To compute the temporal distances between different patterns with different initial states, we use the first-order dependent Markov chains parameterized by the probability of alternation $\left(p_{A}\right)$ between consecutive trials and the corresponding generating functions (Figure 1). ${ }^{1}$ Define $E\left[T_{j \mid i}\right]$ as the expected number of transitions from the initial state $i$ until the

[^512]

Figure 1: Markov chains for generating the waiting times $E\left[T_{\mathrm{HH} \mid \varnothing]}\right]$ and $E\left[T_{\mathrm{HT} \mid \varnothing}\right]$ given the initial empty state $\varnothing$ (Figure $\mathbf{A}$ ), and the additional times $E\left[T_{H \mathrm{H} \mid \mathrm{H}}\right], E\left[T_{\mathrm{HT} \mid \mathrm{H}}\right]$, and $E\left[T_{\mathrm{T} \mid \mathrm{H}}\right]$, given the same initial state $H$ (Figure B). In each chain, states $S_{j \mid i}$ represent all possible sequences that start from the pattern $i(i=\varnothing$ means starting anew) and end with the first arrival of the pattern $j$. States $M_{k}$ represent all possible sequences that end with the pattern $k$ but do not contain the expected pattern $j$. Transitions between nonempty states are labeled as either repetition (R) or alternation (A). Figure $\mathbf{C}$ : Pairwise precedence odds between patterns when the probability of alternation $p_{A}=1 / 2$, for example, the odds are 3 to 1 that one is to first encounter TH than to first encounter HH .
first arrival of the pattern $j$. When the initial state is empty $i=\varnothing$ (i.e., the counting process starts anew), $E\left[T_{j \mid \varnothing}\right]$ is referred to as the waiting time of pattern $j$. For example, from Figure 1A, the waiting times for the patterns HH and HT are respectively,

$$
\begin{align*}
& E\left[T_{\mathrm{HH} \mid \varnothing]}=1+\frac{1}{2 p_{A}}+\frac{2}{1-p_{A}},\right. \\
& E\left[T_{\mathrm{HT} \mid \varnothing]}=1+\frac{1}{2 p_{A}}+\frac{1}{p_{A}} .\right. \tag{1}
\end{align*}
$$

When $p_{A}=1 / 2$ (namely, independent Bernoulli trials with a fair coin where repetitions and alternations are equally likely), we have $E\left[T_{\mathrm{HH} \mid \varnothing}\right]=6$ and $E\left[T_{\mathrm{HT} \mid \varnothing \varnothing}\right]=4$.

When the initial state is not empty, $E\left[T_{j \mid j}\right]$ is referred to as the additional time for pattern $j$ given the initial state $i$. For example, from Figure 1B, we have

$$
\begin{equation*}
E\left[T_{\mathrm{HH} \mid \mathrm{H}}\right]=\frac{2}{1-p_{A}}, \quad E\left[T_{\mathrm{HT} \mid \mathrm{H}]}\right]=E\left[T_{\mathrm{T} \mid \mathrm{H}}\right]=\frac{1}{p_{A}} . \tag{2}
\end{equation*}
$$

At $p_{A}=1 / 2$, we have $E\left[T_{\mathrm{HH} \mid \mathrm{H}}\right]=4$ and $E\left[T_{\mathrm{HT} \mid \mathrm{H}}\right]=E\left[T_{\mathrm{T} \mid \mathrm{H}}\right]=2$.

When the initial state $i$ is exactly the desired pattern $j$, $E\left[T_{j \mid}\right]$ denotes the expected number of transitions between any two consecutive occurrences of the pattern $j$, and is referred to as the mean time of pattern $j$. Since the first-order Markov chain is memoryless between consecutive transitions, we have relations such as $E\left[T_{\mathrm{HH} \mid \mathrm{HH}]}\right]=E\left[T_{\mathrm{HH} \mid \mathrm{H}}\right]$, and $E\left[T_{\mathrm{HT} \mid \mathrm{HT}}\right]=E\left[T_{\mathrm{HT} \mid \mathrm{T}}\right]$. Therefore, the mean times for the patterns HH and HT are respectively,

$$
\begin{equation*}
E\left[T_{\mathrm{HH} \mid \mathrm{H}}\right]=\frac{2}{1-p_{A}}, \quad E\left[T_{\mathrm{HT} \mid \mathrm{T}]}\right]=\frac{2}{p_{A}} . \tag{3}
\end{equation*}
$$

At $p_{A}=1 / 2$, we have $E\left[T_{\mathrm{HH} \mid \mathrm{H}]}\right]=E\left[T_{\mathrm{HT} \mid \mathrm{T}}\right]=4$. The inverse of mean time is frequency. For example, $E\left[T_{H H \mid H}\right]=4$ means that we expect to see the pattern HH once in every 4 tosses of an fair coin.

Among these different measures, the most striking distinction is that at $p_{A}=1 / 2$, we have $E\left[T_{\mathrm{HH}} \mathrm{H}\right]=4$ but $E\left[T_{\mathrm{HT} \mid \mathrm{H}}\right]=2$, in spite of the fact that given an H , the next digit is equally likely to be either an H or a T . This is because a reoccurrence of the pattern HH can "reuse" the ending elements from its previous occurrence, but a reoccurrence of the pattern HT must always start anew. This statistical property of faster transition times when starting anew is known as new better than used (NBU) (Ross, 2007). Essentially, the NBU property is due to the overlap between a pattern and a shifted copy of itself or between different patterns. For example, as shown in Figure 1B, pattern HH overlaps with its shifted copy by one element H , but pattern HT does not. Then, towards the destination state $S_{\mathrm{HH} \mid \mathrm{H}}$, anytime things go astray (i.e., the process ends in state $M_{\mathrm{T}}$ ), the waiting for HH has to start all over. In contrast, the waiting for HT is always on average two flip away from the state $M_{\mathrm{H}}$. As a result, the transition to $S_{\mathrm{HH} \mid \mathrm{H}}$ is "delayed" than the transition to $S_{\mathrm{HT} \mid \mathrm{H}}$. This overlap also explains the pairwise precedence relation shown in Figure 1C. For example, in the competition between the patterns HH and TH , the former reuses the last element of the latter but the latter starts anew. As a result, if we toss a fair coin repeatedly (i.e., $p_{A}=1 / 2$ ), the odds are 3 to 1 that we first encounter TH than first encounter HH .

## A Neural Model of Temporal Integration

The NBU property of pattern times has fundamental implications in neural encoding of pattern events. As shown in Figure 1, different measures of waiting time, additional time, mean time and pairwise precedence odds are all due to the overlap between temporal patterns. Recent developments in neuroscience and computational models suggest that neural encodings of events and values are always overlapped, and it is the encoding of neural populations that give rise to higher-level and more abstract representations (Adolphs, 2015; Dehaene \& Brannon, 2010; Pouget et al., 2013). In the domain of temporal integration, probabilistic encoding must consider the overlap between representations at different times, namely, recurrent processing (Elman, 1990). Then, we would immediately conjecture that via merely encoding the random sequences that unfold over time, populations of neurons would naturally capture the temporal structures depicted by the pattern times statistics.

Figure 2: A neural network model of temporal integration (figures adopted from Sun et al., 2015). Figure A: A two-unit input layer scans a sequence of binary digits one digit at a time ("online" input at time $t$ ), while its temporal context representation keeps a copy of the previous input ("context" at time $t-1$ ). A 100 -unit internal prediction layer attempts to predict the next input, while its temporal context representation keeps a copy of the model's prediction at time $t-1$. Figure B: After unsupervised training, the model shows fewer repetition detectors than alternation detectors ( $R: A$ ratio $<1$ ) when the actual probability of alternation is greater than $3 / 7$.

We have recently reported a biologically-motivated neural model that behaves consistently in accord with the pattern time statistics (Sun et al., 2015). The architecture of the model and the main result are shown in Figure 2. The model employs a recently developed neural algorithm for temporal integration (O'Reilly, Wyatte, \& Rohrlich, 2014). At the sensory level, a 2-unit input layer scans non-overlapping signals of heads (H) versus tails (T) one digit at a time from sequences generated by the first-order dependent Markov trials. Then, a 100-unit internal prediction layer attempts to predict the next input, with the benefit of a prior temporal context representation. The bidirectional activation dynamics between the input layer and the internal prediction layer allow us to use a single input layer for both providing inputs and receiving predictions.

Through unsupervised learning, the model was trained with binary sequences generated at various levels of probability of alternation $\left(p_{A}\right)$. After training, the model was tested with a sequence generated at the same $p_{A}$ level. By activation-based receptive field analysis, we decoded the representations on the internal prediction layer and classified its units as either repetition detectors (whose activations are significantly correlated with the input pattern either HH or TT), or alternation detectors (activations correlated with either HT or TH). We then counted the numbers of detectors and used the $R / A$ ratio (repetition over alternation) to measure the model's performance (Figure 2B).

Most interestingly, at $p_{A}=1 / 2$ (i.e., flipping a fair coin independently), despite the same training frequency of the patterns (i.e., the same mean time, see, Equation 3), the model consistently produced fewer repetition detectors than alternation detectors at a ratio of $R / A \approx .70$. We then used this $R / A$ ratio to compute the subjective probability of alternation, $p_{A}^{\prime}$,
as the model's internal representation of its experienced $p_{A}$,

$$
p_{A}^{\prime}=\frac{A}{R+A}=\frac{1}{1+R / A} \approx 0.59
$$

This $p_{A}^{\prime}$ value was consistent with the value from empirical findings. From a comprehensive review of previous studies (Falk \& Konold, 1997), a unanimous finding was that people perceived or generated random sequences with a $p_{A}^{\prime}$ value around $0.58 \sim 0.63$. Moreover, we found that this $p_{A}^{\prime}$ value directly produces the besting-fitting bias-gain parameter in an existing Bayesian model for subjective randomness of longer patterns (Goodfellow, 1938; Griffiths \& Tenenbaum, 2001).

## A Minimal Neural Network Model

The model presented in Figure 2 has a prediction layer of 100 units, and its temporal context representation is equivalent to another 100 units as in a recurrent neural network. Then, an immediate question is, how many neurons are required to produce the minimal effect of the alternation bias? Apparently, to differentiate repetition versus alternation patterns, we need at least two types of detectors. However, we also notice that if patterns are aggregated too "early", namely, combining HH with TT and combining HT with TH before counting each of the four detectors, the alternation bias would be "washed out" (see the supplementary material by Sun et al., 2015). In addition, the pairwise precedence odds shown in Figure 1C indicates that to differentiate all patterns of length two, we need at least four detector neurons.

Figure 3: An eight-unit neural network model of temporal integration. A two-unit input layer scans a sequence of binary digits one digit at a time ("online" input at time $t$ ), while its temporal context representation keeps a copy of the previous input ("context" at time $t-1$ ). The prediction layer has four units for detecting each of the four binary patterns of length two. The status of each detector is determined by the projection weights from the input units. For example, detectors HH and HT receive the same projection weights from the context input units, but detector HH receives a stronger weight from the online input unit H , and detector HT receives a stronger weight from the online input unit T .

Figure 3 shows the structure of an eight-unit model for temporal integration. The model is called "minimal" as it uses the least number of neurons to produce the minimal effect of the alternation bias in the gambler's fallacy. Its input layer is identical to the bigger model in Figure 2, with two units for scanning the "online" input at time $t$ and two units for keeping a copy of the "context" input at time $t-1$. However, its
prediction layer has only four units without explicit temporal context representation. Also different from the bigger model where the initial status of detectors was set by random weights, the detectors in the eight-unit model are initially set by distinctive projection weights from the input units. For example, detectors HH and HT receive the same projection weights from the context input units, but detector HH receives a stronger weight from the online input unit H , and detector HT receives a stronger weight from the online input unit T . In other words, given the same initial state H , detector HH tends to predict a repetition and detector HT tends to predict an alternation.

Crucially, the controlled weights allow a more precisely controlled experiment by eliminating variations produced by random weights. In the bigger model, different detectors would "naturally" emerge by a random initialization of weights. However, this may produce a disparity in the number of detector types at the initial stage (e.g., more HT detectors than HH detectors), and such a disparity has to be accounted for by averaging multiple simulations with different random initializations. This disparity is eliminated in the eight-unit model, such that the model as a whole is initially unbiased toward any of the four patterns. (We have implemented different sets of controlled weights, e.g., 0.2 versus 0.8 , or 0.4 versus 0.6 , and find that they all produce the same results.)

Figure 4: Pattern dissociation at different levels of the probability of alternation $p_{A}$ after training. The repetition detectors HH and TT only showed higher activations when the model was trained with sequences generated by $p_{A}<1 / 3$. Box plots represent distribution quantile.

The eight-unit model was trained and tested in the same way as the bigger model, and the only difference is the analyses of the test results. Instead of counting the number of detectors, we directly measure the activations of each detector given different input patterns. Figure 4 shows the main result. We first notice that after being trained with truly random sequences (i.e., $p_{A}=1 / 2$ in independent fair coin tossing), the aver-
aged activations of detectors were significantly lower when the current inputs were repetition patterns (HH or TT) than alternation patterns (HT or TH). That is, in spite of the initially unbiased representations of all patterns and the equal training frequency (i.e., the mean time is the same for all patterns at $p_{A}=1 / 2$ ), repetition patterns eventually were significantly under-represented than alternation patterns.

Figure 5: The updating trajectories of projection weights from context input units to detector units HH and TH during the training phase. The initial weight values are marked by the circles at the first trial. For example, at $p_{A}=1 / 2$, the unit initially designated as the HH detector became an TH detector after approximately 200 trials, as all its weight values from the context units switched to the opposite side of 0.5 , whereas the unit initially designated as the TH detector remained stable. The same trend was also observed between TT and HT detectors. The projection weights from the online input units remained about the same thus are not plotted here.

To locate the source of the alternation bias, we found that during the training phase, the projection weights from the context input units to each detector underwent a dramatic remapping (Figure 5), whereas the projection weights from the online input units remained about the same.

Specifically, at $p_{A}=1 / 2$, the detector unit HH initially received a weight of 0.7 from the context input unit H and a weight of 0.3 from the context input unit T (hence its initially designated detecting status). After about 200 trials, these two weights switched to the opposite sides of 0.5 , effectively "switching" the HH detector into a TH detector (but not a HT detector). Similarly, the TT detector switched to an HT detector (but not a TH detector). The directions of these switches corresponded exactly to the pairwise precedence relationship depicted in Figure 1C. At $p_{A}=2 / 3$, the switch was even more obvious. At $p_{A}=1 / 6$, it was the alternation detectors' turn to
be under-represented and switched to the repetition detectors. Finally at $p_{A}=1 / 3$, all projection weights from the context units approached then stabilized around 0.5 , so that the model eventually learned to be indifferent to the contextual information, resulting in unbiased activations for all patterns as shown in Figure 4.

Moreover, we also tested models with only a subset of particular detectors (e.g., HH versus TH only). When $p_{A}=1 / 2$, regardless of the initial pattern preference set by the projection weights, the model would eventually react indifferently to all patterns. This result indicates that in order to capture different pattern time statistics or the pairwise precedence odds between patterns of length two (Figure 1), the inhibitory competition between at least four types of detectors is required. When we tested models with only online input units, the model showed the same indifference at $p_{A}=1 / 2$. This indicates that predictive learning, namely, predicting what will happen next based on the historical context, is critical in producing the alternation bias. Together, these observations confirmed our hypothesis that this eight-unit model is a minimal model to produce the alternation bias in the gambler's fallacy.

In comparison, the alternation bias exhibited by the minimal eight-unit model in Figure 3 is in the same direction as that exhibited by the bigger model in Figure 2. However, the equilibrium point (the $p_{A}$ level where the model was indifferent to all patterns) was different (compare Figure 2 with Figure 4). Specifically, the equilibrium point was $p_{A}=1 / 3$ for the eightunit model but $p_{A}=3 / 7$ for the bigger model. This indicates that the minimal model was more sensitive to the waiting time (delay) than to the mean time (frequency) of pattern occurrences, because by Equations 1 and 3, all patterns have the same waiting time but different mean times at $p_{A}=1 / 3$,

$$
E\left[T_{\mathrm{HH} \mid \varnothing}\right]=E\left[T_{\mathrm{HT} \mid \varnothing}\right]=11 / 2, \quad E\left[T_{\mathrm{HH} \mid \mathrm{H}}\right]=3, \quad E\left[T_{\mathrm{HT} \mid \mathrm{T}}\right]=6 .
$$

In contrast, the bigger model was more "balanced" toward both statistics, because at $p_{A}=3 / 7$,

$$
E\left[T_{\mathrm{HH} \mid \varnothing}\right]+E\left[T_{\mathrm{HH} \mid \mathrm{H}}\right]=E\left[T_{\mathrm{HT} \mid \varnothing}\right]+E\left[T_{\mathrm{HT} \mid \mathrm{T}}\right]=55 / 6
$$

One particular reason for such difference is that the competition would be stronger among fewer detectors due to the homeostatic mechanism implemented in the network. This mechanism keeps individual neurons from firing too much or too little over time, which is essentially a normalization mechanism in self-organizing learning at long time scales (Bienenstock, Cooper, \& Munro, 1982; Cooper, 2000; Hebb, 1949; O’Reilly, Munakata, Frank, Hazy, \& Contributors, 2012). As a consequence, the bigger model with more neurons would be more likely to maintain diversity in the specialization of neurons thus its equilibrium point could be determined by both waiting time and mean time statistics.

## Conclusion

Overall, our results from both models suggest that pattern dissociation can naturally emerge from temporal reconstructions of the input data. Particularly with the minimal eight-neuron
model, detector neurons "reoriented attention" to the past information (i.e., remapping the projection weights from the context units), and the driving force behind such reorientation was more of the waiting time rather than of the mean time of patterns. As for the model with more neurons we reported earlier, the specialization of neurons would be more diversified thus would enable the model to develop sensitivity to both types of pattern time statistics.

The observation that both models exhibited the alternation bias is consistent with the representativeness bias underpinning the gambler's fallacy (Gilovich et al., 1985; Tversky \& Kahneman, 1974). For example, Figure 4 show that at $p_{A}=1 / 2$, the model had higher activations for alternation patterns than repetition patterns, in spite of the sequential independence of events. Critically, such bias emerged through unsupervised training without any pre-defined hypothesis structures, since both models were initially symmetrically structured, and were not provided with any prior knowledge on how different $p_{A}$ levels would affect the occurrences of different patterns.

Given the simplicity of our models, one far-reaching implication is that cognitive biases and structured abstractions can emerge early and locally at the level of sensory processing. Nevertheless, it should be noted that our models only address purely bottom-up learning mechanisms without implementing any top-down learning or higher-level representations such as beliefs or goals. For the early and locally developed biases to be maintained and utilized in later and global processes, higher-level representations and top-down structures must also be involved through a hierarchical structure of abstractions (Munakata et al., 2011; Tenenbaum et al., 2011).

Lastly, probabilistic thinking has to consider the consequence of time (Buchanan, 2013; Hawkins \& Blakeslee, 2004). Our findings suggest that rich semantics in the learning environment can be extracted by neuron populations in predictive learning through temporal integration. This learning over time would lead to the structured hypothesis spaces such as those required by Bayesian inference thus provide essential building blocks in bridging the gap between neural computations and overt behavior.

# Temporal variability in moral value judgement 

Alexandra Surdina (a.surdina@warwick.ac.uk)<br>Department of Psychology, University of Warwick Coventry CV4 7AL, United Kingdom

Adam Sanborn (a.n.sanborn@warwick.ac.uk)<br>Department of Psychology, University of Warwick Coventry CV4 7AL, United Kingdom

#### Abstract

Moral judgments are known to change in response to changes in external conditions. But how variable are moral judgments over time in the absence of environmental variation? The moral domain has been described in terms of five moral foundations, categories that appear to capture moral judgment across cultures. We examined the temporal consistency of repeated responses to the moral foundations questionnaire over short time periods, fitted a set of mixed effects models to the data and compared them. We found correlations between changes in participant responses for different foundations over time, suggesting a structure with at least two underlying stochastic processes: one for moral judgments involving harm and fairness, and another for moral judgments related to loyalty, authority, and purity.

Keywords: morality, moral foundations theory, consistency, variability

## Introduction

Morality is a vital part of who we are. A person's moral beliefs are tied into their identity (Aquino \& Reed II, 2002; Aquino et al., 2009) - humans believe that if their moral values changed, they would change (Heiphetz et al., 2016). Are people's intuitions about this correct? Are our moral values consistent over time?

Since moral beliefs tend to be associated with a person's sense of identity, we should expect people's underlying moral values to largely endure over short time periods. Yet, there have been many recent explorations of moral inconsistency. These have included manipulations of two types - manipulations of response timing, or manipulations by exposure to new information or decisions. In terms of timing, we now know that time-limited decisions appear to be more altruistic (Rand et al., 2012) and that choices can be influenced by forcing decisions at a specific point in time (Pärnamets et al., 2015), indicating that the actual decision outcome is time-sensitive. Regarding information or decisions, dishonest behaviour increases future dishonesty (Garrett et al., 2016; Engelmann \& Fehr, 2016). A morally good action makes a subsequent morally bad action more appealing and vice versa, effects known as moral cleansing and moral licensing (Merritt et al., 2010; Sachdeva et al., 2009). Exposure to a moral dilemma leads to belief revision in moral decisions that persists for multiple hours (Horne et al., 2015).

The fact that changes in external circumstances can influence the outcomes of moral decisions is hardly surprising assuming morality evolved as an adaptive strategy (Machery \& Mallon, 2010). Likewise, viewing moral judgment as a decision process, we would expect the effects of changed response timing on general decisionmaking (McClelland, 1979; Usher \& McClelland, 2001) to transfer into the moral domain. But in the absense of such manipulations, are our moral judgments fundamentally noisy? Outside of the moral domain, there is evidence in decision making research that people's decisions vary stochastically even in cases where external conditions remain constant (Mosteller \& Nogee, 1951). We are interested in exploring whether there is a corresponding moral variability beyond the actual decision process: are our moral values different from moment to moment, even in the absence of new information or manipulations of response timing?

Moral Foundations Theory (MFT) provides a way to look at this. It is based on a dominant model of morality, the social intuitionist model, according to which moral choices are made primarily intuitively and then justified post hoc (Haidt, 2001). MFT maps out the moral domain in terms of six fundamental hidden parameters that appear to capture an individual's moral judgment (Graham et al., 2009), enabling us to distinguish between conservative and liberal political profiles on the basis of an agent's foundation weights. This idea that there are foundational categories that guide intuitive moral judgement has the potential to explain people's tendency to disagree on moral issues, and predict future moral judgement based on the individual scores. If we can find a systematic structure in the stochastic changes of different foundation scores beyond merely a layer of noise, this would point towards moral variability, rather than just motor variability or variability in how the response scale is used.

In line with the aforementioned results indicating temporal consistency, moral foundation scores appear stable over longer time periods; Graham et al. (2011) tested participants again after approximately a month and found that their moral foundation scores exhibited test-retest reliability. Yet, effects such as moral licensing and moral cleansing - where the outcome of an individual's moral decision influences subsequent moral de-
cisions, even decisions made by others in their ingroup (Kouchaki, 2011), over the course of single experimental sessions and thus shorter timescales - suggest the possibility of an interaction between moral foundations. Moreover, the list of known moral foundations is likely incomplete - a view shared by moral foundations theorists (Haidt \& Joseph, 2011).

Viewing moral decisions as a sampling process from a distribution that represents an agent's moral values, we can use the framework provided by MFT to investigate hidden parameters which predict an individual's moral variability. Conversely, observing within-subject variability over time can help us understand to which extent individual moral variability reflects between-individual variability that has been used to support the existence of MFT (Graham et al., 2011). Are we all sometimes a little bit more conservative and sometimes a little bit more liberal in our moral judgments and values?

In this paper, we aim to discuss the extent to which randomness plays a role in moral judgment over time by collecting responses to the moral foundations questionnaire delivered repeatedly. We subsequently fit a set of models to the data and compare them. If the variability we observe stems merely from randomness in the decision process, we expect variation in individual responses to be explained by a single noise-generating process. We find evidence for at least two separate stochastic processes associated with different sets of moral foundations, indicating the existence of inherent variability in moral values.

## Method

## Participants

The participant pool consisted of 80 psychology undergraduate students (mean age 19 years, $90 \%$ female). 14 participants were excluded from the analysis due to wrong responses on the two 'catch' trials, as done by Graham et al. (2011).

## Materials

The original moral foundations questionnaire (MFQ30) asks participants to respond using a $1-6$ scale; to enhance precision and avoid subjects simply recalling previous answers, the participants in our task had to use a slider bar to indicate their responses instead:

In addition, our version of the questionnaire contained four further questions (see Figure 1). Those were chosen so as not to correspond in any obvious way to the five foundations measured in the MFQ30, nor to the recent addition of the liberty foundation (Graham et al., 2012; Haidt, 2012). We added these questions because we wanted the same number of presumably neutral trials as the number of foundation-related questions - the

MFQ30 includes six question for each foundation but only two neutral 'catch' items.

Figure 1: Moral foundations questionnaire. Questions added by us are marked with $\left(^{*}\right)$.

## Procedure

The questionnaire was presented six times in randomised order, with a word search task before the last two trials. In each trial, one of the two question types was displayed (see Figure 1, left and right side, respectively), along with one of the statements for that question type. Randomisation was implemented so that each statement was shown to the participant exactly once in each block: The set of questions within each block was shuffled, and presented within the block in randomised order, so no regular pattern in the order of foundations would occur.

After four blocks, a word search task ${ }^{1}$ was shown for 6 minutes to provide a timed break ${ }^{2}$ : Participants had to find and mark words in a 18 x 18 letter square filled with a selection of words and random letters, based on the WordFind.js library (Scheidel, 2012). With the exception of the timed word search task, participants provided responses at their own pace. The experiment took approximately $20-25$ minutes to complete.

## Results

Since participant responses are indicated using slider bars, foundation scores change between the blocks (participants will be unable to recall the exact position of the slider for previous trials). But beyond the expected variation resulting from differences in participant's slider operation accuracy, is there a relationship between these changes in different moral foundation scores?

## Means

As found by Graham et al. (2011), we anticipated and found our psychology undergraduate subject pool in the UK to remain largely at the liberal end of the U.S. political spectrum. Welch's t-test shows that the differences between the means for harm and fairness $(p=.16)$ and for loyalty and authority $(\mathrm{p}=.44)$ are not significant. All other pairs of means indeed differ significantly ( $\mathrm{p}<.001$ ). In particular, the first two foundation means differ significantly from the last three, with higher subject scores for harm $(M=72.9, S D=24.6)$ and fairness $(M=70.3$, $\mathrm{SD}=23.6$ ) and lower scores for loyalty $(\mathrm{M}=51.1, \mathrm{SD}=$ 27.1), authority ( $\mathrm{M}=48.8, \mathrm{SD}=26.1$ ) and purity ( $\mathrm{M}=$ 42.1, $\mathrm{SD}=28.8$ ). The between-subject standard deviation is notably larger than the within-subject standard deviation (see Figure 3), supporting the MFT framework for examining between-subject differences.

A within-subjects $\mathrm{ANOVA}^{3}$ showed a main effect of both foundation $(\mathrm{F}(5,325)=72.67, \mathrm{p}<.001)$ and block $(\mathrm{F}(5,325)=6.26, \mathrm{p}<.001)$ on average slider bar values, as well as an interaction between foundation and block $(\mathrm{F}(25,1625)=1.764, \mathrm{p}=0.011)$. But we are mainly interested in changes in the absence of new information, and Figure 5 suggests that the very first block in which the whole questionnaire was new to the participant qualitatively differs from the others. Excluding the first

[^513]

Figure 2: Spider plot of means for each foundation and block.

Figure 3: Average slider value for each response, and the average of within-subject standard deviations. The catch trials and the baseline level are marked in blue.
block from the analysis indeed makes the effects of block $(\mathrm{F}(4,260)=6.26, \mathrm{p}=.47)$ and the interaction effect between foundation and block $(F(20,1300)=1.201, \mathrm{p}=.24)$ in the ANOVA above no longer significant: While moral foundation scores differ between Block 1 and the other blocks, for the later blocks alone, this is no longer true.

## Variability over time

We also expected that within-foundation variance, i.e. the variance between participant responses to the sets of questions for each respective foundation, would decrease over time: As time passes, people's certainty which choice they will make will increase as they get more familiar with the questionnaire. Moreover, we thought we might be able to observe a shift towards more extreme values for each question over time - as people become increasingly familiar with the set of questions they will
encounter, there would be less need to for caution about new options which are more or less morally upsetting than the previous maximum or minimum, respectively.

We computed residual slider values by subtracting the within-subject mean for each foundation from the slider values for each trial. The two hypotheses above can be rephrased as: The slider residual variance for each participant and block decreases as a reflection of the increase in certainty; and the average absolute residual value increases over time as a result of the decision drifting towards the extremes.

Figure 4: Changes over time, by foundation. The colours represent the different blocks.

In fact, we found no significant effect of block number on foundation variance: Again, an ANOVA only yields significant results for the variance hypothesis $(\mathrm{F}(5,325)=18.71, \mathrm{p}<.001)$ and the absolute residual hypothesis $(\mathrm{F}(5,325)=47.4, \mathrm{p}<.001)$ if we are taking the very first block into account - here, a slight decrease after the first block can be spotted (see Figure 5). If we are looking at only the other blocks, we do not find any significant change in the variance $(\mathrm{F}(4,260)=1.90, \mathrm{p}=.11)$, nor in the absolute slider residual $(\mathrm{F}(4,260)=1.22, \mathrm{p}=.30)$.

## Between-foundation variability

One hypothesis is that changes in moral foundations that are opposed with respect to their representation on the political spectrum, such as harm and purity, will balance each other out - that is, they are negatively correlated (Fig. 6a). Each person may have a constant morality 'budget', and thus an increase in a moral foundation score will inevitably be accompanied by a decrease in others. This would imply that people's position on the liberal-conservative spectrum might not be fixed. Another hypothesis is that changes in opposing moral foundations are positively correlated (Fig. 6b). This would for instance be the case if people's moral profile was

Figure 5: Absolute value and within-subject standard deviation of slider residual over time
indeed fixed, and the sampled moral foundation scores are scaled by a time-dependent factor. Alternatively, changes in different moral foundations may not be correlated at all.

Figure 6: Relative changes in foundation scores

We did not find evidence for any of these relationships between participant scores for different foundations. On the contrary, the changes in foundation scores over time were not particularly large.

To test for interactions between changes in different foundation scores, we modelled the data using mixed effects models with a full covariance matrix and a diagonal covariance matrix, respectively. We created dummy coded variables for each foundation. Since we did not detect any notable change in the means after the first block, we now focused on the variability and removed the influence of the means entirely by modelling slider residuals: we calculated the mean slider value for each question for each participant, and subtracted it from the raw slider values. We used residuals for each question rather than for each foundation score because of the differences in responses to the different questions within each foundation (see Figure 4). Furthermore, we excluded the first block in which all information had been newly introduced from the analysis. We fitted two models to the data: First, a model including a full covariance matrix and thus allowing for interactions between the different foundations, and second, a model with a diagonal covariance matrix reflecting the assumption that sampling occurs for each foundation individually.

As a baseline model, we used a model assuming a random slider residual for each participant and block, sam-
pled from the same distribution for each foundation (random noise model). The models for the slider residual $y_{i j k l}$ of Participant $i$ in Block $j$ for a question or statement $l$ relating to Foundation $k$ are:

$$
\begin{equation*}
y_{i j k l}=u_{i j}+u_{i j k}+\varepsilon_{i j k l}, \tag{M1-M3}
\end{equation*}
$$

with $u_{i j} \sim \mathcal{N}(0, \sigma)$, and

$$
\begin{align*}
& u_{i j k}=0  \tag{M1}\\
& \left(\begin{array}{l}
u_{i j 1} \\
u_{i j 2} \\
u_{i j 3} \\
u_{i j 4} \\
u_{i j 5}
\end{array}\right) \sim \mathcal{N}\left(\mathbf{0},\left[\begin{array}{lllll}
\sigma_{11} & \sigma_{12} & \sigma_{13} & \sigma_{14} & \sigma_{15} \\
\sigma_{21} & \sigma_{22} & \sigma_{23} & \sigma_{24} & \sigma_{25} \\
\sigma_{31} & \sigma_{32} & \sigma_{33} & \sigma_{34} & \sigma_{35} \\
\sigma_{41} & \sigma_{42} & \sigma_{43} & \sigma_{44} & \sigma_{45} \\
\sigma_{51} & \sigma_{52} & \sigma_{53} & \sigma_{54} & \sigma_{55}
\end{array}\right]\right)  \tag{M2}\\
& \left(\begin{array}{l}
u_{i j 1} \\
u_{i j 2} \\
u_{i j 3} \\
u_{i j 4} \\
u_{i j 5}
\end{array}\right) \sim \mathcal{N}\left(\mathbf{0},\left[\begin{array}{ccccc}
\sigma_{11} & 0 & 0 & 0 & 0 \\
0 & \sigma_{22} & 0 & 0 & 0 \\
0 & 0 & \sigma_{33} & 0 & 0 \\
0 & 0 & 0 & \sigma_{44} & 0 \\
0 & 0 & 0 & 0 & \sigma_{55}
\end{array}\right]\right) \tag{M3}
\end{align*}
$$

The model M2 $\left(\chi^{2}(10)=26.98, p=.003\right)$ differs significantly from the baseline model M1. Comparing the models M1-M3 to each other suggests that M2 $(\mathrm{BIC}=71058)$ has a lower BIC value than M1 $(\mathrm{BIC}=70960)$ and M3 ( $\mathrm{BIC}=70993$ ). M2, which has a full covariance matrix, shows an interesting pattern of dependencies between the different foundation types:

| Foundation | Harm | Fair | Loya | Auth |
| :--- | :--- | :--- | :--- | :--- |
| Fair | 1 |  |  |  |
| Loya | -0.86 | -0.86 |  |  |
| Auth | -0.95 | -0.95 | 0.95 |  |
| Puri | -0.7 | -0.7 | 0.64 | 0.80 |

Responses for harm and fairness appear to be positively correlated with each other and negatively correlated with responses for the other foundations, and vice versa. This would be less surprising if it was merely capturing a between-participant relationship between foundation scores. Note however that this model describes the slider residuals which add up to zero for each foundation and participant - yet, this result suggests that participants who drag the slider bar a bit further to the right for harm-related questions than in the last block will do a similar thing with the fairness-question slider, but the opposite with sliders on loyalty, authority and purity trials.
Is there some overlap between which property of morality harm and fairness on the one hand and loyalty, authority and purity on the other hand are measuring? Since the mean foundation scores for harm and fairness, and the scores for loyalty, authority, and purity seem similar to each other (see Figure 2), we introduced alternative models that only distinguish between these two groups instead of the individual foundations.

To find out if we could confirm the five-dimensional moral foundations structure, we fitted a set of linear
mixed effects models to the data. As an alternative, we dummy-coded two foundation types (the 'individualising' foundations harm and fairness and the 'binding' foundations loyalty, authority, and purity (Graham et al., 2009)). Again, we fitted a full covariance model and a diagonal covariance model to the data, adding the two models below to our list of candidate models. They are describing the slider residual $y_{i j m l}$ of Participant $i$ in Block $j$ for a question $l$ of Foundation type $m$ :

$$
\begin{equation*}
y_{i j m l}=u_{i j}+u_{i j m}+\varepsilon_{i j m l}, \tag{M4-M5}
\end{equation*}
$$

with

$$
\begin{align*}
& \binom{u_{i j 1}}{u_{i j 2}} \sim \mathcal{N}\left(\mathbf{0},\left[\begin{array}{ll}
\sigma_{11} & \sigma_{12} \\
\sigma_{21} & \sigma_{22}
\end{array}\right]\right)  \tag{M4}\\
& \binom{u_{i j 1}}{u_{i j 2}} \sim \mathcal{N}\left(\mathbf{0},\left[\begin{array}{cc}
\sigma_{11} & 0 \\
0 & \sigma_{22}
\end{array}\right]\right) \tag{M5}
\end{align*}
$$

We find that out of these, the model M5 differs significantly from the baseline model $\left(\chi^{2}(2)=27.85, p<.001\right)$. Comparing M4 (BIC=70960) and M5 (BIC=70951) to the models above suggests that M5 is preferable to M2 and M4. Thus, it appears that from a model comparison perspective, the main distinction in the moral foundation framework lies in the two different foundation types rather than the individual foundations, and that at this level of description, between-foundation correlations do not play a prominent role.

## Discussion

We found that people showed moral variability even in the absence of new information or time pressure. This moral variability is distinguishable from response variability because we found two random processes that were associated with different sets of moral foundations. The evidence for MFT is based on an analysis of betweenindividual responses to the MFQ (Graham et al., 2011), and much of this may actually be due to the withinindividual variability that we have found. This withinindividual variability may also be what allows timing interventions to have an effect (Pärnamets et al., 2015), and might potentially even allow to influence the outcomes of value-related decisions (such as election results).

While for our dataset a simpler two-type model was preferable to the more complex model including five moral foundations, we hesitate to draw general conclusions about the number of moral foundations due to the small size and relative cultural homogeneity of our subject pool. Yet, our brief glimpse at candidates for additional foundations suggests the possibility of a wider underlying structure of which MFT has captured but a part.
A common criticism of MFT is that the known moral foundations are unlikely to capture moral judgment in its entirety (Suhler \& Churchland, 2011). We had expected
our added questions to be rated similarly irrelevant to morality as the more conservative moral foundations in our liberal subject pool. Somewhat surprisingly, the responses to our added, 'neutral' foundation appear to be less neutral overall. We chose the four additional statements in the neutral foundation because we suspected that they might turn out to be morally relevant. Figure 3 suggests that questions 2 and 5 in particular (see Figures 1 and 4) indeed resonate with our participants' values. While the act of lying may arguably be related to the purity scale, it is remarkably more morally relevant than any of the purity questions. This particularly utilitarian view on having children also appears to lie outside of the given scales.

Interesting open questions remain that reach beyond refining and expanding MFT. While we observe a range of scores for different moral foundations, we do not yet understand the actual decision process: How are different moral values integrated in a decision between options that are morally relevant for more than one moral foundation, or options that are uncertain? Which impact does moral variability have on the kinds of moral decisions we face every day?

# Enforced pointing gesture can indicate invisible objects behind a wall

#### Abstract

The pointing gesture is regarded as indicating an object or location in the environment. People sometimes point to invisible objects, but the inferential mechanism is not known. This study examined comprehension of pointing with a bent index finger at an invisible object behind a wall. The experimenter pointed at an object using either typical pointing or "enforced pointing" behind a wall that was either opaque or transparent. In enforced pointing, the experimenter moved his arm in an arc movement. The participants guessed which object was being denoted. The wall was also either relatively high or relatively low. When the participants looked at typical pointing, they thought that objects both in front of the wall and behind the wall were being denoted. However, when they looked at enforced pointing, they more frequently thought that objects behind the wall were denoted. People seemed to use pragmatic knowledge on this "enforced" pointing gesture.

Keywords: gesture; declarative pointing; common ground; non-linguistic information

## Introduction

The pointing gesture usually indicates direction. If any object or location exists in the indicated direction, such object or location is interpreted as denoted. Clark (2003) discussed use of attention-getting gestures of pointing and placing. He noted that pointing at a referent and placing a referent are both useful ways to convey information about referents. In pointing, a person directs the addressee's attention to the referent object; for example, a customer may point at a package of medicine that is difficult for him or her to reach but is easy for the clerk. In placing, a person puts a referent object in the area of an addressee's attention; for example, a customer may place a package of medicine on the checkout counter where a clerk waits. These communications are possible without saying any words. To communicate smoothly, people must share mutual understanding of pointing at referents and placing referents in different situations. Clark (1996) proposed that people use "common ground" as implicit mutual knowledge in human communication. Previous research has focused mostly on language and verbally describable information included in common ground. Non-verbal information such as gestures must also be comprehended using common
ground as to how people use gestures in different situations; however, usage of gestures as common ground has not yet been thoroughly explored. Pointing gestures are often used with demonstratives (Coventry et al., 2008; 2014). Pointing gestures are also used to examine children's inferential ability (Doherty et al., 2004; Kobayashi, 2007). In these studies, the addresser can easily share information about visible objects using visual joint attention and common ground.

Kita (2003) discussed that the semiotic processes-that is, interpretation of a pointing gesture and its referent-and intended meaning of the overall action must be analyzed in interpretation of a pointing gesture. The referent of a pointing gesture can be ambiguous in many situations and in many ways. People must make correct inferences about the observed pointing gesture. Tomasello (2008) discussed that a customer points at an empty glass, and a bartender understands the request of the customer ("Please fill the glass"). In other situations-for example, a client and a glass designer - the client is pointing at an empty glass may be interested in or selects the design of the glass.

Goodwin (2003) suggests that an "activity framework" specifies which features of the environment are relevant for the ongoing activity and, hence, are likely to be the referent of a pointing gesture. Goodwin also suggests that different forms of pointing may correlate with particular types of referents.

Pointing is usually used for visible objects when an indicator and an observer can jointly attend to the same object or location. People sometimes point to invisible objects, but the inferential mechanism is not known. Kobayashi and Yasuda (2015) examined how people interpret the experimenter's pointing with a bent index finger at an invisible object behind a panel. The experimenter pointed at bottles that were placed either in front of the panel or behind the panel using a straight index finger or a bent index finger, and the participants guessed which object was being indicated. In the with-obstacle condition, bent pointing tended to be interpreted as referring to all the objects, both in front and behind the panel. However, this tendency was not observed with straight index-finger pointing. Thus, when the participants looked at
straight pointing, they thought that only the objects in front of the panel were being indicated. However, when they looked at bent pointing, they thought that objects both in front of and behind the wall were being indicated. The significance level of the shape of the pointing finger's effect was substantially large ( $\eta^{2}=0.804$ ) and the results suggest that people think bent pointing can refer to objects behind walls, but straight pointing cannot. The study suggests that people have "common ground" in their interpretation of different types of pointing.

This study examined comprehension of pointing with a bent index finger at an invisible object behind a wall. The present study examined participants' interpretation of the experimenter's pointing at an object using either typical pointing or "enforced pointing" behind a wall that was either opaque or transparent. In enforced pointing, the experimenter moved his arm in arc movement. The participants guessed which object was being denoted. The wall was also either relatively high $(28 \mathrm{~cm})$ or relatively low ( 14 cm ). We examined the effect of pointing movement because this iconic movement may suggest the indicator's intention of "overriding the wall." We examined the transparency of the wall because, if the wall is transparent, "overriding" intention may look ambiguous. The reason is that objects behind the transparent wall can be indicated without such effortful movement. However, if the wall is opaque, the "overriding" intention may be naturally understood. We also examined the height of the wall. The enforced pointing movement was more easily understood when a relatively high ( 28 cm ) wall was used than when a relatively low ( 14 cm ) wall was used.

## Methods

## Participants

Sixteen Japanese undergraduate university students ( $M$ age $=22.0$ years; $S D=0.816 ; 1$ female) participated. The experiment was conducted in accordance with Tokyo Denki University's code of ethics.

## Experimental setting

Fig. 1 shows the experimental setup. On the table, there were 4 small bottles ( $\mathrm{W}: 3 \mathrm{~cm} \times \mathrm{H}: 7 \mathrm{~cm}$ ) designated $1,2,3$, and 4 with a different color on each bottle. Bottles were placed 10 cm apart. Bottle \#1 was placed 75 cm away from the edge of the side of the table where the experimenter sat. The experimenter sat on one side of the table and wore a black sun visor during the experiment so that participants could not see the experimenter's gaze direction. The participant sat at the table at a right angle to the experimenter. The panel ( $\mathrm{W}: 14 \mathrm{~cm} \times \mathrm{H}: 28 \mathrm{~cm}$ ) was placed in the middle of the table between bottles \#2 and \#3. Participants were randomly assigned to all conditions.

The experimental conditions consisted of two types each of pointing (2: typical vs. enforced), visibility (2: visible vs. invisible), and position ( 2 : lengthwise vs. widthwise).

Regarding the pointing condition, "typical pointing" was when the experimenter pointed at the referent with his arm extended horizontally and his index finger kept bent (Fig. 2); "enforced pointing" was when the experimenter pointed at the referent with his arm moving in arc and his index finger kept bent (Fig. 3).

Fig. 1: Experimental setup in "invisible" with "lengthwise" conditions. Objects were placed 10 cm apart.

Fig. 2: Flow of typical pointing

Fig. 3: Flow of enforced pointing
Regarding the visibility condition, "visible" meant that a transparent panel was used; the experimenter and the participant could see all bottles. "Invisible" meant that a black opaque panel was used; the experimenter could not directly look at bottles \#3 and \#4. The participant could see all bottles. In the obstacle position condition, the height of the "lengthwise" obstacle was 28.0 cm , and the width was 14.0 cm . The height of the "widthwise" obstacle was 14.0 cm , and the width was 28.0 cm . For example, in the "visible" with "lengthwise" obstacle condition, there was a
small transparent lengthwise panel on the table (Fig. 4a). In the "invisible" with "widthwise" obstacle condition, there was a small black opaque widthwise panel on the table (Fig. 4b).

Fig. 4: Each type of obstacle; "a" is used in "visible" with "lengthwise" conditions and "b" is used in "invisible" with "widthwise" conditions.

## Procedure

First, the experimenter and the participant looked at all the bottles placed on the table. Then, the participant sat on the experimenter's chair and looked at the table. Then, the experimenter put the panel between bottles \#2 and \#3, and the participant again looked at the table. Thus, the participant experienced the experimenter's view in both visible and invisible obstacle conditions.

In the typical pointing with invisible widthwise obstacle condition, the experimenter put the black-opaque widthwise panel between bottles \#2 and \#3 and said to the participant, "I cannot see bottles \#3 and \#4. Now, I will point at one of the four bottles." Then, the experimenter pointed at bottle \#3 using the typical index finger. Next, the experimenter pointed at bottle \#3 continuously and said, "Now, I am pointing at something. What is the color of the bottle you would guess I am pointing at?" The participant responded orally using the bottle color. The bottle corresponded to the distance from the edge of the table: Bottle \#1's distance was 75 cm ; \#2, $85 \mathrm{~cm} ; \# 3,95 \mathrm{~cm}$; and \#4, 105 cm . All bottles were of different colors, and bottle positions were randomized. In addition, the experimenter wore a sun visor so that the participant could not see the experimenter's eye gaze.

In the enforced pointing condition, the procedure was the same as with the typical pointing except that enforced pointing was used. In the visible condition, the procedure was the same as with the invisible condition except that the visible condition was used. In each block, the experimenter pointed at bottle \#3, and there were 24 trials in all. Overall, the order of color bottles of these blocks was counterbalanced between the participants.

The experimenter's pointing was trained to show the same pointing gesture in either the typical pointing or the enforced pointing in the aspects of speed of movement. In
addition, the angle of his forefinger maintained the same shape (Fig. 2 and 3).

## Results

Fig. 5 shows the participant's responses when the experimenter pointed at the object in each pointing and each visibility condition. A 2 (Pointing: typical, enforced) $\times 2$ (Visibility: visible, invisible) $\times 2$ (Position: lengthwise, widthwise) three-way ANOVA was performed with the number of the bottle that the participant responded as the dependent measure. There was a marginally significant main effect of Pointing, $F(1,15)=3.479, p=.08, \eta^{2}=0.050$. There was also a significant interaction of Pointing $\times$ Visibility, $F(1,15)=5.497, p<.05, \eta^{2}=0.015$.

To explore the significant Pointing $\times$ Visibility interaction, the simple main effects of Pointing within each Visibility and Visibility within each Pointing were analyzed. The simple main effect test revealed that there was a significant difference between typical pointing and enforced pointing in the invisible obstacle, $F(1,15)=7.120, p<.05, \eta^{2}=0.106$. There was also a marginally significant difference between the visible and invisible obstacles in typical pointing, $F(1,15)=3.407, p=.08, \eta^{2}=0.029$. Other effects were not significant (all $p>.05$ ).

When enforced pointing was used $(M=2.958, S E=$ 0.166 ), participants interpreted a farther bottle as being indicated than when the typical pointing was used ( $M=$ $2.427, S E=0.175$ ) in the invisible obstacle condition.

Fig. 5 Participants' responses when the experimenter pointed at bottle \#3 using each type of pointing in each visibility and position condition. * denotes a significant difference. Error bars denote the standard errors of the means.

## Discussion

This study examined comprehension of pointing with an enforced movement of a bent index finger at an invisible object behind a wall. The study examined participants' interpretation of an experimenter's pointing using either typical pointing or "enforced pointing" at an object behind a wall that was either opaque or transparent. In enforced pointing, the experimenter moved his arm in an arc movement. The participants guessed which object was being denoted. The wall was also either relatively high ( 28 cm ) or relatively low ( 14 cm ).

When the participants looked at typical pointing, they thought objects both in front of the wall and behind the wall were being denoted. However, when they looked at enforce pointing with an opaque wall, they more frequently thought objects behind the wall were denoted. The height of the wall did not have any effect in this experiment.

Participants interpreted that enforced pointing could "override" the wall if the wall was opaque. They might think enforced pointing suggested an overriding trajectory (Fig. 6) to point to an invisible object behind the wall. However, for the objects behind the transparent wall, enforced pointing was not necessary. Thus, this enforced movement was sufficiently informative for participants to interpret the indicator's intention to "override" the wall. That seems to be the reason why the height of the wall had no effect.

The study suggested that people use an indicator's arm movement and the features of the environment to comprehend the referent of pointing. The result suggests that we have "common ground" in terms of interpretation of different types of pointing. Furthermore, we think the linguistic-cognitive framework presented by Relevance Theory (Sperber \& Wilson, 1995; Wilson \& Sperber, 2004) may be applied to our result. Discussing Relevance Theory from a biological perspective, Scott-Phillips (2010) stated that humans' and other animals' every signal carries a presumption of its own optimal pertinence. Here, non-verbal signals such as human gestures can be processed as relevant signals in addition to utterances.

It can be said that the study suffers from reduction of pointing situations. The study investigated only the interpretation of enforced pointing in the controlled experiment. It is necessary to study the production in addition to the interpretation of enforced pointing in a more real human environment.

#### Abstract

The present study was aimed at assessing the effect of object similarities on participants' evaluations of analogical quality. Results from an experimental condition in which the relations involved in the compared situations were explicitly highlighted, showed that general object similarities (membership to same category) positively affected the evaluations of analogical quality. In contrast, no such effect was found under another experimental condition in which the analogical comparisons between the same situations were framed by a schema-governed category. An analysis of participants' justifications revealed that the object similarities that were taken into account under this second condition were related to central dimensions of the schema-governed category that was used to frame the analogies. We explain these findings within the category assignment approach developed by Minervino et al., and discuss the implications of this alternative perspective of analogical reasoning for the role of similarities between entities playing several thematic roles.

Keywords: analogy; schema-governed category; semantic similarity.

## Introduction

Drawing an analogy consists in recognizing that two situations are comparable because they share a common relational structure despite their superficial differences. Frequently, the purpose of analogical comparisons is to transfer knowledge from one of those situations (the base analog) to the other (the target analog) to enhance its comprehension (Gentner, 1983; Holyoak, 1984).

The structure-mapping theory (Gentner, 1983, 1989; Gentner \& Markman, 1997) and the multiconstraint theory (Holyoak \& Thagard, 1989; Hummel \& Holyoak, 1997) have dominated the discussion about analogical reasoning since the 1980s. Due to the commonalities between these two theories we will refer to them as the standard approach. According to this approach, analogical reasoning involves, among other subprocesses, a mapping between base and target elements, and an evaluation of the quality of the
analogy. Both theories agree in that the quality of a match will be considered higher or lower to the extent that the alignment satisfies the structural constraints of one-to-one mapping and parallel connectivity (Gentner, 1989; Holyoak \& Thagard, 1989). Nevertheless, the mentioned theories differ with respect to the role of semantics in the evaluation of an analogy. Structure-mapping theory posits that relational similarity is the only factor that counts when evaluating an analogy, with object similarities playing no role at all (Gentner, 1983, 1989). On the other hand, the multiconstraint theory contends that semantic similarity between objects is also taken into account during quality evaluations (Holyoak, 1984; Holyoak \& Thagard, 1989). The mechanisms proposed by these theories for estimating semantic similarity tend to resort to general knowledge like the one represented in networks (Minervino, Oberholzer, \& Trench, 2013). The scarce available evidence (Gentner, Ratterman \& Forbus, 1993; Gentner \& Kurtz, 2006) is consistent with structure mapping theory: it shows a clear relational focus, with only a minimal influence of object similarities on judgments of analogical relatedness.

To illustrate the implications of the relational focus in a more concrete way, suppose that people were faced with a task of rating the quality of the analogies that hold between the top and bottom scenes of Figure 1. Dismissing the similarity between the objects computer mouse and laptop as two members of the entity category computer equipment, and the semantic differences between a computer mouse and a pair of socks (two objects lacking a common entity category), people would probably rate Facts A and B as equally analogous to the Key fact, because they are three cases of giving, and what counts in quality evaluations are relational similarities.

In the present research we present an alternative approach to standard theories of analogy, with implications on the role of object similarities during analogical comparisons. While we tend to agree with the multiconstraint theory in granting a role to object similarities, we posit that the computation of object properties that takes place during

Figure 1. One example of an analogy in which the base (key) and target situations (A and B) have similar relations, but hold general differences among their objects.
evaluations of analogical quality does not involve assessing the proximity between base and a target objects within a hierarchically organized network of concepts. The proposals of the standard theories may be suitable for certain kind of analogies like those used by Gentner and Kurtz (2006). For example, the analogical relatedness between John bought the candy and John took the lollipop could be decided considering the similarity between buy and take in isolation. However, standard proposals might not be appropriate in those cases in which the interaction between the propositional elements composing the analogs gives rise to exemplars of a schema-governed relational category.

Exemplars of a given schema-governed category like aggression share a common schematic structure (Gentner \& Kurtz, 2005; Goldwater, Markman \& Stilwell, 2011; Markman \& Stilwell, 2001), which could be instantiated by a wide range of exemplars, like the preschooler threw a pen to his partner, the soccer player broke a leg to his rival and the girl sank her brother's head into a bucket. The alternative approach of analogical reasoning that we are presenting here supposes that two situations would be considered analogous if they could be assigned to a common schema-governed category (Minervino et al., 2013; Oberholzer, Trench \& Minervino, 2011). Frequently, in real communicational scenarios a certain schema-governed category is explicitly introduced previous to the acts of comparing and evaluating the analogability of two situations. For example, a man could tell to a friend: "Hey, I have seen cheating-like behaviors in my wife: The other day she hid her cellphone from me". To express comprehension, the friend could reply by telling an analogous situation: "The same thing happened to me! My wife hid her credit
card records from me". On the other hand, in absence of a framing schema-governed category, the comparison could be alternatively focused in the lower-level actions implied in the compared situations (e.g., the two situations could be considered analogous just as cases of hide). While standard theories of analogies seem appropriate to explain the lowerlevel type of analogical processing, the assignment approach is focused on a higher-level type of analogical reasoning guided by schema-governed categories.

With respect to the evaluation of analogies, the assignment approach posits that relational similarity is not necessary nor sufficient. Note in above examples that the preschooler threw a pen to his partner and the soccer player broke a leg to his rival could be considered analogous as cases of aggression despite not sharing similar relations (i.e., throw is not semantically similar to brake). Furthermore, hiding the cellphone from the husband could be considered as not analogous to hiding the pie from the husband besides sharing the relation hide, due to the fact that they could not be assigned to a common schemagoverned category (e.g., cheating-like behavior).

With respect to the role of objects in analogical relatedness judgments, the assignment approach posits that object similarities are taken into account to the extent that they could modify the value that the facts under comparison displayed on one dimension of the schema-governed category to which the analogs belong. For example, in Figure 1, the assignment approach predicts that if the comparison is framed by the schema-governed category awarding, people would rate Fact B as more analogous to the Key fact than Fact A because of the closeness of those first two situations in the value that they exhibit along the importance of the awarding. Object properties that count in evaluating the analogical relatedness of the Key fact with respect to Facts A and B are those related to the importance of the awarding, for example, the price of each object. Thus, as a pair of socks has a similar price than a computer mouse, the quality of the analogy between the Key fact and the Fact B would be better rated than the quality of the analogy between the Key fact and the Fact A, in which the award consists of a more expensive laptop. This treatment of semantics differs from the one given by standard theories of analogy, because it does not consider similarities and differences between objects like those provided by general knowledge networks (e.g., the similarity between a computer mouse and a laptop as members of the category computer equipment). Instead, the mechanism proposed by the assignment's approach for computing semantic similarities takes into account those aspects of objects that become relevant as an effect of the schema-governed category that is framing the comparison. For example, the price of the objects becomes relevant because it affects the values that the compared situations exhibit in the dimension of importance of the awarding.

The objective of this study was to assess whether the object similarities in properties that affect the value of the compared situations in a certain dimension of the framing
schema-governed category have an effect on quality evaluations of the analogy, as opposed to general object similarities, operationalized as membership to same category ${ }^{1}$. With this purpose, we designed an experiment in which two groups of participants received triplet of images like the ones displayed in Figure 1, which were framed either by a relation or by a schema-governed category. While one of the target objects maintained general similarities with respect to the base object in terms of their membership to a same category (e.g., computer mouse and laptop), the object of the second target did not hold general similarities with the base object (e.g., computer mouse and pair of socks). Nevertheless, the second target object could be considered more similar than the first one with respect to the base object in terms of a property (e.g., the price of the awards) that becomes relevant under a schema-governed category framing (e.g., awarding). In light of existing evidence regarding the negligible role of objects during standard analogical comparisons, we predicted that participants whose analogies were framed by the central relation (i.e., action represented by a verb) of the compared situations would rate both targets as being equally analogous to the base situation. However, the above considerations about the likely role of schema-governed categories during analogical comparisons led us to predict that framing the analogies under a common schema-governed category would lead participants to give higher scores to target analogs whose objects were not taxonomically related to those of the base situation, but which allowed a matching with respect to the base situation in terms of their value along a relevant dimension of the framing category.

## Method

## Participants and design

Forty students of Psychology at the University of Comahue (mean age $=21.4$ years, $S D=2.08$ ) volunteered to participate in the experiment, and were randomly assigned to one of two experimental conditions. The experiment has a $2 \times 2$ repeated measures design, with the independent variable framing of the analogies (same relation vs. same schema-governed category) as a between subject factor, and general object similarity between base and target (presence vs. absence), as a within subject factor. The dependent variable was the quality evaluation of analogies.

## Procedure

Participants of the two conditions of the experiment received a brief instructional text. It anticipated that they would receive several sets of three drawings in which a first scene (Key fact) would be followed by two analogous

[^514]scenes (Fact $A$ and $B$, respectively), that is, by two "situations that are analogous to the first one in essential aspects, despite being different in others". Participants were told that they should consider whether the Fact A or B seems to them as more analogous to the Key fact, or if both could be seen as equally analogous to the Key fact. The instructional material also anticipated that each set of scenes would be preceded by a brief description of the actions involved in the three drawings of the set, and followed by a prompt to provide ratings for the extent to which Facts A and $B$ could be considered analogous to the Key fact, and a verbal justification for their scoring. After reading these instructions, participants were provided with a set of practice materials. They did not receive any feedback about the content of their responses during this practice or during the experiment itself, but they did receive feedback about how to carry out the tasks. Upon reading the instructions and solving the practice trial on a computer display, all of the participants were asked to analyze each of the subsequent triplets of visual scenes at their own pace, typing their responses into the spaces provided in the Word file, and advancing to the next screen once they had finished the tasks of each set. Participants of both groups received six critical sets of scenes interleaved by six filler sets designed to prevent participants from grasping the response pattern that was favored by the manipulation in each condition. Each trial, which appeared on a different screen of the computer file, displayed a first visual scene (the base analog, named Key fact) on the uppermost section of the screen, followed by two alternative visual scenes (the targets, named respectively Fact A and Fact B) placed one next to the other (see Figure 1). Participants in the similar relation framing condition ( $\mathrm{n}=20$ ) received all triplets preceded by a brief statement stressing the verb that applied across the scenes (e.g., "These are three instances of giving"). In contrast, participants in the similar schema-governed category framing condition $(\mathrm{n}=20)$ received all triplets preceded by a schema-governed category that could be applied to all scenes (e.g., "These are three instances of awardings").

## First task: Evaluation of the quality of the analogies

 Using a 5-point Likert scale ( $1=$ barely analogous; $5=$ completely analogous), participants were asked to rate (1) the extent to which the Key fact could be considered analogous to the Fact A, and (2) the extent to which the Key fact could be considered analogous to the Fact B.Second task: Verbal justifications of the quality scores Participants were encouraged to write down a verbal justification for the previously assigned scores. For this task, they were presented with three possible kinds of unfulfilled answers followed by a blank space: (1a) "I have assigned a higher score to the comparison between Key fact/Fact A than to the comparison between Key fact/Fact $B$ because...", (1b) "I have assigned a higher score to the comparison between Key fact/Fact B than to the comparison between Key fact/Fact A because..." or (1c) "I have assigned the same scores to both comparisons because...".

## Materials

Six critical sets of drawings were built, each one comprising a base situation and two target situations (see Table 1). The characters and the actions they were performing were identical across the three scenes of each set, and could be framed either as instantiations of a common relation (e.g., two cases of giving) or as instantiations of a common schema-governed category (e.g., two instances of awarding). In contrast to the characters and their actions, which were kept constant across the three scenes of each set, the objects involved in such actions were varied. The object of one of the targets was similar in general aspects to its corresponding base object (e.g., a computer mouse and a laptop are two exemplars of the entity category computer equipment), but could not be equated to the base object along a central dimension of the schema-governed category that could be potentially applied to both scenes (e.g., if the base and the first target were framed under the schema-governed category awarding, then the importance of winning a laptop is not comparable to that of winning a computer mouse). The objects involved in the second target were chosen to display the opposite pattern: they did not maintain general object similarities with respect to the base object, but could nevertheless be equated to the base object in certain properties that become relevant under a schema-governed category framing that could be potentially applied to both scenes (e.g., while computer mouse and a pair of socks are not similar, they constitute awards of comparable importance). The order of presentation of the critical sets and the right/left position of their corresponding targets were counterbalanced.

Table 1: Experimental materials

| Set <br> \# | Framing SGC/ <br> Relation | Description of the pictorial situations |
| :---: | :---: | :---: |
| 1 | Physical exercise/ Relocate | A man is relocating big desks (BA)/ tiny stools (TA1)/ truck wheels (TA2) inside a room |
| 2 | Bragging/ Point | A man is pointing a sports car (BA)/ bicycle (TA1)/big house (TA2) to a woman |
| 3 | Smuggling/ Load | A man is loading led TV's (BA)/ fans (TA1)/ paintings (TA2) into a truck |
| 4 | Celebration/ Open | A woman is opening a bottle of champagne (BA)/ soda (TA1) / cake box (TA2) |
| 5 | Awarding/ Give | A man is giving a computer mouse (BA) / laptop (TA1)/ pair of socks (TA2) to a woman |
| 6 | Electricity consumption/ Plug | A woman is plugging in a table lamp (BA)/ floodlight (TA1) / radio (TA2) |

Note. SGC: Schema-governed Category; BA: Base Analog; TA1: Target Analog 1; TA2: Target Analog 2.

## Results

A $2 \times 2$ ANOVA with Framing condition (same relation vs same schema governed category) as between-subjects factor and General object similarity (presence vs absence) as within-subjects factor was conducted to assess how these variables impacted the perceived quality of analogies. Main effects were neither found for condition, $F(1,38)=1.01$, $M S e=0.76, p=.31$, nor for general object similarity, $F(1,38)=3.93, M S e=0.90, p=.055)$. However, there was a significant interaction between the framing condition and general object similarity, $F(1,38)=146.32, M S e=33.58, p$ < . 01 (see Figure 2). Post-hoc Tukey HSD tests revealed that in the same relation condition the ratings of the quality of the analogy were significantly higher for items with general object similarity ( $M=3.77, S D=0.697$ ) than for items without general object similarity $(M=2.68, S D=$ $0.739, p<.01$ ). Against structure mapping, these results showed that general object similarities affected the perceived quality of analogies framed by a relation. The opposite pattern of results was observed across the same schema-governed framing condition, in which the items without general object similarity but with similar dimensional value obtained significantly higher ratings ( $M=$ 3.78, $S D=0.549$ ) than items with general object similarities ( $M=2.27, S D=0.797, p<.01$ ).

A further qualitative analysis of the verbal justifications was performed in order to explore the principles underlying the evaluations of the quality of analogies. Two independent judges, both cognitive psychologists, were instructed to classify the principles applied by participants in their justifications into one of three categories: related to general object similarities, related to a verb, or related to a dimension of the framing schema-governed category. Judges should classify the principle as related to general object similarities if participants' justifications referred object similarities and differences that were not related to the verb or to the schema-governed category used to frame each triplet of images (i.e., that could be identified and conceptualized independently of the specific framing verb or schema-governed category). Judges were told that responses of this type may include similarities and differences between intrinsic properties of objects, their functions or their taxonomic membership, and were provided with examples (e.g., a computer mouse has the same color than a laptop). The principle should be classified as related to a verb if participants mentioned similarities and differences in object properties that affect dimensions of the framing relations (e.g., a computer mouse is easier to give than a laptop). Judges should classify the principle as related to a dimension of the framing schemagoverned category if participants mentioned similarities and differences between object properties that are related to a dimension of the framing schema-governed category (e.g., receiving a laptop is a more important awarding compared to receiving a computer mouse). Judges agreed in $86 \%$ of the cases, and cases of disagreement were resolved by discussion. This qualitative analysis showed that in the

Figure 2. Interaction between framing condition and general object similarity in quality evaluations.
condition framed by a relation, participants' justifications followed a principle related to general object similarities in $75 \%$ of the cases, and a principle based on dimensions of the verbs in $25 \%$ of the cases. In contrast, in the condition framed by a schema-governed category, participants used the principle related to general object similarities only in $7 \%$ of the cases, whereas in the remaining $93 \%$ of the cases they applied the principle related to a dimension of the framing schema-governed category. None of the responses of the schema-governed framing condition referred to a principle related to the verb. This analysis provides complementary evidence that general object similarities are taken into account in the same relation framing condition, but had almost no influence over quality evaluations of the schema-governed framing condition. Moreover, justifications' analysis confirmed that object similarities that count in quality evaluations of analogies framed by a schema-governed category are those related to object properties that bear on the degree to which the facts under comparison match along a relevant dimension of the framing category.

## Discussion

The present study showed that when matched objects belong to the same category, this similarity positively influences the perceived quality of a "standard" analogy (i.e., an analogy not framed by a schema-governed category). One possible explanation of the inconsistency between this finding and previous evidence (e.g., Gentner \& Kurtz, 2006; Gentner et al., 1993) could be that in our study participants were asked to justify their ratings, and there is some evidence that justifying ratings of analogical relatedness can lead to poorer discrimination between superficial and structural aspects of analogies (Sieck, Quinn \& Schooler, 1999). In any case, the central finding of the present study was that when an analogy is framed in terms of a schema-
governed category, the object properties that matter when assessing analogical comparisons are those that affect the value of the compared situations along certain dimensions of the framing schema-governed category, as opposed to the type of object similarities considered by the standard approach.

A question that may arise from our study refers to whether the framing of analogical comparisons under schema-governed categories (as in our schema-governed condition) represents a frequent or a rare occurrence in daily real-life scenarios. An example widely discussed by the multiconstraint theory indeed suggests that schemagoverned analogies are rather frequent, and that the conceptualization of similarities and differences between objects has clear implications for the generation of analogical inferences. In the context of the Vietnam/Persian Gulf analogy, Holyoak and Thagard (1995) mention that the contrast between the jungle of Vietnam and the desert sands of Kuwait was key to predicting whether the army of Saddam could be defeated by air strikes: As opposed to the aptness of the Vietnamese jungle for concealing the army, the desert sands are not of great help. As this example clearly illustrates, the comparison is framed under the schema-governed category war, and under this framing certain properties of the object ground become relevantproperties that one would not analyze in the absence of such particular framing. It is our intuition that many analogical comparisons that take place in everyday contexts are contextually framed in terms of schema-governed categories: Is the economic crisis of 2008 analogous to that of 1930?, Are the terrorist attacks perpetrated by Muslim fanatics analogous to those of radical independists of Ireland?, Is the populism led by Donald Trump analogous to the one led by Cristina Fernández de Kirchner?

The discrimination between analogies that are processed under a schema-governed category and those that are not is relevant to designing experimental materials as well as to interpret results of existing studies on analogical thinking. Just to illustrate, Figure 3 displays one of the sets of pictures employed by Markman and Gentner (1996, p. 242) to determine whether alignable differences count more than non-alignable differences during similarity judgments. If forced to decide which of the alternative target scenes is more analogous to the base situation, readers would probably choose the one on the left, as did participants of such study. As posited by the authors, what explains this preference is the fact that while the replacement of the target object by a bird represents an alignable difference in the context of the rightmost scene, such replacement represents a non alignable difference within the left scene. Alternatively, one could sensibly argue that while the left scene has to do with the physical ability of aiming at a target, the right scene represents a case of the schema-governed category zoocide. The processing of analogies under schema-governed categories does not always require the external provision of a suitable schema-governed category. As shown by Minervino et al. (2013), schema-governed categories could be naturally activated in reasoners by the

Figure 3. Sample of materials used to determine whether alignable differences or nonalignable differences count more during similarity evaluations. Adapted from
"Commonalities and differences in similarity comparisons", by A.B. Markman \& D. Gentner, 1996, Memory \& Cognition, 2, p. 242
situations themselves. In fact, during the construction of the stimuli employed in the present study we found it hard to devise situations for which the schema-governed categories that were explicitly presented in the schema-governed category framing condition would not be automatically evoked by participants in the same relation condition.

While the present study shows that a schema-governed category framing leads people to highlight object properties (e.g., price of the award) that are relevant to analogical quality evaluations, a question that may arise is whether just activating those properties without activating the whole schema will yield the same results. An experiment that could shed light on this would involve a comparison between the schema-governed framing condition of the present experiment and another identical condition in which the woman (i.e., the patient of the awarding) was replaced by a billionaire. While the consideration of the price of the objects under the first condition allowed participants to rate the Key fact as more analogous to the Fact A than to the Fact B, we hypothesize that under the other condition people would rate both facts A and B as almost equally analogous to the Key fact. This would evidence that in the schema-governed category framing condition people are not just taking into account object properties, but are considering the interaction between object and patient properties (e.g., object's price and richness of the patient). Thus, it seems likely that people take into account the interaction between the fillers of every thematic-role (e.g., object, patient, agent, and instrument) and their relevant properties to judge the analogability of the compared situations. Future studies should assess the adequacy of these and other predictions that stem from the category assignment approach.

# What can Hand Movements Tell us about Audience Engagement? 

Lida Theodorou (l.theodorou@qmul.ac.uk)<br>School of Electronic Engineering and Computer Science, Mile End Road London, E1 4NS<br>Patrick Healey (p.healey@qmul.ac.uk)<br>School of Electronic Engineering and Computer Science, Mile End Road London, E1 4NS

#### Abstract

Conventional seated audiences have relatively restricted opportunities for response. Perhaps the most salient is applause but they use their hands to make other visible movements: to fix hair, adjust glasses, scratch ears. The question we address here is whether these apparently incidental movements may provide systematic clues about an audience's level of engagement with a performance. We investigate this in the context of contemporary dance performances by analysing audience hand movements in four performances at the London Contemporary Dance School. Hand movements were tracked using a reflective wristband worn by each audience member. A blob detection algorithm applied to the video recording examined whether changes in hand movement are associated with audience arousal levels to the performance. The results show that hands move least during the most preferred and most during the least preferred dance pieces. We conclude that still hands are a signal of higher levels of engagement.

Keywords: Audience; Engagement; Blob Detection; Hand movement; Handedness; Contemporary Dance.

## Introduction: Interacting with Audiences

In many live performances audiences are separated from performers; seated in the dark observing the performance. The primary conventional opportunity for members of an audience to express their satisfaction or dissatisfaction about a performance is through applause and/or cheering. Nonetheless, audiences have notoriously recruited other means of signalling their ongoing responses including the organised and carefully timed use of apparently innocent activities such as coughing (Wagener, 2012; Broth, 2011).

Our programmatic hypothesis is that audiences' ongoing responses are part of a bi-directional system of audience-performer communication that distinguishes live from recorded performance. A key motivation for this hypothesis is that performers themselves distinguish between "good" or "bad" audiences for the same performance and between moments of engagement or "lift" and moments of boredom in an audience (Healey, Oxley, Schober, \& Welton, 2009). The question this raises is what could performers be detecting in these situations that informs their dynamic sense of how well a performance is going. Here, we consider an especially restrictive case: contemporary dance. In a typical performance the audience will be in the dark, the performers behind bright lights and loud music accompanying the dancing. Audience behaviours are restricted by conventions on the types of response that it is considered acceptable to display. Performers are constrained by the need to concentrate on the physical movements required for their performance. In
contrast to live genres such as Street Performance, Stand-up Comedy or Drama there few, if any, opportunities for direct eye contact or verbal exchanges with the audience. Almost the only available channel of communication between audience and performers is body movements.

One overt physical response that is visually salient and potentially detectable by dancers is audience hand movements. Casual observation of a dance audience reveals a wide range of ongoing hand-movements by audience members involving an apparently diverse set of activities: scratching, adjusting hair, adjusting glasses, support the chin and drinking amongst others. The question addressed here is whether these movements may provide a signal of audience engagement and thereby form part of a feedback cycle between the performers and their audience.

## Measuring Audience Responses

Understanding and sensing audience responses can provide an evaluation tool to help performance directors understand how their work is received. Performance unfolds in time, making the collection of data more problematic for researchers (Schubert, Vincs, \& Stevens, 2009). However, there are a growing number of studies in dance research that use sensing technologies to examine dancer positions in time (Calvo-Merino, Glaser, Grèzes, Passingham, \& Haggard, 2005) although very little research has focused specifically on audiences (Katevas, Healey, \& Harris, 2015; Gardair, Healey, \& Welton, 2011; Vincs, Stevens, \& Schubert, 2010; Healey et al., 2009).

The most obvious way that one can measure satisfaction in audiences is from the levels of applause. Mann, Faria, Sumpter, and Krause (2013) used a mathematical model to quantify the role of social contagion in the starting and stopping of applause during a presentation. They found that the rate at which new individuals start clapping is proportional to how many people are already clapping. However, this is a measure of response after the end of the presentation rather than a concurrent response. An alternative approach asks participants to make explicit self-reports of their responses during a performance. Vincs et al. (2010) took this approach with a 'portable Audience Response Facility' (pARF), a PDA that records participant's ratings of engagement during a dance work. They found that periods of high self-reported engagement often follow choreographic surprises, and that periods of low engagement tend to be associated with more pre-
dictable dance structures (Vincs et al., 2010; Vincs, Schubert, \& Stevens, 2009). Using a post-performance methodology, Stevens et al. (2009), explored the reactions of 472 audience members as they watched contemporary dance by using an Audience Response Tool (ART) that collects responses using qualitative and quantitative questionnaires. Some of the items probed participants on their experience and enjoyment of the performance included visual and aural cues, dancer characteristics, movement, choreography, novelty, spatial elements, intellectual and emotional stimulation. Unfortunately, the act of asking participants to evaluate the performance after its end has the disadvantage of the "peak-end" effect, which shows that a measure taken immediately after an experience is strongly influenced by the peak emotion and by the emotion experienced at the end of the experience.

Two non-intrusive approaches have demonstrated connections between the movements of performers and audiences as an element of live feedback between performers and audience. Healey et al. (2009) pioneered the use of motion capture techniques in this context by exploring the intercorrelations between patterns of head movement between a seminar speaker and their audience during a seminar. The results of their study indicate that head movements of the performer are reliably triggered by head movement of audience members. Using a detailed ethnographic approach, Gardair et al. (2011) examined audience dynamics in a study of street performance in Covent Garden. She explored how passers-by notice when a street performance is happening, by first becoming watchers and then transformed into audience members. Gardair argued that people's body orientations show the spaces that people most often interact and also that people use their body torque to express their engagement levels with the performance.

## What Do Hand Movements Signal?

Although hand movements are visually salient they have a wide variety of potential causes. It is especially challenging to interpret naturally occurring audience hand behaviour without convergent verbal feedback. Most of the gesture literature focuses on explicitly designed co-speech gestures. Audience hand behaviour includes hand to face gestures or selftouch gestures (STG) that appear to lack overt, intentional design and may be performed with little or no awareness (Harrigan, Kues, Steffen, \& Rosenthal, 1987). One important class of non-speech hand movements that are relevant for audiences are self-touch gestures (STG's). According to Harrigan et al. (1987), 55\% of STG are applied to head or face, $8 \%$ are applied to the legs and $2 \%$ of STG are directed to the trunk. They are thus likely to be visible at a distance.

Studies have shown that there is an increase in selftouching behaviour in stressful and fearful situations (Butzen, Bissonnette, \& McBrayer, 2005; Heaven \& McBrayer, 2000) although Ekman and Friesen (1972) suggested that STGs may also occur when a person is relaxed. Butzen et al. (2005) found a significant increase of STG in response to a video about chiggers compared to another kind of video. In a study from Heaven and McBrayer (2000) the participants listened
to texts about leeches and canaries and then had to answer several questions. Although there were no differences between the two listening conditions there was an increase in STG for the leeches text during the answering period. Rogels, Roelen, and Van Meen (1990) found that children between 3 and 6 years showed more self-touch gestures while talking about a cartoon they had just seen than while watching the cartoon. Other studies (Grunwald, Weiss, Mueller, \& Rall, 2014) hypothesise that there is a relationship between the frequency of STG and arousal. Barroso and Feld (1986) investigated this by testing the occurrence of self-touch gestures performed with one or both hands as a function of four different auditory attention tasks. They found that with increasing complexity and attentional demands both one and two handed self-touch gestures increased. Handedness also appears to play a role. Kimura (1972) showed right handed participants perform STG's equally often with the left and the right hand. However, there is evidence that people use their right and left hand for different reasons while talking. Kipp and Martin (2009) found an association of handedness with the emotional dimensions of arousal. In particular, they found that the right hand is used more when experiencing anger and the left hand when experiencing relaxed and positive feelings. According to Roether, Omlor, and Giese (2010) the body seems asymmetric in its emotional expressivity. The left side uses higher energy and higher amplitude for emotional movements than the right side.

Hand behaviour and boredom is another relationship that might help us interpret audience hand movements. According to Kroes (2005) people experiencing boredom tend to relax their body muscles. Bull (1978) claims that there are specific head positions that characterise boredom such as drops head, turns head and head lean. Bored people also tend to use their hands to support their head or perform self-touching gestures (rubbing or clutching face). However, Kroes (Kroes, 2005) notes that this hand behaviour is a sign of low arousal but it might not be a sign of dissatisfaction. According to BianchiBerthouze, Kim, and Patel (2007), boredom is mostly associated with the decrease of body movement. However, contradictory findings show that increase of movement was associated with frustration, loss of interest and boredom (Kapoor, Burleson, \& Picard, 2007), this suggests that boredom can also correlate with episodes of high movement. In summary, we believe that the claims in the literature about movements and boredom are not entirely consistent and seem to depend a lot on the social context of the activity.

Overall, the interpretation of hand gestures is problematic however, it appears that STG are implicated in the regulation of emotional and cognitive processes. Based on the literature presented above we believe that in the context of contemporary dance audience hand movement might give us information about audience engagement to the performance. We try to investigate this by first testing the general hand behaviour patterns that evoke in an audience and then examine whether these patterns affect the audience engagement. This paper
presents some initial results relevant to audience hand motion patterns by testing the following hypotheses. The first two hypotheses examine whether hands are an important sign of audience engagement that might be detectable by the dancers.

Hypothesis 1 (H1): Audience hand movements provide a potentially salient signal of response to performers.

Hypothesis 2 (H2): If hand movements have a special status as a response signal they should diverge from other movements.

In addition, hypothesis 3 and 4 examine the relationship of hand speed with engagement and/or boredom. In contrast to the association of boredom with low movement described above, we believe that in the context of a dance performance applies the opposite. Based on this we will test the following hypotheses:

Hypothesis 3 (H3): Less movement of hands on face signals engagement.

Hypothesis 4 (H4): More movement of hands on face signals disengagement.

These hypotheses will be tested using the methodology described below.

## Performances by London Contemporary Dance School

The study presented in this paper took place at "ThePlace" theater in London where four contemporary dance pieces performed by dancers of the London Contemporary Dance School(LCD). As part of our second study on audience responses, we filmed audiences and dancers during the performance. The performance lasted for 1 hour and 40 minutes and consisted of 4,20 minute dance pieces (part 1 to part 4) and a 20 minute interval between the second and the third piece (see figure 1). Each dance was performed by LCD postgraduate students and directed by commissioned professional choreographers.

Figure 1: Performances Part 1 to Part 4 (from left to right) performed by LCD.

## Methods

## Equipment set-up

In order to be able to capture a big enough sample of the audience, we used two Basler ace (1280x1024px resolution) night vision cameras. An infrared light (IR) was attached on top of each camera so as to be able to film the audience during the dark periods of the performance. Both cameras and IR lights were placed on the theatre truss on top of the stage pointing towards the part of the audience to be filmed (See figure 2). For the filming of the dancers a JVC professional camera was
hanged from the rig facing the stage. For a synchronised double GEV camera recording we used Gecko software made by Vision Experts operated on a Windows 10 pc . Gecko gave us more data accuracy since it provides a timestamp on each frame and is able to capture 45 frames per second.

Figure 2: Plan drawing of "ThePlace's" theatre showing equipment setup.

## Hand tracking: Reflective Wristbands

Apart from filming the audience and the dancers, the methodological aim of this study was to extract the hand (wrist) movements of each audience member automatically. In order to do this, we created bracelets made of 5 mm reflective rope. A small plastic bag with two reflective bracelets together with instructions of how to wear them was placed on the arm of each theatre seat (See figure 3). Each audience member had to wear one wristband on each hand. The bracelets were only visible in the video recordings because of the IR lights shooting directly on them. This was the cheapest and easiest solution we could find to do an automatic tracking and record continuous wrist movements.

Figure 3: Front and back side of ziplock plastic bag with two reflective wristbands and how to wear instructions (left). Blob detection algorithm running on audience footage (right).

## Hand and body data extraction

A blob detection algorithm made by the blobscanner processing library was applied on audience footage to track the reflective wristbands on each frame (See right image on figure 3). Blob detection is a computer vision method that is able to detect similar regions in a digital image, such as those with the same brightness or colour, compared to surrounding regions. In our case a blob is a region of white pixels (reflective
wristbands) in the image. By applying this method on the videos, we extracted the position $x, y$ of each blob in the image or in other words the right and left wrist locations of each audience member in each frame of the performance.

However, due to the complexity of the human hand movement and the limitations of the algorithm it was impossible to get a stable continuous detection of the hands since the algorithm was unable to attach and keep the correct blob on each hand throughout the frames. Due to this limitation, the data was extracted first, the hand positions $\mathrm{x}, \mathrm{y}$ were played back on top of the footage and some manual work was done to help the algorithm pinpoint the correct blob for each hand for the whole duration of the video. By doing this we ended up with a datafile with the $x, y$ positions of left and right hand of each audience member during each dance piece. In order to be able to test the significance of the hands in the performance, we compare their behaviour with that of the rest of the body. To measure the general upper-body movement of the audience, we used an optical flow algorithm. In particular we applied the algorithm on each person separately removing the optical flow vectors of each person's hands. This gave us the upper-body movement of each person without the movement of the hands (See images on figure 4).

Figure 4: Captured areas for optical flow.

## Results

The informal observation of the video footage showed that there were very few overt responses in the audience; the most salient identifiable movements were those of bringing the hands up to the face. Overall, we extracted hand motion data from 27 audience members ( 18 females and 9 males). In order to test if audience hands produce enough movement to be detectable by the dancers (H1), we measure the duration of hands being up and down as well as the hand speed during the performance. The results indicate that people have their hands on their faces for about half of the performance ( $42 \%$ of the time have their hands up compared to $58 \%$ that they have them down) while the hands are moving faster when they are up compared to when they are down, in a resting position. We examine separately the case of hands to the face by calculating the number of times each hand is moving (fix hair, adjust glasses, scratch ears) or not (hands on chin or supporting head). We found that overall the number of times the hands are moving is approximately the same with the times the hands are still ( $48 \%$ moving, $52 \%$ still).

Therefore, it appears that the audience performs enough hand movements for the performers to detect. In order to examine if hand movement could provide us signals of audience affective state (H2), we compare its similarity to the movement of the upper-body. Figure 5 shows audience body movement and hand movement for each part averaged every 1 minute. From these two graphs, it is apparent that body and hands behave differently throughout the performance while overall there is a decrease of movement from part 1 to part 3 followed by a sharp increase in the movement of the hands at the end of part 4. From these two plots, it is apparent that audience body movement is low in part 2 compared to the other 3 parts while hand movement seems to be lowest in part 3. In summary, these findings provide us with some evidence that hand movement might be a significant audience response that might be detectable by the performers and can potentially give us information regarding audience engagement to the performance.

Figure 5: Upper-body speed (left) and hand speed (right) for each part of the performance averaged every 1 minute.

Focusing separately on each part of the performance, we next examine audience engagement levels by testing how long people keep their hands up or down and how do hands behave when they are up to the face (H3, H4). The left plot on figure 6 shows the amount of time hands are up or down in each part. It is apparent that people keep their hands on their face for longer as the performance progresses from part 1 to part 3 , although that duration decreases slightly in part 4 . The right plot on figure 6 shows the number of times hands are up (moving/not moving) for each part of the performance. From this plot, it appears that the mobility of the hands decreases as the performance progresses. Looking at the two plots, we see differences between the 4 parts of the performance. In part 1 , hands seem to be down for longer while when they are up their mobility is relatively high. Overall, part 1 presents more moving than still hands. In part 3, people have their hands up for longer, however most of the time hands are still when they are up. This means that in part 3 we have an increase in the number of still hands on face. Finally, parts 2 and 4 are somewhere in between with the only difference that in part 2 hands
are more likely to be found down while the opposite is true for part 4. In summary, it seems that there is an increase in the number of hands being on face while hands are getting stiller as the performance progresses. This result fits with the movement of the body that also decreases from part 1 to part 3. At the end of part 4 both body and hand speed increase. We compared these results with audience preference levels for each part through an online survey sent to participants with a range of familiarities to dance. The main aim of the survey was to ask people to watch the footage of the 4 dance pieces and rank them in order of preference. The order of the performances was randomised for each participant. We collected answers from 21 people ( 18 females and 3 males), 8 of which were professionally connected to dance and were watching dance more that 4 times a year. The rest were dance enthusiasts that were going to dance performances 3 to 4 times a year. The results of the survey indicate that the 2nd part of the performance is the most preferred, 3rd part comes next while 1st and 4th are the least preferred in that order. In comparison to the previously mentioned results, we observe that during the most preferred parts (part 2,3) there are more hands still on face while in the least preferred there is a higher mobility of the hands that gets more distinct at the second half of part 4, very end of the performance.

Figure 6: Duration of hands being up and down for each part of the performance (left). Number of time hands are up (Moving and Not moving) for each part of the performance (right).

An unexpected finding of this study is the different behaviour between audiences left and right hand. Overall, during the performance the left hand moves slightly faster than the right while the right hand is more likely to be found up on the face compared to the left. The first plot on figure 7 shows the mean speed of the left and right hand for each part of the performance. In parts 1 and 2 the left hand seems to move faster compare to the right while in the Part 3 and 4 is the other way around, the speed of the right hand is slightly higher compared to the left. Finally, the second plot on figure 7 shows the average number of times left and the right hand were found up for each part of the performance. This plot indicates that there is a difference between the number of times people use their left and right hand which is getting
progressively bigger from part 1 to part 4.

Figure 7: Mean hand speed of left and right hand for each part of the performance (left). Mean number of times left and right hand were up during each part (right).

## Discussion

The results described above provide us with some initial clues to the importance of overt audience reactions to contemporary dance. Like Theodorou, Healey, and Smeraldi (2016), these results show that overall, audiences have their hands up to their faces for about half the performance while the speed of hand movements varies a lot throughout. This suggests that there is audience hand movements that are both frequent and potentially detectable to the dancers. Previous studies have shown that audience faces tend to be expressionless during dance performances and so hands might be the part of the body provide signals of satisfaction or dissatisfaction (Theodorou et al., 2016). Combined with the preferences expressed in the survey, the results show that the most preferred performances are the ones that the audience moves least while during the least preferred performances hand movement increases and people perform more self-touching gestures. We interpret this finding as suggesting that people become restless and this leads to more spontaneous self-touching gestures. These observations suggest that it is actually the lack of movement that is a key signal of how engaged people are in the performance and fidgeting and spontaneous self-touching relate more to audiences boredom or nervousness (Healey, Theodorou, \& Woods, Forthcoming 2017). However, the ratings collected by the online survey can only capture overall preference levels, rather than the momentary engagement of the audience. This is something that needs to be explored in future work by, for example, showing people shorter videos from different parts of a performance instead of judging the dance piece as a whole.

An unexpected finding of the study was the systematically different behaviour of the left and right hand throughout the performance. In particular, the results indicate that overall the left hand moves faster compared to the right while the right hand is more likely to be found up. This finding is opposite to what we found in our first study which showed that people have their left hand up more times and for longer compared to the right hand. These different hand responses may indicate that people have a left-right asymmetry in their expres-
siveness when watching dance. Kipp and Martin (2009) have proposed that there is an association of gesture handedness with the emotional dimensions of pleasure and arousal. In the future we plan to examine this association further, and test the aforementioned questions of boredom and engagement using a more controlled methodology with recruited audience members.

## Acknowledgments

This work was funded by the Engineering and Physical Sciences Research Council (EPSRC) as part of the Centre for Doctoral Training in Media and Arts Technology. The authors extend a personal thank to Peter Laycock producer of "The Place" for letting us film the performances, as well as Marco Cifre,Sam Wood and Petros Koutsolampros for helping with all the technical requirements.

#### Abstract

Analogical reasoning, the mapping of structured relations across conceptual domains, is commonly recognized as essential to human cognition, but young children often perform poorly in the classical $\mathrm{A}: \mathrm{B}:: \mathrm{C}:$ ? analogical reasoning task. Particularly, young children have trouble when the objects in the task are not strongly associated with each other, and/or when there are strong associative lures among the potential answers. Here, we examine whether successive trials that repeat the same relation needed to solve the analogy can help overcome some of the challenges with weakly associated items. In the first of two experiments, our results were mixed. In the second, we simplified the design, and were able to more clearly show a benefit of repeating relations across consecutively solved problems.

Keywords: Analogical reasoning; development.

## Introduction

Analogical reasoning lies at the core of human cognition (Holyoak, 2012; Hofstadter \& Sander, 2013). It refers to the transfer of a structured set of relations from a source domain to a target domain, which can often generate insights into how to solve novel problems and generate new ideas (e.g., Gick \& Holyoak, 1980; Lindsey, Wood \& Markman, 2008). A typical way to research and assess analogical thinking ability is the $\mathrm{A}: \mathrm{B}:: \mathrm{C}: \mathrm{D}$ analogy (e.g., dog:doghouse::bird: ? solution "Nest", in which the "lives in" relation must be abstracted).

Many experiments have been devoted to the study of ontogenetic changes in analogical reasoning ability (Gentner, 1988; Holyoak, Junn, \& Billman, 1984; Richland, Morrison, \& Holyoak, 2006; Thibaut, French, \& Vezneva, 2010b). Children's analogical reasoning capacities improve as their knowledge of the involved relations, or their abilities to resist irrelevant information increase (e.g., Goswami, 1992). Several models have been proposed in order to explain these changes. They fall roughly into two subclasses: models that try to explain development of analogical reasoning by emphasizing the increase of structured knowledge about the world (Goswami, 1992) and models that emphasize the maturation of control processes, such as working memory or response inhibition (Halford, Wilson, \& Phillips, 1998; Richland et al., 2006).

Richland et al. (2006) and Thibaut and colleagues (Thibaut, French, \& Vezneva, 2008, 2010b; Thibaut, French, Vezneva, Gérard, \& Glady, 2011) posited that while
knowledge of relations is necessary for analogical reasoning, it is insufficient. They claimed that cognitive control processes are also critical for strategically inhibiting irrelevant information and responding consistently with the task main goal. Thibaut et al. interpreted their results as showing that younger children's difficulties with analogy making arose because of insufficiently developed control processes, specifically inhibition. In one experiment involving semantic $\mathrm{A}: \mathrm{B}:: \mathrm{C}$ : ? analogies with four possible responses Thibaut, French, and Vezneva, (2010b) compared weak and strong analogies (i.e., analogies in which the items of the $A: B$ and $C: D$ pairs were weakly, or strongly, associated). Results revealed poorer results in weak (e.g., shirt:suitcase::toy:box) analogies than in strong ones, especially when the number of distractor items was high (i.e., three vs. one). Importantly, the authors controlled to ensure that the children knew the semantic relations within the pair (i.e., the semantic relations between A and B, and between $C$ and $D$ ). Thus, children's failure to map the $A: B$ pair on the potential C:D target pair could not be explained by a lack of knowledge. They showed that a greater number of distractors led to poorer performance in the case of weak analogies. They suggested that for strongly associated A:B and $\mathrm{C}: \mathrm{D}$ item pairs, children were not interfered with by the semantic distractors. In contrast, when the problem involved weakly associated items, mapping the $\mathrm{A}: \mathrm{B}$ pair onto the $\mathrm{C}: \mathrm{D}$ pair requires more than simply accessing the obvious semantic dimensions of the items.
The authors characterized analogy-making as a search through a space of features and potential relations. The number of relations holding between any $A: B$ pair is potentially large because, depending on the context, any number of different relations might be relevant (French, 1995). As mentioned above, the structure of the search space and the presence or absence of competing nonanalogical solutions have an effect on the search, especially for young children, who have greater difficulty handling the cognitive load associated with a more elaborate search of the space of possible solutions.

The notion of "searching in a semantic space" was directly investigated in an eye-tracking study by Thibaut and French (2016; Thibaut, French, Missault, Gérard, \& Glady, 2011). The authors used an eye-tracker because cognitive monitoring is difficult to assess with the sole
performance measures (i.e., error measures and reaction times) that are usually used in the literature (e.g., Rattermann \& Gentner, 1998; Richland et al., 2006).

In a $\mathrm{A}: \mathrm{B}:: \mathrm{C}: \mathrm{D}$ format, they found key differences between adults and children in the temporal organization of their respective search profiles. First, adults focused on the A and B pair at the beginning of the trial, paying less or no attention to C and to stimuli in the solution set. Later they focused on C and the Target, which they compared with the semantically related distractor. By contrast, children devoted more time on C on which they actively focused during the entire trial and was used as an anchor stimulus, compared to A and B for adults, and that the Target and the semantic distractor were focused on earlier by children than by adults. These results suggest that children might fail in analogical reasoning tasks because they do not pay sufficient attention to A and B or do not include them in their search for the "one that goes with C".

This analysis led us to the central prediction of the present paper. We started with the general hypothesis that young children find it hard to follow the instructions, that is, to integrate A and B in their exploration of C and the solution set. However, as Thibaut et al (2010b) showed, strongly associated items constrain the search space sufficiently for children to readily map the relevant relation, with no ill effects of distractors. Here we examine whether presenting successive trials that require the same relation to solve the analogy will improves its use. That is, perhaps the semantic search does not need to start from scratch with weakly associated items if the relevant relation was still active in memory when the next item with the same relation is introduced. This account would predict that a blocked presentation of trials, which presents blocks of successive trial with same relation, would outperform an interleaved presentation format which would alternate between relations on successive trials (see Rohrer \& Pashler, 2010). An advantage for blocked presentation would also be consistent with structural alignment accounts that emphasize that comparing pairs of objects bound by the same relation should help abstract that relation and generalize it to more disparate sets of objects because the process of comparison itself serves to shift attention to common relations and away from superficial differences between objects (Gentner, 2010). That is, multiple strongly associated pairs objects bound by the same relation should help children recognize when that relation applies to more weakly associated objects.

On the other hand, models of memory and discrimination learning predict benefits from interleaved presentation (Rohrer \& Pashler, 2010). That is, spacing out instances of the same relation may elicit deeper processing each time it is retrieved, strengthening its memory compared to sequential presentations, which may reduce the attention paid to the repeated item (e.g., Greene, 1989). Additionally, spacing has been shown to aid not just memory, but generalization in young children (Vlach, Ankowsky, \& Sandhofer, 2012) potentially because at each new instance,
only the most relevant information is re-activated (i.e, the information common to both initial and later items), while irrelevant information is forgotten. Further, interleaving may build on the advantages of temporally spacing out examples by also filling in the temporal gaps with problems that rely on distinct structural relations. This interleaving of different relations can often aid learning and problem solving by setting up useful contrasts, sharpening the understanding of each relation.
In two experiments, we directly test the prediction that a blocked presentation will improve performance, shared by a semantic-search account and a structural-alignment account, against the prediction that interleaved presentation will improve performance, made by memory and discrimination learning accounts.

## Experiment 1

In the first experiment, we aimed to test (1) whether accuracy using a relation improved over multiple trials wherein that specific relation solved the analogy (2) whether Weak trials specifically benefitted from following Strong trials and 3. whether these benefits depended on either a Blocked or Interleaved presentation.

## Methods

## Participants

Subjects were 474 -5-year-old preschool children ( $\mathrm{M}=56$ months; range, 49 to 64 months). Their participation to the experiment was submitted to informed consent of their parents.

The subjects were equally divided into two groups: Blocked group ( $\mathrm{N}=24 ; \mathrm{M}=55$ months; range, 49-62 months) and Interleaved group ( $\mathrm{N}=23$; $\mathrm{M}=57$ months; range, $50-64$ months). Participants were randomly assigned to the blocked or the interleaved condition.

## Materials

The experiment consisted of 2 practice trials, 12 learning trials and 4 posttest trials, which occurred with a minute delay after the learning trials. (See Table 1 for the list of trials). Analogies were of the $\mathrm{A}: \mathrm{B}:: \mathrm{C}:$ ? format and were composed of 7 items (colored pictures; see Figure 1). The problem consisted of the A:B pair (the source), the C item (the target), and an empty rectangle. The solution set was composed of four stimuli: the analogical answer, two distractors that were semantically related to the C item, and 1 distractor that was not semantically related to C. Positions of the different alternatives were counterbalanced across trials. There were two types of analogies, called "strong" and "weak". Strong and weak analogies were defined in terms of the semantic association strength within each pair of pictures defining an analogy, that is between A and B, and between C and the analogical target. It was determined by university students. They were asked to rate to what extent each item of the pair made them think of the other one. It was stressed that the task was to rate how strongly
the two items were associated in their mind. The ratings were on a 1-to-7 scale. The strongly associated trials were composed of strongly associated A-B and C- T(arget) pairs, and the weakly associated trials were composed of weakly associated A-B and C-T(arget) pairs. The mean C-Target association strength was 3.53 ( $\mathrm{SD}=1.11$ ) for the weak analogies, and $4.89(\mathrm{SD}=1.44)$. for the strong.

In both learning conditions, there were 4 relations (tool for, produces, contains, becomes). For each relation, there were 3 learning trials, composed of 2 strong analogies and 1 weak analogy. In half of the trials, the two strong analogies were introduced before the weak trial whereas the reverse was true for the other half of trials. In the blocked condition, the three trials for one relation came in a row (either weak, strong 1, strong2, or strong1, strong2, weak, with two relations starting with a strong analogy and two relations with a weak analogy) whereas in the interleaved condition, each of the 4 relations was displayed once in a row, followed by another exemplar of the four relations. Two relations out of 4 started with a weak analogy and two relations by a strong. This was done in such a way that in both conditions the same "weak-strong-strong" or "strong-strong-weak" sequence were introduced for each relation. The 4 posttest trials were weak trials, one per relation. There were four versions of the blocked condition and four versions of the interleaved condition to counterbalance the order of the presentation of the relations, exemplars within the relations (e.g., which weak exemplar was in the post-test and which in the learning phase), which relations had strong exemplars first and which had weak.

The trials were presented to the children on a screen through a PowerPoint file.

## Procedure

Children were individually tested in their school, in a quiet room. In both the blocked and the interleaved conditions, the 7 items defining one trial were displayed simultaneously. There were two practice trials. In the first practice trial, the task was explained to children as follows: "Let me explain how it works. At first, you have to find why these two pictures [showing A and B] go well together. So, why do you think [A] goes with [B]? OK! You see this one [showing C]? It is alone. What you have to do is to find one picture in these four images [showing the four answer options] that goes well with this one [C] in the same way as this one [B] goes with [A] so the two pairs of pictures go together. Which picture goes up there [showing the empty slot] with [C] like [B] with [A]? The child gave an answer and justified his/her choice. Then, the experimenter rephrased the entire trial, explaining and emphasizing why "A and B" and "C and Target" go together for the same reason. During the second practice trial, they were asked to do the same. When children did not attend to the A:B pair while explaining their choice, they were asked to do so, and care was taken to ensure that they understood the instructions during the training trials. In the relational learning phase, they were asked to do the same thing that
was explained to them during the experiment trials and to justify their answer afterward. No feedback was given for the relational learning trials. The experiment was then interrupted for one minute. The experimenter and the child talked freely. Then, the four test trials, one per relation, were introduced as novel trials.

## Contains- Weak 1

Contains- Strong 1

analogical

semantic

semantic

unrelated

Figure 1: Two examples of analogies used for the "contains" relation, one "weak" and one "strong". Analogical: Analogical answer; Semantic: Distractor semantically related to the C item; Unrelated: distractor semantically unrelated to C.

At the end of the experiment, children's understanding of the semantic relation between A and B and between C and Target was assessed. They were shown the A:B pairs and were asked why the two items of each pair went together. The same was true for the C:Target pairs (see Thibaut et al., 2011, for more details).

## Results

We first removed all the trials in which children could not identify one of the two semantic relations, either $A: B$ or C:D. As a result, 49 trials out of 752 trials (the majority of them for "car producing exhausts) were removed from
subsequent analysis. We first ran a two-way ANOVA on the proportions of correct answers for weak analogies with Position of weak (Before strong, After strong, At test) as a within factor and Presentation (Blocked, Interleaved) as a between-subject factor. It revealed a significant main effect of Position of weak, F $(2,90)=3.50, \mathrm{p}<.05, \eta^{2}=.07$. See Table 1. A Tukey HSD test revealed that the weak analogies were marginally significantly better understood when they were introduced after strong items rather before strong ( $\mathrm{p}=$ $.056)$ or at test $(\mathrm{p}=.075)$ with $24 \%, 39 \%$ and $25 \%$ of correct answers for the weak before the strong items, after the strong and at test, respectively. There was a decline for the weak items at test, which failed to reach significance, p $=.074$, compared to the second weak item). There was no main effect of Presentation and no interaction. A three-way ANOVA was conducted on the percentage of correct answers for strong stimuli, with Type of trials (Before weak, After weak), Position (First, Second strong) as within factors, and Presentation (Blocked, Interleaved) as a between factor. It revealed a main effect of Position, F (1, $45)=6.00, \mathrm{p}<.05, \eta^{2}=.12$ ), with the second strong higher than the first strong ( $\mathrm{M}=49 \%$ and $60 \%$, for the first and second respectively). There was no main effect of Position and no significant effect of Presentation, and no interaction between any of the factors.

Table 1: E1 Means (SD's) for the proportion of accurate responses for each trial type

|  | Blocked | Interleaved |
| :--- | :--- | :--- |
| Strong 1 | $.49(.22)$ | $.49(.25)$ |
| Strong 2 | $.55(.26)$ | $.65(.20)$ |
| Weak, before Strong | $.27(.36)$ | $.22(.29)$ |
| Weak, after Strong | $.35(.40)$ | $.43(.43)$ |
| Weak, after delay | $.23(.21)$ | $.27(.20)$ |

## Discussion

Results were mixed. On the one hand, for both Strong and Weak items, there were main effects of Position, suggesting that repeating relations improves performance. While the numerical increase of Weak trials following a Strong appears to be the root of the main effect of Position for those trials, post-hoc tests specifically looking at a benefit of a Weak trial following a Strong did not find a significant advantage contrasting it with either one of the other positions alone. In addition, there was no significant difference between a Blocked and an Interleaved mode of presentation, and not a significant effect specifically for Weak trials following Strong ones. Further, even after a delay of just one minute, there was quite low performance for weak items at test, perhaps due to that interruption. Indeed participants engaged in an informal discussion with the experimenter and this might have contributed to decrease their attention.

## Experiment 2

Because of the mixed results, perhaps due to a lack of power, we simplified the design for the second experiment. First the teaching/test phase distinction was abolished. The same four relations were used with four trials each without any delay between trials. Another simplification was that the two strong analogies were always introduced before the weak analogies. The idea was to test whether weak analogies, that are more difficult than the strong analogies, would get more positive influence from strong analogies in the Blocked or in the Interleaved condition. The design of E1, with some Weak trials appearing after a delay and others before the Strong trials, may have prevented any potential benefit that a blocked presentation could provide. This simplified design will have a greater potential to detect any effect of Presentation. In addition, any effect of Presentation would show that experience with a specific relation improves performance over an above a general order effect which may simply reflect more general improvement at performing the task. The same hypotheses as in Experiment 1 apply here.

## Methods

## Participants

Subjects were 57 4-5-year-old preschool children ( $M=55.4$ months; range, 49 to 63 months). Their participation to the experiment was submitted to informed consent of their parents.

The subjects were equally divided into two groups: Blocked group ( $\mathrm{N}=29 ; \mathrm{M}=54$ months; range, 49 to 62 months) and Interleaved group ( $\mathrm{N}=28 ; \mathrm{M}=56$ months; range, 50 to 63 months). Participants were randomly assigned to the blocked or the interleaved condition.

## Materials

The same set of analogies as in Experiment 1 was used, except for three pictures that were replaced in this novel version. In the two presentation conditions, the two strong analogies were always introduced before the two weak analogies. In the Blocked, the four analogies (trials) illustrating one relation (e;g., contains) were introduced before the four analogies depicting the next relation (e.g., tools for) were introduced. In each case, the two strong trials were introduced before the two weak trials. In the interleaved case, one strong analogy from each of the four relations were first introduced. It was followed by the second strong analogy of each of the fours relations which in turn was followed by the first and the second weak analogies. There were four versions of the blocked condition and four versions of the interleaved condition in which the order of presentation of the first and second strong, and of the first of second weak was modified.

## Procedure

The same procedure as in Experiment 1 was used here, except that there was no test phase. The experiment started with two practice trials, and was followed by the 16 learning
trials. There was no feedback in the learning trials.

## Results

We ran a three-way ANOVA, with Presentation (Blocked, Interleaved) as a between factor, Analogy type (Strong, Weak), and Item Position (First, Second) as within subject factors. It revealed that strong analogies were significantly better understood than weak analogies ( 52 vs $30 \%$ ), $\mathrm{F}(1,55$ ) $=43.45, \mathrm{p}<.0001, \eta^{2}=.44$, and that the blocked presentation gave better results than the interleaved presentation, $\mathrm{F}(1,55)=8.22, \mathrm{p}<.01, \eta^{2}=.13(\mathrm{M}=46 \%$ vs $36 \%$ ). The key association strength $x$ presentation interaction was also significant, $\mathrm{F}(1,55)=4.22, \mathrm{p}<.05, \eta^{2}$ $=.07$,showing that the difference between strong and weak analogies was larger in the interleaved case than in the blocked case. However, to examine effects on the Weak Trials specifically, we conducted a Presentation (Blocked, Interleaved) X Position (First, Second) mixed-effects ANOVA, which showed a main effect of Presentation, with Blocked $(M=38 \%)$ eliciting higher accuracy than Interleaved $(\mathrm{M}=21 \%)$. $\mathrm{F}(1,55)=12.24, \mathrm{p}<.005, \eta^{2}=.18$ (no other effects approached significance). See Figure 2.

Figure 2: E2 Means and standard errors for proportion of accurate responses.

## Discussion

Overall, the experiment showed that the Blocked condition led to better results than the Interleaved condition: seeing the four trials illustrating a given relation in a row led to better results than seeing the same relation in an interleaved way. Importantly, Presentation interacted with Association strength because the difference between Blocked and Interleaved conditions was concentrated in the Weak trials when analyzed alone. That is, examining Figure 2 clearly shows that Presentation order had little effect on the Strong trials, but did effect the Weak trials. When Weak trials directly followed Strong in the Blocked condition, this elicited more accurate use of the repeated relation.

Taking the two experiments together, a clear picture starts to emerge. Both experiments showed effects of the position of individual trials, generally supporting the idea that the use of a relation in one analogy problem can constrain the semantic search in a subsequent problem. The more simple design of E2 revealed an overall advantage of blocked presentation, supporting a semantic-search or structural alignment account, and suggests that the design of E1 was not sensitive to this advantage. In addition, while potentially an overall order effect could explain the effect of position in E1, in E2 the Blocked advantage is independent of an overall order effect, as the trials were matched in terms of the number of trials preceding them.

In Experiment 2, children in the blocked condition can first discover or build the relation using the two strong trials, then apply it to the following weak items that appear immediately after, without being interfered by the other relations. This limits memory decline between the strong and the weak trials. In the interleaved case, the larger decline between strong and weak items suggests that the interval between the weak and strong items was too important to allow a strong-to-weak generalization. Or the relations interfered one with the others.

While we showed preliminary support for the Blocked advantage further research is needed to confirm this advantage, and to clarify what kind of effects, if any, exists for sequence and presentation on Strong trials. For example, in E1 the second Strong trial was performed at a higher rate than the first, but during E2, it was the reverse! Both experiments were properly counter-balanced, so this difference is not due to item-differences. Additionally, if the Blocked advantage is further confirmed, then further research needs to test how blocking trials supports analogical problem solving. At the moment it is unclear whether this potential advantage is rooted in aiding the strategic retrieval of the relevant relational representation without changing that representation (as deficits in strategic semantic retrieval often explains poor reasoning performance in young children, Whitaker et al., 2017), or whether the successive trials allow for the children to abstract the relational commonalities, creating a representation less tied to the specifics of highly associated objects. Regardless, at this point, there is little evidence that the kinds of memory processes that specifically produce spaced and interleaved advantages in other domains seem to not play a crucial role in strengthening the use of relational representations in analogical problem solving. Interleaved schedules seem most helpful when the primary challenge concerns refining representations to aid discrimination. Our data suggests that this kind of "relational fine-tuning" or discriminating among similar relations is not a primary cause for children's poor performance.

Here their effect, if any, was in favor of the Blocked trials. However, they may be crucial in helping to establish longer-lasting relational representations, given the post-test results from E1 showing the advantages from Blocked presentation may be quite short-lived. One way to test for
lasting effects of the blocked presentation, would be to add the same set of weak trials at the end of the experiment and compare how participants behave in that case. A lasting difference between the two conditions in favor of the blocked trials would be strong argument in favor of this condition. Understanding how relational representations can be robust to temporal delays is a crucial direction for future research.

# Generalizing novel names in comparison settings: Role of conceptual distance during learning and at test 

Jean-Pierre Thibaut (jean-pierre.thibaut@u-bourgogne.fr)<br>LEAD-CNRS, UMR 5022, Université de Bourgogne Franche-Comté, Pôle AAFE - Esplanade Erasme, 21065 Dijon, France

Arnaud Witt (arnaud.witt@u-bourgogne.fr)<br>LEAD-CNRS, UMR 5022, Université de Bourgogne Franche-Comté, Pôle AAFE - Esplanade Erasme, 21065 Dijon, France

#### Abstract

In a comparison setting (two stimuli), we tested 4- and 6-yearold children's generalization of novel names for objects. We manipulated the semantic distance between the two learning items (e.g., two bracelets versus a bracelet and a watch), and the semantic distance between the learning items and the test items (e.g., a pendant versus a bow tie). We tested whether smaller semantic distance between learning items would lead to more taxonomic (vs. perceptual) choices at test, than broader semantic distance during learning, especially in the case of distant test stimuli. Results revealed main effects of learning distance, of generalization distance and that only children aged 6 years benefited from broader semantic during learning at test. Four year-old children failed to generalize to far test stimuli even with semantically distant learning items. We discuss how conceptual distance during learning differentially affects generalization performance across age groups.

Keywords: Comparison, Distinctiveness, Conceptual development, Executive Functions.

## Introduction

When learning novel concepts for objects, children have to capture which object dimensions are important to define the corresponding concept and neglect idiosyncratic aspects, particularly irrelevant perceptual dimensions (e.g., Murphy, 2002, for a discussion). Indeed, in many cases perceptual similarities (e.g., objects from different categories displaying the same texture and/or the same color) or differences are more salient than variations along the relevant features.

Do children spontaneously generalize novel names according to perceptual similarities such as shape similarities or do they use deeper core knowledge? On one hand, there is large evidence showing that children's early words refer to deep conceptual properties. This has been shown in triad selection tasks, in which young children are shown a standard object and are later asked to choose between a categorically related object and a thematic match. -"This [standard] is a dax. Can you find another dax?". Children usually select the categorically related object (Markman, 1989, see Imai, Gentner, \& Uchida 1994, for evidence that children generalize on the basis of shape in this paradigm). On the other hand, there is evidence that, early in development, children often generalize object novel names to perceptually similar objects, especially "shape-
similar objects" (Landau, Smith, \& Jones, 1988; Smith, Jones, \& Landau, 1992).
In many cases, perceptual similarities between the standard and the test object are conceptually irrelevant. It has been shown that ignoring these salient irrelevant perceptual similarities can be challenging for young children (e.g., Augier \& Thibaut, 2013; Gentner \& Namy, 1999). Hence, understanding what situations promote nonobvious over salient properties is a crucial issue for cognitive science and concept learning. There is now considerable evidence that comparison learning situations promote generalization based on deeper conceptual properties than classical learning situations in which children are provided with only one learning exemplar.
A large body of research in both children and adults shows that comparison can highlight nonobvious shared properties. For example, Gentner and Namy (1999) used pictures of objects from familiar taxonomic categories (e.g. fruits) to teach a novel name and tested 4 -year-olds novel names extensions to other referents. In a one-standard condition (e.g. an apple introduced as a blicket) children preferred to extend the new label to a perceptually similar object (e.g. a balloon) rather than to a taxonomically-related-but-perceptually-dissimilar object (e.g. a banana). This preference was reversed when children had the opportunity to compare two standards (e.g. an apple and an orange, introduced as blickets).
The benefits of comparison have been demonstrated for object names (e.g., Gentner \& Namy, 1999; Augier \& Thibaut, 2013), adjectives (e.g., Waxman \& Klibanoff, 2000), action verbs (e.g., Childers \& Paik, 2009), names for parts (Gentner, Loewenstein, \& Hung, 2007), relational nouns (Gentner, Anggoro, \& Klibanoff, 2011; Thibaut \& Witt, 2015) and perceptual categories (e.g., Hammer, Diesendruck, Weinshall, \& Hochstein, 2009). Augier and Thibaut (2013) also obtained this positive effect of comparison with unfamiliar objects. Four- and 6-year-olds were randomly assigned to a no-comparison (one object) condition or to a comparison condition (two objects). In both conditions, the same two posttest objects were used. In the no-comparison condition, the standard - training - item had the same texture but not the same shape as one of two test objects. The standard also shared its shape but not its texture with the other test object. In the comparison condition, they pitted an unfamiliar test object displaying a perceptually non-salient dimension (texture) that was shared
with both training items against another unfamiliar object that shared a perceptually salient dimension (shape) with one of the two training standards only. In the no-comparison condition, a majority of children extended the new label to the same-shape test object. By contrast, in the comparison condition, a majority of children extended the novel name to the same-texture match rather than to a stimulus that had the same shape as one of the two standards. Taken together, these results show that comparison situations are a powerful tool for conceptually-based rather than superficially based novel name learning in children.
However, a growing body of research shows that comparisons generate cognitive costs. Recent studies on semantic analogies (Richland, Morrison, \& Holyoak, 2006; Thibaut, French, \& Vezneva, 2010a) or perceptual analogies (Thibaut, French, \& Vezneva, 2010b) (see also Richland \& Burchinal, 2013) support this cognitive costs hypothesis. In these studies, irrelevant perceptual features or semantic distractors explained part of children's performance. The hypothesis was that these experimental conditions required inhibition and flexibility. Thus, finding out nonobvious relevant relations requires inhibiting superficial irrelevant dimensions and integrating more difficult dimensions.
In this context, Augier and Thibaut (2013) manipulated the number of items to-be-compared in 4-year-old and 6-year-old children. According to the authors, introducing more evidence in favor of the target dimension (texture) also means more comparisons and more information to integrate, generating more executive costs. They included age as a factor. They hypothesized that the younger group might not benefit from increasing the number of items in the same way. Results showed that both groups benefited from the two-standard condition. However, only the older group benefited from an increased number of standards (four standards versus two standards).
In the same executive control framework, Thibaut and Witt (2015) studied relational categories with 42-month-old children. Relational categories are defined by relations between objects rather than by the intrinsic properties of the objects involved in these relations (e.g., neighbor). In this experiment, they used relational categories such as "the knife is the dax for the apple" (Gentner, Anggoro, \& Klibanoff, 2011). They manipulated the number of pairs of pictures of objects used in the training phase to illustrate a relational category ( 2,3 or 4 pairs such as an apple and a knife for "the knife is the dax for the apple") and the distance between the domains depicting the relation. For example, a knife with an apple and another knife with an orange come from close domains whereas a knife with an apple and a log with a saw come from more remote conceptual domains. In the transfer phase, results revealed that three learning pairs were better than two or four and that learning pairs from remote domains were led to better generalization than learning pairs from close domains. These results suggest that increasing the quantity of relevant information might interfere with young children's ability to abstract relevant dimensions in this type of task. More
generally, they suggest that there is an optimal number of information that can be integrated in such comparison situations. It is likely that this optimal number increases with age. The distance between domain effect suggests that a broader conceptual distance between learning exemplars helped participants abstracting the relevant relation between objects. A smaller distance between domains might have led participants to constrain the semantic domains around very similar entities (e.g., fruits) and similar operators (e.g., knifes).

## Goals of the present experiment

We examined the effect of learning and transfer distance in a comparison of real objects task (e.g., two apples, or two fruits, see Gentner \& Namy, 1999). Most former studies with real object categories contrasted no-comparison and comparison conditions. We will focus on comparison conditions and study in which condition(s) comparison leads to better conceptual generalization in a novel name learning task. A closer look at the stimuli in former studies reveals that the objects in the learning pairs come from semantic domains the semantic distance of which is not well controlled for. The same is true for the conceptually related transfer item. In other words, the distance between semantic domains in the learning items, and the distance between the learning items and the transfer items (i.e. the conceptually related target) has not been controlled as independent variables. However, it can be argued that the "width" of learning and generalization depends on the learning exemplars. There is a large body of literature showing to what extent generalization depends on the nature of the training items (Son, Landy, \& Goldstone, 2008), on the one side, and factors affecting the generalization width on the other side (e.g., Klahr \& Chen, 2011). Thus, knowing at which distance children generalize is a main issue in the study of the ontogeny of categories, subordinate, basic, and superordinate categories.
In the following experiment, we manipulated the semantic distances between both the learning items and the test items (in the generalization phase). Further, we compared two age groups (4- and 6- year-olds) in order to study cognitive resources might interact with these distances. Indeed, children of different ages might not benefit from comparison situations in the same way as a function of the distance between learning instances and the distance between learning and transfer instances. For example, it might well be that both age groups would generalize similarly in the close learning and close generalization case, whereas younger participants might encounter more difficulties to capture conceptual similarities in the case of more distant learning items and or to apply them to more distant domains.

## Methods

Participants One hundred French speaking preschoolers were tested individually in a quiet room at their school. Two age groups were recruited. The younger group was
composed of 48 children (mean age $=4$ years, 9 months; SD $=6.7$ months; range: $50-65$ months) and the older group was composed of 52 children (mean age $=6$ years, 8 months, $\mathrm{SD}=3.8$ months, range: $74-87$ months) were randomly assigned to one of the two experimental conditions with 52 (close learning items) or 48 (far learning items) children per condition. Informed consent was obtained from their school and their parents.

Design Four and six-year-old children were compared. This factor was crossed with learning distance (Close vs. Far learning, between subject factor) and Generalization (Close vs. Far generalization, within subject factor).

Materials Seven sets of six objects were created for each distance condition (close or far) (See Table 1). Each picture was displayed on a 8 cm by 8 cm piece of cardboard. Each set corresponded to one category of objects (e.g., clothing accessories, food, tools, etc.). The learning pair was composed of one learning object and either a close training object (close learning condition), or a more distant training object (far learning condition) (see Figure 1). Thus, we

Figure 1: Example of a stimulus set and instructions adapted for the four experimental conditions crossing the learning distance (Close vs. Far learning) and Generalization (Close vs. Far generalization) factors.
manipulated the conceptual distance between the two training objects that were compared in each learning condition (Close or Far) in our comparison paradigm. For each object category (e.g., clothing accessories), the close learning objects were composed of perceptually and semantically close items (e.g., a bracelet - a curb chain), while the far pairs were composed of perceptually similar but conceptually more distant items (e.g., a bracelet - a watch) (see Table 1). The two test pictures consisted of two objects in both the close and the far generalization conditions: an item that was perceptually similar but semantically unrelated to the two training items (e.g., a tire in our bracelet case) and a taxonomic choice. As a function of the generalization condition, close or far, the taxonomic
choice was semantically close or more distant to the learning items (e.g., a jewel pendant in the close generalization case, or a bow tie in the far generalization case). Figure 1 depicts the objects used to instantiate the close and far learning distance and the close and far generalization conditions for the "clothing accessories" object category.

Table 1: List of items for the close and far conditions

|  | Learning |  |  | Generalization |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Initial item | close item | far item | percetive | close taxonomic | far taxonomic |
| SET 1 |  |  |  |  |  |  |
| "clothing accessories" | bracelet | curb chain | watch | tire | pendant | bow tie |
| "tools" | hamer1 | hamer2 | axe | ostrich head | pair of pincers | chainsaw |
| "clothing" | sock1 | sock2 | jeans | pipe | sweater | hat |
| "food" | apple1 | apple2 | cherry | bulb | banana | beefsteak |
| "animals" | ladybird1 | ladybird2 | beetle | ball | butterfly | duck |
| "music player" | guitar1 | guitar2 | cello | bottle | keybord | hi-fi |
| "game/toy" | ball1 | ball2 | cuddly toy | orange | Lego | video game |
| Set2 |  |  |  |  |  |  |
| "food" | pear1 | pear2 | strawberry | candle | pineapple | fry |
| "food2" | pumpkin1 | pumpkin2 | tomato | ball | cucumber | grilled chicken |
| "house tools/appliances | "house |  |  |  |  |  |
| "animals" | snake 1 | snake2 | lizard | rope | alligator | bird |
| "vehicle" | bike1 | bike2 | scooter | glasses | rollerblade | boat |
| "office items" | pencil1 | pencil2 | ruler | candy cane | scissors | laptop |
| "clothing accesorries" | knit cap1 | knit cap2 | hardhat | turtle | crown | boots |

Independent similarity ratings from 54 students confirmed that the close learning object condition were conceptually closer one to the other than the objects composing the far learning pairs, $t(26)=3.98, p<.001$, and that close generalization stimuli were semantically more similar to the two learning stimuli than far generalization stimuli, $t(26)=$ $6.86, p<.001$. For the purpose of our experiment it is crucial that semantically related generalization items are perceptually less similar to the learning items than the perceptually similar lures. Perceptual similarity ratings revealed that the perceptual choices were perceptually more similar to the learning items than the semantically related choices (taxonomic choices) in both the close and the far conditions, $t(26)=14.03, p<.001$ and $t(26)=18.49, p<$ .001. Importantly, we also performed perceptual similarity and conceptual similarity ratings between the close learning stimuli (e.g., two apples) and the far learning stimuli (e.g., an apple and a cherry) on the one side and the taxonomically related generalization item. They showed that overall the generalization stimuli were equally distant to both types of learning items. This was true for both types of generalization items: close generalization items, perceptual distance, $t(26)=.70, p=.46$, semantic distance, $t(26)=$ $1.21, p=.41$; far generalization: perceptual distance, $t(26)$ $=.24, p=.65$, semantic distance, $t(26)=.43, p=.89$. This
is central because we want to avoid that performance differences between close and far generalization items to be due to perceptual but also semantic similarity differences between learning items. We included semantic similarity differences in order to keep only taxonomic distance influence. For example, if we get a difference between close and far generalization items (e.g. between jewel pendent and bow tie) we do not want it to be due to other semantic information (e.g., the fact that the jewel pendent would be more thematically related to bracelet than the bow tie) than the taxonomic distance.
Each learning pair was randomly associated with one out of 14 two-syllable novel names (e.g., youma, buxi, dajo, zatu, sepon, xanto, vira, etc.) (see procedure).

## Procedure

The experiment started with two practice trials. They were followed by fourteen experimental trials presented in a random order. Each standard learning stimulus was introduced with a novel count noun (Landau, Smith \& Jones, 1988) (e.g. "this is a buxi" and "this is a buxi TOO" for the other standard). A puppet named Yoshi was used in order to make the task more attractive for children and to make the use of non-words to refer to known objects more meaningful with the following instructions: "In this game we are going to learn the language of Yoshi. Yoshi is living far away from here". The objects were presented sequentially and were left in view during the entire trial. The two learning stimuli were presented in a row and their location was determined randomly. The forced-choice test phase was identical in all conditions. The two test objects (i.e., the perceptual and the taxonomic matches) were introduced and the child was asked to point to the one which was also a member of the category (e.g., "Show me which one of these two is ALSO a buxi").

## Results

We performed a 2 Age (4 vs. 6-year-olds) x 2 Training distance (Close vs. Far distance) x 2 Generalization (Close vs. Far) ANOVA on the percentage of taxonomic choices (see Figure 2). Age and Training distance were betweensubject factors and Generalization a within-subject factor. There were significantly more taxonomic choices in the Far training condition ( $M=64.4 \%$; $S D=22.74$ ) than in the Close training condition ( $M=51.3 \% ; S D=28.73$ ), $F(1,96)$ $=6.06, p=.016, \eta_{P}^{2}=.06$. The main effect of Age was not significant, $F(1,96)=1.14, p=.29, \eta_{P}^{2}=.01$ (4-years: $M=$ $54.9 \%$; 6-years: $M=60 \%$ ) and Training distance did not interact with Age, $F<1$. In addition, children performed better in the Close Generalization condition ( $M=64.79 \%$; $S D=29.69$ ) than in the Far Generalization condition ( $M=$ $51.4 \% ; S D=28.42), F(1,96)=29.79, p<.001, \eta_{P}^{2}=.24$, but the Generalization effect did not interact neither with Age, $F<1$, nor with Training distance, $F<1$, and the triple Generalization x Age x Training distance interaction effect did not reach significance, $F<1$.

When comparisons with chance were run, student-t tests for independent groups with Bonferroni correction for multiple comparisons revealed that children performed above chance in the Close generalization condition, in the Far learning condition only, (respectively, 4 years: $t(23)=$ $3.49, p=.002$; 6 years: $t(25)=6.82, p<.001)$ but not when the learning items were conceptually close (respectively, 4 years: $t(23)=1.09, p=.28 ; 6$ years: $t(23)=1.04, p=.30)$. Interestingly, in the Far Generalization condition, only the 6-year-old children performed significantly above chance, $t(25)=3.29, p<.0125$, while the performance of the younger children did not differ from chance, $t(23)=.63, p=$ . 53.

Figure 2: Percentage of Taxonomic choices as a function of the conceptual distance between during learning (close vs.
far learning distance) and at test (close vs. far generalization). The error bars correspond to one standard error and the dashed line represents chance level (50\%).

Taken together these findings show a clear impact of conceptual distance in our comparison framework, the Far learning condition giving more taxonomic choices than the Close learning condition. Our results also show that the Close generalization is easier than the Far generalization condition. Even though our results revealed no main effect of Age effect and interaction of this factor with learning distance, comparisons with chance confirm the beneficial role of conceptual distance between the learning items and suggested that in Far Generalization contexts only the older children may benefit of comparison between conceptually distant learning items.

## Discussion

As mentioned in the introduction, there is a large body of studies showing that young children generalize novel names according to shape when only one standard stimulus is introduced in the learning phase. Our study capitalized on the idea that comparison situations during lexical learning favor deeper generalizations based on less obvious features that will, as a result, favor taxonomic generalization. However, Augier and Thibaut (2013) showed that
comparison situations generated cognitive costs that might prevent younger children from using all the available information. This result suggested that the effect of comparison on generalization depends on the ease of processing dimensional similarities and differences. Our rationale was that the deep commonalities in close learning items can easily be accessed because of many conceptual commonalities. However, this situation might have provided little information regarding conceptual similarities subtending generalizations to broader categories. On the contrary, comparisons between distant learning items may be more difficult to unify conceptually because conceptual similarities would be more difficult to abstract. By contrast, comparisons might provide more abstract knowledge supporting broader generalizations. Because younger children might encounter more difficulties to capture conceptual similarities in the case of distant learning items and or to apply them to distant domains, we hypothesized that conceptual distance during learning and at test might differentially impact benefits of comparison across groups of age. World knowledge might also contribute to the difference between age groups, since older children have more knowledge regarding the objects than younger children.
Our results showed that both age groups benefited from broader inter-item conceptual distance during the learning phase since they perform better in the far learning case than in the close one. However, close generalization was better than the far generalization. Taken together, these two results suggest that broader learning range lead to better close generalization. The fact that only the older children performed above chance in the far generalization condition in the far learning case suggests a development from, first, a better performance in the case of broad learning distance to, second, a progressively better performance in the generalization width. This last result suggests that if all age groups were able to benefit from conceptual distance during the learning phase, the benefit is probably qualitatively different across age groups. We think that far learning allowed both groups to defocus from perceptual similarities and to access basic conceptual similarities ("is a jewel"), while far learning would help older children to abstract superordinate properties ("is a clothing accessory"), making the former able to perform correct taxonomic choices only in the close generalization condition ("the pendant is a jewel too"), while the latter were able to generalize in the close as well as in the far condition (" the pendant and the bow tie are clothing accessories too").
Importantly, this pattern of results backs up the classical result in developmental psychology that superordinate categories are more difficult to learn than basic level categories (Mervis \& Rosch, 1981; Murphy, 2002) and decomposes the sources of this difficulty. Children might have more difficulties to generalize to broad categories rather than to abstract from broad conceptual distances during learning. Here, we used a perceptual lure. It should be interesting to study how participants abstract categories
that are less grounded in perceptually similar instances of the same category.
To conclude, our study suggests that making appropriate use of comparison might entirely depends on tiny differences along the properties of what is compared and on executive capacity to process them. This finding has important implication about the role comparison plays in learning. Indeed, the executive constraints on comparison processing might explain under which conditions comparison can or cannot be fruitful.

#### Abstract

Skepticism towards science has risen sharply in recent years. Cognitive scientists can help address this issue by illuminating how people conceptualize the scientific process, paving the way for improved communication with the public. We recruited a large sample of lay Americans, as well as academics in the sciences and humanities, to answer a series of questions assessing their views about science. Because metaphors have been identified as useful tools for communicating about complex domains, we asked participants to choose which of two metaphors-working on a puzzle or scaling a mountain-best captured their beliefs about the scientific process. Results revealed substantial variation in perceptions of science across groups, and we highlight the ways in which scientists seem to conceptualize science differently from non-scientists. Importantly, metaphor preference was associated with particular patterns of thinking, though not always in our originally hypothesized direction. We discuss the implications of these findings.

Keywords: metaphor, science, concepts, public perceptions

## Introduction

Scientific research requires a variety of skills and involves a range of tasks and experiences. It can be like piecing together a puzzle, in which a diverse set of empirical findings are connected to fill in the details of big-picture scientific theories. And it can be like climbing a mountain, in which careful planning and steadfast persistence are necessary to move projects forward. Both of these metaphors-working on a puzzle and scaling a mountaincapture aspects of the scientific process. In this paper, we use these two metaphors to gauge how people think about science. We recruited a large sample of the general public, as well as academics in the sciences and humanities, to answer a series of questions assessing their views about science, scientific practices, and the priorities of working scientists. They also selected which of the two metaphors (puzzle or mountain) better represented their beliefs about science, and we explored associations between this choice and broader patterns of thinking about scientific practice.

Understanding how people conceptualize science is important given the widespread anxiety about everything from climate change to vaccines to genetically modified
organisms (Achenbach, 2015). Indeed, recent populist political movements have been accompanied by an increasing distrust in science and data. In a recent US poll, almost half of participants (and over two-thirds of President Trump's base) said they did not trust the economic data being reported by government agencies (Ryssdal, 2016). There is also concern in the scientific community about the quality of science education and the lack of public investment in science: "An overwhelming majority of scientists [over 75\%] see the public's limited scientific knowledge as a problem for science," according to another recent poll (Funk \& Rainie, 2015).

The lack of support for science represents a direct threat to addressing important real-world situations like climate change and, potentially, the stability of societal institutions at large (Otto, 2016). As one recent Washington Post article concluded, "This is how a democracy crumbles: not with a bang, but with data trutherism" (Rampell, 2016).

Recent work in the cognitive sciences has explored how to improve communication with the public for specific scientific issues like climate change and public health (Flusberg, Matlock, \& Thibodeau, 2017; Thibodeau, Perko, \& Flusberg, 2015). Metaphors have been identified as useful communication and explanatory tools, as they can help people make sense of complex issues by relating them to more familiar domains, leveraging the schematic knowledge people already have in order to reason about new and complicated subjects (Thibodeau, Crow, \& Flusberg, 2016). To date, however, little research has investigated the role of metaphor in thinking about the scientific process itself (but see Thibodeau, 2016, and Harwood, Reiff, \& Phillipson, 2005).

In addition to addressing practical concerns about public perceptions of science, therefore, the present work also has theoretical implications, as cognitive scientists (particularly cognitive linguists) often treat metaphor as a window into how people think (e.g., Fairclough, 2013; Lakoff \& Johnson, 1980). That is, puzzle and mountain metaphors for science seem to have different entailments, which may suggest that people who talk about science as a puzzle think about the scientific process differently than people who talk about science as a mountain. On the other hand, some have
questioned this approach because of the assumptions that are made about the nature of thinking simply from observing patterns of language use (Keysar \& Bly, 1995; McGlone, 2011; Murphy, 1996, 1997).

One of the few studies to address this issue in the context of reasoning about science involved structured interviews with scientists aimed at identifying (a) key characteristics of scientific inquiry and (b) metaphors that scientists use to conceptualize these issues (Harwood et al., 2005). The goal was to improve science education by encouraging science teachers to use metaphors in the classroom more deliberately. The results indicated that scientists' descriptions of the scientific process emphasized five key characteristics: open-mindedness, putting yourself in your work, utilizing resources, problem solving, and making connections. These characteristics were then matched to conceptual metaphors that the scientists used in the interviews. For example, a puzzle metaphor was often used to emphasize how scientists seek to make connections; an artist metaphor was used to stress the importance of being open-minded; a gardening metaphor was used to talk about immersing oneself in their work.

One possibility is that these metaphors can encourage non-scientists to think about the scientific process in a way that is more consistent with how scientists think about scientific inquiry (Harwood et al., 2005). However, an alternative possibility is that the meaning of these metaphors will be different for scientists and non-scientists. That is, the knowledge and experience that people have with science may influence how they interpret metaphors for the scientific process. A recent investigation into how different groups of people understand militaristic metaphors in biology like invasive species suggests support for the latter possibility (Larson, Nerlich, \& Wallis, 2005): a metaphor that means one thing to scientists can mean something else to non-scientists.

Therefore, the present study represents an important empirical step in comparing how different groups of people interpret metaphors for the scientific process. Do people actually think about science in a way that is consistent with the metaphor they would use to talk about it?

## Experiment

## Methods

Participants A sample of 518 people representing the general public was recruited from Amazon's Mechanical Turk $\left(60 \%\right.$ female; $\left.M_{\text {age }}=35\right)$. A second sample of academics was recruited from the faculty listings of college and university websites in the United States, drawn from a list of top research and liberal arts institutions. We created a list of 2,000 academics, roughly half representing the sciences (i.e. faculty working in Physics, Chemistry, or Biology Departments), and half representing the humanities (i.e. faculty working in English, History, or Philosophy Departments). An email asking for voluntary participation in the survey, yielded responses from 156 academics ( 93 from the sciences and 63 from the humanities).

Although we were primarily interested in comparing how scientists and the general public think about science, we were also interested in understanding why these groups may think differently. Including the group of academics from the humanities helps to address this question. Like scientists, this sample is highly educated, familiar with working on projects that can take long periods of time, and conduct their work in a college or university setting. On the other hand, like participants from the general public, this sample may not be as familiar with the day-to-day experience of conducting scientific work. As a result, including the humanists allows us to investigate why the general public might hold views about science that are different from scientists. For instance, are differences related to more general factors like education level or related to factors more directly tied to being immersed in scientific work?

Materials \& Design All participants were asked to choose between two metaphors for science. The instructions for this judgment read, "We are interested in how people think about science. Which of the following metaphors best captures how you view the process of working on a scientific project?" The order of the two options-Working on a puzzle or Scaling a mountain-was counterbalanced. ${ }^{1}$

These two metaphors for science were chosen because of their use in prior work (Thibodeau, 2016), and because they are commonly used by scientists to talk about the scientific process (Harwood et al., 2005). Thibodeau (2016), for example, found that metaphorically framing a scientist's work as a puzzle led people to value "testing completely novel theories" over "using methods that are simple for others to follow," whereas framing the scientist's work as a climbing a mountain led people to value using simple methods over testing novel theories.

All participants were also asked to rank six aspects of the scientific process in order of importance, three of which were designed to be more consistent with the entailments of the puzzle metaphor and three of which were designed to be more consistent with the entailments of the mountain climbing metaphor (see Table 1). The relationship between the entailments and metaphors was based on prior work (Harwood et al., 2005; Thibodeau, 2016), and experimenter intuition; one goal of the study is to test whether different groups of people have similar intuitions about the relationship between the entailments and metaphors. The order of the statements was randomized across participants. ${ }^{2}$

[^515]We compare how the three populations (General Public; Scientists; Humanists) rank the statements overall, and we test whether people who prefer the puzzle metaphor for science rank the puzzle-congruent statements as more important than the mountain-congruent statements (and vice versa for the mountain metaphor).

Table 1. Tasks related to the scientific process that were ranked by participants.

| Actions and Behaviors Related to Science | Metaphor |
| :--- | :--- |
| 1. Find creative ways to study important research questions | Puzzle |
| 2. Seek insight from diverse sources | Puzzle |
| 3. Find connections between seemingly unrelated ideas | Puzzle |
| 4. Make a detailed research plan | Mountain |
| 5. Persist in the face of setbacks | Mountain |
| 6. Revise theories in light of new data or counter-evidence | Mountain |

Finally, participants were asked to complete the 40 -item Scientific Attitude Inventory II (SAI II), which is designed to measure attitudes related to science along six dimensions (Moore \& Foy, 1997; see Table 2). This instrument has been used to measure perceptions of science among students and the general public, and to predict who is likely to pursue a career in a STEM field (e.g., Bathgate, Schunn, \& Correnti, 2014; Moore \& Foy, 1997).

As with the rank order task, we use responses from the SAI II to compare how the three populations think about science and to test whether certain dimensions of the scale map onto the view that science is like working on puzzle versus scaling a mountain.

Table 2. Six dimensions of the SAI II and example items..

| Dimension | Example Item |
| :--- | :--- |
| Theory | Scientific ideas can be changed. |
| Limited | Scientists cannot always find the answers to their questions. |
| Empirical | Scientific questions are answered by observing things. |
| Goal | Ideas are the important result of science. |
| Public | Every citizen should understand science. |
| Interest | I would enjoy studying science. |

At the end of the survey, participants from the general public were asked background and demographic questions, including their gender, age, education level, math/science training, political ideology (0, Very liberal, to 100, Very conservative), and personality (the Big Five personality dimensions; Gosling, Rentfrow, \& Swann, 2003). Academics were asked to identify as working in the humanities or sciences.

## Results

Metaphor Preference Among participants sampled from the general public, $89 \%$ preferred the puzzle metaphor for science, $\chi^{2}(1)=315.09, p<.001$. The puzzle metaphor was also preferred by $89 \%$ of academics, $\chi^{2}(1)=92.31, p<.001$, although scientists (84\%) were marginally more likely to choose the mountain metaphor compared to humanists (95\%), $\chi^{2}(1)=3.71, p=.054$.

For the sample recruited from the general public, we tested whether any of the individual difference measures (i.e. gender, age, education level, math/science training,
political ideology, personality) predicted participants' choice of metaphor. The only reliable predictor of participants' choice was age: older participants were especially likely to endorse the puzzle metaphor for science, $B=.40, S E=.17, p=.016$.

Ranking Priorities We first compare how the three populations ranked the six statements about science, focusing on contrasts between scientists and (a) humanists and (b) participants from the general public. Then we test for a relationship between participants' preferred metaphor and their rankings of the statements. For this second analysis, we excluded the humanists because of the small number who preferred the mountain metaphor $(n=3)$.

First, a mixed-effects linear model was fit to the rankings with statement (1-6) treated as a within-subjects effect and sample (public, humanists, scientists) treated as a betweensubjects effect (Bates, Maechler, Bolker, \& Walker, 2014). The model revealed that the samples gave different rankings to the statements, $\chi^{2}(5)=209.91, p<.001$.

Figure 1. Mean ranking of six statements about science by sample: of the general public, academics working in the humanities, and academics working in the sciences.

Figure 1 illustrates how participants from the three groups ranked the statements overall. One pattern to note is that scientists tended to show more agreement on how the statements were ranked (Kendall's $W=.25$ ) than participants from the general public ( $W=.07$ ) or humanists ( $W=.21$ ). For instance, "planning" was ranked as the most important aspect of science by the general public, with $53 \%$ of participants from this sample ranking it first or second. In contrast, "creativity" was ranked as the most important aspect of science by scientists, with $76 \%$ of participants from this sample ranking it first or second. On the other end of the spectrum, "finding connections" was ranked as the least important aspect of science by the general public ( $46 \%$ ranked it fifth or sixth), while "planning" was ranked as the least important aspect of science by scientists ( $66 \%$ ranked it fifth or sixth). This suggests that scientists, as a group, have a more consistent conception of the scientific process than the general public; the humanists showed an intermediate level of consistency.

Figure 2. Comparing rankings of scientists to those of people from the general public and humanists with a measure of effect size (Cohen's $d$ ). Bars that extend to the right indicate that scientists ranked the statement as more important (purple: compared to participants from the general public; orange: compared to humanists); bars that extend to the left indicate that scientists ranked the statement as less important. Stars indicate a statistically significant difference between scientists and the comparison group.

Figure 2 shows how scientists ranked the statements compared to the other two groups of participants by plotting a measure of effect size (Cohen's $d$ ). As shown, scientists tended to place less emphasis on planning than humanists, $t(154)=3.69, p<.001$, or participants from the general public, $t(609)=10.21, p<.001$. On the other hand, scientists tended to place more emphasis on persistence than humanists, $t(154)=2.82, p=.005$, or participants from the general public, $t(609)=2.95, p=.003$. The two groups of academics ranked the other four statements similarly. Scientists and the sample from the general public ranked three of the remaining four statements differently: scientists placed less emphasis on seeking diverse sources of insight, $t(609)=2.49, p=.013$, but more emphasis on finding connections between seemingly unrelated ideas, $t(609)=$ 2.21, $p=.027$, and creativity, $t(609)=6.72, p<.001$; these two groups placed similar emphasis on revising theories in light of new data.

A second analysis tested whether people who considered science to be more like a puzzle ranked puzzle-congruent statements as more important than people who considered science to be more like mountain climbing. A mixed-effects linear model was fit to the data with predictors for statement type (puzzle- or mountain-congruent), metaphor choice (puzzle or mountain), and sample (scientists versus general public), which revealed an interaction between the statement type and metaphor choice, $\chi^{2}(1)=4.07, p=.044$. Contrary
to our initial hypothesis, preference for the puzzle metaphor was associated with prioritizing the mountain-congruent statements (and vice versa). This pattern was consistent across both groups of participants (i.e. there was no 3 -way interaction between statement type, metaphor choice, and sample), $\chi^{2}(1)=1.39, p=.239$ (see Figure 3). Of note, the analysis also revealed an interaction between sample and statement type, $\chi^{2}(1)=38.44, p<.001$, such that scientists tended to rank the puzzle-congruent statements as more important, regardless of preferred metaphor, than participants from the general public.

Figure 3. Mean ranking of statements by type (puzzle- or mountain-congruent) and metaphor chosen (puzzle or mountain) for the two samples analyzed (from the general public and of scientists).

People who preferred the mountain metaphor were particularly likely to rank "finding connections" ( $M=3.69$, $S D=1.52$ ) as more important than people who preferred the puzzle metaphor $(M=4.15, S D=1.53)$, whereas people who preferred the puzzle metaphor were particularly likely to rank "planning" ( $M=3.09, S D=1.91$ ) as more important than people who preferred the mountain metaphor ( $M=$ $3.44, S D=2.00$ ).

This finding is consistent with the view that the two metaphors capture structured ways of thinking about the scientific process that are different from one another. People who reported thinking science was a puzzle ranked the statements in a systematically different way than people who reported thinking science was a mountain. However, the finding is inconsistent with how we had mapped the entailments of the metaphors onto the statements, suggesting that the intuitions of language researchers may differ from how metaphoric language is used and understood in the real world.

It is also possible that behaviors on the two taskschoosing a metaphor and ranking the statements-were complementary. People may have had a sense of the limitations of their preferred metaphor, which they expressed in the rank-order task (or vice versa). For instance, a participant may believe that finding connections and planning are both vital to the scientific process. Such a belief may lead this participant to choose the puzzle metaphor as more appropriate (because it captures the value of finding connections) and also to rank planning highly (since it is captured less well by the puzzle metaphor). In
other words, participants may consider many aspects of science to be important, not just those that are consistent with the entailments of a single metaphor. This may lead them to express a preference for one metaphor, as required by our forced-choice task, and then to emphasize inconsistent entailments in the rank-order task.

Scientific Attitude Inventory A similar set of analyses was applied to data from the SAI II. First, we found differences in the extent to which participants endorsed the six dimensions measured by the survey, $\chi^{2}(5)=1637.2, p<$ .001: participants agreed most strongly with statements about the necessity of adopting an empirical mindset, followed by statements about the importance of public outreach, about an interest in doing scientific work, that the scope of science is limited to observable phenomena, and finally, that the end goal of science is ideas (rather than a tangible product like technology).

Figure 4. Comparing ratings of scientists to those of people from the general public and humanists with a measure of effect size (Cohen's $d$ ). Bars that extend to the right indicate that scientists rated the dimension as more important (purple: compared to participants from the general public; orange: compared to humanists); bars that extend to the left indicate that scientists rated the dimension as less important. Stars indicate a statistically significant difference between scientists and the comparison group.

Second, the analysis revealed differences in how the three samples rated the statements, $\chi^{2}(2)=196.57, p<.001$. Overall, scientists tended to endorse the statements more strongly than participants from the general public, $B=.45$, $S E=.03, p<.001$, and humanists, $B=.17, S E=.04, p<$ .001. Humanists endorsed the statements more strongly than participants from the general public, $B=.28, S E=.04, p<$ . 001 .

Third, the analysis revealed an interaction between ratings of the dimensions and the three samples, $\chi^{2}(10)=199.57, p$ $<.001$. As shown in Figure 4, scientists endorsed all six dimensions more strongly than participants from the general public, $p \mathrm{~s}<.001$. Compared to humanists, scientists more strongly endorsed having an empirical mindset, the view that public support is important, and were more likely to say they enjoyed doing scientific work, $p \mathrm{~s}<.01$, whereas humanists were more likely to view science as being limited to the study of natural phenomena, $p<.001$. The two groups of academics expressed similar views about scientific theorizing and about the end-goal of scientific work.

Figure 5. Differences in ratings by metaphor chosen for people from the general public and scientists, illustrated by a measure of effect size (Cohen's $d$ ). Bars that extend to the right indicate higher ratings among people who preferred the puzzle metaphor; bars that extend to the left indicate higher ratings among people who preferred the mountain metaphor.

Finally, we tested for a relationship between the metaphor participants preferred and ratings of the dimensions (excluding data from humanists). As illustrated in Figure 5, among scientists, preference for the mountain metaphor was associated more strongly with the view that scientific study is limited to natural phenomena, $t(91)=2.72, p=.009$; among the general public, preference for the puzzle metaphor was associated with a more empirical mindset, $t(516)=2.35, p=.019$, the view that public support is important, $t(516)=2.53, p=.012$, and a stronger interest in doing scientific work, $t(516)=3.46, p<.001$. These results provide further evidence that the two metaphors capture different ways of thinking about the scientific process, but also suggest that what exactly is captured by the metaphors is different for scientists and non-scientists.

## Discussion

Skepticism towards scientific research can be found among the general public as well as politicians on both sides of the political aisle, raising significant concerns about the current quality of science education and communication. As an initial step towards addressing this critical issue, we aimed to illuminate how people think about the scientific process itself, contrasting the beliefs of scientists with those of academics in the humanities and members of the general public, and exploring the role of metaphor in representing broad conceptual viewpoints.

We found several notable similarities and differences in how scientists and non-scientists conceptualized the scientific process. Of particular interest, scientists tended to prioritize persistence more than the two samples of nonscientists, who tended to prioritize planning more than the scientists. This suggests that being immersed in scientific work makes salient the determination needed to complete research projects. Simply hearing about scientific findings in the classroom or the news, on the other hand, may make it seem like scientists spend most of their time planning. In line with this distinction, scientists were more likely than non-scientists to think science was like scaling a mountain, although all three groups showed an overall preference for the puzzle metaphor.

Individuals who preferred the puzzle metaphor tended, counter-intuitively, to value statements about science that were designed to be congruent with the mountain metaphor (and vice versa). Preference for the puzzle metaphor was also associated with a more empirical mindset, the view that public support is important for scientific progress, and an interest in doing scientific work-but only among the general public, not among scientists. These findings imply that metaphors for science will be interpreted differently depending on one's scientific knowledge and expertise. The findings also highlight the importance of identifying the systems of knowledge associated with metaphor use rather than merely assuming them (Keysar \& Bly, 1995; McGlone, 2011; Murphy, 1996, 1997).

Future research in this area should explore additional metaphors for scientific inquiry. For instance, one scientist in the study suggested that science was more like mapmaking or exploring than it was like working on a puzzle or scaling a mountain. Future work should also investigate whether these metaphors can causally influence how people think about the scientific process.

#### Abstract

Metaphors have been shown to be effective explanatory and communicative tools, shaping how people think and reason about complex domains. To date, however, most studies have addressed only coarse-grained effects of metaphor framing, leaving many questions unanswered about the relative power of metaphor compared to more literal linguistic framing devices. We addressed this issue in a large, pre-registered framing study, comparing the effects of describing the role of police officers as (a) metaphorical guardians of a community (b) literal protectors of a community, and (c) a no-label control. We found no main effect of framing condition, suggesting that positively valenced metaphors may exert little influence on their own in this domain. However, we did observe an interaction between condition and political ideology, such that the guardian metaphor was especially effective at improving attitudes towards police officers for liberals, whose initial approval ratings were relatively low.

Keywords: metaphor, framing, attitudes, policing

## Introduction

"Evolutionary sequences," wrote the popular biologist Steven Jay Gould (1977, p. 61), "are not rungs on a ladder, but our retrospective reconstruction of a circuitous path running like a labyrinth, branch to branch, from the base of the bush to a lineage now surviving at its top." Metaphorical explanations like this are common, and research has established that they can be effective as well: framing a discussion or explanation with metaphor has been shown to shape how people understand and reason about a range of complex issues (Flubserg, Matlock, \& Thibodeau, 2017; Sopory \& Dillard, 2002; Thibodeau, 2016; Thibodeau \& Boroditsky, 2011; Thibodeau, Crow, \& Flusberg, 2016).

In a recent study, for example, Thibodeau, Crow, and Flusberg (2016) sought to test the explanatory power of metaphor in the context of people's understanding of-and attitudes towards-law enforcement. Our primary research question was whether or not people would spontaneously use the structure of a metaphorical source domain (guardian or warrior) to reason about a target domain (policing).

One way that we tested this question was by having participants read that police officers are either guardians or warriors of the community before reporting on their attitudes toward policing and the criminal justice system. We found that participants who had read that police officers are guardians expressed more positive attitudes about policing and the criminal justice system, overall, compared to people who had read that police officers are warriors.

This effect may be the result of the emotional tone that is set by the metaphors: we found that guardian, in the context of policing, conveys a more positive emotional valence than warrior.

In addition, we found that the metaphorical explanations selectively affected certain attitudes toward policing and the criminal justice system more than others. Specifically, people who read that police officers are guardians expressed a more favorable "attitude toward police practices" than people who read that police officers are warriors, but the metaphorical explanation had no effect on participants' views about the "difficulty of being a police officer." This was consistent with the results of an initial norming study, where a separate group of participants made an explicit judgment about which metaphor-guardian or warrior-was more appropriate for the current state of policing (rather than being exposed to just one of the metaphors). That is, the norming study found that people who came into the study with the view that police officers are more like guardians expressed more a favorable view of police practices compared to people who considered police officers to be warriors. However, people who considered police officers to be guardians expressed similar beliefs about the difficulty of being a police officer as people who considered police officers to be warriors. Taken together, these findings suggest that the metaphors instantiate different schematic knowledge structures for policing and the criminal justice system-and that they capture and convey more than an emotional tone.

A second way that we tested our research question was by having participants list a synonym either to "guardian" or "warrior" before reporting on their attitudes toward the police and criminal justice system. We found no effect of these lexical primes: people who listed a synonym for "guardian" expressed similar attitudes toward policing and the criminal justice system as people who listed a synonym for "warrior." Participants expressed more moderate attitudes in these conditions compared to the conditions in which a metaphor was used to explain the role of police officers (i.e. less positive than participants who read that police officers are guardians but more positive than participants who read that police officers are warriors).

We interpreted these results as showing (a) that metaphorically framing police officers as guardians activates a different mental model of policing (with a different affective profile) than metaphorically framing police officers as warriors, and (b) that simply seeing the
word "guardian" or "warrior" is insufficient to activate this mental model. In other words, people have prior knowledge about what it means to be a guardian (and warrior). This knowledge influences how people think about policing when police officers are explicitly described as guardians (or warriors)-but not when people are asked questions about policing after simply seeing the word "guardian" (or "warrior").

A natural follow up question to this study might be: which metaphor has a bigger effect on how people think about policing? Intuitively, it may seem like there is an easy way to address this question: by running a condition that does not include a metaphorical explanation. One might expect that describing police officers as guardians would lead to a more positive view of policing compared to a "neutral control" condition, and that describing police officers as warriors would lead to a more negative view of policing compared to a "neutral control" condition. In addition, one might be tempted to infer that the metaphor condition that is more different from the "neutral control" condition is having a bigger effect on people (cf. Reijnierse, Burgers, \& Steen, 2015; Steen, Reijnierse, \& Burgers, 2014).

However, as we have argued before (see Thibodeau, In press; Thibodeau \& Boroditsky, 2015), there are many differences between metaphor frames and "neutral control" conditions that make such comparisons difficult to interpret. For example, it is not clear that there is a suitable nonmetaphorical counterpart to the "guardian" and "warrior" metaphors for policing (e.g., a term like "protector" could be used, since it is less metaphorical than the two metaphorical frames; but its meaning seems more similar to "guardian" than "warrior," making it a poor candidate to serve a "neutral control" condition along side the two metaphorical conditions). Comparing the two metaphorical frames to a condition that omitted a nominal descriptor altogether would confound a variety of factors between the two metaphor conditions and the "neutral control" condition, including the valence, tone, and word frequency of the language used to describe policing-not just the metaphoricity of the conditions.

We do, however, think that there are research questions that warrant a comparison between metaphorical frames and non-metaphorical counterparts. Here, we consider such a case. Namely, does a guardian metaphor lead people to adopt a more favorable view of policing than a comparable literal description of the role police officers play in the community? Addressing this question is important when considering the potential practical applications of research on the persuasive power of metaphor. Therefore, we compared three conditions in the present study, building on the work described in Thibodeau, Crow, \& Flusberg (2016). Before reporting their attitudes towards law enforcement and the criminal justice system, participants read one of the following framing prompts:
a. Police officers are the guardians of modern communities. They are strong men and women who serve a vital role in society.
b. Police officers are the protectors of modern communities. They are strong men and women who serve a vital role in society.
c. [No label control: participants simply answered the targeted questions about police officers in this condition]

We chose "protector" as a non-metaphorical counterpart to guardian because it was the word most frequently used to explain what it means for police officers to be guardians in the original study (Thibodeau, Crow, \& Flusberg, in press). In the context of this more applied question, we did not include a condition that described police officers as warriors, since such a description would be expected to elicit comparatively negative views of police officers. Instead, we compared the effects of a metaphor frame (and a matched literal frame) to a "neutral control" condition because we were interested in whether and to what extent describing police officers as guardians leads people to express a more favorable view of policing.

We were also interested in a mechanistic question about the role of metaphor in explanatory discourse, which we addressed by comparing the guardian and protector conditions. Are metaphors more persuasive than literal counterparts? In a meta-analysis, Sopory and Dillard (2002) found that metaphors are about $6 \%$ more persuasive than literal language, which they attributed to the power of metaphors to organize the way people think about a target domain.

The design of the current study provides a novel context for testing this claim. One possibility is that the guardian metaphor may call to mind a more coherent and favorable mental model of policing than the non-metaphorical counterpart, protector, and lead people to the most positive view of police officers and the criminal justice systemmore positive than the protector and "neutral control" conditions.

An alternative possibility, though, is that the literal counterpart to guardian (protector) serves a similar organizational function in describing the role of police officers in the community. That is, depending on the complexity of the target domain and intended meaning of the metaphor, there may be issues for which a literal frame is as effective as a metaphorical one in shaping thought. Support for this possibility would be found if people express similarly positive views of the police in these two conditions-both of which should lead people to a more positive view of policing than the "neutral control" condition. Such a finding would contribute to the literature by identifying an important boundary condition on metaphor framing effects (cf. Steen, Reijnierse, \& Burgers, 2014).

In addition to the framing experiment, we also conducted a norming study to assess the perceived metaphoricity and emotional valence of three possible descriptions of police officers: (a) guardians of modern communities, (b) protectors of modern communities, and (c) warriors of modern communities. One critical assumption that was
made in our prior work was that the terms guardian and warrior were actually interpreted as metaphors, and not, for example, as literal descriptions of the role of police officers ${ }^{1}$. The norming study allows us to test this assumption. We expected that the guardian and warrior descriptions would be rated as more metaphorical than protector. The norming study also allowed us to quantify the emotional tone of the three descriptions. We expected that the guardian and protector descriptions would be rated as conveying a more positive emotional valence than warrior. Both studies were pre-registered on the Open Science Framework: osf.io/eb853.

## Norming Study

## Methods

Participants We recruited 100 participants for the norming study from Amazon's Mechanical Turk. After excluding participants who failed to finish the study or provide a valid completion code, we were left with data from 88 participants for analysis ( $51 \%$ male; $M_{\text {age }}=33$ ).

Materials and Design Participants were asked to rate the metaphoricity (1, Not at all metaphorical, to 5, Very metaphorical) and valence (1, Very negative, to 5, Very positive) of three statements on 5-point scales (Thibodeau \& Boroditsky, 2015).
a. Police officers are guardians.
b. Police officers are warriors.
c. Police officers are protectors.

These statements were presented on the same screen; the order of the statements was randomized across participants.

Afterward, participants were asked background and demographic questions, including their gender, age, education level, political ideology ( 0 , Very liberal, to 100 , Very conservative), and political affiliation (Democrat, Independent, Republican, Other). They also completed the attitudes towards policing measure described in the experiment below, although we did not analyze responses to these questions for participants in the norming study.

## Results and Discussion

A repeated measures ANOVA revealed differences in the rated metaphoricity of the three statements, $F(2,174)=$ 27.59, $p<.001, \eta^{2}=.24$. Warrior $(M=3.56, S D=1.33)$ was rated as more metaphorical than guardian $(M=3.02$, $S D=1.21), t(87)=3.48, p<.001$, or protector $(M=2.38$, $S D=1.28), t(87)=6.35, p<.001$; guardian was rated as more metaphorical than protector, $t(87)=4.82, p<.001$ (see Figure 1).

[^516]On the one hand, this pattern of results confirms our intuition that the terms warrior and guardian are perceived as more metaphorical than the term protector in the context of describing the role of police officers. On the other hand, we did not predict that the term warrior would be viewed as more metaphorical than guardian.

One possibility is that people consider the guardian metaphor to be more apt (cf. Glucksberg, 2001), which affects judgments of metaphoricity (Thibodeau, Sikos, \& Durgin, 2015). In our original study, $82 \%$ of participants thought police officers should strive to be guardians (rather than warriors) of their communities (Thibodeau, Crow, \& Flusberg, 2016). Talking about police officers in a way that is inconsistent with a preferred mental model of policing (i.e. in a way that is less apt) may lead people to think the description is more metaphorical. In any case, the critical difference in metaphoricity for the present study pertains to the contrast between guardian and protector: as expected, people interpreted guardian to be more metaphorical than protector.

A second repeated measures ANOVA revealed differences in the rated valence of the three statements, $F(2$, $174)=51.01, p<.001, \eta^{2}=.37$. Warrior $(M=3.38, S D=$ 1.21) was rated as more negative than both guardian ( $M=$ 4.32, $S D=0.80), t(87)=7.22, p<.001$, and protector $(M=$ 4.49, $S D=0.82$ ), $t(87)=8.04, p<.001$; protector was rated as more positively valenced than guardian, $t(87)=2.19, p=$ .031 (see Figure 1).

Again, this pattern largely conforms to our predictions: guardian and protector both express a positive view of policing compared to warrior. Although protector was judged to be more positive than guardian, this difference was fairly small.

Figure 1. Ratings of the metaphoricity and valence of three descriptions of police officers. Error bars denote standard errors of the means.

## Experiment

In the experiment, we tested whether describing police officers as guardians, compared to protectors (and to a condition that lacked a label for police officers), leads to
more positive attitudes toward policing. That is, previous work has suggested that metaphorical language is more persuasive than literal language, owing to the organizational role that metaphors play in discussions of complex issues (Sopory \& Dillard, 2002). The norming study suggests that guardian and protector differ substantially in the extent to which they are metaphorical, but only slightly in the emotional tone that they convey (in favor of the nonmetaphorical label).

If the guardian label leads people to express to more positive attitudes towards policing than protector, the experiment would provide further evidence of the persuasive value of metaphor (over and above comparable literal language). If people express similar attitudes in the guardian and protector conditions, on the other hand, it would suggest that, in some cases, non-metaphorical language can serve a similar organizational function as metaphorical language.

## Methods

Participants We recruited 600 participants to participate in the experiment on Amazon's Mechanical Turk. After excluding participants who failed to finish the study or provide a valid completion code, we were left with data from 592 participants for analysis ( $49 \%$ male; $M_{\text {age }}=34$ ).

Materials and Design Participants were randomly assigned to one of three conditions. In one, police officers were described as guardians, "Police officers are the guardians of modern communities-strong men and women who serve a vital role in society." In the second, police officers were described as protectors, "Police officers are the protectors of modern communities-strong men and women who serve a vital role in society." A comparable sentence about police officers was omitted from the third condition. In other words, there was no description of police officers in the third condition; this group simply answered the follow-up questions about policing. Participants in all three groups were instructed, "Although most people agree that police are necessary for maintaining law and order, there is disagreement about a variety of issues related to policing. On the following screen, you will be asked several questions about your view of police officers and the criminal justice system. Please answer candidly; your responses are anonymous."

Then participants were asked eight questions about policing and the criminal justice system. Consistent with Thibodeau, Crow, and Flusberg (2016), three of the questions were asked on a 7-point scale: "Police officers have a _ job" (from very easy to very difficult), "Police officers are _ at maintaining law and order" (from very ineffective to very effective), and "How would you describe the criminal justice system in the U.S.?" (from very far from the ideal to very near to the ideal). The other five questions included two response options, asking about whether participants thought police treated citizens equally (yes/no), whether they thought the police were more fair or unfair,
more honest or deceitful, more selfish or selfless, and whether participants felt safe or unsafe around police officers. Responses to all eight of these questions were combined into a single measure of participants' attitudes toward policing, using principal components analysis (see Thibodeau, Crow, \& Flusberg, 2016).

Finally, participants completed the same demographics questions as participants in the Norming Study.

## Results

A between-subjects ANOVA with predictors for condition (guardian, protector, none) revealed no effect of the descriptions on participants' attitudes toward policing, $F(2,589)=0.18, p=.837$. That is, neither the guardian $(M$ $=3.12, S D=1.28)$ nor the protector $(M=3.14, S D=1.45)$ labels for police officers led people to a more positive attitude toward policing compared to a description that lacked a label $(M=3.20, S D=1.44)$. And the two treatment conditions (guardian vs. protector) did not differ from one another.

Given the lack of support for our primary prediction, we considered alternative hypotheses that could be explored in the data. One salient possibility highlights the role of peoples' prior beliefs (e.g., Hardisty, Johnson, \& Weber, 2009; Johnson \& Taylor, 1981; Thibodeau \& Boroditsky, 2011; Thibodeau \& Flusberg, 2017) in combination with a mechanistic claim about how metaphors are processed-by serving as peripheral or heuristic cues, rather than through a process of conscious deliberation and rationalization (cf. Chaiken, Wood, \& Eagly, 1996; Petty \& Cacioppo, 1986).

That is, prior work has found that framing manipulations are, not surprisingly, more impactful on people who have room to be persuaded about an issue (i.e. are not already at ceiling). For instance, Hardisty, Johnson, \& Weber (2009) found that Democrats would support a program designed to decrease the level of carbon dioxide in the environment, regardless of whether it was described as an "offset" program or a "tax." Since Democrats tended to support this type of environmental action, their attitudes were relatively consistent, regardless of how it was framed (i.e. a ceiling effect). Republicans, on the other hand, showed lower support for the program overall, affording more opportunity for attitude change. In turn, Hardisty et al. (2009) found that Republicans were more likely to endorse the program when it was framed as an "offset" than a "tax."

Since political conservativeness tends to be associated with more positive attitudes toward policing (Gerber \& Jackson, 2017), this suggests that the framing manipulation-describing police officers as guardians or protectors-may have a more pronounced effect among politically liberal participants.

One reason to think that the guardian frame will be more persuasive among liberal participants than the protector frame is that metaphors have been argued to exert a persuasive influence through an indirect route. People who are skeptical about the increasing tendency for violence among police officers may perceive the term protector as an
overt attempt to change the way they think about police practices, making them resistant to the persuasive appeal. In contrast, the term guardian may not register as a persuasive message and, thus, bypass this sort of counter-arguing among participants (cf. Chaiken, Wood, \& Eagly, 1996; Petty \& Cacioppo, 1986).

To examine these possibilities, we conducted a second analysis on the data in which political ideology (a continuous variable ranging from 0 , Very liberal to 100 , Very conservative) was included as a covariate. To conduct this analysis, we first tested for an expected positive relationship between political ideology and attitudes toward policing. We found a strong positive relationship, $F(1,590)$ $=79.54, p<.001:$ the more politically conservative the participant, the more positive their view of the police, $B=$ $.34, S E=.04, p<.001$. We then tested for an interaction between political conservativeness and condition (guardian, protector, none), which was significant, $F(2,586)=3.06, p$ $=.048$. Of note, the relationship between political conservativeness and condition did not differ for a contrast between the "neutral control" condition and the protector condition, $F(1,397)=1.53, p=.217$. However, the relationship between political conservativeness and condition did differ when contrasting the "neutral control" condition to the guardian condition, $F(1,391)=6.52, p=$ .011 (see Figure 2).

Political Ideology
Figure 2. Attitudes toward policing by political ideology (left = very liberal; right $=$ very conservative) and frame (none, protector, guardian). Lowess smoothing ( $f=2 / 3$ ) was applied to the lines to facilitate presentation of the trends.

Specifically, among the most liberal participants (i.e., those who reported a score less than 33 on the continuum of political ideology that ranged from 0 , very liberal, to 100 , very conservative; $n=256$ ), attitudes toward policing were more positive in the guardian condition ( $M=2.93, S D=$
1.06) than in the protector condition ( $M=2.54, S D=1.44$ ), $t(160)=1.98, p=.049$; but no different from the condition that lacked a label $(M=2.63, S D=1.52), t(178)=1.54, p=$ .126. There were no differences between conditions for participants whose political ideology was in the middle of the ideological spectrum (i.e. between 33 and $66 ; n=229$ ), $p \mathrm{~s}>.1$, and no differences between conditions for participants whose political ideology was at the conservative end of the spectrum (i.e. $>66 ; n=107$ ), $p \mathrm{~s}>.1$.

## Discussion

In response to mounting tensions between law enforcement and civilians, former president Barack Obama commissioned a task force on $21^{\text {st }}$ century policing, which released its final report in 2015 (Ramsey \& Robinson, 2015). The report suggested that to increase trust between police officers and the communities they serve, "Law enforcement culture should embrace a guardian-rather than a warrior-mindset." In a previous set of experiments, we used this real-world example as a case study to explore the power of explanatory metaphors, demonstrating that describing police offers as guardians did in fact lead people to express more positive attitudes towards law enforcement than describing them as warriors (Thibodeau, Crow, \& Flusberg, 2016). Because of the real-world applications of this line of research, however, there are additional questions that warrant empirical investigation.

In the present study, we took a preliminary step in this direction by asking whether metaphorical framing provides any additional persuasive power over and above a more literal linguistic descriptor. In an initial norming study, we confirmed that describing police officers as guardians of a community was perceived as more metaphorical than describing them as protectors of a community. In our main experiment, we contrasted the effects of framing the role of law enforcement using these two terms, along with a "neutral" control condition that included no framing device.

Our initial analysis revealed that participants in these three conditions did not differ overall with respect to their attitudes towards policing. This could suggest that there is little advantage to using metaphorical framing compared to more literal language (or even to no frame whatsoever) in a practical attempt to improve attitudes towards policing in the United States. This also offers some support for the view that in our original study, it was the more negatively valenced warrior metaphor that was "doing the work," so to speak, in shifting attitudes towards policing (i.e., in a negative direction). This would be consistent with a large body of work in psychology that suggests people are typically more sensitive to negative information (or losses) than positive information (or gains; Baumeister et al., 2001).

However, we also considered an alternative possibility: that individual differences in prior attitudes towards policing (e.g., due to ideological commitments) might interact with our framing manipulation in a principled fashion. Previous research has shown that framing effects are most effective when they target people who are not at
ceiling (or floor) on an issue already (i.e., who have room to be persuaded; Hardisty, Johnson, \& Weber, 2009; Thibodeau \& Boroditsky, 2011; Thibodeau \& Flusberg, 2017). In the present case, we reasoned that because ideologically conservative participants would have come into the study with very positive views of policing already (Gerber \& Jackson, 2017), they might be less persuaded by a positive metaphorical frame compared to more liberal participants. To test this possibility, we included a continuous measure of political ideology as a covariate in an exploratory analysis.

The results of this analysis supported our revised hypothesis: for the most liberal participants, framing police officers as guardians of the community led to more positive attitudes compared to framing them as protectors of the community. This is consistent with previous work demonstrating a principled interaction between metaphor framing and prior beliefs (Hardisty, Johnson, \& Weber, 2009; Thibodeau \& Boroditsky, 2011; Thibodeau \& Flusberg, 2017), and lends support to the view that metaphors may provide an additional persuasive punch compared to more literal language (at least under certain conditions; Sopory \& Dillard, 2002).

Taken together, these findings paint a more nuanced picture of the relationship between, and consequences of, metaphorical versus literal framing, at least in domain of attitudes towards policing. To be sure, more research in this vein is required, especially considering the practical applications of this sort of work, and the assumptions that often accompany reasoning about metaphor and thought (Lakoff \& Johnson, 1980; Ramsay \& Robinson, 2015). We suggest researchers and public policy communicators interested in these issues should aim for more large-scale, pre-registered, and nuanced empirical studies of framing effects.

#### Abstract

We present two experiments on the role of culture in the categorization of object part-whole structures. A triadic categorization task pitted shape against function as factors driving similarity judgments on selected parts of different types of objects. Speakers of American English were significantly more likely than speakers of two indigenous languages of Mexico, Tseltal Maya and Isthmus Zapotec, to choose categorization by function, even when familiarity of the various stimulus objects was factored in. In the second study, members of the two indigenous groups matched parts of a doll to parts of novel objects of unfamiliar shape. The Tseltal participants were significantly more likely to match according to a shape-analytical algorithm rather than global analogy, consistent with predictions based on prevalent strategies in verbal part labeling in the two languages. We conclude that while cognition of object parts undoubtedly has a strong biological basis, there are also robust cultural effects.

Keywords: object mereology; meronymy; shape perception; function; cross-cultural research

## Introduction

The ability to categorize objects crucially involves identifying their parts. In general, mereology - the conceptualization of parts, and of how they relate to each other and to the wholes they form - is deeply involved in how humans make sense of their physical world.

A strong case can be made that the segmentation of physical objects into parts has a basis in shape recognition (Biederman 1987; Marr 1982; Palmer 1977; Tversky \& Hemenway 1984; inter alia) and is thus likely biologically grounded. At the same time, function plays a key role in the categorization of both body parts of living things and object parts of artifacts (e.g., Croft \& Cruse 2004: 153-156; Rose \& Schaffer 2015; Svorou 1994: 78-79, 91-92; Tversky 1989). Ears and lids can come in a great many distinct shapes; what unites these diverse manifestations is the function they play in the whole of which they are a part. But
the attribution of functions depends on knowledge, beliefs, and assumptions that are at least to a large extent learned. Function dependence thus creates an opening for cultural effects in cognition of parts.

In addition, there is some evidence suggesting that the role of shape, and geometry more generally, in mereological cognition may be to some extent subject to cultural variation as well. This evidence comes from meronymy, the nomenclature for object parts. In-depth studies of the meronymy of non-Indo-European languages are few and far between. But the few available reports present evidence of striking differences vis-à-vis the terminology familiar from English and other European languages.

Our interest in this complex was aroused by descriptions of the meronymies of two indigenous languages of southern Mexico, Ayoquesco Zapotec (MacLaury 1989) and Tseltal Maya (Levinson 1994). Both languages belong to the Mesoamerican linguistic and cultural area, the members of which have been in contact with one another for millennia (Campbell, Kaufman \& Smith-Stark 1986).

A feature that the accounts of MacLaury (1989) and Levinson (1994) converge on is a core set of meronyms that are assigned both to body parts of humans and animals and to the parts of inanimate objects (though not generally to plants). They claim that labeling of object parts with general-purpose body part terms is pervasive, and based largely on shape and geometry. In contrast, function-based meronyms for inanimate objects are largely absent.

Where the two systems appear to diverge is in the strategies used to assign the generalized meronyms to object parts. MacLaury (1989) describes a strategy strictly based on a global analogical mapping from the human body in canonical erect position to the object in its actual orientation at the time the assignment pertains to. (See Figure 1A for the part labelings that this account predicts for a novel object.) The parts that are named in this manner, the 'head,' 'face,' 'sides,' 'back,' and 'buttocks,' have fixed spatial
relationships to each other in any object. For instance, if one knows which part of the object is called its 'face,' and the vertical axis is determined, one can correctly predict the locations of its 'head,' 'sides,' 'back,' and 'buttocks.' The orientation of the object with respect to gravity is crucial; for example, the topmost part is the 'head,' no matter what the structure of that part happens to be, and changing the orientation of the object causes the labels to be reassigned.

In contrast, Levinson (1994) discusses the process by which meronyms are assigned to objects in Tseltal as an algorithm that takes a visual segmentation of the object as its input. (See Figure 1B for an example this account's predicted labelings for a novel object.) Axes of generalized cones are identified for the main volume and any secondary volumes of the object, as well as axes of symmetry. A sense of direction is assigned to each axis, and meronyms are assigned to the ends of the axes, in some instances taking the shape of the part into account. So, for instance, the default meronym for the head (in the vector sense) of the main axis is the word for 'head,' but if that region of the object is pointy, 'nose' is used, and if it is a negative space, 'mouth' is used. This system does not take into account the orientation of the object with regard to gravity, and because the axes are in certain ways independent of each other, meronyms do not occur in a fixed spatial schema. ${ }^{1}$

The question we wish to address in this paper is whether these putatively distinctive properties of meronymy are restricted to language, or whether they are associated with deeper cognitive differences - between Mesoamericans and English speakers on the one hand, and between Zapotec and Tseltal speakers on the other. We present two studies. Experiment 1 explores the respective role of shape and function in object part categorization, comparing data from speakers of Tseltal, Zapotec, and American English in a three-population design. Based on the available descriptions of verbal behavior, we predict function to play a greater role in the mereological categorizations of Americans than in those of either Tseltal or Zapotec participants.

Experiment 2 compares Tseltal and Zapotec participants in terms of their preference for categorizing the parts of unfamiliar objects by comparing them globally to the human body vs. by doing so based on the shape-analytical algorithm even when it is not licensed by a global mapping. If the differences in part categorization strategies go beyond language, we predict that the Tseltal participants should be more likely to prefer mappings that are at odds with global analogies.

## Experiment 1: shape vs. function

Speakers of English, Tseltal Maya, and Isthmus Zapotec compared images (with one exception, photographs were used) of part-whole configurations. Isthmus Zapotec is

[^517]

Figure 1. A: Meronyms predicted by the global mapping account. B: Meronyms predicted by the algorithmic account.
closely related to Ayoquesco Zapotec as described by MacLaury (1989); ongoing field research by the third author suggests that MacLaury's analysis of Ayoquesco meronymy applies to Isthmus Zapotec as well as far as the predictions of the present study are concerned, though with additional complications (Pérez Báez 2011). Each trial involved a triad of images. The participants selected the configuration that was least like the other two. The triads were composed so as to trade off functional against shape-based similarity. Since function attribution likely depends on the participants' knowledge of the object, a norming study was carried out to assess their familiarity with the stimuli.

## Method

Participants. 27 participants of each population were recruited at field sites in La Ventosa, Oaxaca, Mexico (Isthmus Zapotec - 16 women, 11 men; 14 young adult, 9 middle-aged, 4 elderly) and Tenejapa, Chiapas, Mexico (Tseltal Maya - 18 women, 7 men; 16 young adults, 8 middle-aged, and 1 elderly, with 2 participants' demographic information missing), the University at Buffalo and in Raynham, Massachusetts (English - 19 women, 8 men; 17 young adults, 6 middle-aged, and 4 elderly). Recruitment was conducted by word of mouth and at the University at Buffalo by flyer. Participants completed the tasks in about 30 minutes and were compensated 100 Pesos (approximately $\$ 5$ ) and $\$ 10$, respectively.

Materials. Each participant was given 12 test trials interspersed with 17 fillers, for a total of 29 trials, preceded by one practice trial of the same design as the fillers. The three pictures for each trial were printed on a single sheet, and the sheets placed into a binder so that one triad could be displayed at a time. The placement of the images on each page was pseudo-randomized, in order to reduce any possible bias toward choosing the picture in any particular one of the three positions.

Each trial consists of showing a participant three pictures of artifacts or plants that are presumably familiar to all three populations, with certain parts highlighted in red, and asking them to choose the one whose highlighted part they judge to
be most different from the other two. The experimental triads are designed to pit shape against function, in that there is a pivot object part and two alternates: the pivot shares its shape with one alternate, and its function with the other. An experimental triad is shown in Figure 2.

The filler trials use the same visual layout as the experimental trials, and the action the participant is expected to perform is the same. However, instead of a single pivot, there are two pictures in which the indicated parts of the object are similar in both shape and function, while the remaining picture's indicated part is the odd one out in terms of both shape and function. Therefore, a shapebased strategy and a function-based strategy would tend to produce the same response. This provides a check on the participants' attention to and comprehension of the task.

Procedure. The participants were instructed in their native languages by the first author and, in the case of the Tseltal and Zapotec participants, by bilingual assistants with experience in linguistic field research, to pick out the partwhole configuration in each triad they considered least like the others. The following standardized instructions were used: "In this game, I am going to show you some drawings and photos of various things - three at a time. And if you are not sure of what some of the objects are, please ask me. One part of each thing is red. Two of the parts are more similar, and the other is different. I want you to look at those parts, and find the different one. You should compare only the parts, not the whole objects. When you decide which is different, circle it using this marker. For example, let's look at these three [the practice triad]. Here there's a dog, with its leg red. And here is a cat, with its head red. And a pig, with its leg red. So, which part is different? Correct, the head. And so, do you have any questions before beginning? ${ }^{2}$

Norming. As part of the follow-up task 'Shape-Function Norming,' participants rated the familiarity of each individual picture used in the Shape-Function Triads. This serves the purpose of checking their interpretation of the pictures and providing additional factors for statistically modeling the experiment's results. Participants rated each of the three pictures in each experimental trial for familiarity, using a five-point Likert scale in their native language.

## Results

Participant exclusions. The responses of two Zapotec participants were excluded from the analysis because their performance on the filler trials was below the preestablished $80 \%$ threshold, indicating that they did not sufficiently comprehend the task.

Trial exclusions. Trials were excluded from the analysis in two situations. In one of these, the participant chose the

[^518]

Figure 2. Example of a test triad for Experiment 1
pivot as the odd one out in the trial in question, which is not interpretable as classifying by shape or function (11 trials in the Zapotec data set, 12 in the Tseltal data set, and 8 in the English data set). In the other situation, they did not give an answer to that trial at all ( 1 trial in the Zapotec data, 0 in the Tseltal data, and 0 in the English data). Approximately 4\% of the data points were missing or excluded.

Analysis. Figure 3 shows the breakdown of responses.
The responses to the norming scale, interpreted as numerals, were centered so that -2 corresponded to "completely unfamiliar" and 2 corresponded to "completely familiar." (The standard deviations of the ratings for each object ranged from 0.37 to 1.26 for the Zapotec speakers, and from 0.23 to 1.49 for the Tseltal speakers.) Within each language population, the mean of these familiarity scores was calculated for each picture in order to generalize across participants. Any picture whose average rating was equal to or greater than 1 was counted as "familiar," and any whose average rating was less than 1 was counted as "unfamiliar." The overall familiarity of each triad was coded by the number of familiar and unfamiliar pictures it contained, from "A" for three familiar pictures through "D" for none, and this code was treated as an ordinal factor in the regression models of the responses.

A binomial logistic mixed-effects regression model was fitted with population (identified by language) and code of triad familiarity as fixed factors, and random intercepts for participant and trial. Tseltal and Zapotec participants proved

Figure 3. Experiment 1 responses by population and type. Error bars represent 95\% prediction intervals.
significantly different from American participants at the $\mathrm{p}<.001$ level and from one another at the $\mathrm{p}<.05$ level. No significant effect of familiarity was obtained.

## Discussion

As predicted, the Mesoamerican participants were more likely to categorize parts by shape than the American participants. Shape in fact strongly dominated the Tseltal and Zapotec speakers' categorizations (at $65.4 \%$ and $76.8 \%$ of responses), whereas function strongly dominated among the English speakers $(67.7 \%){ }^{3}$ Familiarity did not appear to significantly affect these ratings, suggesting that the selection of the stimuli from among objects of everyday interactions for all three cultures was successful. It is possible, however, that the similarity judgments were influenced by subvocal use of meronyms.

## Experiment 2: global vs. shape-analytical mapping

The purpose of this experiment was to test for population differences in mereological cognition, by obtaining responses of nonverbal mapping from body parts to the parts of novel objects. This was done with the researcher indicating various parts of a humanoid doll, and asking the participants to find as many corresponding parts as they could on the Novel Objects. In order to test for effects of subvocal rehearsal, this task had two conditions: In one condition, the participants did a verbal elicitation task before the experiment, and in the other condition, they did not.

## Method

Participants. 44 Tseltal speakers ( 29 women, 16 men; mean age 39.7, SD 12.6) and 45 Isthmus Zapotec speakers ( 33 women, 12 men; mean age 33.2, SD 13.6) were recruited and tested in La Ventosa, Oaxaca, Mexico (Isthmus Zapotec) and San Cristóbal de las Casas, Chiapas, Mexico (Tseltal), relying again on word of mouth. The task took about an hour to complete and the participants were compensated 100 Pesos (approximately \$5).

Materials. The tasks used as stimuli a set of six solid plastic forms, part of the MesoSpace Novel Objects stimuli. ${ }^{4}$ These are abstract forms that, as far as possible, bear little resemblance to any item familiar to the participants, so that the objects are not biased toward any particular meronym assignment strategy, and the participants have to fall back on their general principles for construing mereological structure. Figure 1 features an example. For the practice

[^519]trial, instead of a Novel Object, a blobby humanoid figure made of Sculpey modeling clay was used. A plastic action figure doll representing a young adult male, fairly realistic in proportions, was used to represent a target body part in each trial - either the head, face, side (flank), back, or buttocks. These five parts were used because both MacLaury (1989) and Levinson (1994) had identified the meronyms for them as belonging to the languages' most productive meronymic systems, and these Zapotec and Tseltal terms are rough translation equivalents with regard to the human body. The participants used bits of Play-Doh to mark the parts of the Novel Objects that they judged as corresponding with these target parts. This doll was in a standing position in each trial, which, if an orientationdependent mapping strategy is used, would favor the choice of the uppermost part of the Novel Object as corresponding with the doll's head, the part(s) of the Novel Object to the participant's left or right as corresponding to the doll's side, etc.

Procedure. Conditions: In order to detect possible subvocal rehearsal effects, half of the participants carried out a verbal labeling task prior to the experiment; the other half did not do this task. Participants were randomly assigned to one condition or the other.
The verbal elicitation task was administered as follows: the participant was handed each of the Novel Objects, one at a time (in an opaque bag to avoid imposing any orientation on the object), asked to take it out and inspect it from all sides, and then prompted to delineate and label its parts. The experimenter recorded the delineated areas on twodimensional images of the objects.
Setup: In each trial, the experimenter set one of the Novel Objects on the tabletop directly in front of participant, sticking it into a base of Play-Doh if it would not stay in the desired orientation unsupported. Each Novel Object was therefore relatively in front of the participant and absolutely to the north (the participants were seated to face north). Trials: In each trial, one of the target parts of the doll was manually indicated by the experimenter. In view of the importance of vertical orientation in Zapotec meronymy, the trials were administered in two orientation variants: "aligned" (that is, the gravitationally-defined vertical axis coincides with the Novel Object's algorithmically-defined 'model axis', i.e., the axis from which the central volume of the object is generated), or "unaligned" (these axes are orthogonal). This yielded a total of 60 test trials: 5 doll parts x 6 Novel Objects x 2 orientations. In addition, there was one practice trial employing instead of a Novel Object a blobby humanoid figure made of Sculpey, designed to abstractly resemble the doll.

Instructions: The participants were instructed that when the experimenter indicated a part on the doll by delineating it with a finger, they should mark with the Play-Doh as many parts on the Novel Object as they thought corresponded to the doll's part, whether this resulted in no part being marked, just one part, or multiple parts. The
participants were instructed in their native languages by bilingual research assistants working with the first author as follows: "I'm going to give you some objects, one at a time. This first object is an example. You can turn it around to see how it is. And I'm going to show you some part of this doll, and you should decide if the object has a part of the same kind. It's possible that it doesn't have any. In that case, simply tell me that it isn't there. It's also possible that it has a part like that, or more than one at a time. In that case, take a bit of this Play-Doh and stick it to the part or parts that are similar. And when it's finished, I want you to lift the object and turn it slowly to show what you have done."

Recording: The responses, in terms of the landing sites on the Novel Objects the participants marked with Play-Doh, were recorded by the first author verbally in English on a coding sheet. The sessions were videotaped in their entirety.

## Results

Participant exclusions. One Zapotec participant's responses had to be excluded because the participant appeared unable to grasp the instructions.

Trial exclusions. 16 of the 60 test trials were excluded from the analysis because the algorithm Levinson (1994) proposed for meronymic labeling in Tseltal predicted that the particular Novel Object lacked a corresponding part, and the Tseltal participants nevertheless in almost all cases identified some part of it despite having been given the option not to select a mapping. These responses therefore could not be evaluated for whether they fulfilled the predictions of the algorithm. One Tseltal trial was not completed. The analysis was thus performed on 1,936 trials with Zapotec participants and 1,979 trials with Tseltal participants.

Coding. In order to code the responses for whether they fit the global mapping account, simplifying assumptions were adopted. When the 'head' of the doll had been indicated, the global prediction was considered fulfilled if and only if the Play-Doh was placed somewhere on the upper region of the object (as defined by the vector of gravity). Globally, the 'buttocks' had to be on the lower region, the 'face' on the region toward the participant, the 'back' on the region away from them, and the 'sides' on the regions to their relative left or right. These regions were interpreted as both surfaces and volumes. So, for example, a placement that was both on the top surface of the object, and also displaced from the center of that surface in the direction toward the participant, would satisfy the prediction for 'head' by virtue of being on the upper part of the object, and would also satisfy the prediction for 'face' by virtue of being on a volume part that is toward the participant. The volume interpretation of parts was also followed for the algorithmic predictions.

Response types. Four response types were distinguished, based on whether the proposed match was predicted solely by global mapping ('Global only'), solely by Levinson's
(1994) shape-analytical algorithm ('Algorithm only'), by both, or by neither. From MacLaury's (1989) global mapping account, two key predictions were derived: the 'face' of any object faces toward the observer, and the 'head' of any object points up against the pull of gravity. Since Levinson's (1994) algorithm is orientationindependent, it was assumed that given a part of the doll and a Novel Object, the intrinsic location of the matched part on the Novel Object will be constant across varied orientations.

Analysis. Figure 4 shows the breakdown of the four response types across the two populations.

Responses in "Doll to Novel Objects Mapping"

Figure 1. Experiment 2 responses by population and type.
Using Begg-Gray approximation of multinomial logistic regression (Begg \& Gray 1984), four binomial logistic mixed effects regression models were fitted, one for each response category, with population identified in terms of language, condition, alignment, and trial as fixed factors, and random intercepts for the stimulus doll part, the Novel Object, and the participant. The Algorithm-only model showed significant effects of population and alignment at the $\mathrm{p}<.001$ level. The Global-only model showed effects of alignment and trial at the $\mathrm{p}<.001$ level. There was a significant interaction between Zapotec and alignment at the $\mathrm{p}<.05$ level. The Both model yielded a significant effect of population at the $\mathrm{p}<.01$ level and alignment and trial at the $\mathrm{p}<.001$ level. The Neither model yielded no significant effects. None of the models produced a significant effect of condition.

## Discussion

As predicted, the Zapotec participants were significantly more likely to propose matches that agreed with global analogical mapping, but violated Levinson's (1994) shapeanalytical algorithm. Also in line with predictions, the orientation of the Novel Object had a significant effect on the Zapotec participants' matches, but not on those proposed by the Tseltal participants. Also as predicted, the "aligned" trials favored responses in the 'both' category. There was no effect of condition; we take this to suggest that subvocal rehearsal played no major part in the results. Subvocal rehearsal would have predicted that the two populations should have performed significantly more
different from one another in the Verbal-priming condition, contrary to fact. ${ }^{5}$

## General discussion

In both experiments, language proved a significant predictor of nonverbal mereological categorization: English speakers significantly preferred categorizing parts in terms of function, whereas Tseltal and Zapotec speakers were significantly more likely to categorize parts by shape (Experiment 1). And Zapotec speakers proved significantly more likely than Tseltal speakers to adhere to global analogy in mapping the parts of the human body to those of inanimate objects of unfamiliar shape, and were also significantly more likely to factor the orientation of the objects into their matches (Experiment 2).

We cannot exclude the possibility of subvocal rehearsal effects in Experiment 1. It is possible that the participants used their native languages for guidance in deciding between function-based and shape-based categorization. Future research will have to determine to what extent our results are truly representative of the nonverbal cognition of these groups. However, our findings are in line with previous research suggesting that geometry, as opposed to function, plays a relatively greater role among Mesoamericans compared to Westerners (Lucy \& Gaskins 2001). Meanwhile, in Experiment 2, we plausibly ruled out a significant contribution from language as a direct resource, suggesting robust differences in nonverbal cognition.

The findings presented here are also in line with Whorfian interpretations according to which language use may habituate speech communities to particular biases in mereological cognition and serve as a conduit of their cultural transmission (Bohnemeyer et al 2015). Here, too, we must defer to future research for ascertaining whether language merely reflects mereological cognition or is a causal factor in it.

## Conclusions

We have provided evidence of the existence of significant cross-cultural differences in the categorization of the mereology of physical objects. This is hardly surprising, as the categorization of objects and their parts clearly depends in part on acquired knowledge. What is surprising, in our view, is that research into such cultural effects is still in its infancy. We hope to have made a small contribution towards rectifying this.

#### Abstract

For the last 80 years, the Stroop task has been used to test theories of attention and cognitive control and it has been applied in many clinical settings. Most theories posit that the overwhelming power of written words overcomes strict instructions to focus on print color and ignore the word. Recent evidence suggests that trials in the Stroop task could in fact be a mixture of reading trials and non-reading trials. Here we conduct a critical test of this mixture hypothesis, where a mixture of processes should satisfy the fixed-point property (Falmagne, 1968).

Keywords: Stroop Effect; Mixture Model; Fixed-Point Analysis

The Stroop effect is one of the most replicated experimental effects in cognitive psychology (see MacLeod, 1991, for a review). The effect has been used to investigate cognitive control, and has also been applied in many clinical settings (Strauss, Sherman, \& Spreen, 2006, p. 477). The task involves naming the print color of a word, where the word itself is typically the name of a color (e.g., the word GREEN printed in red print requires a response of 'red'; Stroop, 1935). People are faster at naming the print color when it matches the word (congruent stimuli, e.g., RED in red) compared to when the word and print color do not match (incongruent stimuli, GREEN in red).

A common measure of the Stroop effect is the difference in mean response time (RT) between congruent and incongruent trials. In the Stroop task, participants are instructed to name the color and ignore the word, yet it seems people cannot help but read the word (e.g., Cohen, Dunbar, \& McClelland, 1990; Melara \& Algom, 2003), which gives rise to faster responses on congruent trials than incongruent trials on average. Although reading must happen on some trials for an effect to be observed, it is not clear whether reading occurs on every trial, or to the same extent across trials.

Eidels, Ryan, Williams, and Algom (2014) compared the Stroop effect obtained from a standard Stroop task to the effect obtained from a novel forced-reading task. In the standard task, participants were asked to classify
the print color of color-words irrespective of the content of the word. In the forced-reading task participants were asked to classify the print color of color-words (e.g., RED, GREEN), but withhold their response when presented with non-color-words (BED, GREED). To conform with the instructions, participants were forced to read every word presented. Consequently, the forcedreading Stroop task yielded a Stroop effect derived from fully processed words on every trial. The researchers found that the magnitude of the Stroop effect in the forced-reading task was larger than in the standard task, suggesting that the standard Stroop effect results from reading on only a portion of trials (see also Tillman, Eidels, \& Finkbeiner, 2016).

One possible account for these results is that on any particular trial of the standard task a participant might only be processing the word to a limited extent, or not processing the word at all. A simple, formal way of explaining how different processes are mixed to yield some observed distribution of RTs is a probability-mixture model (Eidels et al., 2014; Tillman et al., 2016). Under this model, the empirical RT distributions observed in either the congruent or incongruent conditions of the standard task are a binary mixture of two unobserved distributions: one distribution of reading trials and one distribution of non-reading trials. A given trial is a sample drawn from the reading distribution (with probability $p$ ) or the non-reading distribution (with probability $1-p)$. The forced-reading task increases the probability of reading to $(p=1)$.

This mixture-of-reading-processes hypothesis can be tested in a number of ways. One method assumes that a mixture of two different RT distributions should result in a bimodal observed distribution, and applies Hartigan's dip test to assess the bimodality. The test assumes the null hypothesis of unimodality over the alternative hypothesis of multimodality. If the dip statistic is greater than the 95th percentile of the reference distribution, then the null hypothesis is rejected and the observed distribution is considered bimodal (Hartigan \& Hartigan, 1985). Another method is to fit both a one-component
and a two-component Gaussian mixture model to the observed data and compare both models using model selection techniques, such as AIC (Akaike, 1974).

In simulation studies, researchers have found that the Hartigan's dip test correctly identifies bi-model distributions only $65 \%$ of the time and the AIC model selection method falsely identifies bimodality $80 \%$ of the time (Freeman \& Dale, 2013). In general, bimodality is difficult to detect in empirical data and requires the underlying distributions to be well separated and variability to be low (Williams, Eidels, \& Townsend, 2014). However, recent software and computational advances may facilitate a more robust approach to this problem. In this paper, we test the hypothesis that the standard Stroop effect results from a mixture of reading processes by using a mathematical property of probability-mixture distributions, the fixed-point property (Falmagne, 1968).

## The Fixed-Point Property

A set of mixture distributions, which are all based on the combination of two base distributions, will all intersect at a common coordinate - the fixed-point property (Falmagne, 1968, see Figure 1). Although this mathematical property could be a powerful means of identifying mixture models, researchers in the past have not commonly employed the fixed-point property test for two reasons (van Maanen, de Jong, \& van Rijn, 2014). Firstly, estimating the probability density function (PDF) of the observed RT distribution from noisy data is not trivial. Secondly, it has been difficult to provide statistical evidence for the presence of the fixedpoint property, which requires providing evidence for the null hypothesis.

We address the first issue by using the Epanechnikov kernel density function (Epanechnikov, 1969), which has been shown to approximate the PDF of RT distributions well (Silverman, 1986; Turner \& Sederberg, 2014). To select a bandwidth for the kernel we use Silverman's "rule of thumb" (Silverman, 1986, p. 48, eq (3.31)). The default software libraries in R ( R Development Core Team, 2016) allow for easy use of both the Epanechnikov kernel and Silverman's "rule of thumb". We address the second issue by using Bayesian methods to assess the degree to which there is no difference between a particular crossing point in all mixture distributions. Bayesian hypothesis testing, or Bayes factors, quantify evidence in favor of either the null hypothesis or the alternative hypothesis as a ratio. For example, when $B F_{10}=5$ the observed data are 5 times more likely under the alternative hypothesis than under the null hypothesis. When $B F_{10}=$ .2 the observed data are 5 times more likely under the null hypothesis than under the alternative hypothesis.

There is some precedent for using a fixed-point analysis to test mixture models in RT data (Brown, Lehmann, \& Poboka, 2006; van Maanen et al., 2014; van Maanen, 2016). For RT distributions, when the observed RTs are

Figure 1: Illustration of the fixed-point property in Stroop distributions. The 'No Reading' distribution consists of $0 \%$ reading trials and the Forced distribution consists of $100 \%$ reading trials. The Standard distribution is a mixture of trials from both distributions. All three distributions will intersect at a common point, which is labeled "Fixed-point property" in the figure.
made up of a mixture of unobserved distributions, there will be one RT for which the probability of providing a response at that particular time is equal for all mixtures (see Figure 1 again).

Here we test whether RT distributions in the Stroop task satisfy this fixed-point property. In the Stroop task participants are requested to classify the print color of color words and ignore the words' meaning. The ubiquitous Stroop effect implies they fail to exclusively focus on color and succumb to the overwhelming (perhaps automatic) attraction of reading. Previous evidence suggests that participants may not always process word meaning to the same extent (Eidels et al., 2014; Tillman et al., 2016). They may process words on some trials and not on others, in a way commensurate with a binary mixture model.

To test the mixture model we presented participants with three experimental conditions, each intended to induce a different level of reading (gauged by the probability p): a color naming task involving rectangles (probability of reading, $p=0$ ), forced reading Stroop task in which each word must be read to its full extent, on each and every trial $(p=1)$, and a standard Stroop task, where participants may involuntarily read the words on some proportion of the trials $(0<p<1)$. A probabilitymixture account of reading in the Stroop task predicts that RT distributions of the three conditions will cross each other at a common point (the 'fixed-point property').

## Method

## Participants

Twenty two students (19 females and 3 males) from the University of Newcastle (mean age $=22.41$ and SD age $=$ 4.74) participated in the study. Participants had a proficiency in English and normal or corrected to normal vision with intact color vision. Each participant completed the standard, forced, and color naming Stroop tasks and participants were reimbursed $\$ 15$ per session.

## Apparatus

Each task was carried out on Dell computers running Windows XP with 17 " Diamond View color monitors. Contrast and brightness were set to 80 and 50 , respectively. We used the Tektronix J17 Lumacolor digital photometer and J1800 series sensor heads to calibrate color clarity across all testing stations. The software 'Presentation' was used to run the experiment and record data. Participants responded using a Cedrus response pad, model RB-830. The response keys on the response pad were marked with color stickers corresponding to the red, green or blue response.

## Stimuli

For the color naming task, the stimuli were color filled rectangles in the center of the screen. For the standard and forced task, the stimuli were were 12 words that were printed in either the color red, green, or blue. The 12 words were RED, GREEN, and BLUE and three variants for each of these words. The variants differed from the color words by one letter and if substituting one letter resulted in a non-word, two letters were changed instead. The variants were GREED, GRAIN, QUEEN, RENT, ROD, BED, BASE, BLUR, and GLUE.

The variants made up the neutral stimuli for the standard and forced-reading task. The neutral stimuli were matched to the color stimuli on length, neighborhood frequency, and phonetics using the software N-Watch (Davis, 2005) and based on the CELEX word frequency database. All words were written in uppercase bold Arial font, with no words exceeding 2.55 cm , or 4 visual degrees when the participant was seated 60 cm from the screen.

Red, green and blue print colors of the words and rectangles had $R G B$ values of $R=220, G=0, B=0$ for red, $\mathrm{R}=0, \mathrm{G}=0, \mathrm{~B}=240$ for blue, and $\mathrm{R}=0, \mathrm{G}=170, \mathrm{~B}=0$ for green. The stimuli made up three conditions in the standard and forced-reading task. The congruent condition consisted of stimuli that had the print color and word match (RED in red, GREEN in green). The incongruent condition consisted of stimuli that had the print color and word mismatch (RED in green, GREEN in red). All non-color words were classified as neutral trials.

## Procedure

Each participant completed three sessions on separate days. Each session involved the standard, forcedreading, or color naming task. The former two took about an hour to complete and consisted of 10 experimental blocks with 1 minute breaks between each. The color task took 20 mins and consisted of one experimental block. The order of task presentation and position of the response buttons was counterbalanced across participants.

Each task was completed in a dark room with a desk lamp as the light source. At the beginning of each session, participants were shown 9 example trials that demonstrated the correct response. They also completed two practice blocks that consisted of 24 trials, with feedback for correct and incorrect responses in the first block.

In the color naming task, participants were instructed to respond to the print color of the rectangles by pressing the corresponding button on the response pad. In the standard task, participants were instructed to ignore the word and respond to the print color of the word. In the forced-reading task, participants were instructed to respond to the print color of words, but withhold responses to neutral words (e.g., BED, GREED, RENT).

On each trial, a fixation cross appeared in the center of the screen for 500 ms , followed by a blank screen for 500 ms . Following this, either a rectangle printed in color (color naming task) or a word printed in color was presented for 500 ms in a random position within 40 pixels distance from the center. The spatial uncertainty prevented participants from using spatial cues to respond. Participants were required to respond within 2500 ms after stimulus presentation before the trial timed out.

The color naming task involved 50 trials of blue, red, and green rectangle presentations, making for 150 trials in total per participant. For the standard and forced task, each of the ten experimental blocks consisted of 18 congruent trials, 36 incongruent trials, and 54 neutral trials. In the forced task, this allowed for half the trials to contain no response, which controls for participants predicting a non-response trial. Each combination of congruent and incongruent stimuli were presented 6 times per block. The order of stimulus presentation was randomized within each block. The RT was recorded in milliseconds.

## Results

The probability mixture account makes two testable predictions. First the fixed cross point, where all three Stroop distributions will have a single RT with equal probability of providing a response at that time - we test this in the following section. The mixture account also predicts that the observed (mixture) distribution will be bound between the faster non-reading distribution and the slower forced-reading distribution. This is exactly
what we observed in our data. The color naming task had a mean RT of 436 ms ( $\mathrm{SD}=132 \mathrm{~ms}$ ). In the congruent condition, the standard and forced-reading tasks had mean RTs of $470 \mathrm{~ms}(\mathrm{SD}=150 \mathrm{~ms})$ and 700 ms (SD $=208 \mathrm{~ms}$ ), respectively. While in the incongruent condition, these tasks had mean RTs of 495 ms ( $\mathrm{SD}=172 \mathrm{~ms}$ ) and 832 ms ( $\mathrm{SD}=233 \mathrm{~ms}$ ), respectively.

We also used Bayesian paired samples $t$-tests to evaluate the evidence for differences between the color naming, standard, and forced-reading mean RTs in the congruent and incongruent conditions. In the congruent condition, participants were slower in the standard task than the color naming task $\left(B F_{10}=8.8 \times 10^{660}\right)$ and were slower in the forced-reading compared to the standard task $\left(B F_{10}=5 \times 10^{559}\right)$. In the incongruent condition, participants were slower in the standard task than the color naming task $\left(B F_{10}=1.2 \times 10^{1295}\right)$ and were slower in the forced-reading task compared to the standard $\left(B F_{10}=6.9 \times 10^{2770}\right)$.

## Fixed-Point Analysis

The analysis was carried out using the 'fp' package (van Maanen et al., 2014) in R (R Development Core Team, 2016) - but we used the Epanechnikov kernel instead of the default Gaussian kernel as recommended by Silverman (1986, p. 43).

The analysis involved calculating the probability density of each RT distribution in each task. For example, focusing only on the congruent condition (and later similarly focusing on the incongruent condition) we estimated the RT distribution for the color naming task, the standard task, and the forced reading task, which by design have a mixture proportion of $p=0,0<p<$ 1 , and $p=1$, respectively. We then found the crossing point of each pair of distributions (i.e., forced-standard, forced-color naming, standard-color naming). The fixedpoint property holds if all pairs cross at the same point along the x and y axis (see Figure 1).

We tested whether the fixed-point property holds for the sample of participants in our study. We calculated the crossing points per pair of mixture proportion tasks for each of the participants for both the congruent and incongruent distributions, but the color naming distribution was the same for both the congruent and incongruent comparison. We then subjected these crossing points to Bayesian analysis of variance (ANOVA). The Bayesian analysis was conducted using the Bayes Factor package (Morey, Rouder, \& Jamil, 2014; Rouder, Morey, Speckman, \& Province, 2012) in R. The Bayes factor from the ANOVA provides evidence for or against the fixed-point property.

We calculated the Bayes factor as the ratio of the evidence for the null hypothesis over the alternative. The null hypothesis posits that there is no difference in crossing points between all distributions in question, and thus suggests that the fixed-point property is satisfied. In line
with Kass and Raftery (1995) we consider a Bayes factor greater than 3 as positive evidence in favor of the null (fixed cross point) and against the alternative hypothesis that there is a difference between crossing points.

The RT distributions for the congruent and incongruent trials are presented in Figure 2. For the congruent condition, the Bayes factor ANOVA revealed that the null model was preferred to the alternative model by a Bayes factor of 1.25 . The data provide equivocal evidence in favor of both the null and alternative hypothesis for the congruent Stroop distributions. For the incongruent condition, the Bayes factor ANOVA revealed that the null model was preferred to the alternative model by a Bayes factor of 2.27 . The data provides evidence in favor of the hypothesis that there is no differences between crossing points, but the evidence is inconclusive.

## General Discussion

In the Stroop task, slower responses on incongruent trials relative to congruent or even neutral trials implies participants read the words despite instructions to focus on color and ignore the words' meaning. Recent evidence suggests participants may read on some proportion of the trials and not on others (Eidels et al., 2014; Tillman et al., 2016). When the observed RT on a single trial is sampled from a non-reading distribution, color naming will not be slowed down by the incongruent word. When the observed RT on a single trial is sampled from a reading distribution, the speed of color naming will be slowed down by an incongruent word, therefore, contributing to a Stroop effect. The magnitude of an observed Stroop effect reflects the proportion of trials in which the participant has read on - the greater the proportion, the larger the effect. To statistically test for this mixture of reading processes in the Stroop task, we ran a fixed-point property analysis on Stroop RT distributions with different reading proportions. We found some evidence for a mixture of distributions in the incongruent condition, but the results of the analysis were not conclusive.

The fixed-point property analysis is one method for testing for a mixture of processes, but it requires the strong assumption that there is a pure mixture of reading and non-reading processes. That is, the approach assumes that the only difference between the three tasks is the proportion of reading trials. This assumption may be compromised by other contaminant processes across the tasks. For example, the Stroop effect can be effected by attentional resources (Kahneman \& Chajczyk, 1983), practice (MacLeod \& Dunbar, 1988), dimensional discriminability and experimental correlation (DishonBerkovits \& Algom, 2000), target set size (La Heij \& Vermeij, 1987), and the number of colored letters in the stimulus word (Besner, Stolz, \& Boutilier, 1997). Further, there are differences in stimuli (words vs rectangles) across tasks. Whilst our results are inconclusive with re-

Figure 2: Overall RT density for congruent and incongruent Stroop distributions.
gards to identifying a mixture process, they certainly do not preclude the mixture hypothesis as being a viable explanation for the Stroop effect.

Our study also reflects the difficulties in distinguishing between single-process and dual-process mental phenomena, which is an issue that besets cognitive psychology (e.g., Yap, Balota, Cortese, \& Watson, 2006; Wixted, 2007; Freeman \& Dale, 2013). Nonetheless, the mixture model of Stroop has clinical, empirical, and theoretical implications. If the Stroop effect distribution is derived from a reading distribution and a non-reading distribution, and the combination of these distributions makes up the observed distribution, then clinical applications of the Stroop task need to consider this mixture of reading processes. For instance, differences in Stroop effect magnitude may not only reflect differences in attentional control, but could simply reflect a difference in the proportion of reading across trials. Empirically, future work could account for the proportion of reading trials by employing the benchmark forced-reading task along with the standard task. Finally, theories of Stroop (e.g., Cohen et al., 1990; Melara \& Algom, 2003) will need to consider what mechanism allows for a Stroop effect to only arise on some proportion of trials but not others. Given these implications, we hope to see more robust testing of the mixture-of-reading-processes hypothesis outlined here.

## Acknowledgments

We would like to thank Katie Berka for data collection and Scott Brown for helpful comments related to the fixed-point analysis.

# Interleaving area problems in the $4^{\text {th }}$ grade classroom: What is the role of context and practice? 

Rachael Todaro (rtodaro@kent.edu) \& Bradley J. Morris (bmorri20@kent.edu)<br>Department of Educational Psychology, 405 White Hall<br>Kent State University, Kent, OH 44242 USA

#### Abstract

Typical mathematics instruction involves blocked practice across a set of conceptually similar problems. Interleaving, or practice across a set of conceptually dissimilar problems, improves learning and transfer by repeatedly reloading information and increasing discrimination of problem features. Similarly, comparing problems across different contexts highlights relevant and irrelevant knowledge. Our experiment is the first to investigate the relative effects of interleaving geometry problems and interleaving contexts. Thirty-three fourth-grade students received the same practice problems but were randomly assigned to one of three conditions: interleaved by math skill, interleaved by context, and interleaved by math skill and by context (i.e., hyperinterleaved). Afterward, each participant was exposed to tests assessing declarative and procedural knowledge. The results suggest that interleaving math skill within varying contexts enhances the acquisition of mathematical procedures.

Keywords: interleaving, cognitive development, mathematics instruction

## Introduction

Mathematics has been subject to a broad array of interventions and techniques that could potentially improve learning, retention, and transfer of knowledge to novel contexts. One promising intervention is known as interleaved practice, in which exposures to concepts (e.g., math skills) are followed by exposures to dissimilar concepts (Rohrer, 2012). Another promising technique is presenting concepts in multiple contexts, which supports generalization (Vlach, Sandhofer, \& Kornell, 2008). The purpose of the present study was to examine the effects of interleaving geometrical problems across two different, yet familiar, contexts. We investigated the effects of interleaving context, math skill, or context and math skill by presenting this information in blocks (i.e., the same format across a series of examples). The main hypothesis of the present study was that interleaving across both context and math skill (hereafter hyper-interleaving) produces an additive effect, which would increase learning, retention, and transfer beyond other conditions because such presentation highlights differences between examples and supports greater discrimination among math skills.

## Mechanisms underlying Interleaving

Presenting math problems in an interleaved fashion improves performance outcomes because this type of presentation supports two fundamental mechanisms for
successful learning: discrimination training and repeated reloading. Discrimination training involves comparing and contrasting problem features, which may leading to a higher likelihood of increased learning of concepts and procedures as well as an increased ability to transfer solution strategies to novel problems (Kang \& Pashler, 2012; Rittle-Johnson \& Star, 2007). Repeated reloading occurs when a student revisits the same type of problem and supports effortful recall of the information, which increases the likelihood for successful encoding (Bjork \& Bjork, 2011).

Presenting interleaved problems typically consists of two components. The first component is the presentation of conceptually dissimilar problem types during the practice session (e.g., a problem about the area of a square following a problem about the area of a triangle). The second component is the distribution of those problems across multiple practice sessions. That is, the student returns to practice the interleaved problems on more than one instance (Rohrer et al, 2014). Presenting interleaved problems supports comparisons and contrasts between members of different categories (e.g., perimeter of squares vs. triangles). In this manner, comparing and contrasting perceptual and conceptual information not only promotes learning regarding how to perform each procedure, but trains the learner to discriminate which solution strategy is appropriate for each problem example (i.e., discriminative contrast; Birnbaum, Kornell, Bjork, \& Bjork, 2013; Kornell \& Bjork, 2008).

Initially, interleaved practice appeared to owe most of its effectiveness to spacing. Spacing is inherent in interleaved practice because there is time between each opportunity to practice concepts. This is distinct from massed practice as it allows students to forget irrelevant information between learning events, which increases the potency of encoding on subsequent presentations (Bjork and Allen, 1970; Cuddy and Jacoby, 1982). However, interleaving does not solely rely on the benefits and efficacy of spacing. Given the same amount of temporal space between each exposure, interleaved presentation produces greater gains in learning than blocked presentation (Kang \& Pashler, 2012). More recent literature emphasizes the importance of repeated reloading (Bjork \& Bjork, 2011), which suggests that accurate memory retrieval is enhanced when a learner must repeatedly reload specific concepts from long-term to shortterm memory. In fact, interleaved practice may provide its benefit more from repeated reloading rather than to the amount of time between successful reloads (e.g. temporal spacing; Kang \& Pashler, 2012).

## Learning with Contexts

Learning is context-dependent (Willingham, 2009). Placing math problems in familiar contexts may not only be an effective presentation method but an additive one as it activates domain knowledge that may facilitate learning and problem solving by providing a framework in which the student can make sense of the concept (Willingham, 2009; Rittle-Johnson \& Star, 2007). Context also offers the learner cues to solve a problem because it draws his/her attention to the right details and improves learning in memory retrieval, problem solving (Godden \& Baddeley, 1975), and reasoning tasks (Cheng \& Holyoak, 1985). The main finding across studies regarding context is that when learning and testing contexts are the same, there is an improvement in performance. These findings also suggest that if a student learns within a single context, she may fail to retrieve information outside the context (i.e., context dependency, Godden \& Baddeley, 1975; Vlach et al., 2011). Distributing learning across multiple events that use multiple contexts can reduce context dependency (Rothkopf, Fisher \& Billington, 1982; Smith, 1982). Additionally, learning across multiple contexts results in a greater number and variance of salient cues during learning, which may increase the likelihood of recall (Smith, 1982; Vlach et al., 2011). When multiple contexts are presented across multiple learning events and these contexts are similar, the shared contextual support leads to greater learning than does providing a single cue from one context (Thiessen \& Saffran, 2003; Vlach et al., 2011).

While ours is the first study to interleave both math skill and context, Rau, Aleven, and Rummel (2013) investigated how interleaving specific dimensions of math problems may affect performance. By either interleaving fraction problems (i.e., dividing fractions) or their graphical representations (i.e., pie chart, number line), they found that interleaving problems was most beneficial to learning whereas interleaving the representations was not. In a follow-up study, Rau, Aleven, Rummel, and Pardos (2014) found that interleaving both dimensions significantly benefited learning over interleaving problems alone.

The present study investigated the relative contributions of interleaved sequencing across math skills and context on declarative knowledge (i.e., knowledge of facts), procedural knowledge (knowledge of how to choose and carry out a procedure), and transfer assessments (i.e., ability to apply knowledge in novel contexts). In addition, we investigated whether these elements produce an additive effect in which their combination produces greater learning gains than either element presented individually. To test these effects, we created a $2 \times 2$ factorial design as follows: math skill interleaved (interleaved math skill/blocked context), context interleaved (blocked math skill/interleaved context), hyperinterleaved (interleaved math skill/interleaved context). The authors chose to omit the fully condition (blocked math skill/blocked context) since it does not address the current research question, as both dimensions are blocked. As mentioned in the introduction, we
hypothesized that the hyperinterleaved group would perform better than the math skill interleaved and context interleaved group on all assessments post-intervention (i.e., posttest, delayed posttest, transfer, and delayed transfer) due to increased discrimination training across contexts and procedures. We also predicted that the math skill interleaved group would perform better than the context interleaved condition since relevant problem features are highlighted.

## Method

## Participants

Thirty-seven children ( 15 girls) ranging from nine to ten years of age were recruited from an elementary school in Northeast Ohio and completed up to six separate sessions. Each child was enrolled in the $4^{\text {th }}$ grade during the 20162017 school year. Four students completed the first session but were not present for either the second or third session and their data were excluded from all analyses. The remaining 33 students completed both sessions of the intervention and were subject to analyses.

## Task

Participants were taught to define and solve for area of four, two-dimensional geometrical shapes: square, triangle, rectangle, and parallelogram. Although various problems resulted in the same numerical solution during pretest, intervention, post-test, transfer, delayed posttest and delayed transfer test, no problem appeared more than once. In each problem, the participants were given the necessary features of each shape to solve the problems successfully (e.g., for a triangle, the base, height, and length of the sides were given). Throughout all sessions of the experiment, the participants needed to select and carryout the appropriate math skill (e.g., solving for the area of each shape).

## Design \& Procedure

The current study included five sessions: a pretest, first and second intervention, a one-day delayed posttest and transfer test, and a 30-day delayed posttest and transfer test. Each of the first four sessions occurred across four consecutive days, one session per day. The fifth session occurred 30 days after the fourth session ended. All sessions occurred in the $4^{\text {th }}$ graders' classroom. Each participant was randomly assigned to one of three conditions: math skill interleaved, context interleaved, or hyper-interleaved. Problems in the math skill interleaved condition were presented such that the area problems were interleaved but blocked by context. Problems in the context interleaved condition were presented such that problem contexts were interleaved but the math skill was blocked. Problems in the hyperinterleaved condition were presented such that both context and math skill were interleaved. See Table 1. The math skills used in the study were formulas in which to solve area (e.g., area of a square). The contexts used in the current study were "indoor maintenance" (How much carpet is needed to cover a bedroom?) and "outdoor renovations" (How many feet of
the playground is covered by mulch). The first author administered all procedures described below.

## Coding Rubric

The coding rubric was created for the purpose of representing the performance expectations for all assessments. The rubric was separated into two component parts (i.e., declarative and procedural knowledge) and provided clear descriptions of criteria needed to satisfy each one. The declarative knowledge component assessed adequate shape drawing as well as accurate defining of geometrical terms (i.e., area). The rubric included acceptable answers (i.e., "space inside of a shape") ranging from one to two points and unacceptable answers (i.e., area around the shape"), which were worth zero points. For the procedural knowledge component, the following criteria were included: two points for the application of the correct procedure, one point for correct answer, and one point for correct unit notation. Inter-rater reliability was strong for the declarative and procedural components, with Cohen's kappa $=.90$ and .96 , respectively.

Table 1: Groups were presented problems interleaved by math skill, context, or by both math skill and context.

| Group | Sequence of Math <br> Skill | Sequence of <br> Context |
| :---: | :---: | :---: |
| Math Skill <br> Interleaved | Interleaved | Blocked |
| Context <br> Interleaved <br> Hyperinterleaved | Blocked | Interleaved |

## Session 1: Pretest

During the first session, participants were administered a pre-test in order to assess prior declarative knowledge regarding the concept of area. One question was asked regarding the definition of area. Students earned up to two points if they included key terms listed on the scoring rubric. They were also asked to draw each shape, which was worth one point. Participants were also asked to define the shapes with the possibility of earning up to two points for each shape's definition. Additionally, within the pretest the participants were given two area problems for each shape to solve, which assessed prior procedural knowledge. Each procedural problem was worth four points. As per the scoring rubric, the participants needed to demonstrate the correct procedure, correct answer, and correct notation of units (e.g., $\mathrm{ft}^{2}$ ). In total, participants were able to earn up to 46 points on the pretest. The participants were given 30 minutes to complete the pretest. The pretest problems did
not contain a context but a box below asking for the area. The participants were expected to show their work inside the box.

## Session 2: Intervention Phase 1

During the second session, students were given a supplemental packet with the definitions of concepts (e.g., height, base, area, etc.) and worked examples (Sweller, 1988) of area problems across all four shapes.

Shortly afterward, students were given a brief lesson about the area of each shape encouraging the students to identify key words such as "cover" for area, show their work in the specified boxes below each figure, and to use their supplemental packet to follow along in the lesson. The lesson lasted between 10-15 minutes.

After the lesson, participants were administered the first phase of the training packet. The entire training packet consisted of 24 area problems to be divided between three sessions of training. Two area problems of each shape were included in each training packet. The first phase of the training packet consisted of a mixture of 8 area problems across either one or both contexts depending on which condition the participants pertained. If the participants had questions, they were directed to the supplemental packet and were advised to focus on the cue words in order to solve for area of the four various shapes. Students were given minimal feedback for the duration of the intervention. The first phase of the intervention lasted approximately 30 minutes.

## Session 3: Intervention Phase 2

The second intervention session was similar to the first. The students received the second set of eight area problems of four different shapes across one or both contexts. The participants were given $25-30$ minutes to complete the second session of the intervention.

## Session 4: Posttest and Transfer Test

The posttest was similar to the pretest but differed in numerical measurements across all four shapes in order to avoid practice effects. The first section required that the students define the concepts of area along with drawing and defining the four different shapes. Again, this section assessed declarative knowledge and was worth a possible 14 points. The participants then completed four area problems of each shape for a total of eight posttest problems. Six questions that contained novel contexts were included in the posttest, in order to assess for transfer of procedural knowledge. The purpose of including these problems was to investigate whether any of the presentation conditions would lead to increased transfer to novel contexts. The transfer problems dealt with contexts distinct from those seen previously in the experiment (baseball fields, cooking, distances riding a bike, etc.). Like the pretest, participants could earn up to four points on each posttest and transfer procedural problem provided that they demonstrate the correct procedure, answer, and unit notation. In total,
participants were able to earn up to 46 points on the posttest and 24 points on transfer problems.

## Session 5: 30-day Delayed Posttest and Transfer Test

The delayed post-test and the delayed transfer test were similar to the original post-test and transfer test. The first section of the delayed posttest was identical to the one-day posttest: the participants defined, drew, and described the concepts and shapes listed. The problems on both the delayed post-test and delayed transfer test only differed slightly on the numerical measurements of the shapes and novel figures in order to avoid practice effects. In total, participants were able to earn up to 46 points on the delayed posttest and 24 points on delayed transfer problems.

Table 2: Means and Standard Deviations $(\mathrm{N}=33)$

| Test | Math Skill <br> Interleaved <br> $(n=12)$ | Context <br> Interleaved <br> $(n=10)$ | Hyper- <br> interleaved <br> $(n=11)$ |
| :--- | :---: | :---: | :---: |
| Pretest |  |  |  |
| Declarative | $5.1(3.0)$ | $5.5(2.8)$ | $5.7(2.8)$ |
| Procedural | $5.1(4.6)$ | $1.7(1.8)$ | $4.4(4.5)$ |
|  |  |  |  |
| Posttest |  |  |  |
| Declarative | $6.3(1.6)$ | $7.4(2.2)$ | $7.1(2.2)$ |
| Procedural | $18.2(8.2)$ | $9.3(5.9)$ | $20.0(9.3)$ |

|  |  |  |  |
| Delayed |  |  |  |
| Posttest | $7.8(1.9)$ | $7.0(2.3)$ | $7.3(2.7)$ |
| Declarative | $19.4(11.8)$ | $14.3(5.8)$ | $23.2(5.2)$ |
| Procedural | $12.9(7.0)$ | $11.1(5.1)$ | $14.8(7.0)$ |
| Transfer |  |  |  |

## Results

Table 2 displays the means and standard deviations for the pretest, posttest, transfer, delayed posttest, and delayed transfer test separated by declarative items, problems, and transfer problems. It is clear in the table that there was a great deal of variability within each group on each of the problem and transfer test scores.

Three repeated measures ANOVAs were conducted to examine the differences in number of points scored as a function of (1) 3 Interleaving Types (between; Math Skill Interleaved, Context Interleaved, and Hyperinterleaved x 3 Procedural Problems (within; Pre, Post, Delayed); (2) 3 Interleaving Types x 2 Transfer Problems (within; Transfer \& Delayed Transfer); (3) 3 Interleaving Types x 3 Declarative Knowledge Problems (within; Pre, Post, Delayed).

## Interleaving x Declarative Knowledge

In this analysis we used the three interleaving types as a between-subjects variable and pretest, posttest, and delayed posttest as a within subject variable. This was to examine whether or not interleaving types influenced declarative knowledge. The test of within subjects effects indicated a main effect of test, $F(2,54)=7.746, M S e=27.033, p<$ $.001, \eta_{p}^{2}=.223$. Within subjects contrasts indicated that participants performed better on the posttest declarative questions compared to the pretest declarative questions, $F(1$, $27)=6.133, M S e=45.633, p=.020, \eta_{p}^{2}=.185$. Although the mean for delayed posttest declarative questions was higher than posttest, this difference was not statistically significant, $F(1,27)=3.381, M S e=12.033, p=.077, \eta_{p}{ }^{2}=$ .111. There was not a significant interaction between test and group from posttest to delayed posttest declarative questions, $F(2,27)=2.931, M S e=10.433, p=.07, \eta_{p}{ }^{2}=$ .178. Tests of between-subjects effects determined that there was not a significant effect of group, $F<1$.

Figure 3: Mean scores of each group on declarative
knowledge. Error bars indicate standard errors of the means.

## Interleaving x Procedural Problems

In this analysis we used the 3 interleaving types as a between subjects variable and pretest, posttest, and delayed posttest as a within subject variable. This was to answer the question of whether or not the different interleaving types impacted the problem solving accuracy of pre, post, and delayed posttest problems. As is evident in Figure 1 regarding procedural problem accuracy, the test of within subjects effects indicated that there was a main effect of test, $F(2,54)=53.46, M S e=2235.54, p<.001, \eta_{p}{ }^{2}=.66$. Within subjects contrast indicated that students performed better on the posttest problems compared to the pretest problems, $F(1$, 27) $=85.19, M S e=4538.70, p<.001, \eta_{p}{ }^{2}=.76$. Although the mean for the delayed posttest problems was higher than the posttest problems, it was not statistically significant, $F(1,27)=3.89, M S e=407.01, p=.117, \eta_{p}^{2}=.089$. The interaction between test and group was approaching statistical significance, $F(1,27)=3.157, M S e=168.175, p$ $=.059, \eta_{p}{ }^{2}=.190$.

The test of between-subjects effects determined that there was a significant main effect of group, $F(1,27)=5.209$, $M S e=136.608, p=.012, \eta_{p}{ }^{2}=.278$. A Bonferroni test of multiple comparisons revealed that participants in the hyperinterleaved condition performed significantly better
from posttest to delayed posttest procedural problems when compared to the context interleaved condition, $p=.011$, whereas the math skill interleaved group did not, $p=.108$. The hyperinterleaved condition did perform better than the math skill interleaved condition on solving procedural problems from post- to delayed post test, however, these findings were not statistically significant, $p>.088$.

Figure 1: Mean scores of each group on procedural knowledge. Error bars indicate standard errors of the means.

## Interleaving x Transfer

In this analysis we used the 3 interleaving types as a between subjects variable and transfer and delayed transfer test as a within subject variable. This was to answer the question of whether or not the different interleaving types impacted the participants' problem accuracy of transfer and delayed transfer test. The test of within subjects effects did not find a main effect of test, $F(1,28)<1, M S e=1.492, p=$ $.805, \eta_{p}{ }^{2}=.040$. Although represented in Figure 2, the context and math skill interleaved groups encountered a rise in performance from transfer to delayed transfer problems, within subjects contrasts revealed that the interaction effects were not significant, $F(1,28)<1, M S e=13.981, p=.566$, $\eta_{p}{ }^{2}=.040$. While the hyperinterleaved group performed best on both transfer tests, tests of between-subjects effects determined that there was not a significant effect of group, $F(1,28)=2.25, M S e=127.801, p=.124, \eta_{p}^{2}=.138$.

Figure 2: Mean scores of each group on transfer of procedural knowledge to novel contexts. Error bars indicate standard errors of the means.

Overall, all groups demonstrated significant learning of procedural problems from pretest to posttest. In fact, there was a main effect of group on the posttest procedural
problems in which the hyperinterleaved group performed significantly better than the context interleaved group and the math skill interleaved group did not. However, the result pattern could be due to lower pretest scores for the context interleaved group.

To further examine the effect of group on assessments, change scores were computed and a one-way ANOVA was conducted. The ANOVA demonstrated that change scores from pretest to posttest of the hyperinterleaved group significantly differed from the context interleaved group, $F(2,28)=3.301, M S e=169.563, p=.05$. Bonferroni tests of multiple comparisons indicated this difference was not statistically significant, $p=.07$. Change scores from pretest to delayed posttest and from posttest to delayed posttest indicated no significant differences between groups, $p \mathrm{~s}>$ .05. Furthermore, there were no differences between groups in changes scores from transfer to delayed transfer, $p>.05$.

## Discussion

Our results demonstrate that when math skill was interleaved (i.e., in the math skill interleaved and hyperinterleaved groups), procedural performance on posttest was significantly better than when math skill was blocked (i.e., context interleaved group). These findings provide additional support for interleaved practice as a technique that enhances memory by increasing the number of repeated reloads and by promoting discriminative contrast among problems. Recall that the context interleaved group blocked the math skill problems and interleaved the contexts. Blocking math skills does not allow the learner space between problems to reload relevant information. Additionally, blocking these problems does not allow the learner to discriminate between the features of other shapes in order to highlight key elements within the problem in order to apply the appropriate procedure.

The lack of statistical differences between the math skill interleaved and the hyperinterleaved group on posttest may be due to the lack of variation between contexts. Recall that practicing problems in multiple, varying contexts typically reduces context dependency, which supports generalization to novel situations. In the current study, the contexts may not have been different enough to decrease the level of context dependency. And, a stronger effect of hyperinterleaving may have been observed if more than two contexts were included in this study. Alternatively, the spacing of practice across two separate sessions of intervention may have equalized the effects of interleaving math skill and hyperinterleaving.

The results of our experiment align with those of Rau et al. (2013; 2014), suggesting two notions. One, math skill is the problem dimension that benefits most from an interleaved practice sequence. Two, interleaving both math skill and another dimension (i.e., context) may enhance learning when compared to interleaving math skill alone. It is important to note that the hyperinterleaved group demonstrated increased learning on all post, delayed posttest, and transfer procedural problems. One explanation
for these findings may be that interleaving context while also interleaving math skill may require more effort on the part of the learner during practice, resulting in enhanced memory. Another explanation is that shuffling familiar contexts during practice may facilitate the application of knowledge outside of the context in which it was learned. This experiment provided an important contribution in understanding the benefits of more effortful interleaved practice when learning new skills and transferring them to novel contexts.

Although the fourth-grade sample size in the current study was small, the apparent trend of interleaving math skills within different contexts that led to better performance seems to be promising. The results suggest that early learning of math skills such as solving for area may benefit from all types of practice, especially when spaced over time. For future research, it may be beneficial to examine the effect of context versus no context in interleaving experiments that evaluate retention and transfer of declarative and procedural knowledge.

## Conclusion

Our experiment demonstrated the potential educational benefits of hyperinterleaving math skill with contexts. The results of the current study suggest that along with the advantages that interleaving area problems offers, shuffling contexts throughout this practice may also contribute to better generalization of these skills. Our study is one of the first to examine the effectiveness of combining interleaved practice with another common instructional technique. Placing examples in a familiar context is often used in classroom settings to make learning tasks recognizable for young learners and this study has provided unique insight on how this technique interacts with that of interleaved practice. More research is necessary to understand how interleaved practice interacts with context and other effective learning techniques, especially within the classroom environment.

# Scarcity impairs online detection and prospective memory

#### Abstract

Operating under limited resources poses significant demands on the cognitive system. Here we demonstrate that people under time scarcity failed to detect time-saving cues as they occur in the environment (Experiment 1a). These time-saving cues, if noticed, would have saved time for the time-poor participants. Moreover, the visuospatial proximity of the time-saving cues to the focal task determined successful detection, suggesting that scarcity altered the spatial scope of attention (Experiment 1b \& 1c). People under time scarcity were also more likely to forget previous instructions to execute future actions (Experiment 2). These instructions, if remembered and followed, would have saved time for the time-poor participants. Failures of online detection and prospective memory are problematic because they cause neglect and forgetting of beneficial information, perpetuating the condition of scarcity. The current study provides a new cognitive account for the counterproductive behaviors in the poor, and relevant implications for interventions.

Keywords: scarcity, attention, perception, memory, recall

## Introduction

The condition of scarcity is widespread and manifests in many domains. For example, four billion people experience severe water scarcity during at least part of each year (Mekonnen \& Hoekstra, 2016), and more than $10 \%$ of the world population live with less than US\$1.90 per day (World Bank, 2016). A growing body of evidence has revealed how scarcity fundamentally shapes the way people perceive the environment and behave accordingly (Mani, Mullainathan, Shafir, \& Zhao, 2013; Mullainathan \& Shafir, 2013; Shah, Mullainathan, \& Shafir, 2012; Shah, Shafir, \& Mullainathan, 2015; Tomm \& Zhao, 2016).

Since the cognitive system is limited in attentional and working memory capacity (Baddeley, 1992; Luck \& Vogel, 1997; Miller, 1956; Pashler, Johnston, \& Ruthruff, 2001; Rock \& Gutman, 1981), scarcity induces a trade-off of attentional and cognitive resources dedicated on the focal task and other tasks that also require attention (Tomm \& Zhao, 2016). This corroborates with past research showing that engagement with complex tasks can cause a failure to notice highly salient events (Simons \& Chabris, 1999), even at the expense of personal safety (see Strayer, Drews, \& Johnson, 2003).

In the current study, we investigate how time scarcity affects the online detection of information, and how time
scarcity affects prospective memory performance. Our study is motivated by past work showing that people only start to increase their efforts to accomplish their goals when a deadline becomes salient (Gersick, 1988). Further, time pressure causes fewer attributes to be considered when choosing between alternatives (Wright, 1974). Given these findings, we propose that time scarcity may enhance attentional focus on the task at hand, while inducing neglect of other information in the environment, even if the information is beneficial. In two experiments, we examined the attentional and memory consequences of time scarcity.

## Experiment 1a

The goal of the first experiment was to investigate how time scarcity affects the online detection of information in the environment. We hypothesize that time scarcity draws attention to the focal task, while inducing neglect of other useful information in the environment.

## Participants

Undergraduate students ( $N=90$ ) were recruited from the Human Subject Pool at the Department of Psychology at the University of British Columbia (UBC), and participated in the experiment in exchange for course credit. All participants provided informed consent to participate. All experiments reported here were approved by the UBC Behavioral Research Ethics Board. We conducted a power analysis using G*Power (Faul, Erdfelder, Lang, \& Buchner, 2007), which showed that given an effect size of 0.6 (based on our prior work, Tomm \& Zhao, 2016), a minimum of 90 participants would be required to have $80 \%$ power to detect the effect in our design.

## Stimuli and Procedure

In the experiment, each participant was asked to solve a series of puzzles on the computer. The puzzles were a total of 50 trials of the Raven's Progressive Matrices (Raven, 2000). Each matrix appeared at the centre of a computer screen. The bottom right corner of the matrix was missing, and participants had to find the right piece that fits with the general pattern in the matrix. Each participant was asked to correctly solve the matrices to earn as many points as possible. In each trial, participants were shown one Raven's
matrix, with the numbered pieces appearing below. The response keys appeared in a vertical list on the left side of the screen. In the top-left corner of the screen, the question number and time remaining were displayed (see Figure 1). Participants were not told of the total number of trials until starting the first trial. To solve each matrix, participants pressed a number key corresponding to the correct piece.

Figure 1. Trial screen for Experiment 1a.
To manipulate time scarcity, participants were randomly assigned with either a rich time budget (they had 40 minutes in total to solve the matrices; the time-rich condition, $N=$ 45 ), or a poor time budget (they only had 10 minutes in total to solve the matrices; the time-poor condition, $N=45$ ). Without explicit instruction or prompting, a time-saving cue appeared in the lower right part of the screen during the experiment. Specifically, on even-numbered trials starting from trial \#24, the cue appeared on the screen stating: "This question is not worth any points. Press 'A' to skip." (see Figure 1) Thus, 14 of the 50 trials were allowed to be skipped without any loss of points. The cue appeared at the same as the matrix for those trials, and remained on the screen for 5000 ms , and then disappeared. These trials presented an opportunity to skip the question in order to save time. Participants were not told anything about the cue. We wanted to see if they were able to detect this message during the experiment and skipped the even-numbered questions from trial \#24.

## Results and Discussion

Participants in the time-poor condition almost unanimously used their entire time budget ( 10 minutes) while participants in the time-rich condition used less than half of their time budget ( 16 minutes). Given this constraint, the time-poor participants spent less time on the task overall compared to time-rich participants $[t(88)=6.51, p<.001, d=1.37]$ (Figure 2a). The time-poor participants completed fewer trials than the time-rich participants $[t(88)=4.71, p<.001$, $d=.99]$ (Figure 2b).

Notably, there was marginal difference in accuracy on the Raven's Progressive Matrices between the time-poor and the time-rich participants $[t(88)=1.69, p=.09, d=.36]$
(Figure 2c). When accounting for the total amount of time spent on the task, the time-poor participants scored higher accuracy per minute than time-rich participants $[t(88)=$ 8.09, $p<.001, d=1.71]$. This result suggests that time scarcity can cause a greater focus on the task at hand, enhancing task performance within the time limit.

Figure 2. Results for Experiment 1a. Error bars represent $\pm 1$ SEM. $* p<.05$, $* * * p<.001$. Note: accuracy was computed for all trials excluding skipped trials.

Examining the number of questions skipped, we found that there was no significant difference in the average number of questions skipped between the time-poor and the time-rich participants $[t(88)=1.23, p=.22, d=.26]$ (Figure 2d). However, only $26.7 \%$ of the participants in the timepoor condition skipped at least once, and there were more time-rich participants (48.9\%) who skipped at least once $\left[X^{2}(1,90)=4.72, p=.03\right]$ (Figure 2e). This result suggests that time scarcity caused a failure to use the time-saving cue appearing on the bottom of the screen.

To control for the total number of trials completed, we calculated skip efficiency as the number of questions skipped divided by the number of possible questions that could be skipped. There was no difference in skip efficiency between the time-poor and the time-rich participants $[t(88)$ $=.91, p=.36, d=.19]$ (Figure 2f).

Among those who skipped at least once, there was no difference in the number of questions skipped between the time-poor and the time-rich participants $[t(31)=.89, p=$ $.38, d=.34$ ] (Figure 2 g ). This means that if the participant noticed the cue at least once, they were able to skip the same number of questions, regardless of scarcity.

To measure retrospective recall of the time-saving cues, we asked participants after completing the task during debriefing to report whether they saw any messages appearing on the screen during the task. We found that the time-poor participants were less likely to report seeing the cues than the time-rich participants $\left[X^{2}(1,84)=3.81, p=\right.$ .05] (Figure 2h).

These results showed that fewer participants under time scarcity skipped the questions at least once, and reported seeing the cues, compared to time-rich participants. This suggests that time scarcity may narrow attention to the central task, while inducing a neglect of peripheral, even beneficial information in the environment. An alternative explanation is inattentional blindness, suggesting that the time-poor participants were less able to attend to salient but task-irrelevant information, than the time-rich participants. To tease these two accounts apart, we conducted the next experiment, probing whether scarcity alters the spatial scope of attention, or the ability to notice salient stimulus. Specifically, we manipulated the location of the time-saving cue, and examined the likelihood of skipping questions as a function of the spatial location of the cue under scarcity.

## Experiment 1b

In this experiment, we reduced the spatial distance between the time-saving cue and the matrix (i.e., the focal task) by moving the cue closer to the center of the screen, and investigated how the spatial proximity of the time-saving cue to the focal task impacted its detection.

## Participants, Stimuli, and Procedure

Participants $(N=87)$ were recruited from the Human Subject Pool at UBC, and participated in the experiment in exchange for course credit. The stimuli and the procedure
were exactly the same as those in Experiment 1a, except one important change: the time-saving cue (i.e., the message to skip even-numbered questions after trial \#24) now appeared directly underneath the Raven's Progressive Matrix after trial \#24 for even-numbered questions (Figure 3).

If the neglect of the time-saving cue in Experiment 1a was due to the spatial narrowing of attention under scarcity, we would predict that the time-poor participants would be more likely to notice the cue, because it was not close to the central task. On the other hand, if the neglect of the timesaving cue was due to inattentional blindness, moving the cue closer to the central task would not affect performance.

Figure 3. Trial screen for Experiment 1b, where the time-saving cue appeared right below the matrix.

## Results and Discussion

Since in Experiment 1a, time scarcity influenced the number of participants who skipped at least once, we examined the same measure here again. We found that now there was no statistical difference in the percent of participants who skipped at least once $\left[X^{2}(1,90)=.71, p=\right.$ .40] (Figure 4a). Comparing Figure 4 a to Figure 2e, the time-rich participants were not influenced by the change in the position of the cue, but the poor seemed to benefit from the closer proximity of the cue to the central task. This suggests that if the cue falls within the spatial scope of attention, the time-poor participants could still take advantage of the cue.

Figure 4. Results for Experiment 1b.

During debriefing, the time-poor participants were marginally less likely to report seeing any messages during the task compared to the time-rich participants $\left[X^{2}(1,88)=\right.$ 3.78, $p=.05$ ] (Figure 4b). Compared to the time-poor participants in Experiment 1a ( $34 \%$ reported noticing the cue), the closer proximity seemed to provide a large benefit to the time-poor participants in Experiment 1b ( $48 \%$ reported noticing the cue). These results support the account that scarcity narrows spatial attention to the focal task.

## Experiment 1c

To further explore the boundary condition of the spatial narrowing effect of scarcity, in this experiment we moved the time-saving cue farther away from the focal task, and examined how likely participants were to notice the cue.

## Participants, Stimuli, and Procedure

Participants $(N=86)$ were recruited from the Human Subject Pool at UBC, and participated in the experiment in exchange for course credit. The stimuli and the procedure were identical to those of Experiment 1a, but this time the time-saving cue appeared in the bottom right corner of the screen (Figure 5), which was even farther away from the focal task than in Experiment 1a.

Figure 5. Trial screen for Experiment 1c, where the time-saving cue appeared far from the matrix, on the bottom right corner of the screen.

## Results and Discussion

We found that participants in both conditions failed to take advantage of cue. There was no statistical difference in the percent of participants who skipped at least once $\left[X^{2}(1,90)=\right.$ $1.54, p=.21]$ (Figure 6a). During debriefing, there was no difference in the likelihood to report seeing any messages during the task between the participants in both conditions $\left[X^{2}(1,87)=2.70, p=.10\right]$ (Figure 6b). In fact, there was a floor effect in both the time-poor and the time-rich participants in skipping the questions or noticing the cue. This suggests that when the cue was spatially far away from the focal task, participants could not notice the cue, regardless of scarcity.

Figure 6. Results for Experiment 1c.

## Experiment 2

Experiments 1a-c showed that time scarcity narrowed attention on the focal task, resulting in the neglect of a timesaving cue which appeared in the peripheral during the experiment. However, in daily life, we do not always have cues in the external environment as reminders for certain actions. Instead, we need to rely on internal cues from memory that need to be activated at the right time to direct actions. For example, in order to pick up groceries on the way home from work, we must remember to turn at the right intersection in order to go to the grocery store. This depends on prospective memory, which is the ability to remember to execute future actions based on previous instructions. Cues for prospective memory are internal, and must be present in mind in order to cue behavior at the right time (Graf, Uttl, \& Dixon, 2002; Loftus, 1971). In this experiment, we examined how time scarcity affects prospective memory performance.

## Participants

Participants $(N=90)$ were recruited from the Human Subject Pool at UBC and completed the study in exchange for course credit.

## Stimuli and Procedure

Participants were asked to solve the same set of 50 Raven's Progressive Matrices used in Experiments 1a-c. As before, participants were randomly assigned either a small time budget ( 5 minutes; the time-poor condition), or a large time budget ( 20 minutes; the time-rich condition). A critical difference in this experiment was that the time-saving cue never appeared in the experiment. Rather, all participants were explicitly instructed at the start of the experiment the following: "Even-numbered questions from number twentyfour on are not worth any points. You can skip these questions without losing any points." This instruction was presented on paper to participants to read, and the experimenter also read through these instructions with each participant to maximize the comprehension of the instruction. As before, the question number and remaining time appeared in the top-left corner of the screen, and the keys available for the participants to press were listed on the
left side of the screen. Note that now the "A (skip)" key is listed among the available keys and was listed for every single question (Figure 7). There were no visual cues during the experiment to remind participants which questions they were allowed to skip. Thus, participants needed to remember to use the opportunity to skip when the applicable questions were reached.

Figure 7. Trial screen for Experiment 2.

## Results and Discussion

Participants in the time-poor condition almost unanimously exhausted their time budgets, while participants in the timerich condition usually completed the experiment with some time to spare (Figure 8a). The time-poor participants spent less time solving the Raven's Matrices than the time-rich participants $[t(88)=13.33, p<.001, d=2.81]$. They also completed significantly fewer trials than the time-rich participants $[t(88)=10.14, p<.001, d=2.14]$ (Figure 8b), and were significantly less accurate $[t(88)=2.29, p=.02, d$ $=.48]$ (Figure 8c). When accounting for the total amount of time spent on the task, the time-poor participants scored higher accuracy per minute than time-rich participants [ $t(88)$ $=9.53, p<.001, d=2.01]$, suggesting that time scarcity enhancing performance on the focal task.

The time-poor participants on average skipped fewer questions than the time-rich participants $[t(88)=2.52, p=$ $.01, d=.53$ ] (Figure 8d). However, this result is likely driven, at least in part, by the considerably smaller number of questions completed by the time-poor participants. Similarly, we found that fewer time-poor participants skipped at least once compared to the time-rich participants $\left[X^{2}(1,90)=10.08, p<.01\right]$ (Figure 8e), but this could be due to the smaller number of possible skips experienced by the time-poor participants. Thus, we examined the skip efficiency defined as the number of questions skipped divided by the number of possible questions that could be skipped experienced by the participant. We found that the time-poor participants were less likely to skip than time-rich participants (two time-poor participants were excluded from this analysis due to failing to reach trial number twentyfour) $[t(86)=2.01, p=.05, d=.43]$ (Figure 8f). This finding suggests that time scarcity impairs prospective
memory performance. We should note that among participants who skipped at least once, there was no difference in the number of questions skipped between the time-poor and the time-rich participants $[t(40)=.59, p=$ $.56, d=.19]$ (Figure 8 g ), or in skip efficiency $[t(40)=.76, p$ $=.45, d=.26]$ (Figure 8h).

Figure 8. Results for Experiment 2. Error bars represent $\pm 1$ SEM. *p<.05, **p $<.01, * * * p<.001$.

## General Discussion

The goal of the present study was to examine how time scarcity impacts attention and prospective memory. We found that people under time scarcity were less likely to take advantage of a time-saving cue that appeared peripheral to the focal task (Experiment 1a), but nonetheless performed well on the focal task under the time constraint. This suggests that people under time scarcity are ironically less likely to notice opportunities to save time. This effect could be explained by a narrowing of spatial attention to the focal task (Experiments $1 \mathrm{~b} \& 1 \mathrm{c}$ ). In the absence of an external cue, participants under time scarcity were less likely to remember to skip questions in the future (Experiment 2), suggesting that they failed to retrieve a cue from memory to execute actions at the right time.

These findings were particularly problematic for people under time scarcity because the attentional neglect of timesaving opportunities or the failure to remember to save time could be detrimental, perpetuating the condition of scarcity and creating a vicious cycle of scarcity. These cognitive impairments could explain a range of counter-productive behaviors observed in the low-income individuals, such as forgetting to follow instructions, or not signing up for public benefit programs. In addition, prospective memory errors can be seen by others as an indication of incompetence of the poor (Graf, 2012). The present findings instead attribute the memory failures not to the poor individuals themselves but to the condition of scarcity. The current study provides useful implications for designing policies and programs to mitigate the impact of scarcity, such as the use of reminders, automatic enrolment, or setting the right default, to reduce the attentional and memory burdens in the poor.

# Specificity and entropy reduction in situated referential processing 

Elli N. Tourtouri (elli@coli.uni-saarland.de)<br>Francesca Delogu (delogu@coli.uni-saarland.de)<br>Matthew W. Crocker (crocker@coli.uni-saarland.de)<br>Department of Language Science \& Technology<br>Saarland University, Saarbrücken, Germany

#### Abstract

In situated communication, reference to an entity in the shared visual context can be established using either an expression that conveys precise (minimally specified) or redundant (over-specified) information. There is, however, a long-lasting debate in psycholinguistics concerning whether the latter hinders referential processing. We present evidence from an eye tracking experiment recording fixations as well as the Index of Cognitive Activity - a novel measure of cognitive workload - supporting the view that overspecifications facilitate processing. We further present original evidence that, above and beyond the effect of specificity, referring expressions that uniformly reduce referential entropy also benefit processing.

Keywords: referential processing; over-specification; visual entropy reduction; eye tracking; Index of Cognitive Activity

## Introduction

Grice's maxims of Quantity (Grice, 1975) stipulate that speakers' utterances be minimally informative, avoiding redundancy. In visually situated communication, this predicts utterances should provide strictly the information necessary for the identification of a referenced object. For example, in the context of a blue and a green ball, the adjective "blue" is necessary to unambiguously establish reference. When there is only one ball, however, the adjective becomes superfluous. Such over-specifications expressions that convey more information than minimally required - are, however, produced by adult speakers at an estimated rate of $10-60 \%$ (see Engelhardt, Bailey \& Ferreira, 2006, and references therein).

Even though Grice arguably did not intend to make any implications about the cognitive processes associated with the violation of his maxims (cf. Geurts \& Rubio-Fernández, 2015), over the past few decades, psycholinguistic research has tried to test their empirical validity. It remains under debate, however, whether or not over-specifications are detrimental to referential processing. A number of studies have suggested that over-specifications impair listeners' online processing and lead to slower and less accurate identification of the target (e.g., Engelhardt, Bailey \& Ferreira, 2006; Engelhardt, Demiral \& Ferreira, 2011; Davies \& Katsos, 2013), while others find evidence that they are as good as minimal descriptions or may even facilitate processing (e.g., Arts, Maes, Noordman \& Jansen, 2011; Tourtouri, Delogu \& Crocker, 2015).

In an ERP experiment, Tourtouri, Delogu and Crocker (2015) presented participants with visual scenes of 6 objects
and audio instructions to locate a target, like "Find the yellow bowl" (in German). The experiment manipulated the specificity of the referring expression by combining the same instruction with different visual displays that rendered it minimally or over-specified. An attenuated N400 effect was found on the noun for over- compared to minimallyspecified references. This finding was interpreted as evidence that over-specifications are in fact beneficial to referential processing, at least when in the presence of visual displays where the over-specified adjective identified exactly one object. That is, at "yellow" the bowl was the only object that fit the description. Interestingly, both color and pattern adjectives were used to identify the target, and the effect was present for both types of adjectives, suggesting that any facilitation of over-specification is not merely due to the perceptual salience of color. It can be argued, however, that the reduced N 400 for overspecifications may just reflect the predictability of the noun as determined by the information on the visual scene in combination with the linguistic input up to the adjective. Therefore, it still remains unanswered whether overspecification has a general facilitatory effect, even when displays allow the adjective to select a second object, which fits a minimally specified continuation of the referring expression, i.e., it is part of a contrast pair.

A similar question was addressed by Sedivy, Tanenhaus, Chambers and Carlson (1999) in a series of experiments that tested (among other things) whether intersective adjectives such as color are interpreted contrastively. Participants' eye movements were tracked while they heard instructions to manipulate objects in a workspace in front of them. The visual scenes consisted of four objects, two that formed a contrast pair differing in color, e.g. a yellow and a pink comb, and two singletons: one sharing the color feature with an object from the pair, e.g. a yellow bowl, and a distractor object of different color. The critical instruction mentioned either of the two objects with the shared feature, and was always heard second, following the instruction referring to an object from the contrast pair. An effect of referent type was found, such that if the target was part of the contrast pair it was looked at faster than if it was not. This result was taken to indicate that initially, before the noun was heard, listeners assigned a contrastive meaning to intersective adjectives, consistent with Grice's maxim of Quantity. We believe, however, that this may not be the case, especially since listeners' attention was already focused on the contrast pair, as the immediately preceding instruction always made reference to one of the contrasting objects (e.g., the pink

Figure 1. Sample visual stimuli for a color item, combined with the instruction "Find the blue ball". The four resulting conditions were A. Minimally specified - High reduction (MS-HR), B. Minimally specified - Low reduction (MS-LR), C. Over-specified - High reduction (OS-HR), D. Over-specified - Low reduction (OS-LR)
comb). Similar results were obtained in the subsequent experiments, where the critical instruction was heard first, but with the use of scalar adjectives, which inherently invoke comparisons between entities.

The current study seeks to determine whether and how over-specifications affect processing of pre-nominally modified referring expressions, when the visual context enables both a minimally and an over-specified reading of intersective adjectives, such as color and pattern. That is, how is referential processing influenced when the adjective is redundant (as in the bottom displays of Fig.1) as opposed to when it is required to uniquely identify the target (as in the top displays of Fig.1)? Furthermore, as the instruction sentence unfolds over time, incoming words incrementally restrict the set of referential candidates. Therefore, in situated communication, the information conveyed by a linguistic unit is determined by the extent to which it reduces the number of potential referents, in addition to the linguistic information of each word, as determined by its probability and preceding context (Shannon, 1948; Crocker, Demberg \& Teich, 2016). In other words, the information on the word "blue" in the sentence "Find the blue ball" is not defined only in terms of its probability to occur in this (linguistic and visual) context, but also by the amount of uncertainty about the target (referential entropy) it reduces. For example, in the left-hand displays of Figure 1 "blue" reduces referential entropy by 1.58 bits, while in the righthand displays it only reduces it by 0.58 bits. The noun, then, eliminates the remaining entropy, reducing it by 1 bit in the
former and by 2 bits in the latter case, resulting in a uniform and a less uniform entropy reduction profile, respectively. This study also touches on whether, above and beyond any effects of specificity, the rate at which the linguistic input reduces referential entropy also influences processing. To examine these questions, we recorded participants' fixations as they viewed displays such as the ones in Figure 1, while listening to instructions like "Find the blue ball" in German, and present results from inspection probabilities to the objects of interest and the Index of Cognitive Activity (Marshall, 2000) per region.

## The Index of Cognitive Activity

It is well established that fluctuations of the pupil size index cognitive effort in a variety of tasks, including language processing (e.g., Just \& Carpenter, 1993). However, changes in the lighting conditions of the environment are also responsible for pupil dilation. The Index of Cognitive Activity (Marshall, 2000) is a measure of cognitive workload that separates variation in pupil size due to cognitive effort and due to light reflex, while also accounting for random noise. The small and rapid pupil dilations that remain are associated with higher cognitive workload (Marshall, 2002). Demberg and Sayeed (2016) showed, for example, that the ICA is sensitive to linguistic manipulations such as ungrammaticality, with conditions related to higher processing demands resulting in higher ICA values. They also demonstrated that ICA is particularly suitable for the Visual World Paradigm, since it is robust to
the change of fixation positions and can thus complement the standard visual attention metrics in order to assess cognitive effort during linguistic processing.

## Experiment

We used a $2 \times 2$ design crossing Specificity (Minimally specified vs Over-specified) and Entropy Reduction (Uniform vs Non-uniform). Based on findings that overspecifications are commonly used by adult speakers during production (cf. Engelhardt et al., 2006; Pechmann, 1989; Rubio-Fernández, 2016; Tarenskeen, Broersma \& Geurts 2015), we hypothesized that over-specification would not impede referential processing, as rational speakers would unlikely use them so frequently if they did. We, therefore, expected that over-specified expressions (OS) would be as easy as, or easier than their minimally-specified (MS) counterparts (as found in the ERP study by Tourtouri et al., 2015). As for the entropy reduction manipulation, we generally expected a greater processing advantage in the uniform reduction (UR) compared to the non-uniform reduction (NR) conditions, as has been proposed for the related measure of surprisal (UID, Jaeger, 2010). Finally, we expected that the two factors should interact, namely that processing would be particularly benefited when the expression was OS and the redundant adjective contributed to the uniform reduction of entropy.

## Method

Participants Twenty-four students from Saarland University (mean age 25, 7 male) participated in the experiment for monetary compensation. They were all native speakers of German with normal or corrected-tonormal vision and normal color perception.

Materials Pictures of 30 common use objects (e.g., balls, mugs, etc.) differing in color (blue, green and red) and pattern (checkered, dotted and striped) were employed to create the visual stimuli. Both color and pattern were used as distinguishing features, because they are intrinsic to the object, as opposed to scalar adjectives such as size that trigger comparisons to other entities on the display. This ensured that any looks to objects in contrast pairs would be driven due to the manipulation and not because of the adjective type. Furthermore, pattern was the mentioned property in half of the trials, in order to make sure that any effect of over-specification would not be merely due to color salience, but would be attributable to the experimental manipulation. Color hue and brightness were adjusted using GIMP (Version 2.8.10). Naming agreement was tested for the object pictures in an offline picture naming study to ensure that they were identifiable in all colors and patterns, and that the names used in the experiment matched participants' own naming preferences. Twenty-four independent participants were presented with the object images in all colors and patterns (distributed over 8 lists), and were asked to name them while always mentioning their
colors and patterns. Only objects with a naming agreement of $80 \%$ or higher were employed in the visual stimuli.

A set of 120 experimental items was created, each item comprising one spoken instruction (with either color or pattern as the target feature) and four visual scenes (essentially four versions of the same scene). The target color, pattern and position were counterbalanced throughout the experiment. Displays for experimental items accommodated all four conditions for both target features, so that nothing would reveal the target before the instruction was heard. To this end, one visual scene contained 6 objects (two pairs of same-type objects and two singletons) in two colors and two patterns, such that the pairs made up the two MS and the singletons the two OS referents for both target features, as shown in Figure 1. Furthermore, displays never
 ensuring that disambiguation of the target would always occur on noun onset. For the same reason only same-gender objects were used per display, as German marks determiners for gender.

In total, 660 visual displays were created, of which 480 were used in experimental items ( $120 \times 4$ conditions), and 180 in fillers. Twelve of the fillers served as practice trials in a familiarization phase. Fillers differed from experimental items in multiple aspects. First, they differed in terms of their display structure, with almost half of the fillers depicting 4 objects ( 3 of the same type and one singleton) and the rest containing 6 objects. Six-object fillers either showed 2 contrast pairs and 2 singletons, where reference was always made to the contrast pair that was not relevant in the experimental items (e.g., the two rucksacks in Fig.1), or they showed a set of 3 same-type objects, a contrast pair and a singleton. The 3 -object sets made a second modifier also required for target identification, thus adding more variation not only to the display types that participants viewed, but also to the referential entropy reduction possibilities. Secondly, fillers differed in terms of the specificity of their instructions, that could be minimally, over-, or under-specified (US), while care was taken so that throughout the entire experiment, participants would hear MS expressions to a greater extent than OS - as is the case in everyday language use - as well as a small portion of US. A set of fillers without pre-nominal modification was also used, that were essentially the minimally specified versions of the OS items, thus assuring that participants would not always expect to hear an adjective and that they would not get overly used to reference being redundant.

In experimental items, displays were paired with audio instructions containing a pre-nominally modified referring expression like "Finde den blauen Ball" (Find the blue ball) in Figure 1, that identified the target by mentioning either its color or its pattern. In fillers, instructions had zero, one or two modifiers. For the latter the order of mention of color and pattern adjectives was counterbalanced. Audio stimuli were recorded with neutral intonation by a young, female speaker of German, in a soundproof booth using Cubase AI5. Speech was continuous and no artificial pauses were
inserted in between words. Sentences were then cut and annotated for adjective and noun onsets using Praat (Version 5.3). Mean word duration was 481.3 ms ( $\mathrm{SD}=32$ ) for the adjectives and $557.2 \mathrm{~ms}(\mathrm{SD}=75.7)$ for the nouns.

Stimuli were distributed over 4 lists using the Latin Square design, and were pseudo-randomized for each participant. At least one filler appeared between consecutive experimental items, and items of the same condition did not appear more than two times in a row. Each participant saw 288 stimuli split in 4 blocks, which allowed for breaks in between blocks. Before the experiment started, a short practice session of 12 filler trials familiarized participants with the task. The experiment was implemented and run using E-prime 2.0 (Psychology Software Tools, Inc.).

Procedure An SMI RED500 eye tracker (SensoMotoric Instruments) attached to the bottom of a 25 inch Dell monitor was used to track participants' eye movements at a rate of 250 Hz . After they gave informed consent and read the instructions, participants were seated at a distance of approximately 60 cm in front of the monitor using a chinrest to minimize head movements. They then completed a familiarization phase, during which the experimenter gave them feedback after each trial, ensuring that the task was clear before the experiment begun. Calibration was performed at the beginning of each block.

A trial started with a fixation cross appearing in the middle of the display for a period controlled by the experimenter. The objects then appeared while the cross was still on screen for another 500 ms , and 1500 ms later the audio instruction started. The objects stayed on the screen for another 500 ms after the audio offset, and a prompt screen to the task appeared asking participants to indicate which side of the screen the target entity was on, or whether it was not possible to tell (US fillers) by pressing the corresponding button on a response pad in front of them. Displays were presented at a $1680 \times 1050$ resolution. One experimental session lasted on average 40 min , depending on whether calibration had to be repeated.

Analysis For the analyses of both measures we considered the regions of the Adjective ("blauen"), and Noun ("Ball"). For the analysis of fixations, we compared inspection probabilities to areas of interest (AOI) across conditions. First, fixations shorter than 80 ms were pooled with the immediately preceding or following fixation, if the distance between them was smaller than 12 pixels, otherwise they were excluded from the analysis. Subsequently, fixations to an AOI within a region, before a saccade outside the area was made, were counted as one inspection. For each AOI and region, we coded trials that contained at least one inspection to the AOI as 1 , and trials that did not as 0 . Therefore, mean values represent inspection probabilities per AOI and region.

As information about the target became incrementally available, different objects and different comparisons were interesting per region. In particular, at the Adjective, the
only available information about the target was its distinguishing property, so the specificity manipulation is still irrelevant (it is still unknown whether the target is minimally or over-specified). We, therefore, compared inspections to the singleton and contrasting objects that bore the target property (cf. the blue ball \& mitten in A\&B, Fig.1) between UR and NR (collapsing across Specificity). Finally, at the Noun, when the target is revealed, both factors become relevant, so we contrasted inspection probabilities to the target (the blue ball: MS in A\&B, OS in C\&D, Fig.1) and to the competitor (the blue mitten: OS in A\&B, MS in C\&D, Fig.1) across conditions.

To calculate the ICA we used BeGaze ${ }^{\text {TM }}$ with the ICA Module (SensoMotoric Instruments) and Workload ${ }^{\text {RT }}$ (EyeTracking, Inc.). Since the ICA values that the BeGaze ${ }^{\mathrm{TM}}$ software outputs are too coarse-grained for the type of effects we expect, we used the ICA Coefficients to compute ICA values per 100 ms (see Demberg \& Sayeed, 2016 for more details). Data points with a pupil diameter smaller than 2.5 SD of that participant were eliminated, and a mean ICA value for both eyes was calculated. As fixation positions are not relevant for the ICA, we were interested only in differences between UR and NR (collapsing across Specificity) for the Adjective, and across conditions for the Noun. We compared mean ICA values across conditions within a window of 600 ms starting from the middle of each region. We analyzed inspection probabilities and ICA values using generalized linear mixed effects models (lme4 package, R Version 3.3.2) with random intercepts for participants and items, as well as random slopes for the predictors of interest. For the analysis of the Adjective, Reduction (UR vs NR) was the predictor of interest. For the analysis of the Noun, the models included the effects of Specificity (OS vs MS), Reduction (UR vs NR), and Target Feature (Color vs Pattern), and their interaction. When the maximal models did not converge, we simplified the random effects structure as suggested by Barr, Levy, Scheepers, and Tily (2013).

## Results

## Adjective

Singletons bearing the target feature (cf. the mitten in A\&B, and ball in C\&D) were inspected equally frequently in UR and NR (Coeff. $=.083, S E=2.317, Z=.829, p>.05)$. Contrast objects (cf. the blue ball in A\&B), on the other hand, were more frequently inspected in UR than in NR (Coeff. $=.329, S E=.0628, Z=3.107, p=.001) .{ }^{1}$ The ICA values (see Fig.2) did not differ significantly between UR and NR (Coeff. $=-.031, S E=.0249, Z=-1.236, p>.05$ ).

[^521]

Figure 2. Mean ICA values per condition and region. Error bars represent $95 \%$ CI.

## Noun

Analyses of inspection probabilities to the target (the blue ball) and competitor (the blue mitten) objects, including target feature as a predictor, produced a significant effect of feature (Coeff. $=.205, S E=.104, Z=1.971, p=.048$ ). We followed up this effect with separate analyses for color and pattern items. For target inspections in color items (Fig.3), we found a main effect of Entropy Reduction with more inspections in UR than in NR (Coeff. $=-.241, S E=.122, Z$ $=-1.971, p=.048$ ), as well as a marginally significant effect of Specificity (Coeff. $=.237, S E=.127, Z=1.877, p=.06$ ), such that the target was inspected more frequently in OS than in MS. The analysis of inspections to the competitor resulted in a main effect of Entropy Reduction with the competitor receiving more inspections in UR than in NR (Coeff. $=.39, S E=.151, Z=2.583, p=.009$ ), and no effect of Specificity ( $p>.05$ ). For pattern items, none of the comparisons produced significant results (all $p>.228$ ). Interestingly, the ICA analysis produced main effects of both Entropy Reduction and Specificity for both color and pattern items (see Fig.2), such that ICA was higher for NR vs UR (Coeff. $=-.07, S E=.024, Z=-2.96, p=.003$ ), and for MS vs OS (Coeff. $=.087, S E=.025, Z=3.42, p<.001)$.

## General Discussion

We investigated the effects of Specificity on situated language processing comparing listeners' inspection patterns and cognitive effort when exposed to minimally or over-specified reference. In accordance with previous research (cf. Arts et al., 2011; Tourtouri et al., 2015) we found a facilitation for OS vs MS on the noun, with the target object receiving more inspections when the referring expression included a redundant vs a contrastive adjective. However, this effect was observed only for color items, raising the question whether what facilitates processing is in fact color salience as opposed to over-specificity in general. The answer is provided by ICA, a novel measure of cognitive workload based on the count of rapid pupil dilations, which we used to directly assess the cognitive effort expended in each condition, showing that in both
color and pattern items OS was indeed easier to process than MS. This discrepancy between the two measures seems to suggest that, while pattern is more difficult to perceive than color, its mention is nevertheless as beneficial to visual search as that of color. Further research is necessary to determine the relation between visual attention as measured by inspection probabilities, and cogntive load as measured by the ICA.

We further examined if and how processing is influenced by a more or less uniform reduction of referential entropy, i.e., of the size of the referential search space. Specifically, we contrasted conditions where the pre-nominal adjective reduced entropy from by 1.58 bits (UR) with cases in which entropy was decreased by only 0.58 bits (NR), to establish whether what determines efficient entropy reduction is determined by the more or less uniform decrease of entropy over the referential expression. Our results seem to provide evidence that processing is facilitated by the uniform reduction of referential entropy, though not in the predicted region. That is, in the Adjective there were no differences for either inspections (to singleton objects) or for ICA values between UR and NR. On the Noun, however, we found indications that the greater reduction of entropy at the first step contributing to a more uniform entropy reduction profile was preferred, since in (both MS and OS) UR conditions the target object collected more inspections (though only in color items), and, perhaps more interestingly, ICA values were lower than in NR (for all types of items). Importantly, this finding demonstrates that the ICA is sensitive to visual search difficulty, capturing differences in the cognitive effort expended with different rates of visual entropy decrease. With respect to our research question, visual search, and therefore referential processing, appears to be more efficient when the remaining set of possible referents at the final step is rather small, as is the case in UR. Interestingly, however, there is no penalty for this increased entropy reduction on the adjective.

We acknowledge that these results are open to alternative interpretations. For example, the absence of an Entropy Reduction effect on the adjective may be due to our operationalization of Uniform and Non-uniform Reduction, and not because the entropy reduction rate only affects the

Figure 3. Inspection probabilities for the noun region in color items. Error bars represent 95\% CI.
final step. That is, reducing referential entropy by 1.58 bits vs 0.58 bits may not be sufficient to induce a differential cost on the adjective. So, if the difference between the remaining entropy in the two conditions was enhanced, by using a larger referent set and going from e.g. 12 to 2 versus to 8 potential referents in Uniform and Non-uniform Reduction, respectively, might serve to amplify a reductionrelated cost on the adjective in the Uniform condition. Relevant to this issue, it would be interesting to compare processing of OS as implemented in this experiment, with their MS counterparts, i.e. without modification of the noun (e.g., "Finde den Ball"), as the latter is not only a case of rapid reduction of entropy, but is also MS. Any facilitation for OS under this comparison should suggest that processing ease for OS is due to the insertion of an intermediate step in reducing visual entropy that makes reduction more uniform. A final possible explanation that is worth pursuing, as it is related to the nature of the ICA measurements, is that ICA may not be sensitive to such modulations of entropy reduction. In other words, ICA may only be able to capture whether visual search has been demanding or not. Future research is of course required to tackle these questions.

In sum, we present eye-tracking evidence confirming that the use of redundant noun modifiers (over-specification) facilitates referential processing. In addition, we showed that listeners rapidly exploit incoming information about the target to reduce the referential search space in situated comprehension. Greater reduction in referential entropy on the adjective - while not associated with any increase in cognitive load in that region - results in an overall more uniform entropy reduction profile and in reduced cognitive effort when processing the noun. This result leads us to conclude that efficient processing is determined by both the degree of specificity of the reference, as well as to the distribution of entropy reduction across the utterance.

## Acknowledgments

We thank Mindaugas Mozuraitis and Maria Staudte for assistance with the eye tracking analyses, and Mirjana Sekicki, Vera Demberg and Ben Peters for help with the ICA analyses. This research was supported by SFB/CRC1102 "Information Density and Linguistic Encoding" awarded by the German Research Foundation (DFG).

#### Abstract

We describe two different cognitive process models of a well known experiment on social influence (Salganik, Dodds, \& Watts, 2006). One model, the social influence model, reproduced the choices that participants took by modeling both the cognitive processes the participant engaged in and the social influences that the participant saw. The second model, the pure cognitive model, used only cognitive capabilities and did not model any social influences that the participant saw. Somewhat surprisingly, the two models showed no difference in quality of fit (the pure cognitive model actually fit slightly better than the social influence model), suggesting that social influence models should take cognitive functions into account in their theories.

Keywords: Cognitive models, social influence, cognitive architectures

## Introduction

People are routinely influenced by other people: this is the crux of social influence. There are many factors that can impact social influence, including the popularity of others (Cialdini, Reno, \& Kallgren, 1990; Latane, 1981), authority or expertise (Cialdini et al., 1990; Milgram, 1963), and culture (Milgram, 1963). While each of these factors can have a large impact in different situations, a fourth factor, visibility -- seeing what others have done or are doing -seems to be among the most important (Cialdini et al., 1990).

Most models of social influence describe the effect in terms of social constructs (e.g., conformity, peer pressure, etc.) and/or networks of people (e.g., families or friends), and that cognition has a relatively minor explanatory role.

For example, MacCoun (2012, in press) has proposed a very successful model of social influence called the uBOP (unidirectional burden of proof). The model itself is a mathematical model in the form

$$
\mathrm{p}=\mathrm{m} /(1+\exp [\mathrm{c}(\mathrm{~S} / \mathrm{T}-\mathrm{b})])
$$

where p is the probability that an individual chooses an option, $m$ is a ceiling parameter, $S$ is the number of people advocating one option, T is the number of advocates advocating a second option, $b$ denotes where an individual is more likely to adopt the group's decision and c reflects the difficulty to make a decision (steepness). This model can successfully characterize the classic Milgram (1969) and Asch (1951) studies with few changes in parameters (MacCoun, 2012; MacCoun, in press).

Social network models have also been used to model social influences. Social networks consist of nodes (people) who are linked through some form of interdependency (family, friends, beliefs, etc.). Social networks have been very successful at differentiating the effects of social ties from other external influences and have been applied to explain phenomena as diverse as smoking (Christakis \& Fowler, 2008) and obesity (Christakis \& Fowler, 2007). Social network models typically use graph theoretic or network models or statistical models (e.g., structural modeling or autoregression).

Cognition in all of these models serves, at best, a purely functional role: people perceive others' actions or remember actions that others have performed, but the theoretical power comes from social or network constructs. The uBOP model can be used to describe both individuals and groups, but has nothing that could be considered a cognitive process. Social network models describe relationships and membership rather than an individual's cognitive activities. The fact that there are few (if any) cognitive processes in these models is, perhaps, not surprising: most of the existing models are not process models. We believe that cognition is a large component of most social behavior and will explore this issue by developing a cognitive process model of a wellknown social influences study (Salganik et al., 2006; Salganik \& Watts, 2009).

Salganik and colleagues investigated the effects of social influence in a cultural market with a novel paradigm
(Salganik et al., 2006; Salganik \& Watts, 2009). Salganik et al. created an artificial music market where participants could listen and download previously unknown songs. Salganik and colleagues created independent instantiations, or worlds, where the markets could grow without influence from other worlds; this was a between subjects manipulation. Individuals in each world could only be influenced by individuals in their own world. This approach allowed the authors to explore how social influences develop over time in different situations. Across two experiments, they looked at two conditions, an independent world and a social influence world. Participants in the independent world made decisions about what songs to listen to based only on the names of the bands and the song, while in the social influence worlds, participants could also see how many times each song had been downloaded by previous participants. In their first experiment, they found a modest social influences effect, but in their second experiment they found a very strong social influences effect. We describe and model the second experiment.

## Method (Salganik et al., 2006)

A complete description of the experiment can be found in Salganik et al. (2006) and Salganik and Watts (2009).

## Participants

There were 7192 participants recruited from a music website (Bolt). There were approximately 700 participants in each of eight social influence worlds and approximately 1400 participants in the independent world. ${ }^{1}$ Participants logged onto the website and various times over 83 days.

## Setup and Procedure

48 Songs were presented in a single column and sorted by the number of downloads for the social influence worlds and in a random order for the independent world. The display was updated as every participant downloaded songs. Additionally, the social influence world displays contained information about the number of downloads each song had received; this information was dynamically updated as the experiment progressed; see Figure 1.

[^522]

Figure 1: A screenshot of the social influence world, taken from Salganik and Watts (2009).

Participants were able to click any song on the list to listen to it. While the song was playing, participants were asked to rate the song on a $1-5$ scale where 1 was "I hate it" and 5 was "I love it." After rating the song, participants could download the song and then could go back to the primary display so they could listen, rate, and download more songs if they chose. Participants were able to download as many of the 48 songs as they wished, but they had to listen to them and rate them before they could download each song.

Each of the social worlds began in a random state, so each social world could evolve based on the participants' behavior in that specific world.

## Measures

There were several different variables that the authors coded in the data. The number of songs each participant listened to and the number of downloads that were made was recorded. The popularity of individual songs was also recorded. One of the most informative variables that was recorded was how often participants listened to a song at a specific rank (regardless of what song it was). When each participant examined songs, each song had a specific market rank (the song with the most downloads had a market rank of \#1).

## Results and Discussion

Salganik et al. reported that participants listened to an average of 3.6 songs and downloaded an average of 1.4 songs. Figure 2 shows the probability that a participant would listen to a song based on its rank market share. Note that all the social influence worlds will be combined for this and all further analyses, as reported in Salganik et al.

Figure 2: The probability that a participant would listen to a song based on its rank market share for both the independent and social influence conditions in Salganik et al.'s experiment.

As Figure 2 suggests, the independent condition was mostly flat, with no strong effect of either social influence or of song quality. However, the social influence conditions showed a very strong effect of social influence: the top ranked song had a $45 \%$ chance of being listened to, while the average song had only a $5 \%$ chance of being listened to. There is also an interesting "hipster" effect when the song that was ranked last got listened to a great deal more than average.

Salganik et al. suggest that these results "confirm that the popularity of the songs affected participants' choices and generally led them to listen to the more popular songs-a result that is consistent with the large literature on social influence and conformity" (Salganik \& Dobbs, 2009, p. 447). They also show that while specific songs were considered better than others, the social influence condition had a substantial effect on the success of the songs.

As suggested earlier, most models of social influence are not cognitive process models. So we developed a cognitive process model of the individuals in this experiment in order to examine the effect of cognition and social influence. By developing a process model, we were able to create two slightly different models: a social influence model and a pure cognitive model. By developing the two models, we will be able to determine how much better the social influence model fits the data beyond the pure cognitive model and thus determine the importance of social influence over basic cognitive factors. The models were developed using the ACT-R architecture.

## Architecture and Model Description

ACT-R is a hybrid symbolic/sub-symbolic production-based system (Anderson et al., 2004; Anderson, 2007). ACT-R consists of a number of modules, buffers, and a central pattern matcher. Modules in ACT-R contain a relatively specific cognitive faculty usually associated with a specific region of the brain. For each module, there are one or more buffers that communicate directly with that module as an interface to the rest of ACT-R. At any point in time, there may be at most one item in any individual buffer; thus, the module's job is to decide what and when to put a symbolic object into a buffer. The pattern matcher uses the contents of the buffer to match specific productions.

ACT-R uses if-then rules (productions) that will fire when their preconditions are met by matching the contents of the buffers. If there is more than one production that can fire, the one with the highest utility (production strength) will fire. Each production can change either internal state (e.g., buffer contents) or perform an action (e.g., click on a button).

ACT-R interfaces with the outside world through the visual module, the aural module, the motor module, and the vocal module. The architecture supports other faculties through intentional, imaginal, temporal and declarative modules.

## High Level Description of the Social Influences Model

There are three components to each model: search, consideration, and decision-making. Each component has different productions that instantiate the specific goal. There model is a pure performance model: there is no learning in the model.

Search ACT-R has a theory about visual attention (Byrne \& Anderson, 1998), which this model follows. In brief, the model searches for an unattended song, then moves its visual attention to that song and then encodes the information about the song. The model determines which song to search for in one of four ways:
(1) The model begins at the top of the display to search for an unattended song. This is typical ACT-R behavior for searching.
(2) The model finds a random song and attends to it.
(3) The model starts at the bottom of the display to search for an unattended song. This is the "hipster" component of the model.
(4) Stop searching completely and finish.

All four of these rules are in competition any time the model has a goal to look for a song. Note that if we were in a different culture where reading occurred in a different direction, the model would need to take those preferences into account. Also note that sometimes the model will have a goal to search for a new song and then give up; participants also began the study and stopped the experiment before listening to any songs.

Consideration After a song has been attended to and encoded, the model next determines whether that song should be listened to or not. It has three options:
(1) The model decides that the song "looks interesting" so it decides to listen to it. We assume that people have some preference for the name of the band or the name of the song; this is a simple version of that preference process.
(2) The model decides that the song "looks terrible" so it decides not to listen to it. Again, this is a simple way to model the preferences that people have.
(3) The song is listened to based on its rank. The probability is a very simple $1 /$ rank. There are other, more sophisticated versions of selection based on group behavior (Mullen, 1983), but this simple version suffices for this model. Note that this is where social influence occurs in this model.
All three of these rules are in competition any time the model has a goal for considering whether to listen to the song. If the model decides not to listen to a song, it searches for another song.

Decision-making If the model does listen to a song, it must next decide whether to download it. The decision to download is very straightforward: there is a $50 \%$ chance the model will decide it should download the song. If it does download the song, the world is updated; if it does not download the song the world is not updated in any way, but the model then searches for another song.

## A series of sample experimental model runs

For the following example, three models are run in the same world; the social influences model is being run in the social influences condition. We assume that each model corresponds to a single simulated participant. The world is updated based on what each model does in the world, and the world is displayed appropriately based on what others have done.

The first thing that the model does in an experiment is to search for a song. The first model in the experiment stops searching and no updating occurs.

The second model in the experiment starts at the top of the list of songs; the first song on the list is unattended, so it encodes it and considers whether to listen to it. The model decides that it will listen to it and then must decide if it should download it. There is a $50 \%$ chance the model will download it, which it does in this case. This song now becomes the most popular with rank 1 and for future participants it will show as the top song on the display. The model then searches for another song, again decides to search from the top and finds the second song, which is the top unattended song. The second song does not look interesting, so the model does not listen to it (and thus does not download it, either). The model next searches for another song, but then stops searching and this model is finished.

The third model sees the previously downloaded song in the first slot. The model, however, chooses a random song from the list and decides to listen and download it. The model next starts at the bottom of the display and looks for an unattended song. The model will listen to this song based on its rank, which is currently 48; so it has approximately a $2 \%$ chance of listening to the song. Luckily, for this run the model will listen to it, so that song now is tied for rank 1 , and all future models will evaluate appropriately. After 2000 model runs, the simulation is stopped and the simulated world is reported.

The run just described was based on the social influences model. In this model, social influence occurs during the consideration stage. ${ }^{2}$ The pure cognitive model was identical to the social influences model, except it did not have pay attention to any social influence. Without social influences, the model simply considers a song based on whether it is "interesting" or "terrible."

For all models, we kept most of the ACT-R parameter defaults. The parameters that were changed include a production noise parameter (.4, which is within a normal range for this parameter) to provide some stocasticity and the aforementioned $50 \%$ probability for downloading a specific song. Parameter fits were run using the social influence model and those same parameters were also used for the pure cognitive model.

## Model fit

First, it is possible to examine how many listens and downloads each model performed and compare them to the experimental data. On average, there were 3.6 listens per participant in the experimental data; both models made 3.2 listens. Comparably, there were an average of 1.4 downloads per participant; both models had 1.6.

Figure 3 shows the fit of the independent condition; both models provide the same results. As Figure 3 suggests, the fit is quite good, with the model data overlapping a great deal with the experimental data. Calculating an $\mathrm{R}^{2}$ is uninformative because both the data and the model are flat. RMSD for this model is .02 , which demonstrates quite a good fit.

[^523]

Figure 3: Data and model of the independent condition.
Figure 4 shows the fit for the social influence model and Figure 5 shows the fit for the pure cognitive model. As is evident from Figures 4 and 5, they both show quite a good fit; Table 1 shows the quantitative fit statistics. The social influence model had a very strong fit in both $\mathrm{R}^{2}$ and RMSE. Somewhat surprisingly, however, the pure cognitive model had a slightly better $\mathrm{R}^{2}$ fit and a comparable RMSE fit. We can conclude from these analyses that the social influence model does not fit better than the pure cognitive model.

## Data/Model Fit

Salganik et al., 2006

Figure 4: Experimental data from the social influence condition and the social influence model.

Figure 5: Experimental data from the social influence condition and the pure cognitive model..

| Model | $\mathbf{R}^{\mathbf{2}}$ | RMSE |
| :--- | :--- | :--- |
| Social Influence | .88 | .023 |
| Pure cognitive model | .92 | .028 |

Table 1: Fit metrics for both the social influence model and the no social influence model. Both models were compared to the social influence condition of Salganik et al. (2006).

## General Discussion

We described a process model of a well-known experiment on social influence (Salganik et al., 2006; Salganik \& Watts, 2009). The experiment showed that when people had access to what others had done, it greatly influenced their behavior, consistent with current theories on social influence (Cialdini et al., 1990; MacCoun, 2012). We built two slightly different cognitive process models that perform the perceptual and cognitive steps in the experiment. Both the social influence model and the pure cognitive model fit the data extremely well. However, somewhat surprisingly, the pure cognitive model fit the experimental data slightly better than the social influence model. We interpret these results as showing that for this experiment, the effect of social influence is very small: a pure cognitive model was able to fit the data at least as well (if not slightly better) than the social influence model.

It was a bit surprising that the pure cognitive model and the social influence model shared so much overlap: this is almost assuredly one of the reasons for the similarity in the two models. This should not come as a big surprise, however: this type of task of searching and selecting objects on a computer screen is a classic cognitive task that
has been investigated both experimentally and theoretically many times.

It could be argued that during the search phase, the scanning down rule is also a social influence rule since participants knew that songs were ranked from top to bottom in order of the number of downloads. However, we would argue that scanning from the top to the bottom of a list is more a cognitive and cultural function than a social influence function. Many other researchers have shown that people in the US search for objects approximately top-down and left-to-right on computer interfaces (Byrne, Anderson, Douglass, \& Matessa, 1999; Norman, 1991; Schunn \& Anderson, 1999).

Note that we are not saying that people are not influenced by social influence. There are many experiments and models that show the importance of social influence. For example, Cialdini et al. (1990) found that when there was evidence that other people had littered, individuals were more likely to litter than when there was evidence that people had not littered. Many other classic experiments have shown the importance of social influence (Asch, 1951; Milgram, 1963)

The model presented here does, however, highlight the importance of cognitive processes in explaining at least some social influence effects. We believe that providing a process level description of cognitive and social behavior will lead to a better understanding of how social influences impact people's behavior. Specificially, we can isolate those processes that may result from cognitive aspects of the task from those processes that result from social influence.

#### Abstract

Mechanistic information can be characterized as the interacting causal components underlying a phenomenon - in short, how something works. Children and adults are notoriously poor at learning, remembering, and applying mechanistic information, so it comes as no surprise that the wisdom of teaching mechanism has come under increasing scrutiny in science education. However, while a rich memory for mechanistic details may be out of the average student's grasp, we argue that exposure to mechanism does not leave students empty-handed. Instead, it refines their intuitions about science and the world in significant ways. For the current study, we focused on one kind of intuition in particular: beliefs about causal complexity. Children ages 611 rated the complexity of a heart and a lock and were then given either mechanistic or non-mechanistic information about them. Afterwards, they were asked if their intuitions about complexity had changed and if so by how much. Three weeks later, children were asked again about their intuitions about complexity. Crucially, children who were given mechanistic information demonstrated a significantly greater shift in their assessments of complexity for both the heart and door lock compared to their counterparts who were given non-mechanistic information. This contradicts the notion that mechanism provides learners with few benefits while also demonstrating how mechanism can be a powerful force in shaping children's intuitions.

Keywords: causal mechanisms; explanation; complexity intuitions; meta-knowledge; cognitive development

## Introduction

Humans possess cognitive systems that enable them to grasp causal relations around them. As early as eight months, children are able to predict outcomes of novel causal events (Sobel \& Kirkham, 2006) and less than a year later, they are capable of making successful causal interventions (Gopnik et al., 2004; Gopnik, Sobel, Schulz,
\& Glymour, 2001), even for causal relationships defined by abstract relational properties (Walker \& Gopnik, 2014).

However, given the rapid growth of human knowledge and technology in the modern era, many of the known causal relations in the world are becoming increasingly complex and inaccessible (Arbersman, 2016). Except for relevant experts, this burgeoning set of causal patterns presents a challenge for how laypeople grasp the causal structure of the world around them. Most adults, for example, are unable to give even a basic explanation of the mechanisms underlying everyday objects like a door lock or a clock, let alone more complicated objects like a car engine or a computer. Similarly, we have a surprisingly poor understanding of the mechanisms underlying the functioning of living things and even how our own bodies work. To make matters worse, laypeople often believe they possess detailed mechanistic knowledge about the world despite having next to none, a phenomenon known as the Illusion of Explanatory Depth (IOED) (Alter, Oppenheimer, \& Zemla, 2010; Rozenblit \& Keil, 2002). These major gaps in adult causal knowledge occur not just in recall but also in recognition. For example, many adults fail to recognize the difference between a schematic of a functional bicycle and one that is completely inoperable (Lawson, 2006). In children, this illusion is present to an even greater degree (Mills \& Keil, 2004).

Our cognitive mechanisms dealing with causality seem to fall short in keeping vivid representations of somewhat complex causal patterns. Despite this tendency to forget mechanistic information, humans however show a certain curiosity about how things work. Children ask for mechanistic information about things they encounter, usually phrased as ubiquitous "why" and "how" questions, starting around three years of age (Callanan \& Oakes, 1992), and they are often relentless in their questioning until
they receive a mechanism-oriented response (Chouinard, 2007; Frazier, Gelman, \& Wellman, 2009). This preference for mechanistic explanation persists into adulthood (e.g., Ahn et al., 1995; Johnson \& Ahn, 2015). In short, despite our poor ability to learn, retain, or recall mechanistic information, people of all ages often show considerable interest, and at times an outright preference, for mechanistic information.

## Mechanisms in the Classroom

A natural reaction to the massive decay in our retention of mechanism is to downplay the need to learn it at all and refocus science education on topics such as the nature of science, epistemological stances, and methodology (Osborne et al, 2003). After all, even if students enjoy learning information about how things work, they fail to retain it; shouldn't we focus on teaching them things they can actually remember? Without denying the importance of topics like epistemology, we argue there are insidious costs in failing to expose children to rich mechanistic details. At root, the benefits of mechanism lie not with the details learned, but with the higher order intuitions acquired and sharpened as a result of teaching mechanism.

More precisely, we argue the bulk of cognitive gain from exposure to mechanism occurs at the "meta-knowledge" level (Kominsky, Zamm \& Keil, in press). Even if we have no idea how a car engine actually works, we do have some intuitions about the underlying mechanisms: for example, we might think it involves metal and plastic components as opposed to organic parts, that it is extremely complex and difficult to learn about, and more crucially, we may also be able to tell apart experts from laypeople when hearing them talk about the mechanism. Thus, even if we do not know the details of how an object works, we often have surprisingly accurate intuitions about how much "stuff" is in a mechanism, how complicated a mechanism is, and whose expertise we can rely on.

Indeed, despite the decay of knowledge about the mechanism itself, some kind of mechanistic information seems to persist: mechanistic information influences causal reasoning (Ahn et al., 1995; Schlottmann, 1999), and mechanism may constrain Bayesian causal learning by reshaping priors about what causal links exist or how strong they are (Griffiths \& Tenenbaum, 2005, 2009). Thus, some aspects of mechanistic information are preserved, but are neither detailed nor complete (e.g., DiSessa, Gillespie, \& Esterly, 2004; Straatemeier, van der Maas, \& Jansen, 2008; Vosniadou, 2002). If most individuals do not retain deep, integrated understandings of "how things work", what kind of mechanistic knowledge does persist?

The current study pursues the beginnings of an answer to this broad question by focusing on intuitions about complexity. Intuition about causal complexity is a good candidate for a kind of meta-knowledge that would persist after memory decay. For instance, one may have a strong feeling that the mechanisms underlying the human ear or a
clock are highly complex without being able to give any accurate descriptions of the mechanism itself.

To summarize, we argue that mechanism instruction is essential to STEM learning as long as we acknowledge what is actually retained over time and what is not. Expecting children to retain fine-grained mechanistic details is simply an unrealistic goal. Instead, focusing mechanistic exposure on building richer meta-mechanistic knowledge establishes both achievable and useful goals. In particular, we argue that exposure to mechanism is a necessary pathway to other forms of more enduring representations such as intuitions about causal complexity, the focus of the current study.

## Experiment

## Stimuli

We chose a heart and a door lock as stimuli because they look quite simple from the outside while having a somewhat rich causal mechanism on the inside. In order to control for a potential reaction of surprise to hidden complexity in the mechanistic condition, the verbal information provided in the non-mechanistic condition included, both for the heart and the door lock, some surprising facts such as "people think that the heart is red but actually the heart itself is dark brown".

The number of words of verbal information presented to the children was matched between the mechanistic (212 words) and non-mechanistic condition (208 words). We also created the text stimuli so that the non-mechanistic information was more superficially complex than the mechanistic information (e.g., Flesh Reading Ease: 79.97 for the non-mechanistic text and 91.53 for the mechanistic text).

## Predictions

We had no predictions about the age of children in this study but included this variable in our analysis as exploratory.

H1) Exposure to mechanistic information should shift children's intuitions of complexity.

H2) The children who underestimate complexity should move towards higher complexity judgments once provided with mechanistic information.

H3) This shift towards higher complexity should still be observable three weeks later.

## Methods

Participants We recruited 144 children from an elementary school in the New Haven, CT area. Our sample was somewhat atypical in two ways: the elementary school is situated in a low SES neighborhood and the elementary school has a strong focus on science (classified as a STEM school). Our sample consisted of 20 Kindergarteners, 15 first graders, 15 second graders, 41 third graders, 34 fourth graders and 18 fifth graders. The experimenters interviewed child participants individually for about ten minutes in a
quiet spot in the school. All participants were rewarded with a small toy.

Training Phase Children were told they would be presented with pictures of things and would be asked if they thought the thing is simple or complicated. Participants were explicitly told both at the very beginning and just after the training phase "there are no right or wrong answers, I just want to know what you think".

The two training questions were designed to introduce children to our complexity scale and to have a clear criterion of exclusion. The training consisted in showing children black and white drawings of an hourglass and grandfather clock. In order to prevent children's intuitions about complexity being driven only by the ease of use - as previous pilot experiments suggested - children were told that "both these two things are easy to use but the way they work is really different", followed by a short justification of why the hourglass is simple ("It's just sand going down") and why a grandfather clock is more complicated ("It has many gears and pendulums inside that all work together to move the hands on the clock").

Children were then presented with black and white drawings of a bicycle and a motorcycle. For each, they were asked whether they thought it was simple or complicated. Depending of their first answer, they were asked if they thought it was "really" simple/complicated or "kind of" simple/complicated. Children's answers on each entity can thus be coded on a 2 point scale (simple or complicated) or on a 4 point scale: really simple ( 0 ), kind of simple (1), kind of complicated (2) and really complicated (3).

Test Phase Just after the training phase, children were presented with a black and white drawing of a heart or a door lock (order of presentation was counterbalanced). They were asked whether they thought the entity was simple or complicated in the same way as in the training phase. All participants were then told that some information about the entity would be presented to them. Half the participants were randomly assigned to the mechanistic condition and the other half were assigned to the non-mechanistic condition. Participants in the mechanistic condition were presented with pictures of the inside of a heart and of a door lock, along with some verbal information about how it works. Participants in the non-mechanistic condition were presented with pictures illustrating some facts about the heart or door locks along with corresponding verbal information matched in length to the mechanistic condition.

After hearing the information, all participants were reminded of their initial complexity judgment and asked if they wanted to keep their answer or if they thought a heart / a lock was more complicated/simple than they had previously thought. Depending on their answer, they were then asked if it is much more complicated/simple than what they though before or a little bit more complicated/simple than what they though before. Their shifts in complexity judgments were coded with a 5 point scale: much more
simple (-2), a little more simple (-1), still what I think (0), a little bit more complicated $(+1)$ and much more complicated $(+2)$. The exact same procedure was repeated with the second entity.

Retention Test, Just after the complexity judgments, all children were asked a series of questions about the information (mechanistic or non-mechanistic) that had been given to them. This test was used to assess the children's retention of the information that was just presented to them in order to measure retention scores on the exact same test three weeks later. Questions were either "yes - no" questions ( 0.5 point); questions about quantity or colors (1 point) or open-ended (2 points). In the mechanistic condition, scores could range from 0 to 12.5 ; in the nonmechanistic condition, scores ranged from 0 to 18.5 . All the scores were normalized to range between 0 and 1 . Based on the Yes/No questions, we calculated the chance level for each condition: 0.10 in the mechanistic condition and 0.04 in the non-mechanistic condition.

Exclusion The 24 children (17\%) who, during the training phase judged a bicycle as more complex than a motorcycle were excluded from the analysis. In addition, since $50 \%$ (9) of the kindergarteners failed to judge a motorcycle as more complex than a bike, all the kindergarteners were excluded from the analyses. The following analyses apply to a sample of 111 children.

## Results

Analysis Children were grouped into three age groups: $1^{\text {st }}$ and $2^{\text {nd }}$ graders $(N=26), 3^{\text {rd }}$ graders $(N=37), 4^{\text {th }}$ and $5^{\text {th }}$ graders ( $N=48$ ).

Our analyses focus on three dependent variables, the absolute value of shift, the raw value - direction -- of shift, and the direction of long-term shift three weeks after the initial measure. We looked at the effect of three independent variables. Two variables were linked to our hypotheses, condition (mechanistic and non-mechanistic) and initial rating (which we grouped in two levels - simple or complicated - instead of the 4 measured ones - kind of / really - in order to increase our statistical power). The third variable was age group ( $1^{\text {st }}$ and $2^{\text {nd }}$ graders, $3^{\text {rd }}$ graders, and $4^{\text {th }}$ and $5^{\text {th }}$ graders), which was exploratory. Only the interactions with condition were tested.

Initial complexity judgments were significantly higher for the heart $(M=1.7, S D=1.14)$ than for the lock $(M=0.96$, $S D=1.03$ ), paired t-test $t(110)=4.79, p<.001$. In the following analyses the two entities were analyzed separately.

Absolute value of shift For both the heart and the lock, we performed a 2 (condition) x 2 (initial rating) x 3 (age groups) fully between-subjects Analysis of Variance (ANOVA) with the absolute value of shift as DV. For both entities, the ANOVAs revealed a main effect of condition $\left(\right.$ Heart: $F(1,103)=4.13, p=.04, \eta_{\mathrm{p}}^{2}=.04$; Lock: $F(1,103)$
$\left.=17.78, p<.001, \eta_{p}{ }^{2}=.14\right)$. Those main effects of condition came from a larger absolute value of shift for children in the mechanistic condition both for the heart ( $M=$ $1.14, S D=0.67$ versus $M=0.87, S D=0.75$ ) and the lock ( $M=1.22, S D=0.60$ versus $M=0.69, S D=0.77$ ).

A main effect of initial ratings was also found for both entities (Heart: $\left(F(1,103)=4.10, p=.05, \eta_{\mathrm{p}}{ }^{2}=.04\right.$; Lock: $\left.F(1,103)=4.07, p=.05, \quad \eta_{\mathrm{p}}^{2}=.03\right)$ corresponding to a larger absolute value of shift for participants initially judging an entity as simple. No other main effects or interactions were significant for either entity.

Direction of shift For each entity, we performed a 2 (condition) x 2 (initial rating) x 3 (age groups) fully between-subjects ANOVA with the shift in complexity judgment measured just after children were exposed to some information as a DV (from -2 to +2 ) (see Fig. 1).

For the heart, a significant interaction between the initial rating and the condition was found $(F(1,103)=5.56, p=$ $.02, \eta_{\mathrm{p}}^{2}=.05$ ). To further explore this interaction, two posthoc two sample t-tests with Bonferroni adjusted alpha levels of .025 per test (.05/2) showed that for the children who initially judged the heart as simple, being exposed to mechanistic information resulted in an average shift towards higher complexity ( $M=0.70, S D=1.36$ ) compared to children exposed to non-mechanistic information ( $M=-$ $0.21, S D=1.23 ; t(39.7)=2.26, p=.02)$. As for children who initially judged the heart as complex, there was no difference in complexity shift between the mechanistic ( $M=$ $-0.09, S D=0.14$ ) and non-mechanistic condition ( $M=0.14$, $S D=1.12 ; t(66.4)=-0.83, p=.41)$.

For the lock, the same analysis did not show any significant effect or interaction.

Analyses of High Initial Retention Participants Median scores were calculated on the retention task for each condition, entity, and crucially for each of the three age groups in order to avoid having mostly older children in the high retention group. In order to explore the possibility that some participants were not paying sufficient attention to the task or had difficulty understanding the material presented to them, children scoring lower than the median in each of the groups were dropped from the sample. All the following analyses are similar to the analyses presented before but includes only the high retention half of our sample (for the heart, $N=35$ in the mechanistic condition and $N=29$ in the non-mechanistic condition; for the lock $N=39$ and $N=31$ respectively).

In terms of absolute value of shift, results for the high retention group were similar to those of the entire sample with a significantly larger shift in the mechanistic condition (main effect of condition. heart: $F(1,56)=5.5, p=.02, \eta_{p}{ }^{2}$ $=.08$; lock: $\left.F(1,62)=6.1, p=.01, \eta_{p}{ }^{2}=.09\right)$. As before, a main effect of initial judgment was found only for the heart $\left(F(1,56)=4.2, p=.05, \eta_{p}{ }^{2}=.06\right)$ but not for the lock $\left(F(1,62)=2.6, p=.11, \eta_{p}{ }^{2}=.04\right)$ ), likely due to a lack of power.

Despite having our sample size cut in half, results on the direction of the shift and on the final ratings were even more in line with our initial hypotheses.

With respect to the direction of the shift for the heart, the ANOVA revealed a significant interaction between condition and initial rating (Heart: $F(1,56)=9.92, p=.01$, $\eta_{p}{ }^{2}=.10$ ). For the lock, as opposed to the same analysis with the entire population, the interaction between condition and initial rating was at trend level $(F(1,62)=3.97, p=.09$, $\eta_{p}{ }^{2}=.04$ ). A main effect of initial judgment was also found for the lock $\left(F(1,62)=4.5, p=.04, \eta_{p}{ }^{2}=.06\right)$ but not for the heart $\left(F(1,56)=2.2, p=.14, \eta_{p}^{2}=.04\right)$. As displayed in Figure 1, one pattern seems similar for both entities: children who start by judging the entity as simple in the mechanistic condition tend to increase their complexity rating to a greater extent compared to both children in the non-mechanistic condition as well as children who start by judging the entity as complicated.

Figure 1: Average value of shift (y-axis) with standard errors bars for the high initial retention group, in the mechanistic (grey) and non-mechanistic condition (white) as a function of initial complexity judgment ( $x$-axis). Results for the heart and lock are presented on the left and right panels respectively.

Shift in complexity three weeks later We again asked children about their intuitions of complexity three weeks later using the same methodology. Twelve children (11\%) had changed schools or were absent during the times we were testing. Therefore, the following analyses apply to a sample of 99 children.

For each entity, we performed the same 2 (condition) x 3 (age group) x 2 (initial rating) with the shift between children's initial rating and their rating three weeks later as a dependent variable (long-term shift).

For both the heart and the lock, we found main effects of initial rating (heart: $F(1,91)=44.9, p<.001, \eta_{p}{ }^{2}=.31$; lock: $\left.F(1,91)=33.6, p<.001, \eta_{p}{ }^{2}=.27\right)$. A main effect of
condition was found at trend level for the heart $(F(1,91)=$ $3.0, p=.08, \eta_{p}{ }^{2}=.02$ ), but not for the lock.

When performing the same analysis on the high initial retention group, ANOVAs continued to show a main effect of initial rating for both entities (heart: $F(1,52)=31.7, p<$ $.001, \eta_{p}{ }^{2}=.33$; lock: $\left.F(1,56)=31.2, p<.001, \eta_{p}^{2}=.34\right)$. This was the only significant effect for the lock. For the heart, there was also a significant interaction between condition and initial rating for the heart $(F(1,52)=6.42, p=$ $\left..01, \eta_{p}^{2}=.07\right)$ as well as a main effect of condition at trend level $\left(\left(F(1,52)=3.46, p=.07, \eta_{p}{ }^{2}=.04\right)\right.$. As displayed in Figure 2, the interaction between condition and initial rating was driven by children initially judging the heart as simple, who moved towards higher complexity in the mechanistic condition ( $M=1.46, S D=0.97$ ) compared to the nonmechanistic condition ( $M=0.25, S D=0.88$; Post-hoc t-test with Bonferroni adjusted alpha levels of .025 per test $(.05 / 2), t(16.0)=2.93, p=.009)$. For children initially judging the heart as complex, there was no significant effect of condition (mechanistic: $M=-0.75, S D=1.16$; nonmechanistic: $M=-0.44, S D=1.04 ; t(36)=-0.85, p=.40)$.

Figure 2: For the high retention group, average value of long term shift (y-axis) with standard errors bars in the mechanistic (grey) and non-mechanistic condition (white) as a function of initial complexity judgment (x-axis). Results for the heart and lock are presented on the left and right panels respectively.

Retention Tests Three weeks later, children's retention scores had significantly dropped significantly by 0.20 in the non-mechanistic condition (from 0.64 to 0.44 , paired t -test: $t(95)=9.30, p<.001)$ and by 0.11 in the mechanistic condition (from 0.44 to $0.33, t(101)=4.67, p<.001$ )

When dividing our population between high versus low initial retention, the low initial retention group did not show any decay in the mechanistic condition (from 0.19 to 0.25 ). By contrast, the high retention group had a decay of 0.20 (from 0.57 to $0.37, t(64)=7.33, p<.001$ ). In the nonmechanistic condition, both groups showed significant
decay (low retention group had a decay of 0.17 , from 0.48 to $0.31, t(41)=5.84, p<.001$; high retention group had a decay of 0.24 , from 0.76 to $0.53, t(53)=7.40, p<.001)$.

## Discussion

Our first hypothesis H1 is well supported by the data with an absolute value of shift significantly larger in the mechanistic condition than in the non-mechanistic condition for the two entities. In short, mechanistic information influences children's intuitions about complexity more than non-mechanistic information.

Hypothesis H2 is supported with respect to the heart: both when analyzing the full population and the high retention group, children in the mechanistic condition who initially judged the heart as simple moved toward higher complexity ratings more than children in the non-mechanistic condition. With respect to the lock, the same hypothesis was only supported by the high retention group. This pattern suggests that the influence of mechanistic information prompts more than unpredictable shifts in children's intuitions. The influence of retention group also suggests that the quality of mechanistic exposure has a discernable impact on children's ultimate intuitions. The finding that the low retention group slightly increased their retention score three weeks later likely means they were near floor from the start, indicating they had encoded and understood little to no mechanistic details presented to them.

For both entities, we also found significant main effects of initial rating in the following direction: children initially judging an entity as simple move toward higher complexity and children initially judging an entity as complex tend to decrease their complexity judgments. This pattern raises a question: to what extent were the shifts simple regressions to the mean? At least in the cases of the heart, a tendency towards the mean is not the only significant influence on children's complexity judgments, even if the influence of mechanistic information works in the same direction. Indeed, mechanistic information shifted initially low complexity judgments higher than the overall tendency to regress towards the mean can explain.

Hypothesis H3 was only weakly supported in the case of the heart, with a main effect of condition at trend level. However, this modest effect fits with our hypothesis, since it is driven by children in the mechanistic condition initially judging the heart as simple who showed, three weeks later, a greater increase in their complexity judgments compared to the non-mechanistic condition. The size of this effect illustrates the challenge of trying to shift children's longterm intuitions about the world with less than 10 minutes of instruction.

Participants' SES, background, and attendance at a school having a strong science and engineering focus may also have diminished the hypothesized effects in two ways: first, low SES children often face increased attentional challenges in school settings (Mezzacappa, 2004; NICHD Early Child Care Research Network, 2003). These challenges may also help explain why our main hypotheses were supported more
by the high retention half of our sample. Second, the STEM focus of the school may have diminished the strength of the main effect of mechanism on the size of the shift by giving children more previous exposure to mechanism than is typical, in turn providing less room for intuitions about complexity to shift in a mere 5-10 minute span.

## Conclusion

Our results have shown that even very short "mechanistic interventions" can lead to immediate and sizable changes in children's intuitions about complexity. Crucially, when those changes happened, they were still observable three weeks later. These results suggest that teaching mechanism early in school can directly influence students' intuitions about science and the world more broadly, even in the long term when the details are long forgotten.

## Acknowledgments

The authors would like to thank Grace Nathman, the Principal of the Quinnipiac Real World Math STEM Elementary School, as well as the teachers and all the members of the school community; with a special thanks to science teacher Stephanie White who helped us at every step of the study.

The authors also thank the National Science Foundation which funded this research (proposal DRL 1561143 to F. Keil).

Finally the authors thank all the members of the Yale Cognition and Development Lab for their helpful feedback.

# The Impact of Presentation Order on the Attraction Effect in Decision-making 

Jennifer S. Trueblood (jennifer.s.trueblood@vanderbilt.edu)<br>Aneesha Dasari (aneesha.dasari@vanderbilt.edu)

Department of Psychology, Vanderbilt University, $11121^{\text {st }}$ Ave S

#### Abstract

The attraction effect in decision-making is a famous example of how preferences are influenced by the availability of other options. One emerging hypothesis for the effect is that biases in attention influence preferences. In the past, these ideas have been explored indirectly through computational modeling and eye tracking. In the present paper, we directly manipulate attention through presentation order, presenting choice options sequentially. Our results show that presentation order has a large impact on the effect - some presentation orders enhance the effect and other orders reverse the effect. To understand these results, we fit a dynamic model, called the Multiattribute Linear Ballistic Accumulator model, to the choice and response time data. Modeling results reveal that presentation order influences the allocation of attention on the positive and negative differences between options. In sum, our results show that attention has a direct impact on the attraction effect.

Keywords: preferential choice; context effects; order effects; response time modeling; Bayesian parameter estimation

## Introduction

Everyday we make hundreds of choices. Some are seemingly trivial -- what cereal should I eat for breakfast? Others have long lasting implications -- what stock should I invest in? Despite their obvious differences, these two decisions have one important thing in common; both can be sensitive to context. That is, our preferences for existing alternatives can be altered by the introduction of new alternatives.

Context effects -- preference changes depending on the availability of other options -- have attracted a great deal of attention among consumer researchers studying high-level decision tasks. In recent work, context effects have also been shown in low-level domains such as perception (Trueblood, Brown, Heathcote, \& Busemeyer, 2013). This suggests that context effects are a general feature of human choice behavior and calls for a common theoretical explanation that applies across paradigms. One emerging hypothesis is that context effects occur because of biases in attention. When comparing options, one might pay attention to some features more than others and this in turn influences preferences. This idea has been explored using dynamic models that implement attention-weighting mechanisms such as Multi-alternative Decision Field Theory (MDFT, Roe, Busemeyer, \& Townsend, 2001), the Leaky Competing Accumulator model (LCA, Usher \& McClelland, 2004), and the Multiattribute Linear Ballistic Accumulator model (MLBA; Trueblood, Brown, and

Heathcote, 2014). In addition, Noguchi and Stewart (2014) used eye tracking to examine the role of visual attention in context effects. Their results suggest that alternatives are compared in pairs and specific patterns of gaze transitions are correlated with context effects. Further, recent work in economics has proposed that context effects might arise due to "rational inattention" (Woodford, 2012). The basic idea is that attention is a scarce resource and places constraints on the amount of information individuals can process during a decision. Taken together, this set of results strongly suggests attention is crucial to context effects. No previous work has directly manipulated attention in the attraction effect.

In the present paper, we directly manipulate attention by presenting choice options sequentially. Studies of context effects typically involve choices among three alternatives where one option is identified as the "target", one option is the "competitor", and the third option is the "decoy". For example, suppose there are two options ( X and Y ) in a choice, which are almost equally attractive. If an alternative D is introduced that is similar to alternative X , but inferior, it makes X more attractive. This is known as the attraction effect (Huber, Payne, \& Puto, 1982). In this example, X is the target, Y is the competitor, and D is the decoy. In all past studies of the attraction effect, the alternatives $\mathrm{X}, \mathrm{Y}$, and D were presented simultaneously and were visible to participants until they made a choice. In the current experiment, we presented the options $\mathrm{X}, \mathrm{Y}$, and D one at a time, thus manipulating what participants saw first, second, and last. Our goal is to understand if changes in attention (as manipulated by presentation order) influence final choices.

Our experiment uses a perceptual version of the attraction effect where participants judge which of three rectangles has the largest area, with height and width as the attributes. The experiment uses the same rectangle stimuli as Trueblood et al. (2013). Using a perceptual version of the attraction effect has a number of advantages including the ability to collect sufficient choice and response time data for computational modeling. In addition, the rectangle attraction task is well established in the literature and the results have been replicated in adults (Farmer, Warren, El-Deredy \& Howes, 2016), children (Zhen \& Yu, 2016), and non-human primates (Parrish, Evans, \& Beran, 2015).

## Experiment

## Participants

Fifty undergraduate students from Vanderbilt University voluntarily participated in this computer-based experiment
in the laboratory at the time of their choosing and received course credit for their participation.

## Methods

Participants were told that they would be shown three rectangles presented one at a time, and that they would have to choose the rectangle that they believed to have the largest area by pressing one of the three indicated keys. There was no value tied to the choice of rectangle (i.e., representation of an earned dollar amount), and participants did not receive feedback for their decisions.

Each rectangle stimulus had various dimensions of height and width, which both acted as attribute dimensions. The dimensions of the rectangles were set by numbers of pixels. The target, competitor, and decoy rectangles were determined by the following procedure. First a set of horizontally oriented rectangles, denoted H , were chosen out of a bivariate normal distribution with a mean of 50 pixels for height and a mean of 80 pixels for width with a variance of 2 pixels. This noise allowed for variation in the rectangles across trials. A second set of rectangles, denoted V , were defined in terms of H , but were oriented vertically. Specifically, the height of the V rectangles was defined as the width of the H rectangles plus a random number selected from the interval $[-2,2]$. The width of the V rectangles was then calculated so that the V and H rectangles had equal area. In half of the trials, the target rectangle $\mathrm{T}_{\mathrm{H}}$ was defined using the H rectangles and in the other half of the trials the target $\mathrm{T}_{\mathrm{V}}$ was defined using the V rectangles. Thus, the orientation of the target (i.e., horizontal or vertical orientation) was counterbalanced so that half of the trials consisted of the horizontally longer target, $\mathrm{T}_{\mathrm{H}}$, and half of the experimental trials consisted of the vertically longer target, $\mathrm{T}_{\mathrm{V}}$. The competitor rectangles, C , were defined in the opposite manner of the target rectangles so that they were given the same area but were oriented opposite to the target (i.e. vertically if the target was horizontal and horizontally if the target was vertical). The decoys used in this experiment were "range" decoys, options that are a little weaker than the target on the target's weakest attribute. Let $\mathrm{D}_{\mathrm{H}}$ denote a horizontally oriented decoy similar to $T_{H}$ and $D_{V}$ denote a vertically oriented decoy similar to $\mathrm{T}_{\mathrm{V}}$. A range decoy $\mathrm{D}_{\mathrm{H}}$ has the same width as $T_{H}$ but a shorter height since height is the shortest (weakest) dimension of a horizontally oriented target. Likewise, the $\mathrm{D}_{\mathrm{V}}$ decoy has the same height as $\mathrm{T}_{\mathrm{V}}$ but a shorter width since width is the shortest (weakest) dimension of a vertically oriented target (see Figure 1 for a schematic of the choice options). The shortest dimension of each decoy was defined as the shortest dimension of the corresponding target minus a random number selected from the interval [7,9].

Each experimental trial began with a fixation cross appearing at the center of a white screen for 0.250 ms . This was followed by the appearance of the numbers " 1 ", " 2 ", and " 3 " from left to right on the screen to indicate that one rectangle will appear above each number. Participants made their choice by pressing the corresponding " 1 ", " 2 ", or " 3 "
key at the top of the keyboard. Black rectangles were shown one at a time. Each rectangle was shown above one of the numbers for 1.0 second before disappearing. The location of each rectangle was randomized across trials. The order of appearance for the rectangles was randomized in a controlled manner, such that experimental trials of each order appeared an equal number of times.

Figure 1: Schematic of the choice options in the rectangle attraction effect task. The options H (horizontally oriented rectangles), V (vertically oriented rectangles), and decoys $D_{H}$ and $D_{V}$ are plotted in a two-dimensional attribute space defined by the logarithm of height and width. The dotted line indicates options that should objectively be indifferent because they have the same area. In the attraction effect, preference for H and V can be affected by the presence of either $D_{H}$ or $D_{V}$.

Each participant completed 720 randomized trials that were divided into eight blocks of 90 trials each. Within the 90 trials of each block, there were 30 filler trials and 10 trials for each of the possible six orders the rectangles could be presented. These six orders are as follows: TCD, CTD, TDC, CDT, DTC, and DCT. Within these orders, there were two variations, one where $T_{H}$ served as the target and one where $\mathrm{T}_{\mathrm{V}}$ served as the target to minimize effect based on orientation of the target rectangle. The 30 filler trials were meant to serve as an estimate of accuracy for participants. Each filler trial had a clearly larger rectangle that would allow participants to make a correct choice.

## Results

One participant's data were removed due to computer error. Overall, the mean accuracy of participants' performance on filler trials was $66.62 \%$ correct with two participants falling two standard deviations below average. However, these participants' data were not removed. This data is analyzed using the relative choice share for the target, or RST, which is defined as the number of target options selected divided by the total number of target plus competitor options selected (i.e., $\mathrm{T} /(\mathrm{C}+\mathrm{T})$, Berkowitsch, Scheibehenne, Rieskamp, 2014). For the results described below we
collapsed across the two different orientations of the target. The attraction effect was still observed with an average of $51.10 \%$ target chosen, significantly different from $50 \%$ target chosen, the theoretical RST if the decoy had no influence $(\mathrm{t}(48)=2.77, \mathrm{p}=0.008)$.

Although the attraction effect was not observed for each presentation order, each presented order of rectangles were also significantly different from the $50 \%$ theoretical RST, refer to Table 1. Figure 2 shows a bar graph of the RST values for each of these orders. A one-way ANOVA showed a significant main effect of order $(F(5,288)=18.27, p<$ 0.001 ). In particular, the orders CTD, CDT, and DTC showed the attraction effect, with RSTs significantly higher than $50 \%$, and the orders TCD, TDC, and DCT had RSTs significantly lower than $50 \%$ (a reverse attraction effect).

Table 1. The RST value as a percentage, the $t$-value, and the p-value for each order.

| Order | RST (\%) | $t(48)$ | $p$-value |
| :--- | :--- | :--- | :--- |
| TCD | 41.99 | -4.75853 | $<0.001$ |
| CTD | 57.62 | 4.7803 | $<0.001$ |
| TDC | 42.71 | -3.0831 | 0.003 |
| CDT | 60.25 | 4.8931 | $<0.001$ |
| DTC | 57.81 | 3.7921 | $<0.001$ |
| DCT | 45.93 | -2.1742 | 0.035 |

Figure 2: Results show the RST for each presentation order of the rectangles as well as collapsed across all orders (combined). The dotted line at 0.5 indicates equal preference for the target and competitor. Bars above the dotted line show the standard attraction effect. Bars below the dotted line show a reversed attraction. Error bars show the standard error of the mean.

## Modeling

In order to better understand how presentation order influences choices in the attraction effect, we fit the MLBA model (Trueblood et al., 2014) to the choice and response time (RT) data. MLBA is a dynamic model that explains why context effects occur in multi-alternative choice. This model explains how preferences are constructed through a dynamic process of comparing the different features of available options. Context effects occur because of differences in the amount of attention given to specific comparisons (for example, if two options are difficult to discriminate on a particular feature, an individual pays more attention to that feature).

## Model Details

MLBA is an extension of the Linear Ballistic Accumulator (LBA) model developed by Brown and Heathcote (2008). The LBA accounts for choice and RTs using independent accumulators that race toward a threshold. The accumulators are linear and accumulate information deterministically. At the beginning of each trial, each accumulator starts at a randomly determined amount of evidence drawn from a uniform distribution on the interval $[0, A]$. The accumulators increase at speeds defined by a set of drift rates, until one of the accumulators reaches the threshold $b$. The option associated with the accumulator that reaches the threshold first is selected. On each trial, the drift rates are drawn from normal distributions with different means and the same standard deviation, $s=1$. The model also has a non-decision time parameter $T_{0}$ that accounts for encoding and motor response times. The MLBA model adds to the LBA model by specifying how drift rates arise from the evaluation of choice options.

Consider three alternatives (indexed as $i, j, k$ ) that have two attributes, $P$ and $Q$, where $P_{i}$ and $Q_{i}$ denote the value of option $i$ on the two attributes. The mean drift rate $d_{i}$ for option $i$ is defined as: $d_{i}=\gamma V_{i j}+\gamma V_{i k}+I_{0}$. The term $V_{i j}$ represents a comparison between options $i$ and $j$. Likewise, $V_{i k}$ represents a comparison between options $i$ and $k$. The term $I_{0}$ is a positive constant to ensure that at least one of the three mean drift rates is positive, avoiding non-termination in the LBA model. For our purposes, we can fix $I_{0}=1$. The parameter $\gamma$ is a scaling parameter that ensures that drift rates are in the appropriate range for the LBA model.

In the valuation function $V_{i j}$, option $i$ is the focal option and option $j$ is evaluated relative to it. Let $\left(u_{P i}, u_{Q i}\right)$ and $\left(u_{P j}\right.$, $u_{Q j}$ ) be the subjective values for options $i$ and $j$. In our experiment, the attribute dimensions, $P$ and $Q$, are the height and width of the rectangles in pixels. A pair of options were experimentally defined as indifferent in they have equal area, for example, $P_{i} \times Q_{i}=P_{j} \times Q_{j}$. We define the subjective values simply as the logarithm of the number of pixels for each dimension (e.g., $u_{P i}=\log \left(P_{i}\right)$ ). Please see Trueblood et al. (2014) for other possible mappings from objective to subjective values. The valuation function $V_{i j}$ is defined by the difference in the subjective values of the options:

$$
V_{i j}=w_{P i j}\left(u_{P i}-u_{P j}\right)+w_{Q i j}\left(u_{Q i}-u_{Q j}\right)
$$

where the weights $w_{P i j}$ and $w_{Q i j}$ reflect the amount of attention given to a particular comparison.

Based on research showing that visual attention (e.g., fixation duration) increases with decreasing discriminability of items (Gould, 1967, 1973), we hypothesize that attention weights are larger when attribute values are more similar and smaller when they are more distinct. Using Shepard's (1987) law of generalization, we define the attention weights as

$$
\begin{gathered}
w_{P i j}=\exp \left(-\lambda_{+}\left|u_{P i}-u_{P j}\right|\right) \text { if } u_{P i} \geq u_{P j} \\
w_{P i j}=\exp \left(-\lambda_{-}\left|u_{P i}-u_{P j}\right|\right) \text { if } u_{P i}<u_{P j} \\
w_{Q i j}=\exp \left(-\beta \lambda_{+}\left|u_{Q i}-u_{Q j}\right|\right) \text { if } u_{Q i} \geq u_{Q j} \\
w_{Q i j}=\exp \left(-\beta \lambda_{-}\left|u_{Q i}-u_{Q j}\right|\right) \text { if } u_{Q i}<u_{Q j}
\end{gathered}
$$

where $\lambda_{+}$and $\lambda_{-}$are free parameters that allow for attention to be asymmetric. That is, the attention weights are different when comparing positive differences in attribute values (i.e., the parameter $\lambda_{+}$) and negative differences in attribute values (i.e., the parameter $\lambda_{\text {_ }}$ ). This follows from work showing that similarity judgments often violate symmetry (Tversky, 1977) as well as modifications to Shepard's law that allow for such violations (Nosofsky, 1991). The parameter $\beta$ is a bias parameter that allows for attributes to be weighted differently. For example, in consumer choice, the attribute of price might receive more weight than the attribute quality. With rectangles, Holmberg and Holmberg (1969) suggested an "elongation effect" where height plays a more important role in area judgment than width.

In summary, the MLBA has the following free parameters: accumulator start-point $A$, threshold $b$, nondecision time $T_{0}$, drift rate scaling $\gamma$, positive attention parameter $\lambda_{+}$, negative attention parameter $\lambda_{-}$, and bias $\beta$.

## Hierarchical Bayesian Parameter Estimation

We fit the MLBA model with hierarchical Bayesian parameter estimation methods using DE-MCMC (Turner, Sederberg, Brown, \& Steyvers, 2013). We note that, as far as we are aware, this is the first time the MLBA (or any dynamic model of context effects) has been fit to both choice data and the full distribution of RT data. In the past, dynamic models of context effects have only been evaluated by qualitative measures or when quantitative fitting was performed, only choice data was used. Thus, we see the present work as a significant methodological step forward in the evaluation of dynamic models of context effects.

In our experiment, there are six order conditions: TCD, CTD, TDC, CDT, DTC, and DCT. We hypothesized that order would influence attention and thus we had separate attention parameters $\lambda_{+}$and $\lambda_{-}$for each condition. We also fit six $\gamma$ scaling parameters, one for each condition. We allowed for different scaling parameters across conditions to accommodate the different attention weights, which directly
impact the magnitude of the drift rates. The remaining parameters were assumed to be the same across conditions.

In our model, we had both group-level (or hyper parameters) and individual-level parameters. The individual-level parameters were drawn from normal distributions defined by the hyper parameters. Let $\mu_{x}$ and $\sigma_{x}$ represent the hyper mean and standard deviation of the group-level normal distribution for parameter $x$. The priors for the hyper means were the following: $\mu_{b} \sim \mathrm{~N}(1,0.5), \mu_{A} \sim$ $\mathrm{N}(1,0.5), \mu_{T 0} \sim \mathrm{~N}(0.25,0.25), \gamma \sim \mathrm{N}(5,1.5), \lambda_{+} \sim \mathrm{N}(0.5,1.5)$, $\lambda_{-} \sim \mathrm{N}(0.5,1.5), \beta \sim \mathrm{N}(1,1.5)$. The priors for all of the hyper standard deviations $\sigma_{x}$ were defined as $\operatorname{Gamma}(1,1)$ distributions expect for the standard deviation for nondecision time, which was $\operatorname{Gamma}(1,0.5)$. We ran 24 MCMC chains for 2500 iterations with a burn-in of 500 iterations. All chains converged.

## Results

To assess the fit of the model, we calculated the correlation between choice and mean RT data with model predictions. The model predictions were calculated by using the mean of the posterior distributions of the individual parameters. The correlation between the choice data and model predictions was $0.886(p<0.001)$. The correlation between the mean RT data and the model predictions was 0.588 ( $\mathrm{p}<0.001$ ). Thus, the model does a good job at capturing general trends in the data.
We also examined how well the model accounted for the average choice data for each condition. Figure 3 shows the mean choice proportions for each option in the 12 different choice sets used in the experiment. The 12 choice sets arise from the two possible placements of the decoy $\left(D_{H}\right.$ or $\left.D_{V}\right)$ in each of the six order conditions. The model predictions were calculated using the mean of the posterior distributions of the individual parameters.

To understand how presentation order influences choices in the attraction effect, we examined the values of the attention weights for the six conditions (see Table 2). Specifically, we examined the posterior means of the grouplevel attention weight parameters ( $\lambda_{+}$and $\lambda_{-}$) for each condition. We did not see any obvious trends in the attention weights when we examined them individually. However, the ratio of the positive weight to the negative weight revealed an interesting pattern. In the conditions that exhibited the standard attraction effect (i.e., CTD, CDT, and DTC), the ratio was smaller than the conditions that exhibited an inverse attraction effect (i.e., TCD , TDC, DCT ). This suggests that presentation order influences the amount of attention given to positive and negative differences in attribute values. When the attraction effect is observed, more attention is placed on negative differences as compared to when the reverse attraction effect occurs.

## Discussion

Our goal in the present paper was to explore the role of attention in the attraction effect through direct manipulation. We manipulated attention through presentation order,

Figure 3. Observed choice proportions and model predictions for 12 choice sets in the rectangle attraction effect task. Each choice set consists of three options (the target, competitor, and decoy). There are two choice sets for each order condition due to the two possible placements of the decoy (either near the horizontally oriented rectangle or the vertically oriented rectangle). The model predictions are shown in light gray and observed choice proportions in dark gray.
presenting the options sequentially rather than simultaneously. The sequential presentation of the options had a large impact on choices - some presentation orders enhanced the attraction effect whereas other presentation orders reversed the attraction effect. To better understand why presentation order impacted choices, we used computational modeling. We fit the MLBA model to choice and response time data. Model fits revealed differences in the attention weights for different presentation orders. For the presentation orders that showed a standard attraction effect, there was increased attention on negative differences as compared to the presentation orders that showed a reverse attraction effect.

Recently, researchers have discovered large individual differences in context effects (Liew, Howe, \& Little, 2016; Trueblood, Brown, \& Heathcote, 2015). Some individuals show the standard effects, but others do not. For some individuals, the effects are even reversed. This has lead to the conclusion that context effects are fragile (Trueblood et al., 2015). This raises two important questions: (1) Why are
the effects fragile? and (2) What underlies individual differences in the effects? The present work provides one possible explanation. The effects are fragile because they result from biases in attention. Small shifts in attention can have dramatic influences on choice. It is possible that individual differences in the effects arise because of individual differences in attention.

Table 2: Posterior means of the group-level attention weight parameters for the six order conditions.

| Condition | $\lambda_{+}$ | $\lambda_{-}$ | $\lambda_{+} / \lambda_{-}$ |
| :--- | :--- | :--- | :--- |
| TCD | 1.50 | 4.25 | 2.83 |
| CTD | 2.05 | 4.51 | 2.20 |
| TDC | 0.92 | 2.06 | 2.24 |
| CDT | 1.39 | 2.52 | 1.81 |
| DTC | 1.86 | 3.43 | 1.84 |
| DCT | 1.11 | 2.48 | 2.23 |

The results of our experiment also pose a challenge to a recent rational model of context effects that claims the effects are a consequence of expected value maximization given noisy observations (Howes, Warren, Farmer, ElDeredy, \& Lewis, 2016). In our experiments, simply changing the presentation order of the same set of options has a dramatic influence on choices. It is unclear how a rational model could account for the influence of presentation order on the effects.

In sum, we have demonstrated that presentation order, which influences attention, can both strengthen and weaken the attraction effect. The MLBA model suggests that presentation order changes the allocation of attention between positive and negative differences between options. These findings provide an explanation for individual differences in context effects and also pose a challenge to recent rational models of the effects.

# Interpretation and Processing Time of Generalized Quantifiers: Why your Mental Space Matters 

Alice Ping Ping Tse (tse@tf.uni-freiburg.de) and Marco Ragni (ragni@tf.uni-freiburg.de)<br>Institut für Informatik, Technische Fakultät, Albert-Ludwigs-Universität Freiburg<br>Georges-Köhler-Allee, Geb. 052, 79110 Freiburg im Breisgau, Germany

#### Abstract

Classical quantifiers (e.g., "all", "some" and "none") have been extensively studied in logic and psychology. In contrast, generalized quantifiers (e.g., "most") allow for fine-grained statements about quantities. The discrepancy in the underlying mental representation and its interpretation among interpreters can affect language use and reasoning. We investigated the effect of quantifier type, quantification space (set size) and monotonicity on processing difficulty (in response time, RT) and response diversity of 77 generalized quantifiers. Shannon entropy was employed to measure response diversity. Our findings indicate: (i) Set size is a significant factor of response diversity, which implies that the underlying space is relevant for the interpretation. (ii) Quantifiers possess a rather static underlying representation within and across tasks within a participant. (iii) Quantifier type and monotonicity can affect response diversity; while the response diversity can predict RT. (iv) In reasoning, the number of generalized quantifiers versus classical quantifiers in a syllogism is a factor of response diversity. Diversity in the interpretation of generalized quantifiers may be a cause of human's deviation from logical responses.

Keywords: generalized quantifiers; syllogism; total set size; monotonicity, individual differences

## Introduction

"Quantifiers" can have two definitions: In logic, a quantifier acts as the binder to denote the relationships between sets. In natural language, a quantifier is a determiner or pronoun indicative of quantity or amount. In daily English, it limits and modifies the quantity of the noun it is attached to. They map categories to types. Hence, they are the basis for many fundamental concepts in different fields, especially logic, linguistics and psychology. In first-order logic, there are only two basic quantifiers: the universal "for all, $\forall$ " and the existential quantifier "there exist (or for some), $\exists$ ", which denote quantities. In Aristotelian logic (Austin, et al., 1971; Westerståhl, 2011), there are three quantifiers, "all/every", "some" (also for "some... not"), and "no". However, the aforementioned first-order quantifiers are too restricted in daily language use. Generalized quantifiers (also known as the second-order predicates or binary quantifiers) are in a wider use in language, for example, when the exact amount is not available (which is quite usual in daily situations) or to emphasize a rather qualitative property of the amount (e.g., "more than half", "most", "a few"). Generalized quantifiers (or just quantifiers) include words and phrases like 'most', 'many', 'few', 'a few', 'some', 'more than half', 'commonly', 'typically' and cardinal numbers (e.g., more than one, and exact numbers such as two, a hundred).

Since the first articles by Barwise and Cooper (1981) in the field of linguistics and Lindström (1966) in the field of logic, an increasing number of research articles have focused on generalized quantifiers. The interpretation of generalized quantifiers can be affected by factors like the quantification space - its total set size (Newstead, Pollard, \& Riezebos, 1987), word frequency (Chase, 1969), monotonicity (Szymanik \& Zajenkowski, 2013), common belief and background knowledge (Newstead \& Collis, 1987; Moxey \& Sanford, 1993), and context and working memory (Zajenkowski, Szymanik, \& Garraffa, 2014). Some psychological studies (e.g., Newstead et al., 1987; Ragni, Eichhorn, Bock, Kern-Isberner, \& Tse, 2017) have demonstrated that many quantifiers do not have a precise true/false cutoff for the quantity they represent, on a scale from 0 to 100 . Even more, the minimum and maximum values of human's subjective valuation responses to individual quantifier can vary a lot (Ragni et al., 2017). This may hint at a fuzzy underlying space of quantifiers among people, in terms of using and interpreting quantifiers (Budescu \& Wallsten, 1985).

Generalized quantifiers have been recently employed in studies of syllogisms ${ }^{1}$, such as the Probability Heuristics Model (PHM; Oaksford \& Chater, 1994). A recent study (Ragni, Singmann, \& Steinlein, 2014) has extended three syllogistic reasoning theories (Matching Hypothesis, Mental Model Theory and Preferred Mental Models) to generalized quantifiers. However, only the two quantifiers - "most" and "few" were included. The interpretation of generalized quantifiers plays a role in most reasoning theories, especially regarding the set relationship. For example, in mental model theory, it is the basis for the construction of mental models. Endorsement of invalid conclusion can be resulted when reasoners commit the illicit conversion fallacy of interpreting "All As are Bs" as equivalent to "All Bs are As" and make a mistake in the initial mental model construction. This is indeed a very common error in syllogistic tasks. While for PHM, it is relevant to the selection of the preferred quantifier in the conclusion.

Knowing the factors affecting the underlying representation of generalized quantifiers is essential for cognitive theories for reasoning. One example is that "most As are

[^524]Bs" is "equivalent" to "most Bs are As" if A and B have the same set size. However, if B has a much larger set size or cardinality than A, then the proposition does not hold after the switch (also known as illicit conversion). About $50 \%$ of the participants in the experiments of a previous study chose "most" as the conclusion quantifier for a syllogism with "most" as the quantifier for both premises ${ }^{2}$ (Chater \& Oaksford, 1999). It is interesting that half of the participants considered A, B and C as having the same cardinality while the other half of the participants may not. About $15 \%$ of the participants in experiment 1 and $20 \%$ of the participants in experiment 2 chose "no valid conclusion" as their responses. It is very possible that these participants may be aware of the fact that the differences in total set sizes of $A, B$ and $C$ can lead to different conclusions for the syllogism.

Factors affecting the variety in the interpretation of quantifiers and underlying space have to be controlled in studies employing these quantifiers. Besides, are there individual differences in the underlying representation of a quantifier? Does the underlying space affect the response diversity? The answers may provide insight for the questions why human participants do not always draw the same or logical conclusions but some particular irrational conclusions are preferred and why more response diversity was found for more difficult reasoning problems (e.g., Khemlani \& Johnson-Laird, 2012). Also, would the degree of vagueness/uncertainty of a quantifier cause more individual differences? What are the factors of the response diversity in the interpretation of generalized quantifiers? Will the degree of uncertainty cause a larger processing difficult which can be reflected by a longer processing time? And what are the factors of processing difficulty of generalized quantifiers? This analysis investigates these questions regarding the underlying space and processing time (difficulty) of generalized quantifiers. More precisely, we focus on three levels of tasks: 1. Spontaneous valuation of the quantity or frequency the quantifier represents in the Subjective Valuation Task. 2. A Truth Judgement Task in which participants were asked to judge if a quantified statement holds true for a picture. 3. Finally, a syllogistic reasoning task with generalized quantifiers that participants were asked to reason and derive a conclusion from two premises of quantified statements. Please refer to the Method section for details about the three tasks.

Two measures of response diversity were employed in this study, namely the standard deviation and Shannon entropy. In information theory, Shannon entropy calculates the expected value of the information transmitted in a message (Shannon \& Weaver, 1949), as a function of the probability of the occurrence of each possible message. For each quantifier, the entropy in the Truth Judgement Task, was calculated by the aggregated normalized probabilities of the truth responses for each of the pictures/scenarios presented (see Method for the details) by the Shannon equation: $-\sum \mathrm{p}_{\mathrm{i}} \log _{2} \mathrm{p}_{\mathrm{i}}$, where $p_{i}$ is the probability of a truth response. There will be

[^525]several "small" probabilities if the response is more diverse. Conversely, if the responses are condensed to a few values, the probabilities of these selected values will be high. The smaller the probability, the larger the entropy value calculated by the equation. And thus, a larger Shannon entropy value indicates more discrepancy in the responses. It was used to measure the response diversity in syllogistic reasoning in a meta-analysis study (Khemlani \& Johnson-Laird, 2012). Standard deviations of the responses in the Subjective Valuation Task and Truth Judgement Task were calculated as well to check if the two measures of diversity agree with each other. For answering the question regarding underlying space, Newstead et al. (1987) found that the amount of entities represented by certain quantifiers (e.g., "some") could be affected by the assumed total set size of the experimental scenario. However, does this hold for all generalized quantifiers? Besides the extra-linguistic factor of total set size, several properties of the quantifier itself can also affect the diversity of human responses (interpretation) and response time. They include, among others, quantifier type, monotonicity, and word frequency. We will elaborate two aspects below.

## Quantifier Types

There are many different ways of classifying quantifiers (e.g., logical quantifiers versus different types of binary quantifiers; simple versus complex quantifiers). In this study, the quantifiers were classified in the sense of natural language, namely frequency versus quantity quantifiers. Many studies have been conducted for quantity quantifier, while there are only few for frequency ones. For instance, Newstead and Collis (1987) studied the context effect in the interpretation of ten frequency quantifiers. In contrast to some previous findings for quantity quantifiers (Chase, 1969; Newstead \& Griggs, 1984; Newstead et al., 1987), no significant set size effect or effect due to the presence of other quantifiers were found. This supported that processing of quantifiers of different types may be different due to their specific properties.

## Monotonicity

A generalized quantifier $\mathrm{Q}_{\mathrm{up}}$ is upward monotone/entailing (or monotone increasing) if and only if for all $M$ and all A , $\mathrm{B} \subseteq \mathrm{B}^{\prime} \subseteq \mathrm{M}, Q_{M}(\mathrm{~A}, \mathrm{~B})$ implies $Q_{M}\left(\mathrm{~A}, \mathrm{~B}^{\prime}\right)$. That means $\mathrm{Q}_{\mathrm{up}}$ license the inference from subsets to supersets. Similarly, a $\mathrm{Q}_{\text {down }}$ is downward monotone/entailing if and only if for all $M$ and all $\mathrm{A}, \mathrm{B} \subseteq \mathrm{B}^{\prime} \subseteq \mathrm{M}, Q_{M}\left(\mathrm{~A}, \mathrm{~B}^{\prime}\right)$ implies $Q_{M}(\mathrm{~A}, \mathrm{~B})$. Contrastive to $\mathrm{Q}_{\mathrm{up}}, \mathrm{Q}_{\text {down }}$ license the inference from supersets to subsets. For example, "Some men are Germans implies some men are Europeans". With the fact that "Germans" is within the set of "Europeans", "some" is an upward monotone quantifier. Similarly, "No men are birds" implies "No men are eagles". With the fact that eagles are birds, "no" is downward monotone. There are nonmonotone quantifiers also, e.g., "exactly three". For example, "exactly three men are Germans" does not imply "exactly three men are Europeans" or vice versa. According to
the definition, many natural language quantifiers are (either upward or downward) monotone, including the three Aristotle quantifiers, "all", "some" and "no". Barwise (1981) suggested that monotone quantifiers are easier to process than non-monotone ones.

## Aims of the Study and Research Questions

We aimed to examine human's interpretation of a large number of generalized quantifiers and factors affecting the response diversity and processing time of these quantifiers to facilitate further studies of generalized quantifiers in different fields. As mentioned before, the significant properties have to be controlled in studies involving these quantifiers in order to eliminate some confounding factors. The analyses focus on three factors, namely total set size, quantifier type (quantity quantifier and frequency quantifier), and monotonicity (upward, downward and non-monotone), according to two domains, namely degree of variation in underlying representation space (among interpreters, in terms of response diversity) and processing difficulty (in terms of processing time) of the generalized quantifiers.

## Research Question 1: Factors of Response Diversity

Unlike "All", "No" or "Seven" (numerical quantifiers), the amount (or proportion) represented by most generalized quantifiers can be rather fuzzy. Humans do not agree with each other regarding the representation space of individual quantifier. What are the factors affecting the differences in the underlying representation space of quantifiers? In other words, are total set size, quantifier type and monotonicity the factors affecting response diversity? Research question 1 (RQ 1) was examined by analyzing the standard deviation (SD) and Shannon entropy measures in both the Subjective Valuation and Truth Judgement Tasks. We hypothesized that the smaller set size condition, quantity quantifiers and upward monotone quantifiers may exhibit smaller response diversities, i.e., smaller standard deviation and entropy measure values.

## Research Question 2: Processing Time

Does greater degree of fuzziness cause a longer processing time (in terms of response time)? Besides, is the monotonicity a factor of processing time as well? Szymanik and Zajenkowski (2013) found a significant interaction effect of monotonicity and the truth value of the quantified statement in a verification task of four quantifiers but failed to find a significant main effect of monotonicity. We extended the study with more quantifiers of different quantifier types. Word frequency was included as a covariant because it has a general effect in word recognition ${ }^{3}$. Quantifiers of higher

[^526]word frequency are expected to be processed faster. We hypothesized that the entropy measures and word frequency are significant predictors of RT; and the quantifier type may affect the RT as well.

## Method

## Participants

104 native English speakers ( $\mathrm{M}=40.8$ years; range $=21-75$ years; 63 females) participated in the online experiment on Amazon Mechanical Turk. We controlled for one participant from a given computer. They received a nominal fee.

## Materials, Design and Procedure

A search for common quantity and frequency quantifiers was performed in Google with the keywords "quantifiers", "frequency quantifiers", "frequency adverbs", "determiners", "how often", "how many", and "how much". 77 generalized quantifiers were selected ${ }^{4}$, with 34 frequency quantifiers (frequency adverbs); and 14,13 and 16 quantity quantifiers which can be used with countable, uncountable and both countable and uncountable nouns (type-both) respectively. Each participant had to perform two tasks:

A Subjective Valuation Task Participants were asked to provide a subjective value of the amount the quantifier represents. They had to move a slidebar to indicate their responses in terms of percentages (from $0 \%$ to $100 \%$ ). Each quantifier was evaluated once.

A Truth Judgement Task Participants had to evaluate the validity of a quantified statement presented above a picture. For the effect of total set size, participants were randomly assigned to either the smaller-set group or larger-set group. The number of participants in each group was counterbalanced. For countable and type-both quantifiers, pictures of 10 circles or 100 circles were displayed, with 0 to all of them colored black (see Fig. 1). While for uncountable and type-both quantifiers, pictures of a heap of sand or desert (composed of 10 heaps of sand) were presented with 0 to $100 \%$ of the sand or desert colored brown (see Fig. 2).

Figure 1: Pictures for countable space in the Truth Judgement Task. Participants received the left (10 circles) or right picture ( 100 circles) and had to evaluate whether a quantified statement like "Some circles are black" (presented at the left hand upper corner) is a true description of the picture or not.

[^527]For frequency quantifiers, timelines of a week with a coffee cup icon for 0 to 7 days or a monthly schedule with an icon of football for 0-31 days were presented. Each quantifier was tested 2 times for each participant in two blocks. Pictures displayed were counterbalanced within participants in the sense that if the participant received less than or equal to half positive situation (e.g., 3 out of 10 circles colored black) in the first block, he/she would receive more than or equal to half positive situation in the second block (e.g., 7 out of 10 circles are black) and vice versa. The same manipulation was applied to all the three scenarios (circles, sand/desert, and timeline/calendar). Type-both quantifiers were tested four times for each participant as they were presented twice in both the circle and sand/desert scenarios. The possible picture options were counterbalanced among participants. For countable and type-both quantifiers, the statement was in the form of "Quantifier (of the) circles are black" or "These circles are Quantifier black" (for "commonly" and "typically"). For the sand/desert situation, the statement was "Quantifier sand is colored brown". The statement was in the form of "Tim Quantifier drinks coffee" or "Tim drinks coffee Quantifier" for the weekly timeline scenario; and "Tim Quantifier plays soccer" or "Tim plays soccer Quantifier" for the monthly calendar scenario. Participants were asked to judge as accurately and quickly as possible whether the statement was a truth description of the picture. Participants always performed the Subjective Valuation Task first.

Figure 2: Pictures for an uncountable space in the Truth Judgement Task. Participants had to judge whether a statement like "Most sand is colored brown" is a true description of the picture or not.

## Results

## The Underlying Representation Space

For the first research question, the diversity in the responses was evaluated by the Shannon entropy and standard deviation measures of the responses in both the Truth Judgement Task and Subjective Valuation Task, as the indices. The standard deviation and entropy measures of the responses were calculated according to the two different set size conditions in the Truth Judgement Task (SD1, Entropy1; and SD2, Entropy2). SD1 and Entropy1 are the standard deviation and entropy measure of the smaller set size pictures (10 circles, 1 heap of sand and weekly timeline). SD2 and Entropy 2 are the standard deviation and entropy measure of the larger set size condition ( 100 circles, desert and monthly schedule). The Spearman's rank correlations between the three SDs and entropy measures were tested both within and
across the two tasks. Significant correlations were found except for SD2 with the entropy in the Subjective Valuation Task and Entropy1, see table 1 for the results. For the effect of set size on the response diversity, significant differences were found between both SD1 and SD2; and Entropy1 and Entropy2, $\mathfrak{t}(76)=-6.142, p<.001$ and $\mathfrak{t}(76)=-7.268, p<$ .001, respectively, with SD2 and Entropy2 being significantly larger. The two measures (SD and entropy) provided similar results, as the entropy measures were more reliable indices for the response diversity (according to the positive correlations across tasks), we used the entropy measures for the following analyses for the sake of simplicity.
Regarding the property of monotonicity, the quantifiers were classified into 28 upward monotone, 23 downward monotone, 11 monotone and 12 non-monotone quantifiers. The effects of the three quantifier properties on the two entropy measures (for underlying space) in the Truth Judgement Task were then tested. The 2 (quantifier type: frequency and quantity) x 4 monotonicity (monotonicity: upward, downward, monotone and non-monotone) MANOVA, with word frequency as a covariate, for the two entropy measures showed that the quantifier type had a significant multivariate effect on the two entropy measures, $\mathrm{F}(2$, $64)=179.820, p<.001$, Wilk's $\lambda=.151, \eta_{\mathrm{p}}{ }^{2}=.849$; as well as monotonicity and word frequency, $\mathrm{F}(6,128)=5.568, p$ < .001 , Wilk's $\lambda=.629, \eta_{\mathrm{p}}^{2}=.207$ and $\mathrm{F}(2,64)=10.130, p<$ .001 , Wilk's $\lambda=.760, \eta_{\mathrm{p}}^{2}=.240$, respectively. The interaction effect of quantifier type and monotonicity was not significant.

The following post-hoc tests were performed according to quantifier type (frequency versus quantity) and monotonicity (upward and downward). The t -tests showed that the two entropy measures (Entropy1 and Entropy2) were reliably different for frequency quantifiers, $\mathrm{t}(33)=-23.426, p<$ .001 , but not for quantity quantifiers. Regarding the monotonicity, the two entropy measures were reliably different for upward and downward monotone quantifiers, Entropyl: $\mathrm{t}(49)=2.328, p=.024$; Entropy2: $\mathrm{t}(49)=3.198, p=.002$.

Differences between the response diversity indices for the first half and second half of the tasks were also examined. Regarding Entropy1 and Entropy2, both t-tests were not significant, Entropy1: $\mathrm{t}(76)=1.236, p=.220$, Entropy2: $\mathrm{t}(76)=.455, p=.650$. For the Subjective Valuation Task, there was no difference between the first and second half of the task neither, $\mathrm{t}(73)=-.067, p=.946$.

## Processing Time

We filtered out the response times which exceed average RT +/- 2 SD according to individual participant. Firstly, a stepwise regression was performed to test if the word frequency and the three entropy measures significantly predicted the response time. The results of the regression analysis showed that the two entropy measures in the Truth Judgement Task explained $38.6 \%$ of the response time (adjusted $\mathrm{R}^{2}=.386$, $\mathrm{F}(2,74)=24.928, p<.001$, Entropy1: $\beta=.975, p<.001$, Entropy2: $\beta=-.603, p<.001$. As the response times of the two quantifier types were significantly different,

Table 1: Results of Spearman's rank correlation of the standard deviation (SD) and entropy measures of the responses in the Subjective Valuation Task (SD and entropy) and Truth Judgement Task (SD1 and SD2; and Entropy1 and Entropy2).

$\mathrm{t}(75)=7.188, p<.001$, the regression was repeated according to the two quantifier types. For frequency quantifiers, word frequency was the only significant predictor, adjusted $\mathrm{R}^{2}=.157, \mathrm{~F}(1,32)=7.128, p=.012 ; \beta=-.427, p=.012$. While for quantity quantifiers, entropy in the Subjective Valuation Task was the only significant predictor of the response time, adjusted $\mathrm{R}^{2}=.136, \mathrm{~F}(1,41)=7.609, p=$ $.009 ; \beta=.396, \quad p=.009$. The effect of monotonicity on response time was not significant. Do generalized quantifiers affect the response diversity in syllogistic reasoning? Syllogisms are chosen as quantifiers are the essence of syllogistic reasoning and so their effect may be most visible.

## Entropy in Reasoning with Generalized Quantifiers: Additional Empirical Support

We reanalyzed the data from Ragni et al. (2014) with the entropy measure for response diversity. Twenty-five native English speakers participated in the online experiment on Amazon Mechanical Turk. Each participant had to solve 40 syllogistic problems with at least one of "most" and "few" being the quantifier of one of the two premises. Participants had to choose the conclusion quantifier of the syllogism among the four classical Aristotle quantifiers and the two generalized quantifiers "most" and "few" (i.e., all, no, some, some...not, most and few), to the question "what follows?" after reading the two premises. The conclusion direction presented (a-c or c-a) was counterbalanced. 20 problems were tested for each conclusion direction. "Most" and "few" appeared in the first premise respectively in 6 of the syllogisms, with the second premise being one of the six quantifiers ( $6 \times 2=12$ problems). For the 8 remaining syllogisms, "most" and "few" appeared in the second premise, with the first premise being one of the four Aristotle quantifiers.

The entropy measure of the responses for each syllogism was calculated and an ANOVA and a t-test were performed. The 2 (conclusion direction: a-c vs. c-a) x 2 (position of the generalized quantifier: first premise vs. second premise) ANOVA showed a significant main factor of the position, $\mathrm{F}(2,39)=4.738, p=.015, \eta_{\mathrm{p}}^{2}=.218$, but both conclusion direction and the interaction effect were not significant. Post-hoc analysis showed that syllogisms with generalized quantifier in the first premise had a significantly higher entropy, $\mathrm{t}(30)=2.174, p=.038$ (2-tailed). The number of
generalized quantifier affects the entropy as well. If both premises contained generalized quantifiers, the entropy was marginally smaller, Independent Samples Test: $t(38)=$ $1.957, p=.058$ (2-tailed) ${ }^{5}$. The marginal result might due to the fact that only 8 syllogisms have two generalized quantifiers but 32 problems have only one generalized quantifiers.

## General Discussion

While extensive research in psychology of reasoning and logic has dealt with the four classical quantifiers ("all", "some", "some...not", and "none"), few cognitive reasoning theories for syllogisms have been extended to generalized quantifiers - and often to "most" and "few" only. Different quantifiers possess different specific properties which affect their interpretation (especially in terms of interpretation diversity) in daily language. For example, for universal quantifiers like "All" and "No", most participants would select $100 \%$ and $0 \%$, respectively, in the Subjective Valuation Task, with few selecting values within $95 \%$ to $99 \%$ and $0 \%$ to $5 \%$, respectively. In contrast, the more "fuzzy" generalized quantifiers elicit a greater diversity in the responses. For example, for "some", we got 6 responses for $20 \%$ and $35 \%$, 5 responses for $25 \%$, and 10 responses for $45 \%$ (among 104 responses). In total, 47 different percentages (out of 101 possible choices) were selected as the responses in the Subjective Valuation Task. It seems that the right tool to analyze the interpretation diversity is missing. We argue that Shannon entropy, which was developed for communication, is an excellent method which can be employed to measure the response diversity of generalized quantifiers.

Using Shannon's entropy to measure response diversity was introduced in this study as it is a binary-based element which fits the dichotomous experimental design of the Truth Judgement Task. It shows reliable correlated results with the classical standard deviation measure within and across tasks. Shannon entropy seems a better measure for response diversity across tasks than the SD. Our results show that the total set size, quantifier types (frequency versus quantity) and monotonicity can affect the interpretation diversity of a quantifier; while the interpretation diversity (in terms of

[^528]entropy measures) can in turn affect the response time. In accordance with the findings of Szymanik and Zajenkowski (2013), we did not find a reliable effect of the monotonicity of quantifiers on RT. One can speculate that the difference in processing difficulty applies to cardinal quantifiers only.

The smaller set size condition has a smaller entropy value as hypothesized, in contrast to the frequency quantifiers and downward monotone quantifiers. Further studies are required to explain this finding. Quantity quantifiers have a slower RT in general and this might be affected by the larger discrepancy in the underlying representation space, which hints a fuzzier underlying representation of quantity quantifiers among participants. However, our results suggest that quantifiers possess a rather static underlying mental representation space within participants, not changing within or across tasks, as there is no difference for the response diversity measures between the first and second half of the tasks.

Despite our finding of total set size being a factor in the interpretation of generalized quantifiers, it is still possible for human to interpret quantifiers without the knowledge of total set size (Van Tiel \& Geurts, 2013). But we can speculate that participants usually represent the underlying set by a default mental model for the respective quantifiers.

Our study shows that total set size, quantifier type, and monotonicity (and word frequency) are all contributing to the possible diversity in the use or reasoning of generalized quantifiers. Based on these factors, natural extensions of theories which already assume models of different sizes and are analogous representations of the state of affairs (like the mental model theory) to incorporate the proposed results is possible. Extension to generalized quantifiers is increasingly important for cognitive reasoning theories to avoid a selfcentered focus, which renders them ultimately useless for explaining or predicting complex everyday communication. Large-scale studies of these generalized quantifiers in reasoning tasks can test if the diversity in the interpretation of these quantifiers is the factor of the response diversity in reasoning tasks. It is possible that differences in the interpretation of the quantifier contribute to the deviation from logical responses, other than reasoning/heuristic processes. Controlling the above significant factors is important for studies involving quantifiers, to avoid hidden experimental confounds. Also, for theories with predictions on response time, it is possible that interpretation diversity is a significant factor. Further studies on this hypothesis are necessary.

# Right hemisphere lateralization and holistic processing do not always go together: An ERP investigation of a training study 

Ricky Van-yip Tso (rvytso@eduhk.hk)<br>1. Department of Psychology; and 2. Psychological Assessment and Clinical Research Unit, Centre for Psychological Health; The Education University of Hong Kong, 10 Lo Ping Road, Tai Po, New Territories, Hong Kong<br>Hangyu Chen (ariachan@connect.hku.hk), Yui Andrew Yeung (andrewy@connect.hku.hk)<br>Terry Kit-fong Au (terryau@hku.hk), \& Janet Hui-wen Hsiao (jhsiao@hku.hk)<br>Department of Psychology, The Jockey Club Tower, Centennial Campus, The University of Hong Kong, Pokfulam Road, Hong Kong

#### Abstract

Holistic processing (HP) and right-hemispheric lateralization both mark expertise in visual object recognition such as face and sub-ordinate object perception. However, counterexamples have been found recently: Experiences of selective attention to parts such as writing experiences in Chinese characters reduced HP while increased right hemisphere lateralization. We investigated the association between HP and brain activities measured by event-related potentials (ERP) in participants trained to recognize artificially-created scripts using either whole-word or grapheme-to-phoneme approaches. Stronger N170 activities were found in both hemispheres in both training approaches. Though the type of training approaches induced opposite directions in correlations between HP and the ERP signals in the right hemisphere: In the whole-word condition, the HP effect increased with stronger right-hemispheric N170 activities; while the direction of this correlation was reversed in the grapheme-to-phoneme condition. This demonstrates that HP and right hemispheric lateralization are separate processes that are associated with different perceptual mechanisms.

Keywords: holistic processing, hemisphere lateralization, ERP, EEG, perceptual expertise

## Introduction

## Holistic processing and right hemisphere lateralization

Holistic processing (HP) has consistently been reported to be a perceptual marker of visual expertise in face and subordinate-level visual object recognition (Bukach et al., 2006; c.f. Mckone, Kanwisher, \& Duchaine, 2007). For example, Gauthier, Williams, Tarr, and Tanaka (1998) trained participants to recognize "Greebles"-novel artificial objects-and found a positive relationship between HP and performance in within-category object recognition. Similarly, when participants were trained to individualize "Ziggerins" (an artificial object type), they showed an increase in HP (Wong, Palmeri, \& Gauthier, 2009).

HP in face perception can be demonstrated with the composite face illusion induced by the composite paradigm: Two identical top halves of two faces are more likely judged as different when the two bottom-half faces are from different faces, (see Rossion, 2013, for a review). The composite illusion suggests that all facial parts are obligatorily attended to, which results in the failure of selectively attention to parts (Richler, Wong, \& Gauthier,
2011). This paradigm demonstrates one of the three types of configural processing according to Maurer et al. (2002).

Hemispheric asymmetry may be another expertise marker for object recognition. Neuroimaging studies generally showed stronger activation in the right occipitotemporal area for face recognition (Rossion, Hanseeuw, \& Dricot, 2012). Complementing this finding, Gauthier and Tarr (2002) found that as participants were trained to recognize individual Greebles, increase in HP was correlated with activation changes in the right occipitotemporal regions. Because of the concurrence of robust HP in face and objection recognition with stronger right-hemisphere (RH) activations, HP is suggested to be a property of RH visual processing (Ramon \& Rossion, 2012). It is also consistent with the holistic-analytic dichotomy proposed in the hemispheric asymmetry literature (Cooper \& Wojan, 2000).

However, recent studies suggest that HP and RH lateralization do not necessarily go together. For example, in Chinese character perception, Hsiao and Cottrell (2009) found that while expert readers showed a reduced HP as compared with novice readers, the left-side bias effect, which is suggested to be an indication of RH lateralization, was shown only in experts ${ }^{1}$. Tso et al. (2014) reported an inverted U-shape development pattern in HP of Chinese characters: as compared with novices, Chinese readers with limited writing experiences showed increased HP, whereas Chinese readers skilled in writing Chinese characters showed reduced. This result suggests that HP is modulated by sensorimotor experiences while RH lateralization is not.

## Theories and model of hemispheric processing

The RH has long been suggested to preferentially execute whole-based/configural/coarse/global processing while partbased/analytic/fine/local processing is more involved in the left hemisphere (LH) (e.g., Sergent, 1982). Ivry and Robertson (1998) proposed the Double Filtering by Frequency (DFF) theory, which suggests that visual information is processed in the brain by frequency-based

[^529]representations at two stages: at the first stage, attention processes select a task-relevant frequency range; at the second stage, high spatial frequency (HSF) information is amplified in the LH while low spatial frequency (LSF) information is amplified in the RH. The DFF theory is able to account for hemispheric asymmetry in processing local (HSF) and global (LSF) information. For example, using Navon's hierarchical patterns (1977; Fig. 1), Sergent (1982) found a left-visual field (LVF)/RH advantage in judgements made based on global information and a right-visual field (RVF)/LH advantage in judgements made based on local information. Similarly, a LVF/RH advantage was found in identifying LSF gratings while a RVF/LH advantage for HSF gratings (e.g., Christman, Kitterie, \& Hellige, 1991). These results suggest that the LH is more tuned to processing local/HSF information while the RH more tuned to processing global/LSF information.

Fig. 1. Hierarchical letter patterns. The pattern on the left shows the global form ' $L$ ' consisting of local elements ' $H$ '. The one on the right shows the global form ' H ' and local elements ' $L$ '.

In visual word recognition, a stronger LH lateralization is typically observed for alphabetic than logographic scripts. Hsiao and Lam (2014) showed that this effect could be accounted for by a computational implementation of the DFF theory: the decomposition of words into graphemes for grapheme-phoneme mapping requires more HSF/LH processing than logographic reading. Hsiao and Cheung (2011) and Hsiao and Galmar (2016) examined the relationship between HP and RH lateralization in visual recognition using the same model (with triangular symbols consisting of 3 English letters and faces respectively). They found a positive correlation between HP and RH lateralization when the recognition task relied purely on the distanced between features (i.e., the second order relationship, a type of configural processing; Maurer et al., 2002), while this correlation became negative when the recognition task relied purely on the identity/features of local components. These results suggest that HP and RH lateralization are separate processes modulated by different recognition requirements. Since the recognition of words in alphabetic languages relies more on the identity of local components for grapheme-phoneme conversion than that in logographic languages, it is possible that alphabetic and logographic reading will result in different relationships between HP and RH lateralization.

## ERP component N170

In EEG studies, the ERP component N170, peaking between 150 and 200 ms after the onset of visual stimulus presentation, was found to be associated with perceptual
expertise effects (e.g. ,Maurer, Zevin, \& McClandiliss, 2008). Consistent with neuroimaging and behavioural research on hemispheric asymmetry in visual object recognition, EEG/ERP studies also showed reliable hemispheric asymmetries of visual expertise effects in N170, such as a larger N170 response in the RH for faces (e.g., Scott \& Nelson, 2007), and a larger N170 response in the LH for words (e.g. Maurer, Brandeis, \& McCandliss, 2005). Thus, the N170 responses towards visual stimuli, which are suggested to reflect occipito-temporal activities in visual object recognition, can be considered an electrophysiological indication of hemispheric asymmetry in visual object processing (e.g., Maurer et al., 2008).

## The present study

Here we aim to examine how different visual object recognition requirements modulate the relationship between HP and RH lateralization. We specifically contrast the difference between visual word recognition in alphabetic and logographic languages, the two major types of scripts currently in use. To do this, we trained participants to recognize artificially-created characters and examined the perceptual and electrophysiological changes. Participants learned to recognize the same set of characters under which the decoding method was manipulated to be using either whole-word (logographic) or grapheme-to-phoneme (alphabetic) approaches. Any difference in the perceptual or hemispheric lateralization changes occurring after the training should mainly come from the difference in the decoding methods (logographic vs. alphabetic). According to the previous studies (e.g., Hsiao \& Galmar, 2016), the requirement of grapheme-phoneme conversion in learning to read the characters alphabetically may induce a negative correlation between HP and RH lateralization, whereas a positive correlation may be observed when learning to read the same characters logographically. This is the first training study to investigate HP and its association with hemispheric lateralization of reading alphabetic and logographic scripts.

## Methods

## Participants

54 college students aged 18 to 26 with no prior knowledge to Korean Hanguls were recruited: 18 of which spoke English as a native language and 34 were Cantonese-English bilinguals who spoke Cantonese as a native language. 25 of them were females. They were right-handed according to the Edinburgh Handedness Inventory (Oldfield, 1971) with normal or corrected to normal vision. Half of them were randomly assigned to the logographic condition while half of them were assigned to the alphabetic condition, with native language and gender matched between the conditions.

## Materials

A total of 30 artificial components were created to make 80 Artificial Korean-like Characters (AKC). The AKCs were of a top-bottom configuration with two top components and one bottom component in each character-this arrangement
simulated the top-heavy configuration of faces as well as a structure of Chinese characters. In the Alphabetic condition, each component in an AKC corresponded to a phoneme. Each AKC mapped onto a syllable with its combination of components following a consonant-vowel-consonant (CVC) phonological rule. In the Logographic condition, each AKC was randomly assigned a syllable pronunciation that appeared in the Alphabetic condition (Fig. 2).

Fig. 2. Examples of (a) AKC components and (b) an AKC

## Training Phrase

Each participant learned all 80 AKCs during 3 learning sessions in 3 consecutive days. Each learning session consisted of two blocks with 40 AKCs learned in each block. Two learning blocks in each learning session allowed participants to be exposed to all 80 AKCs per day. In the Logographic condition, each AKC was shown as a whole character for four times in each trial, accompanied by its pronunciation read by a female voice in each display. Each of the first three displays lasted for 500 ms , with the fourth display stayed on the screen for the participants to familiarize with for 5 seconds. In the Alphabetic condition, each AKC was also shown as a whole character for four times in each trial. A different component was highlighted in each of the first 3 displays, accompanied by the pronunciation of the component's phoneme read in a female voice in each display, for 500 ms . The last display of the AKC was accompanied by the pronunciation of the whole AKC and stayed on the screen for 5 seconds.

To monitor and encourage learning progress, after each learning session, participants completed a forced-choice quiz. In each trial, two AKCs were displayed on the screen accompanied by a syllable sound. Participants chose the AKC that matched the sound by pressing the corresponding buttons on a response box. There were a total number of 160 trials with each AKC-sound pair appearing twice. A feedback on the correctness with the accumulated percentage of correct responses was given immediately at the end of each trial. At the end of the last training session, participants in both the Alphabetic and Logographic condition developed over $80 \%$ accuracy in the quiz.

## Post-test and Pretest

Participants performed a complete composite task and a sequential matching task with EEG recording with AKC stimuli once before and once after the training
Complete Composite Task. We employed the complete composite paradigm to examine HP of AKCs, adopting the procedures from Hsiao and Cottrell (2009). Eighty pairs of AKCs taught in the training were selected. 20 pairs were presented in each of the four conditions: same-congruent, different-congruent, same-incongruent, and differentincongruent trials (Fig. 3a). In the congruent trials, the
attended halves and the irrelevant halves led to the same response (i.e. both the attended part and the irrelevant part were the same or different). In the incongruent trials, the attended halves and the irrelevant halves led to different responses: In same incongruent trials, the attended halves were the same while the irrelevant halves were different; whereas in different incongruent trials, the attended halves were different while the irrelevant halves were the same ${ }^{2}$.

Each trial started with a fixation cross for 1000 ms , followed by a cue indicating the part that participants should attend to (either top or bottom) for 1000 ms . A pair of AKCs-one above and the other one below the initial fixation respectively, about five degrees of visual angel away from each other-appeared for 500 ms , followed by a mask. Participants were instructed to judge whether the attended halves of the two AKCs were the same or not as quickly and as accurately as possible by pressing the corresponding buttons on the response box (Fig. 3). Accuracy of each trial was recorded.

Fig. 3. (a) Illustration of stimulus pairs in the complete composite paradigm; the attended components are circled in red. (b) Trial sequences, the red line shows the splitting point between top and bottom halves.

Each AKC was approximately $1.5 \mathrm{~cm} \times 1.5 \mathrm{~cm}$ in size on the screen, spanned about 1.6 degree of visual angle at a viewing distance of 55 cm . The participants' discrimination sensitivity A' was measured as:

$$
A^{\prime}=0.5+\left[\operatorname{sign}(H-F) \frac{(H-F)^{2}+|H-F|}{4 \max (H, F)-4 H F}\right]
$$

where H and F are the hit and false alarm rate respectively. We used $A^{\prime}$ to measure sensitivity due to its bias-free nonparametric property, as $d^{\prime}$ may be affected by response biases when normality and equal standard deviations are not assumed (Stanislaw \& Todorov, 1999). We measured Holistic $A^{\prime}$ as a normalized measure of HP that takes into consideration the individual baseline performance differences (Singer \& Sheinberg, 2006): the greater the magnitude, the stronger the degree of holistic processing.

$$
\text { Holistic } A^{\prime}=\frac{A^{\prime} \text { in congruent condition }-A^{\prime} \text { in incongruent condition }}{A^{\prime} \text { in congruent condition }+A^{\prime} \text { in incongruent condition }}
$$

[^530]EEG recording and analysis A sequential matching task was used to measure ERPs in response to the presentation of AKCs. The task consisted of 240 trials, separated into 6 blocks. Each trial started with a central fixation for 500 ms , followed by an AKC appearing at the screen center for 150 ms . The screen then turned blank for 1000 ms . A second character then appeared at the center and remained until participants made a response judging whether the two characters were the same or different. Each character subtended a visual angle of around 1.7 degree. Participants were instructed not to blink during a trial until they saw the letter ' B ' on the screen. These trials were conducted using E-prime v2.0 (Psychology Software Tools, Pittsburgh, PA).

EEGs were recorded using a 64-channel ANT system (Electro-cap International). EEG activities were sampled at 512 Hz . The data analysis was performed using EEGLAB (Delarme \& Makeig, 2004) and ERPLAB (Lopez-Calderon \& Luck, 2014). Only trials with correct responses were included in the EEG analysis. Bin-based epochs were extracted from -200 ms to 800 ms of the stimulus onset. The time window 140 to $200 \mathrm{~ms}(170 \pm 30 \mathrm{~ms})$ was chosen based on the grand average data of the participants in the Alphabetic and Logographic training conditions for identifying N170 peak amplitudes. PO7 electrode in the LH and its symmetrical electrode PO8 in the RH were selected for analysis as these electrodes were where the peak amplitude was found within the selected time window (see Hsiao et al., 2007 Yoncheva et al., 2010).

## Results <br> Holistic processing (HP)

Repeated-measures ANOVA was used to investigate HP effects (time: Pretest vs. Post-test x condition: alphabetic vs. logographic). For Holistic $A^{\prime}$, there was a marginal effect of time, $F(1,47)=2.868, p=.097, \eta_{p}{ }^{2}=.057$ : HP decreased as the result of training. There was no main effect of condition or an interaction between time and condition. ${ }^{3}$ (Fig. 4).

Fig. 4. Holistic A' in the pretest and post-test in the Alphabetic and Logographic conditions

## EEG neural correlates

Mixed ANOVA was used for analyzing N170 peak amplitude data (Time: Pretest vs. Post-test x Hemisphere:

[^531]Left vs Right x Condition: Alphabetic vs. Logographic). A significant main effect of time was observed, $F(1,53)=$ $7.457, \mathrm{p}=.009, \eta_{p}{ }^{2}=.123$, showing that N170 amplitude was increased after training. There was a marginal main effect of hemisphere, $F(1,53)=3.064, \mathrm{p}=.086, \eta_{p}{ }^{2}=.055$, and a marginal effect of condition, $F(1,53)=3.678, p=$ $.061, \eta_{p}{ }^{2}=.065$. No significant interaction effect was observed.

Fig. 5. N170 responses ( $\mu \mathrm{V}$ ) in (a) PO7 (left hemisphere) and (b) PO8 (right hemisphere) in the pretest and post-test, averaged across all participants.

## Pearson's correlation and moderation analysis

Correlation analyses between Holistic $A^{\prime}$ and N170 amplitude at PO7 (LH) and PO8 (RH) were performed separately for the Alphabetic and Logographic conditions to examine the relationship between HP and RH lateralization. In the Alphabetic condition, Holistic $A^{\prime}$ in the post-test was correlated positively with the N170 amplitude at PO8 (RH) in the post-test, $r^{2}=.435, p<0.05$, as well as the N170 amplitude change between the pretest and the post-test at PO8, $r^{2}=.506, p<0.05$. In contrast, these correlations were negative in the logographic condition, $r^{2}=-.483, p<0.05$, and, $r^{2}=-.409, p<0.05$, respectively. See Fig. 6

Fig. 6. The correlation between Holistic A' and PO8 N170 Amplitude ( $\mu \mathrm{V}$ ).

To further understand the differences in the direction of the correlations between Holistic A' and N170 amplitude at PO8 in the post-test, a moderation analysis was conducted. In the first step, training condition (Logographic vs. Alphabetic) and N170 amplitude at PO8 were entered in the regression analysis. In the second step, the interaction term between training condition (Logographic vs. Alphabetic) and N170 amplitude at PO8 was entered, and it explained a significant increase in variance in Holistic $A^{\prime}, \Delta R^{2}=0.203$, $\mathrm{F}(1,48)=11.593, p=.001$. Thus, training condition significantly moderated the correlations between Holistic A'
and N170 amplitude at PO8 in the post-test: While a more negative/larger N170 amplitude at PO8 correlated with a weaker HP effect in the alphabetic condition, a more negative/larger N170 amplitude at PO8 correlated with a stronger HP effect in the logographic condition (Fig. 5). This suggests a stronger N170 activity correlated with a weaker HP effect in the alphabetic condition, while it is vice versa in the logographic condition in the RH. However, we did not find significant correlations between HP and N170 at PO7 in either condition.

## Discussions

In the current study, we aimed to examine how learning to read words alphabetically or logographically modulates the relationship between holistic processing (HP) and right hemisphere ( RH ) lateralization in the perception of visual words. Previous computational modeling studies have suggested that in visual object recognition, when the recognition task relies purely on the distances among local components (second order relationships, a type of configural processing; Maurer et al., 2002), there was a positive correlation between HP and RH lateralization. In contrast, when the recognition task relies purely on the identity of local components, this correlation becomes negative (Hsiao \& Cheung, 2011; Hsiao \& Galmar, 2016). This result is consistent with the face recognition and perceptual expertise literature, which typically shows an increase in HP coincided with RH lateralization, especially when the task involved processing of configural information (e.g., Gauthier \& Tarr, 2002; Ramon \& Rossion, 2012). It is also consistent with the literature on expert Chinese character processing: decreased HP due to writing experience, which required selective attention to local components, was correlated with increased left side bias/RH processing (Tso et al., 2014). Here we tested this modeling prediction through a training study, in which we measured changes in HP and ERP N170 amplitude as the result of learning to read artificial Korean-like characters (AKCs) either alphabetically or logographically.

Our study revealed that training to read AKCs in either the Alphabetic or the Logographic conditions increased N170 amplitude in both hemispheres at electrodes PO8 and PO7. This result is consistent with the perceptual expertise literature, which typically showed an increased N170 amplitude as the result of the expertise (e.g. Maurer et al., 2008; Tanaka \& Curren, 2001).

More importantly, in the post-test, we found that the HP effect of AKCs correlated with N170 amplitude in the RH differently between the 2 conditions: while the correlation analysis showed the stronger the HP effect, the more negative the N170 amplitude at PO8 in the Logographic condition, the direction of this correlation was reversed in the Alphabetic condition. It seems that different learning approaches to recognizing a written script moderates the direction of the correlation between HP and neural activities in the right occipital temporal regions. This effect is consistent with the modeling data based on the DFF theory
(Hsiao \& Galmar, 2016; Hsiao \& Cheung, 2011). In the Logographic condition, participants may have used a wholeword recognition approach, which led to increased HP, as well as a higher sensitivity to the distances the components, a type of configural processing (Maurer et al., 2002). This type of configural processing has been shown to involve RH lateralization (Scott \& Nelson, 2006). Thus, in this condition, RH lateralization and holistic processing are positively correlated with each other. In contrast, in the Alphabetic condition, the requirement of graphemephoneme conversion during learning may have encouraged local featural/high spatial frequency processing for identifying local component, which is typically leftlateralized (Ivry \& Robertson, 1998). In addition to identifying local components, word recognition in the Alphabetic condition also required recognizing components in a particular sequence/configuration, or more specifically, the first order relationship among features (Maurer et al., 2002). This processing may require integration of information among components, leading to increase in HP. Thus, in the Alphabetic condition, HP was negatively correlated with RH lateralization, since the increase in HP due to the use of configural information for relative positions of components (i.e., the first order relationship among features) may coincide with decreased reliance on RH global processing. Future work will examine these possibilities.

Consistent with the modeling data, the current results suggest that HP (as measured in the composite paradigm) and RH lateralization do not always go together in visual object recognition. It depends on the requirements of the recognition task. Consistent with this finding, in an fMRI study, Harris and Aquirre (2010) showed that neurons in the right occipito-temporal region (fusiform face area, FFA) could flexibly represented two facial features either conjointly (suggesting HP) or separately, depending on the recognition task requirements. Note however that our current results regarding the relationship between HP and RH lateralization is limited to the HP as measured in the composite paradigm. In the literature, HP effects have been demonstrated using different paradigms, such as the partwhole task (Farah, Wilson, Drain, \& Tanaka, 1998) in addition to the composite paradigm. HP effects demonstrated using different paradigms likely involve different underlying mechanisms (Richler et al., 2012). Future work will examine whether similar relationships between HP and RH lateralization can also be observed using other HP paradigms.

In conclusion, this is the first training study to report on the changes in both HP and hemispheric lateralization in learning to read an artificial script under different decoding methods (i.e., logographic vs. alphabetic). Different learning approaches induced opposite directions of correlations between HP and RH activities: Learning a script alphabetically induced a negative correlation between HP and RH lateralization, while that induced by learning a logographic script was positive. It seems that HP and RH
lateralization do not always go together, depending on the decoding strategy in visual object recognition, or more specifically, the type of configural information used in the recognition processes.

#### Abstract

Even advanced Spanish speakers of second language English tend to confuse the pronouns 'he' and 'she', often without even noticing their mistake (Lahoz, 1991). A study by AntónMéndez (2010) has indicated that a possible reason for this error is the fact that Spanish is a pro-drop language. In order to test this hypothesis, we used an extension of Dual-path (Chang, 2002), a computational cognitive model of sentence production, to simulate two models of bilingual speech production of second language English. One model had Spanish (ES) as a native language, whereas the other learned a Spanish-like language that used the pronoun at all times (non-pro-drop Spanish, NPD_ES). When tested on L2 English sentences, the bilingual pro-drop Spanish model produced significantly more gender pronoun errors, confirming that pronoun dropping could indeed be responsible for the gender confusion in natural language use as well.

Keywords: L2 pronoun errors, language transfer, Dual-path model, bilingual sentence production

## Introduction

Second language (L2) speech errors have been employed in the past as a means to understand bilingual speech production as well as the acquisition process of a foreign language (Antón-Méndez, 2010; Poulisse, 1999). Certain L2 errors are observed more often due to discrepancies between the first language (L1) and the L2. For example, if the expression of a message in the L 2 requires the inclusion of a specific feature that would not be necessary in the L1, then speakers of these two languages may produce a speech error in their L2 due to L1 transfer (Odlin, 1989). In this study, we focus on a gender-related L2 pronoun error that has been observed among native speakers of Spanish and Italian; namely, errors involving the third person singular nominative pronouns 'he' and 'she'. Even advanced Spanish speakers of L2 English occasionally confuse the two pronouns, referring to an actress as 'he' or a father as 'she', often without even noticing their mistake (Lahoz, 1991). At first, this phenomenon seems surprising because the Spanish language does have two equivalent pronouns ('él' for 'he' and 'ella' for 'she'), and also a very strong separation between the two genders, even more so than in English. For instance, depending on the suffix a word can be feminine or masculine (e.g., maestro - teacher
[masculine], maestra - teacher [feminine]; niño - child [masculine, a.k.a. boy], niña - child [feminine, a.k.a. girl]). This means that the gender mistakes that Spanish speakers make in English cannot be attributed to the lack of familiarity with the distinction. Furthermore, the challenge the English pronoun system poses for native speakers of Spanish could not be due to its inherent difficulty, as this would mean that most non-native speakers of English, regardless of their L1, would produce the same mistake. As Lahoz (1991) noted, a low proficiency level of the native Spanish speakers is not a reason either. This was also demonstrated in the experiments of Antón-Méndez (2010), where the participants showed an intermediate to upper intermediate knowledge of English. Finally, note that the gender mismatch error cannot be classified as a syntactic error; the produced sentence is grammatically correct, but it conveys the wrong meaning.

A hypothesis which has been put forward (Lahoz, 1991; Antón-Méndez, 2010) regarding the cause of errors in the use of English pronouns is the pro-drop status of the Spanish but not the English language. In pro-drop languages, nominative personal pronouns are often omitted (1b) because the number and person information is conveyed in the conjugated verb (Davidson, 1996), whereas in English the omission of the pronoun would result in an ungrammatical sentence (2b).
1.(a) Él/ella tiene un perro (Spanish)
(b) tiene un perro
2.(a) $\mathrm{He} /$ she has a dog (English)
(b) * has a dog

It is hard to imagine, however, how the pro-drop feature of the L1 might result in a gender pronoun error ("He's walking", when referring to a woman) instead of an omission ("Is walking"), which would be the case in a direct language transfer.

As a matter of fact, native speakers of Spanish have been noted to produce another gender-related pronoun error in English, this time regarding possessive pronouns ('his', 'her'). Due to the high frequency of this type of errors, a lot more
emphasis has been given to the misuse of these pronouns than the subject pronouns (White, Muñoz, \& Collins, 2007; Anton-Mendez, 2011). The reason that English possessive pronouns pose a challenge for native speakers of Spanish is most likely that in Romance languages the possessive pronoun agrees in gender and number with the possessum, namely the noun that follows, whereas in Germanic languages such as English the possessive pronoun refers to the antecedent. For example:
i. His daughters are on vacation.
[his: 3rd person masculine singular]
ii. Sus hijas están de vacaciones.
[sus: 3rd person feminine plural]
Due to the different information encoding Spanish speakers of English may occasionally make gender mistakes such as "He called her mother", where 'her' refers to the antecedent ('he') and not a different female person. This is because 'mother' is female, and a Spanish speaker would use that gender information to construct the possessive pronoun in Spanish. The resulting error in English is, of course, confusing, as a speaker of English would not guess that 'her' in this case refers to the same subject ('he'). The gender error in the case of L2 English possessive pronouns seems clearly due to L1 transfer, because the properties of Spanish are directly applied to English. In the case of the subject pronoun gender errors, on the other hand, it is not evident that the pro-drop feature of one language would lead to a gender error in L2. The present study addresses only the latter type of errors.

Antón-Méndez (2010) has investigated the hypothesis that the pro-drop feature of Spanish is responsible for the gender pronoun errors in L2 English ("pro-drop hypothesis"). She conducted an experiment eliciting semi-spontaneous speech in English, where she compared native Spanish and native French speakers of L2 English with respect to the pronoun errors they produced. French was chosen as it is a Romance language that is similar to Spanish in several aspects, but which, in contrast to the Spanish language, is not a pro-drop language. Each test group consisted of 20 participants who were comparable in terms of education, age of English acquisition, frequency of use and proficiency. The participants were shown 43 illustrations and were asked questions designed to elicit pronoun production. The subjects were instructed to respond freely, and the pronoun errors they produced were recorded. The types of reported errors fall in the following categories: person errors (e.g., 'I' instead of 'you'), number errors (e.g., 'I' instead of 'we'), gender errors ('he' instead of 'she' and vice-versa), animacy errors (e.g., 'he' instead of 'it'), omission errors (e.g., 'is swimming'), insertion errors (e.g., 'the boy he played' instead of 'the boy played') and other errors (e.g., 'it' instead of 'there' in 'there is').

Spanish speakers of L2 English indeed made significantly more gender errors $(4.30 \%)$ compared to other types of pro-
noun errors and to the French group $(0.68 \%)^{1}$. The pronoun errors recorded were not due to erroneous transfer of the Spanish L1 grammar, as the Spanish speakers made no omission errors ('is swimming'); thus, in none of the items of Antón-Méndez's experiment did the subjects omit a pronoun, which would have been the case in a grammatical transfer. Importantly, even though there were slightly more 'he' than 'she' errors (he: $5.68 \%$, she: $2.98 \%$ ), the difference is not statistically significant. Therefore, the Spanish speakers were not using a default pronoun (e.g., always 'he' instead of 'she'). The use of 'he' as the default pronoun would have suggested that another factor might underlie the error, for instance, the difficulty that the English phonology poses for speakers of Spanish. The Spanish phonology does not contain the phonemes $/ \mathrm{J} /$ in 'she' and $/ \mathrm{h} /$ in 'he', therefore one explanation for the gender pronoun issue could be at the phonological level. In the present study we focused only on the pro-drop feature, not because we disregard the potential role of the phonology, but because we wanted to investigate whether the pro-drop feature has the capacity of causing this type of gender errors in L2.

In order to focus on the pro-drop feature, we simulated bilingual sentence production using computational cognitive modeling. The pro-drop feature is not the sole difference between the French and Spanish languages, and one could argue that the differences in the error patterns between the two groups could have been partially attributed to confounding factors, for instance, to a different L2 English teaching system in Spain and France.

Using computational modeling we can remove all possible confounds and therefore minimize the variance by focusing only on the phenomenon of interest, which in this case is the pro-drop feature and its possible effect on L2 English pronouns. For this reason, we modified Dual-path (Chang, 2002), a computational cognitive model of sentence production, to account for bilingualism. We then compared L2 English speech production of simulated native speakers of Spanish (ES) on the one hand, to L2 production of simulated native speakers of a Spanish-like language ('non-pro-drop Spanish', NPD_ES) on the other hand. The latter contained all the features of the Spanish language (lexicon, allowed structures) except the pro-drop feature; therefore, pronouns needed to be used at all times. All input languages (ES, NPD_ES and EN) were artificially generated and based on the Spanish and English language, using a subset of their lexica and syntactic structures. If the bilingual Spanish-English (ES-EN) Dualpath model produces significantly more subject pronoun errors in English than its Spanish-like non-pro-drop equivalent (NPD_ES-EN), it will be clear that the pro-drop feature of the Spanish language is the reason for this particular L2 error in the simulation, as the two simulated languages differ only in their pro-dropness. If this is the case, we will have confirmed

[^532]that the pro-drop feature has the capacity to lead to gender pronoun errors in L2 English.

## Method

In order to simulate Spanish speakers of L2 English, we developed two bilingual models using a modified version of Dual-path which is a connectionist model based on the Simple Recurrent Network (SRN; Elman, 1990) achitecture (Chang, 2002).

## Bilingual Dual-path model

Dual-path (Figure 1) learns to convert a message into a sentence by predicting the sentence word by word ("next word prediction"). It has two pathways (hence the name) that influence the production of each word; the meaning system which learns concepts, roles and event semantics, and the sequencing system which is an SRN that learns to abstract syntactic patterns. Both paths influence the word output layer. The sequencing system consists of one recurrent hidden layer (of 30 units in our simulations) and two "compress" layers (of 12 units each) that are placed between the input word, the hidden layer and the output word.

The meaning system learns to map the input word onto a concept, which is linked to a specific thematic role (that is given for each sentence through fixed connections). The fixed connections allow the separation between concepts and roles, which, in turn, enables the model to generalize and to produce words in novel places. The thematic role is connected to the hidden layer, and so is the "event-semantics" layer. The hidden layer spreads the activation to the next thematic role (in the meaning path, and the "compress" unit in the syntactic path), which is in turn linked to a specific predicted concept that is used as input to the output word layer, along with the "compress" unit.

In the original model, all layers use the tanh activation function, except the output layer that uses softmax. In the modified version of the model, we also employed softmax for the predicted role layer. This led to a stricter selection of the upcoming thematic role which helped overcome a difficulty that the model had with learning the correct articles regarding gender and definiteness (e.g., 'a' vs 'the'). Furthermore, our version has a "target language" layer in the meaning path that is used as an additional input to the hidden layer, along with the "event-semantics" layer. The "target language" denotes the intended spoken language and helps the model handle more than one language. The modified model can be found at https://github.com/xtsoukala/dual_path.

## Input languages

Message Dual-path is trained using randomly generated sentences paired with their meaning (Chang, Dell, \& Bock, 2006). The meaning (message) contained information regarding four thematic roles (AGENT, PATIENT, ACTION, RECIPIENT). A concept (e.g., 'WOMAN' for the English word 'woman' or Spanish word 'mujer') was assigned to each thematic role depending on the meaning that needed
to be expressed (e.g., in the sentence "the woman run -s" the message would include AGENT=WOMAN, DEF). Furthermore, the message contained event-semantic information (denoted as ' $E$ '), which gave information regarding the tense (PRESENT or PAST) and aspect (SIMPLE or PROGRESSIVE). The message contained information about the target language (ES or EN) as well. This information was given at the beginning of the sentence along with the roles and the event-semantics, so that the model knew whether it was supposed to produce an English or Spanish sentence.

Structures The allowed structures for all languages were the following (where ' $S$ ', the subject, is omitted in the prodrop case):

1. (S)V: (Subject) - Verb, e.g., "He runs"
2. (S)VO: (Subject) - Verb - Object, e.g., "She kicked the ball"
3. (S)VIODO: (Subject) - Verb - Indirect Object - Direct Object, e.g., "He gave the girl a book"
4. (S)VDOIO: (Subject) - Verb - Indirect Object - Direct Object, e.g., "He gave a book to the girl"

The sentences in English and in non-pro-drop Spanish always started with a pronoun, and the sentences in pro-drop Spanish never started with a pronoun but always with a verb.

Lexicon The total lexicon consisted of 34 nouns: 11 male ('man', 'boy', 'father', 'brother', 'dog', 'hombre', 'niño', 'padre', 'hermano', 'perro', 'maestro'), 11 female ('woman', 'girl', 'mother', 'sister', 'cat', 'mujer', 'niña', 'madre', 'hermana', 'gata', 'enfermera') and 12 inanimate ('ball', 'stick', 'toy', 'kite', 'key', 'bag', 'pelota', 'palo', 'juguete', 'cometa', 'llave', 'bolso'), 24 verbs (e.g., 'give', 'show', 'walk', 'throw', 'present', 'dar', 'lanzar', 'presentar', 'nadar', 'caminar') and 26 function words (e.g., articles ('a', 'the', 'un', 'una', 'el', 'la'), pronouns ('he', 'she', 'él', 'ella') and auxiliary verbs ('is', 'was', 'está', 'estaba')).

The model treats the verb lemma ('give') and the suffix ('-s') as two different units. Note that syntactic information (such as 'verb', 'noun') is not given explicitly, but is learned by the model during training through the syntactic path. The syntactic gender was also learned implicitly during training through the article of Noun Phrases (NP) and pronouns. Semantic gender (e.g., 'ACTRESS, F', 'ACTOR, M') was not included in the model.

Thematic roles could be expressed using either an NP with definite (DEF) or indefinite (INDEF) articles (e.g., 'the woman', 'a woman') or the pronoun (PRON) equivalent ('she').

Figure 1: Bilingual Dual-path model

Example The following message would be the same across languages:

AGENT=WOMAN, PRON;
ACTION=GIVE;
PATIENT=INDEF, KEY;

## RECIPIENT=DEF, GIRL;

E=SIMPLE, PRESENT, AGENT, PATIENT, RECIPIENT
and it would be expressed linguistically in the following manner for the three languages:

1. she give -s the girl a key. [EN]
2. d -a a la niña una llave . [ES]
3. ella d -a a la niña una llave . [NPD_ES]

## Training

The two models were trained on 2000 randomly generated sentences (training set) and tested on 500 unseen sentences (test set). The models contained almost identical sets, with the only difference that the NPD_ES model expressed the subject pronoun at all times, whereas the ES model never did and always started with a verb. For each model we ran 100 simulations using the same input, but different random initial weights per simulation, as the input and the weights are the only non-deterministic parts of the model. The models were trained for 20 epochs, where 1 epoch corresponds to a full iteration of the training set ( 2000 sentences). At the beginning of each epoch, the training set was shuffled. In order to simulate late L2 acquisition, we first trained the models for 20 epochs using Spanish input only, and then used the fully trained weights as initial weights for the bilingual models. The bilingual input consisted of newly generated (2000 training and 500 test) sentences, this time using $50 \%$ (prodrop or non-pro-drop according to the model) Spanish and $50 \%$ English. We excluded from the analysis 7 simulations that did not manage to learn at least $75 \%$ of the test set by

Figure 2: Performance on the training and test sets over the training period ( 20 epochs) averaged over 93 simulations for the two bilingual models. Performance is measured in percentage of correctly produced Spanish and English sentences.
the end of the training in one of the two models, leading to a total of 93 simulations. Both bilingual models were able to perform equally well by the end of the training, reaching $99.69 \%$ correct for ES-EN and $99.70 \%$ correct for NPD_ESEN (Figure 2) on the test set that contained English and Spanish sentences.

## Results

In order to assess the performance of the two bilingual models on L2 pronouns, we focused only on the English sentences ( $50 \%$ of the test set). If a pronoun error was detected and the sentence was grammatical, it was classified as a gender pronoun error. We compared the performance of the two bilingual models with regard to the gender pronoun error production. If the models had a comparable performance we would not be able to confirm that the pro-drop feature has the capacity to lead to gender pronoun errors in L2 English. If, on the other hand, the NPD_ES model made fewer gender pronoun

Figure 3: Production of English gender errors (in log scale) averaged over 93 simulations for the two bilingual models. Note that the gaps in the non-pro-drop model are because $\log (0)$, for $0 \%$ error rate, is not defined, and therefore not plotted.
errors than the ES model it would indicate that the pro-drop feature is a possible explanation.

The non-pro-drop Spanish-English (NPD_ES-EN) bilingual model (Figure 3) produced almost no gender pronoun errors (maximum percentage: $0.11 \%$ ) whereas the bilingual model based on pro-drop Spanish (ES-EN) initially produced $9.75 \%$ pronoun errors, gradually dropping to $0.05 \%$.

Crucially, the ES-EN model never reached $0 \%$ (minimum error rate: $0.02 \%$ ) whereas the NPD_ES-EN model did. Following visual inspection, we ran a $z$-test for proportions from epoch 5 onwards to test for a difference in error rate between the models. The difference is significant $(z=7 ; \mathrm{p}<.001)$.

## Discussion

Our simulations showed that a bilingual model with L1 prodrop Spanish and L2 English produced significantly more gender pronoun errors than a similar model with L1 non-prodrop Spanish. These sentences were grammatically correct: the only error they contained was a pronoun with incorrect gender. Given that the only difference between the two L1s was the pro-drop feature, we have demonstrated that the prodrop nature of Spanish can indeed cause the gender pronoun error as observed in L1 Spanish speakers of L2 English.

Why the pro-drop feature does not lead to a direct language transfer ("is walking") in either the model or humans remains to be investigated, as the current simulations and results do not explain how pro-dropness in L1 could lead to gender errors in L2. Nevertheless, having a computational model that simulates the gender pronoun errors in L2 English can point us in the right direction. Our hypothesis for the occurrence of the gender error is that the gender information is not as crucial for the message planning, at least in the subject position, of a pro-drop language, and is therefore weaker or omitted,
even when producing sentences in a non-pro-drop L2.
It is important to point out that the Dual-path model does not contain a phonological level (Garrett, 1988). One might have thought that the reason Spanish speakers confuse the words 'he' and 'she' is because of the difficulty the English phonology poses for native speakers of Spanish. However, our simulations have produced gender errors without having any phonological representations. This does not mean that phonology could not play a role, but rather that it is not the only possible explanation.

It is also crucial to note two simplifying assumptions in these simulations. First, as mentioned in the Method section, the input for all three languages (EN, ES, NPD_ES) was artificially generated and it only represented a subset of the actual languages. In general, using natural input would be preferable as it would increase the validity and naturalness of the results. However, the benefit of miniature languages that are typically used in cognitive modeling is that they can be easily manipulated. For instance, in the simulations described here we were able to add and remove the pro-drop feature at will, leaving everything else the same, and thus to isolate this important feature from confounding factors.

Second, a crucial simplifying assumption in the miniature language is the absence of full NP subjects. We therefore repeated the simulations using new input for all languages, this time including $50 \%$ pronouns at the subject position and $50 \%$ noun phrases. Preliminary simulations show no gender errors in either model, which means that further research is needed using more natural language input, starting with a more naturalistic proportion of pronouns and NPs in the subject position based on English and Spanish corpora.

## Conclusion

Computational modeling can be used to validate or generate linguistic hypotheses while focusing on specific factors of interest and minimizing the variance. In this study, we have addressed the question as to whether the pro-drop feature of the Spanish language has the capacity to cause the gender pronoun errors that Spanish speakers of L2 English have been shown to produce (Lahoz, 1991; Antón-Méndez, 2010). The reported simulations showed that the model with L1 pro-drop Spanish produced more gender pronoun errors in L2 English than the model with L1 non-pro-drop Spanish, which is a necessary but not sufficient condition for the pro-drop hypothesis.

#### Abstract

Statistical learning paradigms traditionally use transitional probabilities as a measure of statistical distribution within a language. The current study suggests that alternative metrics may exist that can account for differences in language processing ability. Two primed lexical decision tasks are used to examine the effects of bigram frequency and diversity on speed and accuracy of word recognition. It is demonstrated that both frequency and diversity contribute to word recognition performance; findings and theoretical implications are discussed.

Keywords: Statistical learning; lexical decision; language

## Introduction

Humans are superlative learners capable of identifying and tracking patterns in their environment, both implicitly and explicitly. This ability has been investigated using both implicit and, more recently, statistical learning paradigms (Perruchet \& Pacton, 2006) across a number of different domains including shapes (Kirkham, Slemmer, \& Johnson, 2002), music (Daikoku, Yatomi, \& Yumoto, 2014; Koelsh et al., 2016; Saffran et al., 1999), tactile stimuli (Conway \& Christianson, 2005) and, most prominently, language acquisition (Newport \& Aslin, 2004; Saffran, Aslin, \& Newport, 1996; Thiessen, \& Erickson, 2013; Vouloumanos, 2008) highlighting the ability of learners, ranging from infant (Saffran et al., 1996) to adult (Koelsh et al., 2016), to track the transitional probabilities (TPs) within a given set of stimuli.

Over the past two decades a plethora of researchers have investigated this phenomenon and have found transitional probabilities to be a robust indicator of performance across a number of different tasks and languages (e.g. Liu \& Kager, 2011; Toro, Sinnett, Soto-Faraco, 2005). This has led to the acceptance of TPs as the standard metric of co-occurrence within natural (and artificial) languages. However, if we consider that the TP of any given stimulus stems from an
interaction between the frequency of sequence XY and the number of potential candidates for Y then we are presented with two alternative metrics of statistical distribution. These, in turn, can be used to investigate the types of statistics which learners can attend to.

When applied to words in natural language these metrics can be termed Bigram Frequency, which is equal to the total number occurrences for a given sequence of two words within a language or representative selection thereof; and Bigram Diversity which can be defined as the number of items that potentially follow word X in the sequence XY .

It is logical to presume that both bigram frequency and diversity would be predictive of performance in languagerelated tasks. Evidence from Freudenthal et al. (2015) demonstrates that a frequency-based chunking mechanism can successfully reduce output errors in children's speech. This suggests that learners can track not only the TPs of the bigrams but also the frequency with which they occur. No evidence yet exists for a diversity-driven account of language proficiency. Nonetheless, it is recognised that predictability is an important facet of language processing (Bates \& MacWhinney, 1987; Glenberg \& Gallese, 2012; Goldberg, Casenhiser, \& Sethuraman, 2005; Pickering \& Garrod, 2004, 2007; Van Berkum et al., 2005); it follows therefore that a larger number of potential competitors for stimulus Y would serve to reduce predictability and thereby prove detrimental to response fluency.

Historically statistical learning paradigms such as those developed by Jusczyk and Aslin (1995, also Saffran, Aslin \& Newport, 1996) have exposed learners to artificial languages with carefully built-in TPs. This allows for admirable control of the input at the expense of both diversity and complexity. It has been argued that these languages are too simplistic to assess the extent to which learners are able to process distributional statistics within natural language (Frank et al, 2010; Johnson \& Tyler, 2010). To highlight this point, Saffran et al. (1996) reported
inter-syllable TPs of 1.0 in their seminal study whereas naturally occurring TPs are often considerably lower (the bigram little baby has a TP of less than 0.002).

Thus, the true test of statistical learning theories is their application to a more naturalistic dataset, one which retains the complexity and diversity of natural language whilst allowing for the accurate tracking of distributional cues; natural language corpora represent such datasets. The British National Corpus (BNC) is a collection of contemporary natural language which comprises approximately 100 -million words of written and spoken British English drawn from a variety of sources ranging from telephone calls to academic journals. By analysing the distributional statistics within the BNC it is possible to present learners with verisimilar but also quantifiable samples of natural language.

This raises another issue however, in that learners already have a great deal of experience interacting with natural languages. This makes traditional methods of testing such as those used by Saffran et al. (1996, also Frank et al., 2010; Jusczyk \& Aslin, 1995) unsuitable for natural language stimuli. Thus, two solutions are immediately apparent; the use of unfamiliar or non-native languages or an alternate method of assessment. Non-native languages would seem to be the ideal solution except that the complexity of these languages means that learners require either long periods of familiarisation or simplified samples in order to obtain actionable data. It is therefore favourable to introduce an alternate measure of language proficiency whilst retaining the complexity of the language and avoiding a lengthy familiarisation process.

The current study seeks to address this issue by assessing language proficiency using a primed lexical decision task (LDT) where the first word of a bigram acts as the prime and the second word the target. It is predicted that, using bigram frequency and diversity as statistical primes, response time for stimuli Y will be predicted by the strength of its association with prime X. Based on this prediction two hypotheses are proposed:

H1: Response times on a LDT will be quicker when primed with high frequency bigrams compared to low frequency or non-bigrams, and

H2: Response times will also be quicker when primed with low diversity bigrams compared to high diversity or non-legal bigrams

## Method

## Participants

Thirty-one participants ( 25 females) aged between 18 and 41 years ( $M=20.77, S D=4.17$ ) were recruited from Nottingham, UK. All participants reported English as their first language and were screened for language difficulties. Participants took part in both experiments and received research credits in exchange for their participation where applicable. An a priori power analysis showed that a sample of at least twenty-four participants was necessary to achieve statistical power of above .8.

## Experiment One

## Design

Experiment one used a LDT to assess the extent to which bigram frequency affects word recognition. The aim of the experiment was to identify any statistical priming effect that may result from high frequency word pairs within natural language.

## Materials

Three 30 -item lists were generated using bigrams found within the BNC in addition to one 90 -item non-word list which was created using entries from the ARC Non-word database (Rastle, Harrington, \& Coltheart, 2002). The BNC contains only samples of British English which increases its validity as a natural language representation for a UK sample.

Bigrams were extracted from the BNC by using a python script to parse the .xml version of the corpus into word pairs before writing them to a database and tallying the number of occurrences. This resulted in a list of $12,293,349$ unique bigrams. A further script was used to remove any bigrams with a frequency of less than 0.1 per million since these were considered too infrequent to provide meaningful data. The remaining corpus was then filtered to exclude any bigrams containing acronyms, initialisations, contractions, hyphenations, non-standard or non-English words, names, numbers expressed as digits, or words with fewer than three letters.

Table 1: Diagnostic means and standard deviations for target words

|  | Bigram Type | Log(Frequency) | Concreteness | Letters | Phonemes |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Experiment one | High Frequency | $3.20(3.86)$ | $3.10(1.09)$ | $5.01(1.48)$ | $4.10(1.24)$ |
|  | Low Frequency | $3.21(3.87)$ | $3.11(1.41)$ | $4.92(1.41)$ | $3.97(1.18)$ |
|  | Non-Bigrams | $3.20(3.86)$ | $3.10(1.08)$ | $5.00(1.48)$ | $4.05(1.27)$ |
| Experiment two | High Diversity | $2.08(0.27)$ | $2.85(0.98)$ | $5.43(1.17)$ | $4.33(1.15)$ |
|  | Low Diversity | $2.01(0.49)$ | $3.96(1.00)$ | $5.00(0.88)$ | $4.00(0.96)$ |
|  | No Diversity | $2.18(0.02)$ | $3.21(1.03)$ | $5.06(1.26)$ | $4.20(1.19)$ |

Stimuli lists were organised according to the frequency with which the bigrams occur within the BNC; the three lists contained bigrams of high ( $>100$ occurrences) or low frequency ( $<20$ occurrences), or bigrams consisting of words that do not appear together in the BNC. A number of metrics were obtained for each of the bigrams including word frequency (http://ucrel.lancs.ac.uk/bncfreq/flists.html), concreteness (Brysbaert, Warriner, \& Kuperman, 2014), number of letters, and number of phonemes. Due to the nature of the sample exact matching across conditions was impossible without compromising the number of available bigrams, however word lists were balanced so as to not differ significantly on any of these characteristics (each $p>$ 0.05 ); list diagnostics are presented in table 1 . Individual word frequencies were log-transformed. Examples of stimuli can be seen in Table 2.

Table 2: Example stimuli for experiment one

| Bigram Type | Example Stimuli (prime target) |
| :--- | :--- |
| High Frequency | recent times; last night; other hand |
| Low Frequency | craggy face; local access; time across |
| Non-bigrams | oval hipster; meet gone; chilli call |

## Procedure

Participants were presented with letter strings and were asked to indicate whether the string constituted a real English word by pressing either ' $z$ ' or ' $m$ ' on a standard QWERTY keyboard; key mapping was systematically varied so that half of all participants used ' $z$ ' to indicate a word and ' m ' to indicate a non-word whilst half responded with ' $m$ ' for words and ' $z$ ' for non-words. Strings were presented for a maximum of 1500 ms and were immediately preceded by a 75 ms prime. All prime-target pairs mapped exactly onto bigrams from the stimuli lists whereby the first word of the bigram acted as a prime and the second word as the target. A fixation point was presented in the centre of the screen for 500 ms prior to each trial. Prime-Target pairs were presented in two blocks each containing fifteen lowfrequency bigrams, fifteen high-frequency bigrams, fifteen non-bigrams, and forty-five non-word trials. The order of presentation for both blocks and trials was randomised for each participant.

## Analysis and Results

All participants scored more than $80 \%$ on the LDT. Data was then trimmed to exclude incorrect responses as well as those made faster than 200 ms , slower than 1500 ms (Perea et al., 2016), or more extreme than three standard deviations from the participant's mean (Madan et al., 2016), following this procedure $2.29 \%$ of correct trials were removed across participants.

All response time data were log-transformed; data was then analysed categorically using a repeated-measures analysis of variance to identify any differences in response
time between the high and low frequency bigrams ( $\mathrm{M}=$ 6.310, $\mathrm{SD}=.080$ ), non-bigrams ( $\mathrm{M} 6.507, \mathrm{SD}=.101$ ) and non-words ( $\mathrm{M}=6.548, \mathrm{SD}=.130$ ).

Bigram frequency had a significant effect on response time, $\mathrm{F}(3,28)=53.759, \mathrm{p}<.001, \eta_{\mathrm{p}}^{2}=.852$. Post hoc pairwise comparison using Bonferroni correction show that words in the non-bigram condition were recognised more slowly than those in both the high (p < .001) and low (p < .001) bigram frequency conditions. There was no difference between high and low frequency bigrams ( $\mathrm{p}=.305$ ). Nonwords were recognised more slowly than words in the high frequency ( $\mathrm{p}<.001$ ), low frequency ( $\mathrm{p}<0.001$ ), and nonbigram conditions ( p . .038). Figure 1 illustrates these differences.

Figure 1: Non-transformed group means for bigram frequency, bars depict standard error

A further repeated-measures analysis of variance was also conducted to assess any differences in response accuracy between the four conditions. Response accuracy also shows an effect of bigram frequency, $\mathrm{F}(3,28)=6.796, \mathrm{p}=.001, \eta_{\mathrm{p}}{ }^{2}$ $=.421$. Post hoc analyses using Bonferroni correction show that participants responded less accurately to words from the non-bigram condition than those in the high ( $\mathrm{p}=.005$ ) or low ( $\mathrm{p}=.002$ ) frequency conditions. All other comparisons were non-significant (each p>.062). Figure 2 shows means and standard error for accuracy.

Figure 2: Proportion of correct responses by group, bars depict standard error.

## Experiment Two

## Design

Experiment two used a LDT to assess the extent to which bigram diversity affects word recognition. The aim of the experiment was to identify any statistical priming effect that may result from the predictability of the second word in a bigram given the diversity of the first.

## Materials

Stimuli were obtained and processed using an identical procedure to experiment one with the exception that the word lists were organised according to high ( $>100$ potential followers) or low ( $<2$ potential followers) diversity or bigrams consisting of primes that do not have followers within the BNC. Word lists were balanced in the same way as the first experiment, each $p>0.06$ with the exception that the low diversity list differed significantly from both the high and no diversity list on concreteness (high: $\mathrm{p}<0.01$, no: $\mathrm{p}<0.01$ ); this is due to the relative scarcity of low diversity bigrams within the BNC and the theoretical decision to prioritise controlling individual word frequency since this represents the largest predictor of word recognition performance (Brysbaert \& New, 2009; Ferrand et al., 2010; Keuleers, Diependaele, \& Brysbaert, 2010; Keuleers et al., 2012; Yap \& Balota, 2009). List diagnostics are presented in table 1. Individual word frequencies were logtransformed. Example stimuli can be seen in Table 3; none of the bigrams were repeated across the two experiments.

Table 3: Example stimuli for experiment two

| Bigram Type | Example Stimuli |
| :--- | :--- |
| High Diversity | that place; with number; this ancient |
| Low Diversity | revolve around; beady eyes; gilded cage |
| No-Diversity | yonder month; ribbed final; orate red |

## Procedure

The experimental procedure was identical to that used in the first experiment.

## Analysis and Results

All participants scored more than $80 \%$ on the LDT. Data was trimmed in the same way as the first experiment and a total of $2.04 \%$ of correct trials were removed. Response time data was log-transformed.

Data was analysed categorically using a repeatedmeasures analysis of variance to identify any differences in response time between the high ( $\mathrm{M}=6.375, \mathrm{SD}=.054$ ), low $(M=6.395, S D=.059)$ and no diversity $(M=6.422$, $\mathrm{SD}=.581)$ bigrams as well as non-words $(\mathrm{M}=6.548, \mathrm{SD}=$ .130); means and standard error can be seen in Figure 3.

Figure 3: Non-transformed group means for bigram diversity, bars depict standard error

Bigram diversity had a significant effect on response time, $\mathrm{F}(3,28)=35.932, \mathrm{p}<.001, \eta_{\mathrm{p}}^{2}=.794$. Post hoc pairwise comparison using Bonferroni correction shows that nonwords were recognised more slowly than those in high (p < .001 ), low ( $\mathrm{p}<.001$ ) and no diversity ( $\mathrm{p}<.001$ ) conditions. Words in the no diversity condition were also recognised more slowly than those in both the high ( $\mathrm{p}=.007$ ) and low ( $\mathrm{p}=.011$ ) diversity conditions; there was no significant difference between high and low diversity bigrams ( $\mathrm{p}=$ .261).

Bigram diversity had no effect on response accuracy, $\mathrm{F}(3,28)=1.486, \mathrm{p}=.208$.

## Comparison with Transitional Probability

Transitional probabilities were calculated for all bigrams using the formula:

$$
\mathrm{P}(\mathrm{Y} \mid \mathrm{X})=\frac{\mathrm{P}(\mathrm{Y}, \mathrm{X})}{\mathrm{P}(\mathrm{X})}
$$

Where Y is the target stimulus and X is the initial word of a given bigram pair.

An item analysis was then run using a multiple linear regression with data from both experiments to assess the relationship between response time (log-transformed) on a LDT and the three key variables bigram frequency, bigram diversity, and transitional probability, $\mathrm{F}(3,168)=2.937, p=$ .035. Individual coefficients (see Table 4.) indicate that bigram frequency represents the strongest predictor of word recognition performance; neither bigram diversity or TP were significant predictors of response time.

Table 4: Coefficients and $p$-values

|  | Beta | Stand. <br> Beta | P |
| :--- | :--- | :---: | :--- |
| Bigram frequency | $-2.51 \mathrm{e}-5$ | -.189 | $<.016$ |
| Bigram diversity | $-1.21 \mathrm{e}-5$ | -.060 | .456 |
| Trans. Probability | -.038 | -.107 | $<.169$ |

## Discussion

The current study aimed to assess whether bigram frequency and bigram diversity would have an effect when used as primes in a LDT. Findings from the categorical analyses suggest a binary interaction between bigram frequency and response time where naturally occurring bigrams are recognised significantly more quickly than illegal bigrams or non-words. The same is also true for bigram diversity.

This suggests that any amount of exposure to a language is beneficial regardless of the frequency or diversity of individual structures within the input. This is an interesting effect which may have been overlooked by previous studies that have focussed on TPs since the methodologies
employed tend to focus on recognition of familiar versus unfamiliar strings. It could be argued however that the bigram frequencies presented in the current study, although highly infrequent, do not accurately represent the extremes of low frequency within the BNC. It is therefore suggested that further investigation needs to access frequencies of less than 0.1 per million in order to identify the absolute minimum amount of exposure required to elicit statistical priming effects.

Comparison of the key predictors also suggests that bigram frequency outperforms TPs as a predictor of response time in a statistically primed LDT. This can be attributed to the lower computational costs associated with tracking bigram frequency compared to the calculation of TPs. To the authors knowledge, the current study is the first to assess statistical learning using a LDT. These findings should therefore be interpreted with caution until they can be demonstrated in alternative paradigms.

It is proposed that the findings presented are evidence for the use of metrics other than TP in statistical learning paradigms, particularly when applied to natural language where TPs tend to be very small. A case can also be made that LDTs are a viable paradigm for the investigation of statistical effects in natural language where traditional recognition tasks may not be appropriate.

Crucially, they suggest that theories of statistical learning can deal with the scale-up in variety and complexity that comes from moving between artificial and natural languages. This begins to address one of the most fundamental criticisms of statistical learning theory.

When interpreting the data presented herein it would be prudent to consider that, although the BNC constitutes a multifarious selection of British English it does not encapsulate the entirety of written and spoken language. It is therefore posited that any findings presented be considered as representative rather than absolute in their accuracy. Future investigation should include the analysis of alternate corpora in order to ensure that any results are not artefactual in nature.

It is recognised that neither bigram frequency or diversity represent a complete account of statistic learning, nor is it suggested that learners utilise these metrics in place of TPs. Rather, it is posited that bigram frequency and, to a lesser extent, diversity constitute 'another brick in the wall' which may one day lead to a comprehensive understanding of how humans process language.

In conclusion, the current study demonstrates that individuals are capable of using bigram frequency and diversity to respond to statistical primes in a lexical decision task and that these metrics may be comparable to transitional probabilities when applied to natural language.

#### Abstract

Variability is important to learning; however, whether it supports or hinders language acquisition is unclear. 3D object studies suggest that children learn words better when target objects vary, however storybook studies indicate that contextual variability impairs learning. We tested a dynamic systems account in which background variability should boost learning by speeding the emergence of new behaviors. Two groups of two-year-old children saw arrays of one novel and two known objects on a screen, and heard a novel or known label. Stimuli were identical across conditions, with the exception that in the constant condition objects appeared on a white background, and in the variable condition backgrounds were colored. Only children in the variable condition showed evidence of word learning, suggesting that extraneous variability supports learning by decontextualizing representations, and indicating that adding low-level entropy to the developmental system can trigger a change in behavior.

Keywords: word learning; language acquisition; variability; memory decontextualization; dynamic systems

Children's early word learning has long fascinated researchers. When a child hears the new word spaceship, linking it with a new toy flying machine rather than their toy dog - or indeed the flying machine's wings, its color, the way it moves, and so on - seems to pose little problem. Given that the space of potential referents is theoretically infinite (Quine, 1960), this ability to quickly map a novel word to a novel object is impressive; indeed, robust referent selection has been observed in children as young as 18 months (Carey \& Bartlett, 1978; Halberda, 2006; HoustonPrice, Plunkett \& Harris, 2005; Markman \& Wachtel, 1988).

However, there is mounting evidence that a single episode of referent selection is not sufficient for full word learning; rather, children learn word-object associations incrementally, forming in-the-moment mappings between labels and objects and strengthening memories of these mappings across repeated encounters via cross situational learning (Horst \& Samuelson, 2008; Smith \& Yu, 2008; Yurovsky, Fricker, Yu, \& Smith, 2014). Clearly, then, memory and language are linked from very early in development (Taylor, Liu, \& Herbert, 2016): learning a new word depends critically on children's ability to form and retain word-object associations. Consequently, the field has recently focused on the multiple factors that affect children's ability to retain word-object mappings, demonstrating that referent selection and word learning are flexible, even fragile processes which depend heavily on the temporal and visual availability of information in the learning environment, for example repetition, competition,
and timing (e.g., Arias-Trejo \& Plunkett, 2010; Horst, Scott, \& Pollard, 2010; Mather \& Plunkett, 2009).

Developmental research has demonstrated that variability of to-be-learned items is a key influencing factor in early learning. For example, visual variability encountered across stimuli facilitates categorization in 6- to 7-month-old infants (Quinn \& Bhatt, 2010), and phonological variability in affect or speaker has been shown to support early word recognition (Rost \& McMurray, 2009). Recent work has revealed a similar effect of variability on word learning: when shown a novel 3D object category with exemplars that varied in color, 30-month-old children learned category labels, but did not when exemplars were identical, or varied in shape and color simultaneously (Twomey, Ranson, \& Horst, 2014). Thus, while some target variability supports word learning, too much variability appears to disrupt it.

In addition to target variability there is good theoretical reason to expect extraneous, non-target variability - entropy - to support word learning. Evidence from adult problemsolving studies suggests that introducing entropy to a task facilitates learning. For example, adults solving a series of gear system problems presented on a computer screen learned a short-cut solution faster when the task contained entropy in the form of variability in spatial location of the stimuli than when stimuli were presented in a consistent spatial location (Stephen, Dixon, \& Isenhower, 2009). On dynamic systems theories of cognition and development, cognitive structure emerges from the dynamic interactions of multiple, coupled components including the learner's body, learning history and in-the-moment characteristics of the task (Thelen \& Smith, 1996). Cognitive structure is instantiated as a stable state ("attractor") in the behavior of this complex system. Dynamic systems of this type exhibit "phase shifts" from one attractor to another, resulting in qualitative and quantitative changes in the system's behavior. Because phase shifts result in behavioral change, from the dynamic systems perspective, they index learning. As Stephen et al. (2009) demonstrate, extraneous entropy during learning destabilizes attractor states, speeding the onset of a phase shift. During development, then, non-target variability should speed up learning by helping new cognitive structure emerge via a shift from one behavioral state to another.

Despite this strong theoretical prediction, evidence for an effect of non-target variability in early learning is mixed. The categorization literature suggests that non-target variability helps learning. For example, Goldenberg \& Johnson (2015) presented 16- to 20-month-old infants with a looking time task. Children saw novel category exemplars
on backgrounds which (a) repeated, (b) varied randomly, or (c) varied within interleaved blocks. Only infants who saw backgrounds which varied in interleaved blocks correctly generalized category labels at test. In contrast, the word learning literature suggests that lack of contextual variability supports word learning: when learning words from a storybook, repeating the context in which 3-year-old children encounter novel words by reading from the same book repeatedly boosts word retention relative to teaching children the same novel words from multiple different books (Horst, Parsons \& Bryan, 2011; Williams \& Horst, 2014). More broadly, however, the prediction from dynamic systems theory that additional entropy should boost word learning in a single task has yet to be explicitly tested. Critically, if background variability helps children learn words, this would provide evidence for continuity in the low-level mechanisms driving learning, from toddlerhood to adulthood. The current study addressed this gap by presenting children with a word learning task in which objects appeared either on a white background or on multiple colored backgrounds. We selected two-year-old children in line with previous research which demonstrates this age group's success in similar looking-based referent selection tasks (Bion, Borovsky \& Fernald, 2013). On the dynamic systems account, children in the variable color condition should show stronger retention of label-object associations than children in the constant color condition.

## Method

## Participants

Thirty typically developing, monolingual English-learning two-year-old children ( 14 girls, $M=22.77$ months, $S D=$ 1.87 months; range $=20.0-26.0$ months) with a mean productive vocabulary of 176.04 words ( $S D=117.50$ words, range $=4-413$ words) and no family history of colorblindness participated. Half of the children were randomly assigned to the constant color condition, and half to the variable color condition. Children's ages and productive vocabularies were the same in either condition ( $p \mathrm{~s}>.30$ ). Data from six children were excluded due to fussiness (1), parental interference (3), bilingualism (1), and an eye tracker sample rate of under $25 \%$ (1). Parents were reimbursed for travel expenses and children received a small gift for participating.

## Stimuli

Each child saw a warm-up, referent selection and test phase. Critically, stimuli for each phase were identical across conditions with the exception that during warm-up and referent selection in the variable color condition objects appeared on colored backgrounds, and in the constant color condition backgrounds were always white. Children also saw engagement and attention-getting stimuli. Overall, warm-up, referent selection and retention stimuli were videos containing 2D photographic images of known and/or novel objects (depicted in Fig. 1).

|  | Known 1 | Known 2 | Novel | Novel label |
| :---: | :---: | :---: | :---: | :---: |
| Set <br> 1 |  |  | zorch |  |
| Set <br> 2 |  |  | tife |  |
| Set |  |  |  |  |
| 3 |  |  |  |  |

Fig 1. Object depicted in the current study.
Known objects were an apple, a ball, a banana, a car, a cup and a fork, and were selected because their labels are familiar to children of this age group (Fenson et al., 1993). Novel objects were a purple, green and black foam rocket (labeled zorch), a spherical yellow object with multiple flexible legs capped with pink and green balls (labeled tife), and a blue kazoo with raised orange spots (labeled blick), selected from an online database of objects unfamiliar to children of this age (NOUN Database; Horst \& Hout, 2015). Each trial consisted of a single video of three objects. Videos were created in Microsoft Powerpoint 2010, and converted to .avi format using Microsoft Windows Live Movie Maker 2011. Each video was accompanied by embedded audio consisting of the same female speaker saying Can you find the [label]? Look at the [label]! Where's the [label]?, as well as sound effects to keep children engaged in the task. Known labels were the appropriate English labels for those objects, and novel labels were blick (kazoo), tife (legs/balls) and zorch (rocket), selected as plausible but unfamiliar English object names. Auditory stimuli commenced 5 s after the start of each trial. First label onsets occurred from $0.78-0.90 \mathrm{~s}$ after the beginning of the auditory stimulus and offsets from 1.27 to 1.58 s ; second label onsets from $2.20-2.48 \mathrm{~s}$ and offsets from $2.65-3.25 \mathrm{~s}$; and third label onsets from $3.54 \mathrm{~s}-4.21$ s and offsets from 4.22 s to 5.19 s .

Engagement. Engagement stimuli consisted of a 7 s video of a female experimenter on a white background, smiling and saying Hello! Let's play a game! Can you find what I'm looking for? in child-directed speech.
Warm-up. Warm-up stimuli were 16 s videos, each depicting a set of three of the known objects, designed to familiarize children with the task. In the first 0.5 s , a small colored rectangle appeared in the middle of a black screen and spun in an anticlockwise circle, expanding until it filled the whole screen, at which point it became the background on which the objects would appear. In the constant color condition, the background on each of the three warm-up trials was white. In the variable color condition, the background was blue, green, pink, purple or red. In the next 2 s the three objects appeared in the top left-hand corner of the screen and bounced diagonally downwards accompanied by a boing sound, coming to a rest in the center of the screen and remaining there for 9.5 s , during which time the
target object was labeled three times (e.g., Can you find the apple? Look at the apple! Where's the apple). During the next 3 s the target object rotated accompanied by a twinkling sound, followed by ostensive auditory feedback (e.g., There's the apple!). In the final 1 s the objects bounced diagonally towards the bottom right hand corner and offscreen, accompanied by the sound of children cheering.
Referent selection. Referent selection trials were 13 s long, and identical to warm-up trials with the exception that children saw one novel and two known stimuli, and there was no ostensive feedback phase. Background colors were either white (constant color) or pseudorandom (variable color), as in the warm-up trials. Object location was pseudorandomized.
Retention. Retention trials were 9.5 s long and proceeded in an identical manner to referent selection trials except that the background was always gray and appeared immediately (i.e., there was no 0.5 s period where the background appeared) and all three objects were novel. Each object was labeled on two trials.

## Procedure and Design

Before the experiment began the experimenter showed caregivers pictures of the known and novel objects to ensure they were appropriately known and novel to the child. All children were familiar with the known objects and unfamiliar with the novel objects. Caregivers were asked to complete a UK adaptation (Hamilton, Plunkett, \& Schafer, 2000) of the MacArthur-Bates Communicative Development Inventory (Fenson et al., 1994), a vocabulary inventory commonly used to score toddlers' receptive and productive vocabulary. Caregivers completed the vocabulary inventory either before or after the experiment, depending on the child's level of engagement.
The eyetracking session took place in a quiet, dimly-lit room. Children sat on their caregiver's lap 50-70 cm in front of a $21.5 " 1920 \times 1080$ computer screen. Beneath the screen a Tobii X120 eyetracker recorded the child's gaze location at 17 ms intervals, and a video camera above the screen recorded the caregiver and child throughout the procedure. Caregivers were instructed not to interact with their child or look at the screen during the task to avoid biasing their child's behavior, and were asked to sit at a $90^{\circ}$ angle from their child to ensure the eyetracker tracked the child's eyes only.

The eyetracker was first calibrated using a five-point infant calibration procedure available in Tobii Studio. Immediately following calibration, children saw the engagement stimulus once.

Warm-up. The three warm-up trials immediately followed the engagement stimulus. The warm-up phase in each condition was identical with the exception that in the constant variable color condition, backgrounds were multiple, uniform colors, while in the constant color condition, backgrounds were white. Which objects appeared, which served as targets, and left-right positioning
of objects were pseudorandomized across children such that no object appeared on more than two successive trials.
Referent selection. Fifteen referent selection trials immediately followed the warm-up phase. An example referent selection phase for the variable color condition is depicted in Fig. 1. Again, the corresponding warm-up phase in the constant color condition was identical with the exception that backgrounds were white. Referent selection trials were presented in three blocks of five trials for each set. Sets were kept constant across trials to maximize children's retention of novel labels (Axelsson \& Horst, 2014); thus, one child might see a block of five repetitions of the apple + fork + zorch set, followed by the banana + cup + tife set, and finally the car + ball + blick set, with block order Latin square counterbalanced across children. In each referent selection block children were asked to look at a known object on two trials and a novel object on three trials. Known/novel trial order and background color (variable color condition only) was pseudorandomized such that no more than two of the same trial type appeared in succession.

Fig. 2. Example referent selection phase.
During referent selection an attention getting stimulus appeared six times pseudorandomly such that it was always succeeded by at least one referent selection trial, and consisted of a 3 s video of the speaker saying What's next? Finally, after the referent selection phase, children saw a 5 s "Well done" video of the speaker saying Well done! All finished! See you soon!
Break. Following referent selection, children took a fiveminute break. During this time they either remained on their caregiver's lap and watched an age-appropriate animation or moved to a seating area in the same room and colored pictures from a book.
Warm-up. After the break children saw a further warm-up trial, presented on a gray background.
Test. Three memory recativtaion and three retention trials immediately followed the warm-up trial, each depicting the three novel objects seen during referent selection. Trial order and object location were pseudorandomized.
Coding and data cleaning. Left, middle and right AOIs were square and centered on each object's stationary position after they had bounced into the screen. Unreliable/offscreen and non-AOI looks were discarded,
resulting in a final dataset of 115,762 referent selection and 61,247 test gaze samples. Individual gaze samples were numerically coded ( $1=$ target look, $0=$ non-target look $)$, creating a raw looking time measure, which was further collapsed into 100 ms time bins for statistical tractability. All subsequent analyses use this target looking measure, and are standardized from the offset of the first label plus 233 ms (Swingley, Pinto, \& Fernald, 1999) to 6733 ms postlabeling.

## Results

Because the focus of the current paper is the effect of extraneous variability on children's word learning, and due to space constraints, we present here the results from the test phase. Analyses of looking during referent selection are reported separately and discussed in detail in Twomey, Ma \& Westermann (under review); overall, however, we found chance level looking and no difference between conditions. At test, each novel object served as a target on one memory reactivation trial and one retention trial. Fig. 3 depicts looking times during the memory reactivation trials and shows little difference in target looking in the two conditions. This conclusion was supported by a linear mixed effects model with main effects of time bin (treated as continuous) and condition and their interaction, with byparticipant random slopes and intercepts for condition and by-item random intercepts to rule out item effects (Barr, Levy, Scheepers \& Tily, 2013). As in referent selection, there was a small but robust increase in looking with time (beta $=0.0019, S E=0.00063, t=2.99, \chi^{2}(1)=10.49, p=$ .0012). However, condition had no independent effect on looking times, and did not interact with time bin (main effect of condition: beta $=0.043, S E=0.00098, t=0.66$, $\chi^{2}(1)=0.12, p=.73$; time bin x condition interaction: beta $=$ $\left.-0.0080, S E=0.00098, t=-0.81, \chi^{2}(1)=0.67, p=.41\right)$.

Data from the three retention trials show a markedly different pattern, however. As Fig. 4 illustrates, children in the variable color condition looked at the target at abovechance levels immediately following labeling and again at around 4000 ms , suggesting that encountering variable colored backgrounds during referent selection facilitated their retention of the novel label-object mappings. A mixed effects model with the same fixed effects structure as above and by-participant and by-item random intercepts and slopes for condition revealed that target looking decreased over time (time bin: beta $=-0.029, S E=0.00078, t=-3.65, \chi^{2}(1)$ $=32.55, p<.001$ ). This effect was constant for children in either condition (time bin x condition: beta $=-0.0010, S E=$ $\left.0.0011, t=-0.87, \chi^{2}(1)=0.75, p=.39\right)$. Critically, however, proportion target looking was greater for children in the variable color condition than in the constant color condition (beta $\left.=-0.26, S E=0.090, t=2.85, \chi^{2}(1)=5.41, p=.020\right)$.

Fig. 3. Proportion target looking during memory reactivation trials. Error bars represent 95\% CIs. Where bins are marked with a point, looking is significantly above chance ( $0.33 ; p<.05$, one-sample, two-tailed $t$-tests; ditto for Fig. 4).

Fig. 4. Proportion target looking during retention trials.

## Discussion

The current study explored whether extraneous variability would boost young children's word learning. We trained two groups of two-year-old children with novel label-object associations via multiple referent selection trials. Stimuli presented to both groups were identical except that half the children saw arrays of novel objects displayed on a white background (constant color condition), and half saw objects on multiple colored backgrounds (variable color condition). Analyses of test trials revealed a clear effect of background variability: while children did not appear to correctly identify previously-seen novel objects during the memory reactivation trials, on retention trials children who had seen variable backgrounds during referent selection looked for longer at target objects than did children who had seen constant colored backgrounds, and did so at levels greater would be expected by chance. Thus, infants who had seen objects on variable backgrounds learned and retained the novel object-label mappings, but infants who had seen the objects on a constant background did not. These results offer converging evidence that following reactivation of memory traces, background variability facilitates learning, raising several interesting issues (see also Twomey et al., under review).
The importance of memory reactivation Children in the variable color condition looked at target objects at chance levels on the three memory reactivation trials, but at levels
greater than expected by chance on the subsequent three retention trials. Typically in word learning studies children see only a single retention trial for each object. Our results suggest that null findings in these studies could be due to a lack of recall ability rather than a lack of learning. These data indicate that including memory reactivation trials in future studies could help shed light on whether children are failing to learn, or failing to recall. Establishing the locus of memory reactivation in the word learning field is therefore critical for a thorough understanding of the delicate memory processes underlying early language acquisition.

Decontextualization in early learning The fact that only children in the variable color condition retained novel labelobject associations may seem unexpected in light of recent work in word learning indicating that consistency in context supports, not impairs, word learning (e.g., Axelsson \& Horst, 2014). Given these results, why should what seems to be a more challenging task (i.e., variable color versus constant color backgrounds) lead to better learning? In fact, our results are in line with a wealth of adult literature demonstrating that background variability supports recall (e.g., Godden \& Baddeley, 1975). More recent work has explored the effect of context on adults' category learning; for example, Finch, Carvalho and Goldstone (2016) showed that variable backgrounds led to better retention of previously-seen exemplars of a bird category.

These results are attributed to a decontextualisation mechanism. When memories are formed after a single encounter, both context and target are encoded. On subsequent encounters, if the context stays the same, it remains part of the representation. These context-dependent memories are harder to recall when the context changes. Godden and Baddeley (1975) describe a classic example of this effect, showing that divers who had learned word lists either on dry land or underwater were better at recalling words learned underwater when tested underwater, and better at recalling words learned on dry land when tested on dry land. When an item is encountered in multiple different environments, however, the representation becomes decontextualized: the context becomes less important to the representation. If an item with a decontextualized representation is encountered in a new environment, then, it is easier to recall than if the representation were contextdependent.

The same mechanisms that explain these adult data can account for children's word learning in the current study. During referent selection, children in the constant color condition learned context-dependent representations, while children in the variable color condition learned decontextualized representations. At test children encountered objects on a gray screen - and critically, neither group had seen objects presented on a gray screen until this point. Thus, recall was possible for children in the variable color condition, who were able to generalize their decontextualized memory traces to the new test context. This raises the question of why contextual consistency in existing studies supports word learning - the opposite of
the current findings. It is possible that different types of context have qualitatively different effects. Here, in line with Stephen et al. (2009), "context" was low-level, extraneous variability. In contrast, the contexts in the existing literature were rich and salient: in the storybook studies, books were constructed from photograph-like images, resulting in a complex visual scene that varied from page to page. In addition, the sentence contexts in which novel words appeared also varied (Horst et al., 2011). Similarly, in the referent selection work, "context" consisted of the competitor objects presented alongside the targets, which were considerably more complex than a simple block of color (Axelsson \& Horst, 2014). Thus, it may be that in rich learning environments, restricting complexity supports learning (Radesky \& Christakis, 2016), while in simpler learning environments, increasing complexity by adding background noise helps learning.

This decontextualization account provides a mechanism by which added variability can support learning, as predicted by the dynamic systems account. Importantly, decontextualization is one among many potential mechanisms by which learning under the dynamic systems account may be shaped. As noted above, this theory predicts that background entropy should facilitate learning by speeding up the emergence of new stable behavioral states (Stephen et al., 2009). However, the dynamic systems account also suggests that other types of variability should support learning, raising the intriguing possibility for future work that entropy introduced in a different modality, for example sound or spatial location, could also support word learning. Work is underway to test these predictions. Overall, however, on either the specific decontextualization account or the broader dynamic systems approach, the current work extends a well-established phenomenon in adult cognition to children with a new task, pointing to a view of development as a continuous process driven by domain-general mechanisms.

# Comparison strategies in the change detection task are influenced by task demands. 

Rob Udale<br>University of Bristol<br>Simon Farrell<br>University of Western Australia<br>Chris Kent<br>University of Bristol

#### Abstract

Current models of visual working memory (VWM) assume that comparing memory with the environment obligatorily involves a spatial comparison process. Can changing task demands determine whether a spatial or non-spatial comparison processes is employed? Study displays of three colored shapes were presented, followed by test displays of three coloured shapes. Participants decided whether a feature changed between displays. Task-irrelevant changes to the probed item's locations or feature bindings reduced memory performance, suggesting that participants employed spatially guided comparison process. This finding occurred irrespective of whether participants decided about the whole display, or only a single cued item within the display. When task-irrelevant feature changes occurred amongst uncued items, performance was unaffected by irrelevant changes in location or feature bindings. These results suggest that participants can flexibly shift comparison strategy in response to changing task demands. These findings have implications for models of VWM, which assume obligatory location-based comparisons in VWM.

# Weight matters: The role of physical weight in non-physical language across age and culture

#### Abstract

Languages commonly use physical properties to discuss distinctly non-physical states and events in the world (e.g., "I'm not a huge fan of licorice"). Here, we investigate the degree to which associations between physical properties and abstract concepts are culturally specific constructs. To do this, we tested three distinct populations-US adults, US children, and adults from an indigenous group in the lowlands of Bolivia, the Tsimane'-on their associations between the physical concept of weight and a variety of abstract attributes (e.g., importance, emotional state, moral worth). We find a strong relationship between the associations of US and Tsimane' adults, but little-to-no relationship between US children and either adult population. These results suggest that the property of weight plays a similar role in everyday thought across cultures, but that it takes time to develop. Further, we found that these associations could not be recovered from a simple semantic embedding analysis, suggesting that the cross-culturally shared connections between physical and abstract attributes may be learned through more complex experiences than language alone.

Marty: Are you trying to tell me that my mother has got the hots for me?
Doc: Precisely!
Marty: Whoa, this is heavy.
Doc: There's that word again: "heavy." Why are things so heavy in the future? Is there a problem with the Earth's gravitational pull?
(Back to the Future. Dir. Robert Zemeckis)

## Introduction

Physical notions weigh in on everyday conversation. We say a person forced herself to meet a deadline, as though she is pushing a cart uphill. We say a deadline is fast approaching, as though an actual train hurtling towards our location in time.

Our concepts of force, causality, space, and substance seem to shape how we talk about the world (Talmy, 1988; Pinker, 2007). Certainly some abstract thoughts rely on a universal understanding of the physical world. If a friend describes writing a paper as 'I'm banging my head against the wall', we can understand they are frustrated, and not literally writing a paper on the effects of head-banging (Figure 1, right). In the reverse direction, our language also shapes how we think about basic concepts, such space and time (e.g. Boroditsky, 2001, Núñez \& Sweetser, 2006). And some thoughts are culture- and language-dependent in their meaning. If a friend says writing feels like carrying the day out in a basket, the thrust would not be universally recognized (Figure 1, left).

Figure 1: Details from Flemish Proverbs by Pieter Bruegel the Elder, 1559. Left: Carrying the day out in a basket, i.e. wasting time Right: Banging one's head against the wall.

The purpose of this paper is not to untangle the knot of development, culture, language, and physical concepts. Rather, we mean to pick up one strand of thought as it relates to an understanding of a physical quality, and to tug on it gently. In particular, we consider the concept of weight (heavy and light), which has received less attention in terms of its impact on thought, compared to concepts like force, space, and time 1 . Intuitively, we seem to associate weight with worth: In 2015, a technical teardown of Beats headphones found that $30 \%$ of their weight was accounted for by metal objects that add no function, but make them feel 'solid and valuable' Einstein, 2015). When a character in Romeo and Juliet exclaims 'O heavy day!', we recognize that as an expression of dismay at an unfortunate event. But is all this because of the quirks of the English language, and our own WEIRD makeup (Henrich et al. 2010), or something deeper about the way weight ties in with concepts such as worth and sadness?

[^533]To examine this question, we asked three groups (US adults, US children, and adults from the indigenous Tsimane' of Bolivia) to pick which of two differently weighted, visually identical boxes was better described by various attributes ( external, internal, mental and non-mental). We reasoned that if the three groups show a systematic bias for some attributes within the group, but no relationship is found between the judgments of these three groups, then the use of a weight concept in our everyday thinking outside a strictly physical context is more likely to be a cultural construct. If the three groups all show similar judgments, then this is evidence in favor of an early shared conceptual organization. If the Western adults show similar judgments to Tsimane' adults, but are not similar to children, this would suggest a shared conceptual organization, but one that takes time to develop. A final option is that all groups will show random behavior, failing to associate any attribute with the boxes in a systematic way, which would be evidence of certain poor decisions about experiment design or a problem with the fundamental research question. The authors were agnostic about the most likely outcome out of the ones just listed.

## Experiment 1: US Adults

## Participants

Participants ( $N=100$, 42 female, median age 32.0 years) were recruited through Amazon's Mechanical Turk service (Crump et al. 2013) and paid a monetary sum for their participation, equivalent to $\$ 9$ per hour. Participants were restricted to those living in the United States.

## Materials and methods

Participants were presented with an image of identical boxes marked A and B (see Figure 2, top), and asked to imagine that there were two boxes before them, as in the image. Participants were asked to imagine lifting up the boxes and discovering that one of the boxes is much heavier (the identity of the heavy box was randomized across participants).

Participants read 12 descriptions in succession, choosing the box that best fit the description. For each description, participants were reminded which box was heavier, and then given a prompt as follows: "Which box is [attribute]?", where the attribute varied from one question to the next. Participants indicated their response using a radio button. The 12 attribute adjectives were presented in random order, chosen from a list of 24 possible attributes that reflect inner traits (e.g., good/bad), external qualities (pretty/ugly), emotions (sad/happy), and external evaluation (cheap/expensive, important/unimportant). For a full list, see Table 1.

Each participant saw only 12 attributes, rather than the full list of 24 , to prevent cognitive fatigue. Participants always saw only one of a possible antonym pair. In total, this meant there were 50 individual ratings per attribute. Following the attribute questions, the participants supplied basic demographic information, and were invited to share any comments they may have.

| Important* / Unimportant* [Not Important] |
| :--- |
| Valuable* / Cheap* ; Old / Young |
| Serious* / Funny* ; Sad* / Happy* |
| Ugly* / Pretty*; Interesting* / Boring* |
| Mean / Nice ; Smart* / Stupid* [Not Smart] |
| Good* / Evil* [Bad] ; Angry / Calm |
| Brave / Coward [Scared] |

Table 1: The 24 attributes applied to the boxes in Experiments 1 and 2, grouped into antonyms. Attributes in [parentheses] indicate a child-friendly replacement for the preceding word, used in Experiment 2. Asterisks indicate words used in Experiment 3.

Figure 2: (i) Illustration of stimuli shown to participants in Experiment 1, for a specific attribute (ii) The boxes used in Experiment 2 with children, and in Experiment 3 with Tsimane' adults.

## Results and analysis

Participants' ratings for each attribute were converted into the following measure: $\frac{\# \text { participants that chose light }}{\# \text { total participants }}$. This weight choice fraction (WCF) goes from 0.0 (all participants chose the heavy box for this attribute) to 1.0 (all participants chose the light box). The results are shown in Figure 3, with bars indicating 95\% bootstrapped confidence intervals (CI, 1000 samples per attribute) around the WCF measure.

Of the 24 attributes, 15 had WCFs with CIs that do not overlap 0.5 , indicating that participants considered these attributes as statistically significantly associated with heavy or light. The same result is obtained when using a two-tail binomial test at the $p=0.05$ level. Such a result is highly unlikely to occur by chance: Using an additional bootstrap analysis that repeats the same procedure from the previous paragraph (counting the number attributes with WCF CIs that do not overlap 0.5), the median (and mean) expected number of attributes with a measure that does not overlap chance is 2. Also, the empirical distribution of participants' WCF is statistically significantly different from a distribution drawn from a random sample that assumes the same participant numbers, but with answers based on an unbiased coin flip (Kolmogorov-Smirnov two-sided test for 2 samples, $K S=0.28, p<0.05$ ) .

The attributes significantly associated with heavy and light seem partially in line with intuition ${ }^{2}$ Heavier boxes are more likely to be seen as valuable, important, and interesting, as opposed to the cheap, unimportant, and boring lighter boxes. This is consistent with the marketing-driven decision by Beats to add superfluous weight to their headphones. This association makes sense given that more weight may imply more "stuff", which could generally be considered more desirable ${ }^{3}$. Participants also associated more personality-type traits with the boxes, in a way that is not accounted for by a simple positive-negative spectrum. Heavy boxes are more good and brave, but also mean and angry. Lighter boxes are more cowardly, but also more pretty. Presumably participants were able to anthropomorphize the boxes to some degree, seeing them as agents. For example, on this analysis a light agent is more likely to run away, and is likely to be younger. However, this does not account for the full pattern of results, such as seeing heavier boxes as more "good" and less "evil".

This pattern also cannot be recovered from a semantic embedding analysis. The analysis worked as follows: We embedded the attributes from Table 1, as well as the words heavy and light, in a high-dimensional semantic vector space, which was constructed using the co-occurrence statistics of several hundred-thousand words in a large corpus Pennington et al. 2014). Specifically, we used 100-dimensional GloVe word vectors pre-trained on the Wikipedia 2014 + Gigaword 5 datasets. Such semantic embeddings have proved useful for measuring similarity between words, in the service of machine-learning applications such as sense-making, translation, and question answering (see for example Vedantam et al., 2015, Wolf et al., 2014, Yu et al., 2015). Intuitively, a shorter euclidean distance or larger cosine similarity between two points in this space indicate a larger degree of similarity between the words that those points represent. After embed-

[^534]| Heavy $0.0 \quad 0.25 \quad 0.5$ | $0.75 \quad 1.0$ Light |
| :---: | :---: | :---: | :---: | :---: |
| Important |  |
| Valuable |  |

Figure 3: Results of Experiment 1: Participant responses per attribute are converted into WCF measure running from 0 (all participants chose the heavy box) to 1 (all participants chose the light box). Bars indicate $95 \%$ bootstrapped confidence intervals around the mean of this measure. Colors indicate the degree to which an attribute is associated with heavy (blue) or light (red). Beige indicates WCFs with CIs overlapping 0.5, indicating a random response or equal association.
ding our terms, we measured the relative euclidean distance between the attributes and the terms heavy and light (that is, distance (heavy, attribute $i_{i}$ ) - distance (light, attribute $i_{i}$ )). We found no correlation between participants' response and this distance. A similar analysis with cosine similarity also found no such relation. This suggests that while useful, basic semantic embedding does not necessarily capture association that is based in physical properties.

While the pattern shown by US adults is interesting on its own, the original driving motivation was comparing this pattern to children and non-US cultures. With that, we turn to children.

## Experiment 2: US Children

## Participants

Fifty individuals were recruited from the Rochester Kid Lab participant pool ( 28 female, Median 4.0 years, range $3-\ell^{4}$ ).

## Materials and Methods

Participants were tested in a designated room in the Rochester Kid Lab. Parents gave their informed consent, and generally did not accompany their children during the test, unless requested, or children expressed shyness. Parents who accompanied their children were explicitly advised not to encourage responses from their child. Families were compensated for their time and child participants were also given a small gift (a shirt or toy).

In the testing room, participants were asked to sit next to a table, where two boxes were laid out. The boxes were $3 \times 3 \times 3$ inches, made of wood, and covered in blue fabric with a gold pattern (see Figure 2, bottom). The boxes were hollow, and inside one of them was a 200 gram metal weight, along with padding to prevent the weight from bouncing and rattling when the box was handled. The locations of the boxes with respect to a participant were randomized across children.

Participants were first asked if they noticed a difference in the boxes, based on visual appearance. Participants were then asked to hold the boxes, and to indicate if there was a difference (which they were able to verbally verify).

The participant continued to hold the boxes in each hand, as they answered the following question: "Which box do you think is [attribute]?", for a randomized set of 12 attributes taken from 24 attributes similar to Experiment 1 (and see Table 1). The study took a maximum of 10 minutes. Participants answered verbally or with a gesture, with the experimenter noting their response. Participants were also asked to explain their answers, but their reasons were scantly supplied and proved inconsistent across children ${ }^{5}$ Again, to prevent cognitive fatigue, participants were asked to judge 12 attributes rather than the full 24 , with each participant seeing only one of a possible pair of antonyms. Thus there were 25 individual ratings per attribute.

## Results and analysis

Participants' ratings for each attribute were again converted into the WCF measure used in Experiment 1 (with 0.0 indicating all participants chose heavy, and 1.0 indicating all chose light). In this case, however, only 3 attributes were

[^535]different from chance, using a two-tailed binomial test at the $p=0.05$ level). The empirical distribution of children's WCFs was also not statistically significant from a distribution drawn from a random sample, one that assumes the same participant numbers but with answers based on the flip of an unbiased coin (Kolmogorov-Smirnov two-sided test for 2 samples, $K S=0.21, p=0.22$ ). It is possible to conclude that children did not understand the task, either because of lowlevel explanations like inappropriate materials and framing, or because physical weight does not play a similar association role in their general thought as it does for US adults.

When correlating with the responses of adults from Experiment 1 , we find there is a weak correlation $\left(r_{s}=0.4, p=0.05\right.$, and see Figure 4. Taken in a positive light, this may indicate a fledgling understanding after all of the full adult association between the attributes used and physical weight. Still, this relationship is statistically tenuous. A median-split by age does not show a difference between younger and older children.

Is it possible US adults exhibit a culture-specific pattern of association with physical weight, one that requires years to acquire? In the last experiment, we consider a non-WEIRD adult population, an indigenous people of Bolivia.

Figure 4: Comparison of adult responses from Experiment 1 with child responses from Experiment 2. The x and y axis both use the same weight-fraction measure, going from heavy to light. The shaded area indicates a $95 \%$ bootstrapped confidence interval on the linear regression model fit.

## Experiment 3: Tsimane’ Adults

The Tsimane are a native people of lowland Bolivia, consisting of several thousand individuals, who live in mostly small
communities in the northeastern department of Beni. Traditional Tsimane' are farming-foragers who subsist off hunting, fishing, and some farming and trade. Members of the Tsimane' have highly variable education levels, and own few artifacts (Huanca, 2006, Reyes-García, 2001). As members of a relatively isolated non-industrial society, Tsimane' have been the topic of several previous studies, from market behavior (Reyes-García, 2001) to counting (Piantadosi et al., 2014), to color concepts (Cibelli et al. 2016), to notions of fairness (Jara-Ettinger et al. 2016).

## Participants

Our final sample included fifty-five individuals ( 33 female, median age $=28.0$ years, range 17-65) from twelve Tsimane' communities.

## Materials and methods

Experiments took place in a community classroom, with a translator reading from a script, and a separate transcriber recording responses. The experiments were conducted in Tsimane', translated from a Spanish script. The translation was confirmed by a second Spanish-Tsimane' translator. Other people were present in the room, but could not see participant responses. Participants were compensated with gift bags equivalent to roughly $\$ 10$ per hour. Participants completed other tasks in addition to the one in this study, with a total testing time of approximately one hour.

Figure 5: Comparing US adults from Experiment 1 with Tsimane' adults from Experiment 3. The x and y axis both use the same WCF measure, going from heavy to light. Shaded area indicates a $95 \%$ bootstrapped confidence interval.

Participants were presented with two identically marked
boxes on a table. These were same boxes used in Experiment 2, and weighted as in Experiment 2 (see Figure 2 bottom). Participants were instructed to pick each box up before any questions were asked. Participants were then asked: "Which box is [attribute]?", and were instructed to point to a box. This was then repeated until all adjectives were covered. The order of the adjectives was randomized, as was the particular adjective from a given pair was randomized. Participants were allowed to pick up the boxes at any point. As participants saw only one word out of a possible pair, there were on average 21 individual ratings per attribute. In general, participants in this experiment went over a subset of 16 of the 24 adjectives in Table 1, due to translation difficulties.

## Results and analysis

As in Experiments 1 and 2, participants' ratings for each attribute were transformed into a WCF measure. Four of the 16 attributes were different from chance, using a two-tailed binomial test at the $p=0.05$ level). In addition, the empirical distribution of Tsimane' WCFs is statistically significant from that drawn from a random sample that assumes the same participant numbers, but with answers sampled from an unbiased coin flip (Kolmogorov-Smirnov two-sided test for 2 samples, $K S=0.36, p<0.05$ ).

We also correlated Tsimane' responses with those of US adults in Experiment 1. We found a significant correlation ( $r_{s}=0.8, p<0.001$, and see Figure 5]. As a final comparison, we correlated Tsimane' responses with those of US children in Experiment 2, and found no significant correlation ( $r_{s}=$ $0.0, p=0.94)$. We next consider the general pattern of results.

## Discussion

Thoughts weigh nothing, but they can weigh heavily on us. A man might feel lighthearted after dispensing with a heavy obligation. We can take matters lightly, but we should not take them too lightly.

Thoughts, obligations, and matters don't actually weigh anything, but we feel their press on us. Our language of thought cleaves the world into concepts that behave like objects with physical properties, located in space and acted on by force Pinker (2007). Conversely, our mental concepts can color our perception of the physical. In this paper we considered the particular physical notion of weight, and its relation to different non-physical qualities such as value, interest and seriousness.

We examined people's associations between weight and these different qualities in Western adults and children, and in members of the non-industrial Tsimane' society. We found a strong relation between the answers given by Tsimane' and Western adults, a tenuous relation between Western adults and children, and no relation between Tsimane' adults and Western children. Taken together, these findings indicate that weight acts a similar cross-cultural role in everyday thought, but that it takes time to fully get its act together. So, it may be language and culture-independent to think of important matters as physically weighing more, for example. However, a
fuller treatment would require relating the attributes to other measures beyond weight, such as imageability and affect.

Different alternative explanations can be put forward for why children provided responses that were inconsistent with one another. First, it is possible that children simply have not had the life experiences required to form strong, systematic associations between abstract attributes and physical properties like weight. Alternatively, it is possible they cannot anthropomorphize the boxes. This seems unlikely, as children can engage in pretend play with inanimate objects, but attributing metarepresentations may have required a more active signaling of the task as pretend play Lillard (1993). It may be that young children lack the basic physical skills associated with telling a heavy object from a light object and predicting their different behaviors, but previous research shows most of the basic intuitions are in place by the lower end of our age range, with young children predicting the effects of different masses interacting, and taking weight into account when planning actions (Baillargeon, 2004, Upshaw \& Sommerville, 2015). Under these alternative explanations that posit children could have experienced confusion about the task, we would typically expect certain behavioral indicators of this state, such as failures, resistance or delays in providing responses. However, in our sample we observed no such indicators. Children were generally swift and willing to select a particular box for each attribute about which we inquired.

This study does not give a definitive final answer to questions of culture, development, and the constructs of thought, but it does shed light on a piece of the puzzle, in the form of weight. Also, it is not hard to think of other physical properties that our methodology could stretch to accommodate, roughly speaking.

## Acknowledgments

We are grateful to Holly Palmeri for her support recruiting and scheduling children in the Rochester Kid Lab, to Tomas Huanca for logistical help with visiting the Tsimane' villages, to Ted Gibson and Julian Jara-Ettinger for provoding support in Bolivia, and to Dino Nate Aez, Robertina Nate Aez, and Salomon Hiza Nate for help translating. We would also like to thank Steve Piantadosi for doing some of the heavy lifting. This material is based upon work supported by the Center for Brains, Minds and Machines (CBMM), funded by NSF STC award CCF-1231216.

# Learning in the Wild: Real-World Experiences Shape Children's Knowledge Organization 

Layla Unger (LUnger@andrew.cmu.edu)<br>Carnegie Mellon University, Department of Psychology, 5000 Forbes Avenue<br>Pittsburgh, PA 15214 USA

Anna V. Fisher (Fisher49@andrew.cmu.edu)<br>Carnegie Mellon University, Department of Psychology, 5000 Forbes Avenue<br>Pittsburgh, PA 15214 USA

#### Abstract

The organization of knowledge according to relations between concepts is critically involved in many cognitive processes, including memory and reasoning. However, the role of learning in shaping knowledge organization has received little direct investigation. Therefore, the present study investigated whether informal learning experiences can drive rapid, substantial changes in knowledge organization in children by measuring the effects of a week-long Zoo summer camp versus a control camp on the degree to which 4- to 9 -year-old children's knowledge about animals was organized according to taxonomic relations. Although taxonomic organization did not differ at pre-test, only Zoo camp children showed increases in taxonomic organization at post-test. These findings provide novel evidence that informal, real-life learning experiences can drive rapid knowledge organization change.

Keywords: Cognitive Development; Semantic Knowledge; Semantic Development

## Introduction

Knowledge is not merely a mentally stored body of information, but rather an interconnected network of concepts linked by meaningful relations (e.g., McClelland \& Rogers, 2003). This organization of knowledge according to meaningful relations between concepts plays a critical role in many cognitive processes, including memory, reasoning, learning, and visual attention (Bjorklund \& Jacobs, 1985; Bower, Clark, Lesgold, \& Winzenz, 1969; Chi, Feltovich, \& Glaser, 1981; Moores, Laiti, \& Chelazzi, 2003; Pinkham, Kaefer, \& Neuman, 2014). Therefore, a key facet of understanding cognition is understanding the development of knowledge organization.

Current conceptual development accounts suggest that learning experiences drive changes in knowledge organization, though the posited nature of such learning processes and the degree to which learning is emphasized in contrast with early (possibly innate) conceptual biases varies across accounts (e.g., Carey, 1985; Fisher, 2015; Gelman, 2003; Tenenbaum, Kemp, Griffiths, \& Goodman, 2011). However, the role of learning in organizing knowledge can only be indirectly inferred from prior research, because no past studies have directly investigated learning experiences that may drive knowledge organization changes. This lack of direct evidence leaves open several key questions about learning-driven knowledge organization change. First, it is
unknown whether such changes result from the protracted accumulation of learning experiences over long-term developmental time-scales (e.g., months and years), or whether they can result from experiences over relatively brief developmental time-scales (e.g., days or weeks). Second, the role of formal education versus day-to-day informal learning experiences in driving knowledge organization change remains poorly understood.

Indirect evidence for the contribution of learning experiences to knowledge organization comes from cognitive development, expertise, and learning science research. Within the cognitive development field, the emergence of knowledge organization has been a focus since the field's inception (Inhelder \& Piaget, 1964). Specifically, numerous studies have attempted to characterize the developmental trajectory of knowledge organization by measuring the degree to which children of different ages possess knowledge of different types of relations between concepts. The relations that have received greatest interest to date include: Similarity based on shared perceptual features (e.g., shape or color); taxonomic relations based on membership in the same, stable category (e.g., mammal); and thematic relations based on cooccurrence in the environment (e.g., dog and bone) (Blaye, Bernard-Peyron, Paour, \& Bonthoux, 2006; Nguyen, 2007; Unger, Fisher, Nugent, Ventura, \& MacLellan, 2016).

Evidence from some cognitive development studies has suggested that children apprehend and reason on the basis of multiple types of relations from an early age (e.g., Gelman \& Coley, 1990; Nguyen, 2007). For example, Nguyen and colleagues used match-to-sample tasks to demonstrate that young children can match target items to both taxonomically and thematically related items versus unrelated items from age two (Nguyen, 2007; Nguyen \& Murphy, 2003). These findings suggest apprehension of multiple relations from early childhood, and thus de-emphasize learning-driven changes in knowledge organization throughout development. However, this conclusion remains controversial. For instance, studies using the same paradigm demonstrated that young children could explain perceptual and thematic, but not taxonomic matches (Sell, 1992; Tversky, 1985). Similarly, Blaye et al. (2006) demonstrated that five-year-old children relied on thematic and perceptual relations to complete an ostensibly taxonomic organization task, whereas older children increasingly used true taxonomic knowledge. These
findings suggest that (1) Young children can make decisions that are consistent with knowledge of a given relation without actually possessing such knowledge, and (2) Relations knowledge develops significantly beyond early childhood.

A handful of recent studies provide direct evidence that knowledge organization indeed evolves gradually across development (Fisher, Godwin, \& Matlen, 2015; Fisher, Godwin, Matlen, \& Unger, 2014; Unger et al., 2016). These studies were designed to capture gradual knowledge organization changes by using a paradigm in which children make graded spatial judgments of the degree to which items are related (Goldstone, 1994). The results of these studies reveal that: (1) Overall, children increasingly differentiate related from unrelated items between ages four and seven, and (2) The influence of specific relations (i.e., thematic and taxonomic) on knowledge organization increases gradually across childhood. In contrast with the perspective suggesting early apprehension of different types of relations, it has been argued that this continuous evolution of knowledge organization implies a key role for learning experiences that transpire throughout childhood. However, these studies provide no direct insight into learning-driven knowledge organization change itself, including whether learning experiences must accumulate over months and years, and whether they must take place in formal education settings.

Further indirect evidence for the effects of learning on knowledge organization comes from expertise studies, which show that expertise in a specialized domain is associated not merely with knowledge of more concepts than novices possess, but the organization of concepts according to relations that are meaningful in the domain (e.g., Chi et al., 1981; Gobbo \& Chi, 1986; Medin, Lynch, Coley, \& Atran, 1997). However, this research does not illuminate whether knowledge organization changes can transpire without extensive learning experiences. Moreover, some researchers have argued that the effects of learning that produce expertize in the formalized knowledge domains studied to date are qualitatively different from the effects of learning in everyday domains (Gelman, 2003). Therefore, the role of everyday learning experiences on driving the acquisition of relations knowledge remains open for debate.

Finally, several learning science studies have measured the effects of brief learning experiences such as educational field trips on knowledge in everyday domains such as animals (e.g., DeWitt \& Storksdieck, 2008; Farmer, Knapp, \& Benton, 2007; Prokop, Tuncer, \& Kvasničák, 2007). However, these studies almost exclusively measured children's knowledge of individual concepts (e.g., "Kangaroo rats have giant feet", Gottfried, 1980, p. 172). Accordingly, this research does not illuminate whether such informal and relatively brief learning experiences can organize children's knowledge according to meaningful relations.

## Present Study

The present study aimed to bridge prior cognitive development, expertise, and learning sciences research by measuring the influence of real-world learning experiences
on knowledge organization. To capture the effects of learning that appear in prior research to transpire over months or years (Fisher et al., 2015; Fisher et al., 2014; Unger et al., 2016), we measured the effects of a concentrated, immersive experience in a domain. Specifically, we measured the effects of a week-long, zoo-based summer camp versus a control, school-affiliated summer camp on 4- to 9 -year old children's knowledge of biological taxonomic relations for a set of animals. We focused on the animal domain because it is familiar to children from an early age, and appears to undergo significant organizational changes with development (Unger et al., 2016). Therefore, this venue provides an ideal opportunity to investigate real-world experience-driven changes in knowledge organization.

## Methods

## Study Sites

Zoo Camp. Zoo camp consisted of lessons, interactions with animals, zoo tours, games, and crafts. Activities for each day were designed around a specific theme, such as "creatures of the night". Each year, the zoo camp organizers choose different themes for each age group. The themes for the age groups spanning our sample (4-5, 6-7, and 8-9 years of age) over the two summers during which testing took place are listed in Table 1 . The majority of themes were not designed to teach biological taxonomic relations, with the exception of themes for children in the 8-9 age group in Year 2 and one instance of a "Reptiles" theme for children in the 4-5 age group in Year 2. These exceptions did not influence our results (see Results). To illustrate how themes shaped camp activities, the activities chosen for the "Extreme Families" theme were as follows. Children took part in two lessons: One about "Extreme Parents" that do or do not protect their offspring (e.g., chickens versus sharks), and another about benefits to animals that live in family groups (e.g., elephant). Children visited in person, completed crafts and played games related to a subset of animals described in lessons.

Control Camp. The Control Camp was a school-affiliated summer camp that did not provide immersive experiences

Table 1: Curriculum themes for each age group.

|  | Year 1 | Year 2 |
| :--- | :--- | :--- |
| 4-5 | Domestic Animals | Animal Locomotion |
|  | Super Senses | Reptiles |
|  | Tropical Treasures | Aquatic Animal Diets |
|  | Savanna Survival | Savanna Animal Patterns |
| 6-7 | Animal Babies | Rainforest |
|  | How Animals Learn | African Savanna |
|  | Animal Families | Ocean |
|  | Aquarium Animals | Islands |
| 8-9 | Extreme Families | Mammals |
|  | Extreme Senses | Birds |
|  | Extreme Architects | Reptiles |
|  | Animal All-Stars | Amphibians |

with animals. At camp, children engaged in outdoor play, dance, crafts, games, and cooking. Additionally, children went on a field trip each week (e.g., to a baseball game), but did not visit the Zoo during this study.

## Participants

Participants were 4 to 9 -year-old children enrolled in the Zoo or the Control Camp located in the same Northeastern US city. The initial sample included 33 Zoo Camp ( 19 females) and 32 Control Camp ( 17 females) children. Of this sample, data from six Zoo Camp children and one Control Camp child were not included in analyses of performance on one of the two outcome measures due to a camera malfunction (see the Scoring section below). Although random assignment to a camp was not possible, children enrolled in the two camps performed equivalently on measures of taxonomic knowledge at pre-test (see Results), and were approximately matched for age (Zoo Camp: $M_{\text {age }}=6.89$ years, $S D=1.43$; Control Camp: $M_{\text {age }}=6.23$ years, $\left.S D=1.21 ; t(57)=1.9, p=.06\right)$.

## Design

The study was a quasi-experiment in which children recruited from Zoo and Control camps participated in both Pre- and Post-Test sessions at the beginning and end of a week of camp. To ensure sufficient number of participants in the Zoo camp condition, data in this condition were collected in the summer of 2015 (Year 1) and 2016 (Year 2), and collapsed across years for analysis.

## Stimuli

The animal stimuli were selected from the zoo camp curricula, such that knowledge in a given age group was assessed for animals about which Zoo Camp children in that age group learned. Accordingly, we developed a separate stimulus set for each age group in each year. Each set consisted of 15 animals, with an equal number of items in each of three biological taxonomic categories: Mammals, birds, and reptiles. To represent the animal stimuli, we used line drawings chosen to minimize perceptual similarity between animals in the same taxonomic category (see examples in Figure 1A-B).

## Materials and Procedures

Participants completed pre- and post-test sessions on Monday and Friday morning of the same week that took place during a "before care" period prior to the start of camp activities. In both Years 1 and 2, these sessions included a Spatial Arrangement Method (SpAM) task (Goldstone, 1994), and in Year 2, children additionally completed a Match-to-Sample task (Figure 1). These tasks have complementary advantages: The match-to-sample task provides a straightforward assessment of taxonomic reasoning that is well-established in developmental research (e.g., Fisher, 2011; Smiley \& Brown, 1979; Waxman \& Namy, 1997), whereas SpAM yields a more graded measure of taxonomic relations knowledge and the degree to which it changes with training. A recent

Figure 1: Schematic depiction of the SpAM task (A) and the match-to-sample task (B).
longitudinal study (Fisher et al., 2014) provided evidence that the two measures converge on the same underlying construct.

SpAM Task. Participants were seated at a game board consisting of a $10 \times 10$ grid, and were told that they were going to play a game in which their job was to help a fictional character, Zibbo, organize his favorite animals on the board (Figure 1-A). The experimenter then showed participants a stimulus sheet that depicted all 15 animal stimuli selected for the child's age group, named each animal, and removed the sheet from view. Next, the experimenter told the participant that they would organize the animals using cards that each depicted an animal on the game board, such that "animals that are the same kind of animal go close together, and different kinds of animals go farther apart". The experimenter placed one of the 15 animal cards on a central game board square, then named and presented each of the remaining cards for the participant one-by-one. Cards were presented in a predetermined, pseudo-random order in which no more than two animals from the same taxonomic group appeared consecutively. Participants were allowed to move cards that they had placed earlier in the task. Finally, the experimenter photographed the board to record the locations of the cards.

Match-to-Sample Task. The animal stimuli for a given age group were arranged into six triads that each consisted of a Target, a Taxonomic Match that belonged to the same taxonomic category as the Target and a Lure that belonged to a different category (Figure 1-B). Of the six triads, two had mammal Targets, two had bird Targets, and two had reptile Targets. Triads were designed to eliminate non-taxonomic cues to Taxonomic Matches, such as visual similarity or shared habitat. For example, a triad might consist of a type of flightless bird such as penguin as the Target, a bird capable of flight such as owl as the Taxonomic Match, and a non-bird such as polar bear as the Lure.

For each triad, the experimenter asked participants to choose whether the Taxonomic Match or the Lure was "same kind of animal" as the Target. The experimenter pointed to and labeled the animals while providing these instructions (e.g., "Which one is the same kind of animal as the penguin, the owl or the polar bear?).

## Results

Of the Zoo Camp sample, children in both Year 1 and Year 2 ( $N=27$ ) completed the SpAM task, whereas only children in Year 2 ( $N=16$ ) completed the Match-to-Sample task. All 32 children in the Control Camp sample were tested during Year

2, and completed both tasks (although one participant's SpAM data were excluded due to camera malfunction).

## Scoring

SpAM Task. The photographs taken following each arrangement trial were scored by treating the $10 \times 10$ board as a coordinate plane, identifying the coordinates of each card, and calculating the Euclidean distance between the coordinates. The range of possible distances was 1 (adjacent cards) to 12.73 (cards on diagonally opposite corners of the board). These distances are taken as a measure of the degree to which participants judge a given pair of animals to be the "same kind of animal", where shorter distances indicate stronger judgments that the pair are of the same kind.

We used these distance data to calculate a Difference Score for each participant at both Pre- and Post-test that captured the degree to which participants placed taxonomically related animals closer together than unrelated animals by subtracting distances between pairs of animals from the same taxonomic category from distances between taxonomically unrelated pairs. Accordingly, larger Difference Scores reflected stronger judgments that taxonomically related versus unrelated animals were of the "same kind".

Match-to-Sample Task. We calculated an Accuracy score for each participant in which we calculated the proportion of times they chose the Taxonomic Match.

## Pre-Test Performance

We first assessed whether participants in both camps performed comparably on the two measures of taxonomic relations knowledge at Pre-Test. Note that the range of Difference Scores on the SpAM task at Pre-Test was -. 65 to 5.25 (chance=0), and of Accuracy scores on the Match-toSample task was .17 to .83 (chance=.5). The results of independent samples t-tests indicated that there was no significant difference at Pre-Test between the performance of participants in the two camps on either measure (SpAM: $M_{\text {zoo }}=.80, M_{\text {control }}=.61, t(56)=.57, p=.57$; Match-to-Sample: $\left.M_{\text {zoo }}=.54, M_{\text {control }}=.58, t(46)=.69, p=.49\right)$. Performance at PreTest on the SpAM task was above chance in both camps (both $t \mathrm{~s}>2.86$, both $p \mathrm{~s}<.01$ ), whereas performance on the Match-toSample task was above chance in the Control Camp only (Zoo: $t(15)=.94, p=.362$, Control: $t(31)=2.61, p=.014$ ).

## Effects of Zoo versus Control Camp

These analyses measured the effects of Zoo Camp versus Control Camp on changes from Pre- to Post-Test in taxonomically organized knowledge: I.e., the degree to which participants' SpAM Difference Scores indicated that they made "same kind" judgments based on taxonomic relations, and the degree to which participants chose the Taxonomic Match on the Match-to-Sample Task.

For each measure, we assessed whether Zoo camp participants manifested greater improvements from Pre- to Post-Test than participants in the Control camp using two analyses. First, we used paired t-tests to compare Pre- versus

Figure 2. Change scores for Zoo and Control Camp participants in SpAM (left) and Match-to-Sample (right) tasks. Error bars represent standard errors of the mean.

Post-Test Difference and Accuracy Scores for participants in each camp separately, and found that whereas Zoo camp participants performed significantly better across both measures at Post- than Pre-test (SpAM: $M_{\text {pre }}=.80, M_{\text {post }}=1.30$, $t(26)=3.01, \quad p=.006$, Cohen's $d=.34$; Match-to-Sample: $M_{\text {pre }}=.54, M_{\text {post }}=.73, t(15)=3.74, p=.002$, Cohen's $\left.d=1.02\right)$, Control camp participants' performance did not improve from pre- to post-test (SpAM: $M_{\text {pre }}=.61, M_{\text {post }}=.59, t(30)=.19$, $p=.85$, Match-to-Sample: $M_{\text {pre }}=.58, M_{\text {post }}=.56, t(31)=.61$, $p=.55$ ).

Second, to compare performance of participants at both camps directly, we calculated a Change Score for each participant in which we subtracted Pre- from Post-Test scores (such that larger Change Scores indicated larger improvements). We then used independent samples $t$-tests to compare SpAM and Match-to-Sample Change Scores between the camps, and observed that across both measures, Change Scores for Zoo Camp participants were larger than those for Control Camp participants (SpAM: $t(56)=2.61$, $p=.011$, Cohen's $d=.68$, Match-to-Sample: $t(46)=3.48$, $p=.001$, Cohen's $d=1.06$; Figure 2).

## Effects of Camp across Age Range

To test whether the effects of attending Zoo versus the Control camp varied with age, we measured the correlation between age and Change Score for each task in each camp. Age was not correlated with Change Score for either task in Control camp participants ( $r_{\text {match-to-sample }}=-.033, r_{\mathrm{SpAM}}=-.002$, $p s>.86$ ), whereas in Zoo camp participants, age was significantly correlated with Match-to-Sample task Change Score ( $r=.56, p=.024$ ) and marginally correlated with SpAM task Change Score ( $r=.33, p=.09$ ) (Figure 3). Moreover, these correlations were not merely due to older children having more taxonomic relations knowledge to start out with: In Zoo camp children, pre-test performance on the SpAM task was not correlated with Change Score ( $r=.11, p=.597$ ) and pre-test performance on the Match-to-Sample task was marginally negatively correlated with Change Score ( $r=-.49, p=.052$ ).

## Influence of Taxonomic Themes

Finally, to test whether these results were driven by the handful of Zoo Camp themes designed to teach taxonomic relations, we re-ran all analyses excluding all data from

Figure 3: Correlations with age of Change Scores in SpAM and Match-to-Sample tasks for each camp shown with best-fit lines.
children in the 8-9 age group in Year 2 who experienced a week of taxonomically-oriented themes ( $N=2$ ), and trials involving reptiles from children in the $4-5$ age group in Year 2 who experienced a reptile-oriented theme ( $N=4$ ). All results reported above remained unchanged: Significant outcomes remained for Pre- to post-test Zoo Camp comparisons, Zoo vs. Control Camp Change Score comparisons, and correlation between age and Match-to-Sample task Change Score in Zoo Camp (all $p \mathrm{~s}<.05$ ).

## Discussion

This study aimed to capture learning-driven changes in knowledge organization in action by measuring the effects of concentrated, real-world learning experiences on the organization of children's knowledge about animals. Specifically, we measured the effects of a week-long Zoobased summer camp on children's knowledge of biological taxonomic relations between animals. We observed that across two converging measures, taxonomic relations increasingly influenced knowledge organization in Zoo but not Control Camp children. These effects transpired despite equivalent Pre-Test performance, suggesting that the difference between camps at Post-Test cannot be attributed to greater prior taxonomic relations knowledge in Zoo Camp children. Moreover, the difference between camps remained
even when data from Zoo Camp children who received explicit taxonomic instruction were removed from analyses. Finally, the results provided evidence that the degree to which Zoo Camp experiences improved taxonomic relations knowledge was associated with age, suggesting that older children learn relations more effectively than younger children (a possibility we discuss further below). Taken together, these findings provide the first direct evidence that learning experiences need not accumulate over lengthy periods of time or take place in formal education settings to shape knowledge organization. Instead, an immersive but relatively brief learning experience in an informal setting can promote significant knowledge organization changes.

## Open Questions

The evidence for learning-driven knowledge organization change presented here highlights the importance of examining the mechanisms by which experience shapes knowledge organization. For example, although the present study was not designed to arbitrate between accounts of conceptual development that place different emphases on early conceptual biases versus domain-general processes and learning mechanisms, our findings are inconsistent with the perspectives emphasizing early conceptual biases towards perceiving entities as organized into taxonomic categories (e.g., Gelman, 2003; Keil, 2007; Wellman \& Gelman, 1992). By the same token, these findings support a key role for learning throughout development in shaping the organization of semantic knowledge (e.g., Fisher et al., 2015; McClelland \& Rogers, 2003; Tenenbaum et al., 2011). Research following on from the present study could further arbitrate between these accounts, particularly with respect to illuminating the nature of learning mechanisms posited to shape knowledge organization given environmental input.

Finally, our results provide some evidence that the magnitude of learning-driven knowledge organization changes increased with age. One characteristic of the learner that may improve with age is prior knowledge organization (Unger et al., 2016). Although taxonomic knowledge at pretest for the specific animals tested in this study was not correlated with learning-driven improvements, it is possible that older children's knowledge of animals in general was better organized than younger children's knowledge. Consequently, it may have been easier for older versus younger children to integrate new information into existing knowledge structures. Future research that investigates the relationship between such learner characteristics and learning-driven knowledge organization changes could illuminate how learning from experience improves with age.

## Conclusions

This study demonstrated that immersive learning experiences at a zoo summer camp produced changes in organization of children's knowledge about animals. These findings build upon research in several domains, including cognitive development, expertise, and the learning sciences by providing the first direct evidence for learning-driven
changes in knowledge organization. Future research should further investigate the mechanisms by which learning drives the development of knowledge organization.

# The Effects of Social Task Setting on Time Perception 

Kerem Alp Usal (e199523@metu.edu.tr)<br>Annette Hohenberger (hohenber@metu.edu.tr)<br>Department of Cognitive Sciences, METU Informatics Institute, Universiteler Mahallesi, Dumlupinar Bulvarı, No:1, 06800, Ankara, Turkey

#### Abstract

This study investigates the effects of the social setting on prospective time estimation, how time is perceived when a task is performed (i) alone, (ii) with a collaborative, or (iii) with a competitive partner. $N=90$ participants were tested ( 30 in each condition). Participants performed a concurrent Simon task for three different durations ( 15,30 and 45 seconds) which was followed by a time reproduction phase. Results revealed a main effect of social condition. Reproduction ratios in dual conditions were smaller than in the single condition and also smaller in the competitive condition compared to the cooperative condition. The results provide first evidence that social condition affects time estimation: time "flies" when we work together, in particular when we compete with a partner, showing that cognitive and social processes are heavily intertwined.

Keywords: time cognition; time perception; joint task; joint action; social Simon effect; social cognition; prospective time estimation

## Introduction

The passage of time has always captured the curiosity of humans. As archaeological studies revealed sundials were in use some 3500 years ago (Vodolazshkaya, 2014). However, measuring the passage of time with clocks is not the same as the "feeling" of how much time has passed. Therefore, it has been suggested that humans have internal and possibly innate mechanisms for keeping track of time and these mechanisms have been studied and explained with internal clock models which facilitate the understanding of how cognitive factors can affect time estimation (Droit-Volet, 2013).

This study brings together two lines of study in cognitive science: time perception and joint action. Time perception is a basic cognitive ability implied in a wide variety of experimental tasks and daily activities (Grondin, 2010). Forming joint attention and performing joint action is another cognitive ability which has recently been the focus of several studies showing that people's performance in any task is heavily affected by joint attention and joint action (Sebanz, Bekkering, \& Knoblich, 2006; Sebanz, Knoblich, \& Prinz, 2003; Vesper et al., 2011). Also, studies in the literature suggest that time perception might be under the influence of a person's mood at that time (Droit-Volet \& Meck, 2007).

The purpose of this study is to provide an experimental research paradigm linking the social aspect of the task setting to participants' prospective time estimation during that task, in order to investigate the effects of the social setting of the task on time perception.

## Time Perception

There are dedicated and intrinsic models for time processing (Ivry \& Schlerf, 2008). The dedicated models are modular, such as the Attentional Gate Model (Block \& Zakay, 2006) or the cerebellar timing hypothesis (Ivry et al., 2002). On the other hand, intrinsic models suggest that time perception is distributed in various neural networks instead of a certain part of the brain (Reutimann et al., 2004).

The Attentional Gate Model contains a pacemaker which emits pulses continuously on a certain rate, and it can only be affected by arousal on a small scale. These pulses flow through an attentional gate, which is regulated by an executive function that determines whether attentional resources should be directed to the task at hand or to the keeping of time, which might be affected by diverting attentional resources to another task. A switch between the attentional gate and the counter starts or stops the connection, and the counter system keeps track of how many pulses have passed since the beginning of the event and stores that information in memory. Later, the number of pulses are retrieved from memory to represent how much time has passed during the given event. Then the decision on the amount of time that has passed is based on the latest information from the counter and the beginning of the counting of the pulses. The additional attentional mechanism for the explanation of mistakes in time estimation seen in humans, especially when there are other attention-demanding tasks in parallel with time estimation (Block \& Zakay, 2006).

The temporal paradigm used in this study is prospective duration judgment, also called "experienced duration" (Block, 2014). In this paradigm, participants are aware that they will perform a time reproduction after some experienced duration (Zakay \& Block, 2004). Participants use their attentional resources to keep track of time while they are performing a secondary task during that interval.

In accordance with the Attentional Gate Model (Block \& Zakay, 2006), the amount of attention devoted to keeping track of time decreases in more demanding secondary tasks, e.g., executive tasks, compared to easier tasks, which results in an underestimation of the actual duration of the interval (Duzcu \& Hohenberger, 2014). As the amount of cognitive load increases, the ratio of reproduced duration to actual duration decreases, which means that participants tend to underestimate time (Block, Hancock, \& Zakay, 2010). This finding is explained by the Attentional Gate Model as follows: the attentional gate is down, because the participant is focusing on the difficult task at hand, and therefore more pulses of the pacemaker are missed.

## The Simon Task

The Simon task is a spatial compatibility task first described in a paper by Simon \& Rudell (1967). The Simon task is a two-choice reaction task and stimulus has relevant (e.g. color) and irrelevant (e.g. location) dimensions. Participants are instructed to respond according to the relevant dimension of the stimulus and not to the irrelevant dimension. The Simon task consists of congruent trials in which the irrelevant dimension is spatially compatible and incongruent trials in which the irrelevant dimension is not spatially compatible.

The first true Simon effect was shown in another study by Simon \& Small (1969). The Simon effect is based on the universal tendency to respond faster when stimulus and response location overlap, i.e. the congruent condition (Hommel, 2011).

## Joint Action

People frequently perform an action together, which is called joint action. The social Simon task is a joint action paradigm in which participants share a Simon task and respond only to half of the stimuli, e.g., blue or red stimuli, occurring on either side of the monitor, respectively. Interestingly, it has been shown that an individual's actions in the social Simon task are represented in the other person's mind and have an impact on their actions. Therefore, the social Simon task results in the same findings as the individual Simon task, i.e., people respond faster to a stimulus on their side ("congruent" condition) as compared to a stimulus on the opposite side ("incongruent" condition) even if the social Simon task does not necessitate a spatial reference as in the individual Simon task. This construction of a mental representation of each other results in an increase in the amount of cognitive load (Sebanz, Knoblich \& Prinz, 2003).

Previous studies have shown that the increase in the amount of cognitive load results in underestimation of time (Block, Hancock \& Zakay, 2010) which is in accordance with the Attentional Gate Model.

The present study brings together time perception and the social Simon task in a single study. It will broaden our understanding of how human time perception is affected by the social setting and the nature of this setting.

## Hypotheses

Our hypothesis is that subjects' time perception during a task is affected by the social setting of the task. In line with the Attentional Gate Model (Block \& Zakay, 2006), we argue that joint settings require more attentional resources than the single setting, since participants co-represent their partners' task, thus leaving less resources for time estimation. Due to social facilitation and attention demands, we expect that subjects will perceive time as proceeding faster during a joint-action task than in a single person task. Furthermore, the nature of the social setting - whether cooperative or competitive - may affect time perception. If subjects experience competitive settings as even more attention-
demanding they may perceive time as proceeding even faster during a competitive joint action task than a cooperative one.

## Method

## Participants

A total of 90 participants ( 42 males, mean age: 25.90, $\mathrm{SD}=5.234$ ) were tested in three different groups. The Single Task group ( $\mathrm{n}=30,14$ males, mean age: $26.03, \mathrm{SD}=6.206$ ) were tested alone whereas the Cooperative Task group ( $\mathrm{n}=30$, 14 males, mean age: $25.03, \mathrm{SD}=5.442$ ) and the Competitive Task group ( $\mathrm{n}=30,14$ males, mean age: $26.63, \mathrm{SD}=3.819$ ) were tested in dyads. Dyads always consisted of participants from the same gender. Participants were recruited through email invitation. They were undergraduate or graduate students from various METU departments. All participants were right-handed and had normal or corrected-to-normal vision. Before the study, ethics approval has been obtained from METU Human Studies Ethical Committee. All participants volunteered to join the study and no monetary reward was offered for participation or performance, since it might affect time perception (Failing \& Theeuwes, 2016).

## The Simon Task

A Simon task was performed for three different duration lengths ( 15,30 and 45 seconds) which was followed by a time reproduction phase. In the single condition, participants were tested alone and they did all Simon tasks and following time reproductions themselves. In the joint conditions (Cooperative and Competitive) participants performed a social Simon task in which each participant was assigned to a specific stimulus color and response button. The participant on the left side was instructed to use only the ' $z$ ' button and respond only to red stimuli whereas the participant on the right side was instructed to use only the '. ' button and respond only to blue stimuli. These buttons were chosen because on a Turkish Q-style keyboard they are the furthest apart horizontally. All participants used their right hand index finger to respond in order to achieve the same setting between dyads, since literature in the field suggests that the position of hands during a social Simon task might affect performance (Liepelt, 2014; Welsh, 2009). Stimuli occurred on the left and right side of the screen, randomly.

Participants in all conditions were told that they would receive points for their correct responses in the Simon task. In the single condition they were told that their points would be compared with other participants individually, in the cooperative condition they were told that their points would be calculated as a team and compared with other teams, and in the competitive condition they were told that each participant's points would be compared with the other participant in the dyad.

## Time Reproduction Task

Before the reproduction phase begun, participants were informed through a message on the screen that they were going to see a big square in the middle of the screen,
indicating the time reproduction phase has begun. Participants used the same button for the time reproduction phase, depending on the color of the big square, i.e. ' $z$ ' for red and '.' for blue.

They were instructed to wait as long as they thought the previous trial has lasted and then press the button to indicate the end of the duration. A message on the screen warned the participants before each time reproduction phase, which stayed on the screen for 2 seconds and the time reproduction has begun automatically afterwards. In the cooperative and competitive conditions, participants were instructed that if the big square was in the color they were responsible for, they were assigned to do the time reproduction. In other words, if it was red, the left participant did time reproduction and if it was blue, the right participant did time reproduction. The order of the color was random and balanced between subjects. Participants in all conditions performed a total of 18 time reproductions (6 of each duration length).

## The Questionnaire

After the test, participants were presented with a short questionnaire. The first 5 questions were presented to participants in all social conditions and they were regarding their mood and self-assessment during the trials. The second part of the questionnaire, which consisted of questions 6 to 9 , were only presented to participants in the joint conditions and were regarding partner-assessment and social warmth. There was also a $10^{\text {th }}$ question which was different amongst the two social conditions. The participants in the cooperative condition were asked to evaluate the quality of their cooperation whereas the participants in the competitive condition were asked the quality of their competition.

## Statistical Analysis

Collected data was analyzed in three different sections: Time Reproduction, the Simon Task and the Questionnaire. For the time reproduction, $3 \times 3$ mixed ANOVAs with social task setting (individual, cooperative, competitive) as a betweensubjects variable and duration (short, medium, long) as a within-subjects variable were conducted on three dependent measures: Duration Ratio (Reproduced Duration/Objective Duration), Absolute Error/Actual Duration and Coefficient of Variation (SD/Mean).

For the Simon task, response times for compatible $v s$ incompatible trials were analyzed as a dependent measure.

For the analysis of the questionnaire, presented options were given values from 1 to 5 , with the most negative option being 1 and the most positive option being 5 . The first 5 questions, which were presented to all participants, were analyzed with a One-way ANOVA for the 3 task settings (Single, Cooperative, Competitive). The second part, which consisted of questions 6-10, were only presented to the participants in dual task settings. A One-way ANOVA for the 2 task settings (Cooperative, Competitive) was carried out for each question.

## Results

## Time Reproduction

The first analysis was performed on Duration Ratios (Reproduced Duration/Objective Duration). The main effect of duration was statistically significant $(F(2,174)=174.64$, $p<.001, \eta_{p}{ }^{2}=.67$ ). Simple contrasts revealed that reproduction ratios were smaller for long durations ( $M=.48, S E=.014$ ) as compared to moderate $(M=.53, S E=.015) \quad(F(1,87)=49.93$, $p<.001, \eta_{p}{ }^{2}=.37$ ) and short durations ( $M=.65, S E=.015$ ) $\left(F(1,87)=225.26, p<.001, \eta_{p}{ }^{2}=.72\right)$, indicating that long durations were underestimated more than moderate and short durations. There was a main effect of task setting ( $F(2,87)=14.59, p<.001, \eta_{p}{ }^{2}=.25$ ). Helmert contrasts revealed a significant difference when the single task setting was compared to both dual task settings $(F(1,88)=18.30, p<.001$, $\eta_{p}{ }^{2}=.17$ ). The reproduction ratios in the dual task settings were smaller $(M=.51, S E=.022)$ than in the single task setting ( $M=.64, \quad S E=.027$ ), indicating that duration was underestimated more by the participants in the dual task settings as compared to the single task setting. Also, the difference between the cooperative task setting compared to the competitive task setting was significant $(F(1,58)=11.42$, $p=.001, \eta_{p}{ }^{2}=.16$ ). Reproduction ratios were smaller, hence durations were more underestimated in the competitive task setting ( $M=.46, S E=.023$ ) compared to the cooperative task setting ( $M=.56, S E=.019$ ) (see Figure 1).

Figure 1: Mean Ratio of Reproduced/Objective Duration across duration lengths for all task settings. (Error bars represent $S E$ and the numbers above the bars show the values of absolute time durations)

The analysis of the absolute errors showed that the main effect of duration was significant $(F(2,174)=157.77, p<.001$, $\left.\eta_{p}{ }^{2}=.64\right)$. Error ratios were higher, indicating that the inaccuracy of participants time estimation was higher in the long duration $(M=.52, S E=.13)$ than the short $(M=.36$, $S E=.12$ ) and the medium duration ( $M=.47, S E=.14$ ). The setting of the task had a significant effect on accuracy $\left(F(2,87)=15.38, p<.001, \eta_{p}{ }^{2}=.26\right)$. The first Helmert contrast revealed that participants in both dual task settings showed higher error ratios $\left(F(1,88)=18.56, p<.001, \eta_{p}{ }^{2}=.17\right)$, hence
were less accurate ( $M=.49, S E=.018$ ) compared to the single task setting $(M=.38, S E=.022)$. Moreover, as the second Helmert contrast revealed $\left(F(1,58)=11.42, p=.001, \eta_{p}{ }^{2}=.16\right)$, error ratios were higher, hence accuracy was lower in the competitive task setting $(M=.54, S E=.016)$ than the cooperative task setting ( $M=.44, S E=.021$ ). The effect of the interaction between duration and task setting was not significant $\left(F(2,87)=1.45, p>.05, \eta_{p}^{2}=.03\right)$ (see Figure 2).

Figure 2: Mean Values of Absolute Error/Objective Duration across duration lengths for all task settings. (Error bars represent $S E$ and the numbers above the bars show the values of absolute errors)

The third analysis was carried out on the Coefficient of Variation, which is calculated by dividing the standard deviation of reproduced durations by the mean reproduced durations. The CV is regarded as a very important variable in Scalar Expectancy Theory because a stable CV is a sign of the scalar invariance of subjective estimation of time across different duration lengths (Church \& Meck, 2003). The effects of duration $\left(F(2,174)=1.58, p>.05, \eta_{p}{ }^{2}=.02\right)$ as well as task setting on the CV were not significant $(F(2,87)=2.7$, $p>.05, \eta_{p}^{2}=.06$ ), indicating scalar invariance, as expected.

## The Simon Task

The analysis of the Simon task revealed that congruency had a significant effect $\left(F(1,87)=101.03, p<.001, \eta_{p}{ }^{2}=.54\right)$. Response times were significantly shorter in the congruent condition ( $M=525.66, S E=2.77$ ) in comparison to the incongruent condition ( $M=533.21, S E=2.79$ ) (see Figure 3). This difference amounts to the "Simon effect". Task setting did not have a significant effect on overall response times ( $\left.F(2,87)=1.53, p>.05, \eta_{p}^{2}=.03\right)$ : participants' reaction speed was similar in single ( $M=535.39, S E=4.29$ ), cooperative ( $M=529.35, S E=5.79$ ) and competitive ( $M=523.57, S E=4.18$ ) task settings. The interaction effect between congruency and task setting was not significant $(F(2,87)=2.24, p>.05$, $\left.\eta_{p}{ }^{2}=.05\right)$. Participants in all task settings were faster in the congruent condition than in the incongruent condition. Overall, these results revealed that the Simon effect was not affected by the various task settings, indicating that the primary time estimation task did not interfere with the secondary, concurrent task.

Figure 3: Mean Values of Response Time for congruent and incongruent trials across task settings. (Error bars represent $S E$ and the numbers above the bars show mean response times)

In order to assess whether the side at which the participant was seated had any effect on the Simon task, a 2 (Congruency: Congruent, Incongruent) x 2 (Participant's Side: Left, Right) Mixed ANOVA was conducted on response times. Participant's side was a between-subject factor and congruency a within-subject factor. This analysis revealed that congruency had a significant effect $\left(F(1,58)=62.47, p<.001, \eta_{p}{ }^{2}=.52\right)$. Participants' response times were significantly lower in the congruent condition ( $M=522.32, S E=3.58$ ) in comparison to the incongruent condition ( $M=530.59, S E=3.60$ ). Participant's side did not have a significant effect on overall response times ( $F(1,58)=0.27, p=.869, \eta_{p}^{2}=.00$ ), i.e., participants' reaction speed was similar on both the left ( $M=527.05, S E=5.17$ ) and the right side ( $M=525.87, S E=4.99$ ). The interaction effect between congruency and side was also not significant $\left(F(1,58)=1.00, p=.321, \eta_{p}^{2}=.02\right)$. Participants on both sides were faster in the congruent condition than in the incongruent condition, which shows that the Simon Effect was observed in participants on both sides (see Figure 4).

Figure 4: Mean Values of Response Time for participant's side across congruency. (Error bars show $S E$ and the numbers above show the values of mean response times)

## The Questionnaire

The analysis of the first five questions revealed that main effects were not significant for enjoyment/boredom during the trial $(F(2,87)=.242, p=.785)$, excitement $(F(2,87)=.079$, $p=.925$ ), pressure $(F(2,87)=.706, p=.496)$, self-assessment for the Simon task $(F(2,87)=1.375, p=.258)$ and selfassessment for the time reproduction task $(F(2,87)=1.457$, $p=.239$ ).

The analysis of the second part of the questionnaire revealed that main effects were not significant for questions 6 to 9: partner-assessment for the Simon task $(F(1,58)=0$, $p=1$ ), partner-assessment for the time reproduction task $(F(1,58)=.887, \quad p=.350)$, friendliness towards partner $(F(1,58)=.267, p=.526)$ and social warmth $(F(1,58)=0, p=1)$.

The results of the $10^{\text {th }}$ question on the quality of their cooperation/competition, revealed a significant main effect $(F(1,58)=10.401, p=.002)$. Participants in the Cooperative task setting assessed their cooperation with a higher value ( $M=3.83, S D=.87$ ) than participants in the Competitive task setting assessed their competition ( $M=2.90, S D=1.32$ ). This means that cooperative dyads reported to feel more as a team, compared to competitive dyads which reported to feel more as rivals.

## Discussion

The results of this study show that there is a strong relation between the social setting of a concurrent executive task and the subjectively perceived duration. Participants estimated the actual duration of the task to be shorter in the joint task settings compared to the single task setting. Also, the nature of the joint action had an impact on the amount of this underestimation, as participants in the competitive task setting underestimated time more in comparison to the participants in the cooperative task setting. These findings are in accordance with previous studies (Dolk et al., 2011; Ford \& Aberdein, 2015; Vesper et al., 2011; Vlainic et al., 2010) showing that joint-action tasks affect cognitive performance. In these studies, the effect concerned their behavior in the Simon task, where a social Simon effect occurred. In our task, however, the social Simon effect is not in the focus of our attention. We were primarily interested in the effect of joint action on the primary task, i.e., the time perception task.

The underestimation of the actual duration can be explained with the Attentional Gate Model (Block \& Zakay, 2006). Previous studies (Sebanz, Bekkering, \& Knoblich, 2006; Sebanz, Knoblich \& Prinz, 2003) have shown that when two or more people are performing a task together, they need to create a mental representation of their partner's part of the task, which requires attentional resources to be shifted towards this demanding task. Additionally, participants in the joint task settings had higher cognitive load due to inhibiting their response when the stimulus on the screen was the color of their partner and it was a no-go trial for them, whereas participants in the individual task setting always had a gotrial since they responded to both colors, and only had to keep track of which button to respond. This means that participants in the joint task settings also had an increase in cognitive load
caused by task switching. Furthermore, participants in the joint task settings had to monitor their partner's responses as well, since their score contributed to the outcome in dual conditions.

Since cognitive load is high and attention is focused on both the executive task and the mental representation of the partner in dual task conditions, the Attentional Gate is low, i.e., little attention is left to keep track of time, which results in a shorter experienced duration. The attention-depleting effect of executive tasks and the underestimation caused by it is well documented in the literature (Block, Hancock \& Zakay, 2010; Duzcu \& Hohenberger, 2014). Here, we have shown that also the social task setting affects this attentional mechanism.

Another possible explanation for the decrease in time estimation observed in the social task settings in comparison to the single task setting might be the effect of the "switch" part of the Attentional Gate Model which determines when attending to the passage of time starts and ends. It might be that when the participant is not acting herself but the partner is acting, these parts are "cut out" of her time experience by the closing of the switch. The switch would only open again when it's the subject's turn again. However, it is not possible to explain the difference between cooperative and competitive task groups with this explanation whereas the difference in cognitive load can explain both results.

Previous studies in the field (Decety et al., 2004; Ruissen \& de Bruijn, 2016) showed that, although both cooperation and competition result in self-other integration, participants in the competitive condition also spend attentional resources on keeping track of the differences between themselves and the other participant in the dyad. Participants in our study had to manage different cognitive loads according to the social condition: Cooperative dyads only needed to follow their cumulative scores, but participants in the competitive condition needed to follow their performance and their partner's performance as separate information, in order to predict who was more successful. This results in a higher cognitive load and thus more severe underestimation of time.

The literature (Droit-Volet \& Gil, 2016; Droit-Volet \& Meck, 2007) suggests that mood has a certain effect on time estimation. However, our questionnaire did not reveal any difference in participants' mood during the experiment, despite the significant contrast in their time estimation. This result suggests that the underestimations were caused by the depletion of attentional resources rather than by the effect of mood on the pacemaker.

Our results have also revealed a significant congruency effect in the Simon task, individual and social, which is in line with the vast literature on the Simon task (Hommel, 2011). The results also indicated that there was no difference in reaction times between participants who were seated on the right side and the left side, which shows that seating did not have any effect on participants' performance.

## Conclusion

The results of this study provide first evidence that social condition affects time estimation: people perceive time to flow faster when they are performing a task with someone in comparison to when they are alone, and even faster when the nature of the social condition is competitive rather than cooperative. This finding can be applied to daily life in education and at the workplace, by supporting joint action over individual work. Our findings also add to the growing literature on "joint action" (Sebanz, Bekkering, \& Knoblich, 2006), showing that there is a strong link between cognitive and social processes. This study has methodological implications in terms of promoting the use of joint settings in cognitive science.

For future studies, experiments that feature another task with similar cognitive load but no social setting would provide information in order to distinguish between the effect of cognitive load and the effect of sociality on time perception. Also, different social manipulations on the same task can provide further explanation whether the difference in time perception is the result of the attentional gate, the switch or the arousal.

# Instruction type and believability influence on metareasoning in a base rate task 

Pavle Valerjev (valerjev@unizd.hr)<br>Department of Psychology, University of Zadar, Obala kralja Petra Krešimira IV 2<br>Zadar, 23000 Croatia<br>Marin Dujmović (marin.dujmovic@gmail.com)<br>Department of Psychology, University of Zadar, Obala kralja Petra Krešimira IV 2<br>Zadar, 23000 Croatia

#### Abstract

Task dependent conflict has been shown to reduce metacognitive judgements of confidence and prolong response times in various reasoning tasks. For this study a modified version of the base rate task was used to induce conflict while measuring response times and judgements of confidence. The aim of this experiment was to determine the influence of different instruction conditions (reasoning according to belief or according to mathematical probability) on fluency and metacognitive judgements. As expected, participants experienced higher levels of conflict when reasoning according to mathematical probability even though conflict effects were present in both conditions. Additionally, higher believability items mitigated conflict influence while reasoning in accordance with belief and increased it when reasoning in accordance with mathematical probability. These results enrich the growing field of metareasoning research and are discussed as such.

Keywords: metacognition; metareasoning; base rate neglect; conflict monitoring; judgement of confidence

## Introduction

The dual process approach in the field of reasoning is based on the hypothesis of two distinct types of processing. Type 1 processing is heuristic based, fast and comes at a low cognitive resource cost, while Type 2 processing is analytic based, slower, less intuitive, and comes at a high resource cost (Evans, 2007). However, this is just a simplified representation of what is a large set of theories. Since this approach encompasses a large number of theories and models we recommend an excellent review by Evans (2012) for a better understanding of all the complexities in this field. Within this framework a cognitive bias can be defined as a dominant Type 1 response when it is not appropriate and results in a normatively incorrect answer. One of the most commonly studied biases is the belief bias in which a believable response is dominant and more acceptable regardless of correctness (Evans, Barston, \& Pollard, 1983). Tasks which elicit the belief bias have mostly been used in studies of formal types of reasoning such as syllogistic logical reasoning. However, there are other tasks in which participants are led to reason according to their belief. One such task is a modified version of Kahneman and Tversky's (1973) classic base rate task.

The modified base rate task is interesting to researchers because it is suitable for introducing conflict between processes that give rise to different responses. To better understand this task, examine a simple example.

Person X is popular.
Person X is chosen at random from a group consisting of 875 postmen and 125 actors.

The question: Which is more probable?

1. Person X is a postman
2. Person $X$ is an actor

In the example above there are two sources of information on which a person can base his or her response. The mathematical ratio (the base rate) of postmen to actors would indicate that the first answer is more probable. However, common belief based on personal, everyday experience would indicate actors are more likely to be popular than postmen. This strong association between the trait of popularity and the group of actors leads most participants to choose answer number two (e.g. Obrecht \& Chesney, 2016; Pennycook, Fugelsang \& Koehler, 2015). By changing the base rate, congruent versions of this task can be constructed and studied in comparison to conflict ones.

Our research is based on the model proposed by Pennycook and his colleagues (2015). They propose that multiple processes generate initial responses to a particular task or problem (Type 1 processes). The initial responses may be congruent or in conflict. Conflict monitoring then detects (or fails to detect) incongruent results of these processes which leads to Type 2 processing (or simple Type 1 processing if no conflict is detected). Type 2 processing then includes both rationalization of the dominant initial response, and what is usually considered pure Type 2 processing - cognitive decoupling (choosing an alternative response). It is important to note that rationalization and decoupling are not necessarily processed on a conscious level. The dominant response is the one with the highest weight, which would explain the difference in influence and persistence of those responses even when instructed to reason by different criteria. In the example given above the belief-based response would represent the dominant initial response, while the mathematical probability response would be the second initial response. This model provides clear hypotheses on the influence of conflict on response times, levels of confidence, required cognitive load and others.

As indicated, conflict monitoring and detection are key processes which link Type 1 and Type 2 processes
according to the proposed model. For the purposes of this study inducing conflict was of the greatest importance. Conflict monitoring and detection have been identified as important processes in a variety of reasoning tasks (De Neys, 2014; De Neys \& Glumicic, 2008). Conflict in base rate tasks is detected even when participants choose the stereotypical answer because it can be observed in prolonged response times (Pennycook et al., 2015). Since conflict detection in these tasks is present regardless of participant response it is interesting how this process effects other psychological constructs and processes.

Metacognition is broadly concerned with knowledge about, the monitoring and evaluation of other mental processes (Nelson \& Narens, 1990). Recent research in the field has been focused on possible sources of metacognitive judgements in various reasoning tasks (Markovits, Thompson, \& Brisson, 2015; Thompson, Evans, \& Campbell, 2013; Thompson \& Johnson, 2014; Thompson et al., 2013). Building on older research concerning metamemory Ackerman and Thompson (2015) lay out a framework of metareasoning. They outline a number of different metareasoning judgements. For example, the judgement of solvability refers to the probability a particular task is solvable based on type of task, prior knowledge and experience of the participant. Of the basic metareasoning judgments we focus on the final judgements of confidence. These judgements represent retrospective confidence that a final solution to a problem or task is correct. Typically, metareasoning studies make use of a variety of tasks which include the possibility of both heuristic and analytical responses. The interpretation of results in these studies then naturally takes into account the dual-process approach to reasoning. Participants usually express more confidence for heuristic-based responses (Thompson, Evans, \& Campbell, 2013). It has also been established that in these types of tasks participants tend to be overconfident and their judgements are not dependent on accuracy (Thompson et al., 2013). Therefore, metacognitive judgements in these tasks are formed based on other cues such as fluency (the speed and ease of generating responses) and the presence of conflicting answers (Thompson et al., 2013). Conflict in base rate tasks has been shown to decrease final judgements of confidence (Pennycook Trippas, Handley, \& Thompson 2014) and prolong response times (Pennycook et al., 2015).

Manipulating the content of tasks is only one way to influence reasoning processes. One of the more interesting manipulations is varying instruction types, giving more weight to a particular type of reasoning or to specific content. Explicit instruction to reason according to logic increases accuracy (Evans, Handley, Neilens, \& Over, 2010) as well as confidence ratings (Trippas, Thompson, \& Handley, 2016), depending on task difficulty. Within the described model of dual processing, instruction type modifies the weight of initially generated responses therefore influencing the level of experienced conflict.

The focus of our study was to determine how simple effects (congruence, instruction type, believability) interact
and effect response times and confidence levels. We predicted participants would experience a greater level of conflict when base rates and stereotypes do not point toward the same answer. This effect should be stronger when instructed to reason based on mathematical probability compared to reasoning based on belief. The level of experienced conflict is expected to increase the likelihood of Type 2 reasoning and manifest as prolonged response times and lowered judgements of confidence. We predicted the addition of different believability levels of stereotypes would influence judgements and response times differently depending on the type of instruction. When reasoning according to belief high believability should mitigate the influence of conflict while increasing it when reasoning according to mathematical probability.

## Method

## Participants and design

The sample ( $\mathrm{N}=38$ ) was recruited among undergraduate psychology students. The experiment was a 2(instruction type) $\times 2$ (congruence) $\times 2$ (believability) repeated measures design.

There were two different instructions. For half of the items participants were instructed to answer according to their belief. The exact instruction was "For the following items respond as fast as you can according to what you know to be probable from everyday experience". For the other half of the items they were instructed to respond in accordance with mathematical probability. The exact instruction was "For the following items respond as fast as you can according to mathematical probability".

The second independent variable varied the level of congruence. For half of the items there was no conflict between belief and mathematics based probability while for the other half there was.

Finally we varied the level of believability of the content by creating two types of items as displayed in the materials section.

In order to control order effects half of the participants first completed the block based on belief instructions and then the one based on mathematical probability, while the other half had the reversed order. Items within each block were randomized for each participant.

## Materials

Previous research with base rate tasks regularly used extreme base rate ratios to achieve the conflict effect, 995/5 and higher (De Neys \& Glumicic, 2008; De Neys, Vartanian, \& Goel., 2008; Obrecht \& Chesney, 2016; Pennycook et al, 2014). We chose to use less extreme and random ratios in order to control for a possible effect of repetitiveness on participant decisions. We implemented clear rules for ratio selection. The highest allowed ratio was $900 / 100$, while the lowest was set at $850 / 150$. Within this spread ratios were generated randomly by a computer algorithm.

To vary believability we followed two different approaches. For half of the items, attributes associated with the person were characteristic of one group, but not exclusive to it. E.g. Person $A$ is physically attractive. Person A is chosen from a group of supermodels or a group of secretaries. Obviously, secretaries can be attractive, but the attribute is an integral part of the concept supermodel. For the other half, we increased the difference in the believability of the attribute for the two groups. For one group the attribute was still integral, but for the other it was highly uncharacteristic, the opposite of what people would expect. E.g. Person B is courageous. Person B is chosen from a group of firefighters or a group of deserters. Courage is an integral part of what people think of firefighting, while cowardice is strongly associated with deserting.

Conflict is achieved when base rate ratios and belief based probability do not point towards the same choice. By adhering to the before mentioned guidelines, forty main and four practice items were selected from a larger pool of constructed items based on researcher scores. Base rate ratios were assigned randomly to the items which were then randomly assigned to experimental conditions. Examples for the four possible combinations of believability and congruence can be seen in Table 1. When combined with the two different instruction types this forms a total of eight experimental conditions (five items per condition).

Table 1: Examples of item types.

|  | Attribute | Subgroups |
| :--- | :--- | :--- |
| Lower <br> believability/Congruent | Elegant | 854 ice skaters, |
| Lower |  | 146 teachers |
| believability/Conflict | Creative | 866 waiters, |
| Higher |  | 134 painters |
| believability/Congruent | Comical | 880 comedians, |
| Higher |  | 120 morticians |
| believability/Conflict | Honest | 842 smugglers, |

The order in which subgroups appeared was randomized among items to avoid habitual responses from our participants.

## Procedure

The experiment was designed in E-Prime v2.0.10.356 and conducted in the Laboratory for Experimental Psychology. Before the main experiment participants underwent practice to associate themselves with the way in which they were required to react. For the main experiment participants were told an attribute describing a person would be presented for a few seconds after which they would receive information about the groups from which the person was randomly selected. Finally, they were presented with a choice and were required to answer from which group they thought the
person was probably chosen based on one of the instruction criteria (belief in one block, and mathematical probability in the other). Confidence judgements were made on a six point scale, with each point representing a percentage of confidence. Scale value 1 represented $50 \%$ confidence (guessing) with each successive value representing an increase of $10 \%$ with the scale value 6 representing $100 \%$ confidence (complete confidence). An example of the single trial procedure can be seen in Figure 1.

Figure 1: Example of a single trial.

## Results

Prior to analysis response time data was processed to eliminate outliers by removing responses outside of the +/3 standard deviation range. Outliers made up of $2.2 \%$ of all responses. Response times were averaged for items within each experimental condition ( 5 items per condition) for final analysis. Confidence ratings were also averaged to get the final confidence judgements for each condition. Before the main analysis two $2 \times 2 \times 2 \times 2$ mixed analyses of variance were conducted with an additional variable of block order (instruction order) to determine whether the order in which participants completed the experiment influenced response times and confidence judgements. In both analyses the main effect of block order and interactions which include the effect were not significant. The results of these analyses show that the order in which participants completed the task had no influence on response times and confidence judgements.

A 2 (instruction condition) x 2 (congruence) x 2 (believability) repeated measures analysis of variance was conducted on response time data. Results of the analysis can be seen in Table 2. A strong main effect of congruence showed response times were significantly shorter for congruent compared to conflict trials. Higher believability in general led to slower responses, but this was due to a strong effect in conflict situations when participants were instructed to reason according to probability (see the threeway interaction interpretation). The main finding of this study is reflected in the significant two-way interaction between instruction type and congruence which is shown in

Figure 2 (for all figures error bars represent 95\% confidence interval for the mean).

Table 2: ANOVA results for response times.

| Effect | $F(1,37)$ | $\eta_{\mathrm{p}}{ }^{2}$ |
| :--- | :---: | :---: |
| Instruction | .05 | .00 |
| Congruence | $11.68^{* *}$ | .24 |
| Believability | $7.07 *$ | .16 |
| Instruction by Congruence | $7.70^{* *}$ | .17 |
| Instruction by Believability | 2.32 | .06 |
| Congruence by Believability | 2.69 | .07 |
| Three-way interaction | $11.34^{* *}$ | .23 |
| ${ }^{* p<.05 \cdot * * p<.01}$ |  |  |

Figure 2: Response times as a function of conflict and instruction type.

The influence of conflict on response times was significantly lower when participants responded in accordance with belief (mean difference between congruent and conflict responses $M_{\text {diff }}=76 \mathrm{~ms}$ ) than when they responded in accordance with mathematical probability ( $M_{\text {diff }}=230.36 \mathrm{~ms}$ ). The three-way interaction effect reflects the different influence of believability depending on the instruction. Higher believability mitigated the influence of conflict when participants responded according to belief, and increased it when they responded in accordance with mathematical probability.

The same analysis was conducted for confidence judgements for which results can be seen in Table 3. The analysis showed a similar pattern of results. Participants expressed lower levels of confidence for conflict compared to congruent items, which is reflected in a large main effect of congruence. Believability, in general, slightly increased confidence ratings but was present in more complex interaction effects. Again, the main finding of this study is best observed by considering the significant two-way interaction between instruction type and congruence in Figure 3. Conflict lowered confidence judgements for mathematics based reasoning (mean difference between
congruent and conflict responses $M_{\text {diff }}=5.24 \%$ ) more than for reasoning based on belief ( $M_{\text {diff }}=2.38 \%$ ).

Table 3: ANOVA results for confidence judgements.

| Effect | $F(1,37)$ | $\eta_{\mathrm{p}}{ }^{2}$ |
| :--- | :---: | :---: |
| Instruction | .21 | .00 |
| Congruence | $20.49^{* *}$ | .36 |
| Believability | $6.54^{*}$ | .15 |
| Instruction by Congruence | $5.63^{*}$ | .13 |
| Instruction by Believability | .36 | .00 |
| Congruence by Believability | 2.30 | .06 |
| Three-way interaction | $4.77^{*}$ | .11 |
| ${ }^{p}<.05 ; * * p<.01$ |  |  |

Figure 3: Confidence judgements as a function of conflict and instruction type.

In the three-way interaction believability increased confidence ratings and mitigated conflict influence when participants responded in accordance with belief, and lowered confidence ratings for conflict items when they responded in accordance with mathematical probability.

Next, we analyzed accuracy depending on instruction type. For the belief based instruction the stereotypical response could be considered as correct, and for the probability instruction the opposite. Accuracy was high for the two belief conditions and the congruent probability condition (above 86\%), but low for conflict trials in the probability condition $(46.84 \%)$. Since this data was not distributed normally, we tested differences using the Wilcox matched pairs test. Instruction to reason according to mathematical probability significantly lowered stereotypical responses in conflict trials $(Z=4.94, p<.01)$, the same was true for the belief instruction condition ( $Z=2.65, p<.01$ ). To evaluate confidence judgements we calculated differences between confidence levels and accuracy for each participant (for this and similar procedures see Koriat, Lichtenstein, \& Fischoff, 1980). An instruction by congruence ANOVA showed a significant interaction effect $(F(1,34)=34.81$, $p<.01, \eta_{\mathrm{p}}{ }^{2}=.51$ ). Results showed the difference between
confidence and accuracy was largest for conflict trials in the probability instruction condition (Figure 4).

Figure 4: Differences between confidence and accuracy as a function of instruction type and congruence

Additionally, analyses of variance were conducted only for responses that were correct depending on the instruction. A total of 25 participants made up this dataset while the rest did not have correct responses for all of the experimental conditions. For both response times and judgements of confidence, results followed a very similar pattern to the analysis of the full dataset. Once again participants were considerably slower for conflict items $(F(1,23)=12.71$, $p<.01, \eta_{\mathrm{p}}{ }^{2}=.36$ ), and slightly slower for more believable items $\left(F(1,23)=9.63, p<.01, \eta_{\mathrm{p}}^{2}=.29\right)$. The instruction type by congruence interaction $\left(F(1,23)=9.54, p<.01, \eta_{\mathrm{p}}^{2}\right.$ $=.29$ ) was again the most interesting result. Conflict had a greater influence on response times when reasoning according to probability than when reasoning according to belief. The three-way interaction was no longer significant but showed the same pattern of results. For judgements of confidence the analysis showed significantly lower levels of confidence in conflict compared to congruent conditions $\left(F(1,23)=19.60, p<.01, \eta_{p}^{2}=.46\right)$. The instruction by congruence interaction remained significant $(F(1,23)=$ 5.62, $p<.05, \eta_{\mathrm{p}}{ }^{2}=.20$ ) and showed conflict lowered confidence judgements to a larger extent than when reasoning according to probability. Additionally, instruction by congruence $\left(F(1,23)=12.37, p<.01, \eta_{\mathrm{p}}{ }^{2}=.35\right)$ and congruence by believability $\left(F(1,23)=4.92, p<.05, \eta_{\mathrm{p}}^{2}=\right.$ .18) interactions showed participants were less confident for high believability items when reasoning according to probability and that conflict had a larger influence on confidence for higher believability items. The three-way interaction was no longer significant, but showed the same pattern of results as the analysis of the total response data.

Finally, we calculated an item-level correlation between response times and confidence ratings. Results ( $r(38)=-.56$, $p<.01$ ) showed that participants gave higher judgements of confidence for items they responded to faster.

## Discussion and conclusions

According to the proposed dual-process model by Pennycook et al. (2015), initial responses are generated by

Type 1 processes in reasoning tasks. If there is a conflict between the initially generated responses, and it is successfully detected, Type 2 processing resolves the conflict in two possible ways. One outcome is the acceptance of a dominant initial response (rationalization), and the other is choosing an alternative response (cognitive decoupling). Because of the expected dominance of belief based responses, we predicted that induced conflict would have a greater influence when instructed to reason based on mathematical probability compared to reasoning based on everyday belief. According to the prediction, this greater influence would initiate Type 2 processes to a larger extent, which would manifest in prolonged response times and lower confidence judgements in the mathematical instruction condition. Both three-way ANOVAs (Tables 2 and 3 ) prove this prediction to be correct. The expected strong main effect of congruence was significant, which is the usual result in this type of research (Pennycook et al., 2015; Pennycook et al., 2014; Thompson \& Johnson, 2014; Thompson et al., 2013). The main findings show that participants responded slower in conflict trials when reasoning according to mathematical probability. Conflict influence was less prominent when reasoning in accordance with everyday belief. This pattern of results is evident for both response times and confidence judgements (Figures 2 and 3). We hypothesize that stereotypical responses have a greater weight during initial response generation (Type 1 processing), which leads to stronger interference of belief on probability based reasoning than vice versa.

Our additional experimental manipulation of stereotype believability resulted in significant three-way interaction effects (Tables 2 and 3 ). When reasoning according to belief, higher believability mitigates the impact of conflict on response times and confidence levels. On the other hand, higher levels of believability increase the influence of conflict when reasoning based on mathematical probability. This result may represent further proof for the existence of differently weighted initial responses among which belief based responses are very prominent.

Participants expressed a higher level of confidence for items which had shorter response times indicating response fluency is a strong cue in the formation of metacognitive judgements. This finding was obtained in recent studies using different thinking and reasoning tasks (see Thompson et al., 2013).

Furthermore, when instructed to reason according to belief, conflict decreased stereotypical responses, but to a far lesser degree than when instructed to reason according to mathematical probability. It is important to note that even when instructed to reason according to probability participants chose belief based responses in over $50 \%$ of conflict trials. This further strengthens the conclusion that everyday belief dominates reasoning in this specific task. Within the framework proposed by Pennnycook et al. (2015), this would indicate instruction to reason according to probability influenced the relative importance of belief and probability information, but did not fully override the
initial dominance of belief based responses. Participants were overconfident only for conflict trials in the probability instruction condition (Figure 4). This was probably due to the fact that in the other three conditions the dominant belief based answers were correct, while in this one that was not the case.

When we analyzed only correct responses the same pattern emerged. As the model predicts, participants were slower and less confident in conflict trials and the conflict had a larger effect when reasoning according to probability. Based on these results, we can conclude that emphasizing a particular way of reasoning can have an effect on the relationship between conflict, response fluency and metareasoning judgements.

When these results are considered together we can conclude everyday belief has a stronger interference on mathematics based reasoning in this type of task than vice versa. Since a main effect of instruction (reasoning type) was not observed, we can speculate the two processes run in parallel, but that the result of the belief based process has a higher weight.

The results may have practical implications, particularly in educational settings. Many tasks require students to ignore intuitive modes of reasoning in favor of analytical thinking, and it is in those types of tasks where results such as found by this study could be applied to increase efficiency.

To conclude, the results of this study confirm the strong influence of conflict on response times and confidence levels in reasoning tasks. The study expands on previous research by introducing further complexity into established relationships between processes. Explicit instructions in combination with different levels of believability moderate the influence of conflict on fluency and confidence judgements. Results may indicate parallel processing of multiple, differently weighted processes, but more sophisticated research is required to explore the findings further.

#### Abstract

We studied the effect of adjunct displays on recall in an expository text (based on McCrudden, Schraw, Lehman, \& Poliquin, 2007) in order to find out which means of display aided pupils in the last years of secondary school to recall information. We included four conditions in the experiment: text only, text and causal diagram, text and images and causal diagram only. Participants were checked for their recall of main ideas and causal sequences. Recall for main ideas did not vary significantly across conditions. Contrary to McCrudden et al. (2007), our results for the causal sequences revealed that participants who studied a causal diagram only could recall more steps from causal sequences than participants in any of the other conditions. We will interpret the findings in the light of the literature on redundancy effects, dual coding theory, and the causal explication hypothesis.

Keywords: Causal diagram; Text comprehension; Causal relationships; Visual/spatial display

## Introduction

We set up an experiment studying the benefits of adding causal diagrams and illustrations to expository texts for recall of information. We will discuss the use of adjunct displays (i.e. visual representations that complement text with the purpose of making the information present more easily understandable and better recalled) in previous research. After that, we will go into more detail on the specific advantages of causal diagrams for text interpretation.

## Benefits of adjunct displays

Adding so called "adjunct displays" i.e. powerpoint presentations, images, causal diagrams, etc. to a spoken or written text does not always entail the expected benefits for the reader or listener. When these kinds of adjunct displays are added to text, they restate the same information of the text in a new form (such as causal diagrams) or add new chunks of information (such as images). The audience's preexisting knowledge about the topic and the amount of overlap between the two sources of information are two variables that need to be considered. When taking these nuances into account, adding visual displays can promote recall, provided they are implemented in the right way.

Vekiri (2002) presented an overview of the advantages of different graphical displays for recall and suggested that graphics make a valuable contribution to learning only when readers can interpret and integrate the information without
extra processing demands. The effects of adding graphics are mediated by variables such as the participants' preexisting knowledge about the subject of study and visuospatial ability. Also, graphic displays need to be adjusted to task demands. E.g. when an important part of text comprehension is understanding cause-effect relations, the diagram should explicate these relations and their interactions (Mayer \& Gallini, 1990). When graphs are used in a right way, they improve understanding. When this is not the case, they often interfere with learning because they impose extra processing demands reducing working memory capacity for learning activities.

Because of the way diagrams organize text and explicate relations, they make it easier to draw inferences about the relations that are present (Robinson \& Kiewra, 1995). Precisely because links are provided between information bits, relations that might otherwise have remained implicit are now more easily computed (Larkin \& Simon, 1987). See also the causal explication hypothesis (Graesser \& Bertus, 1998; McCrudden et al., 2007, p. 372): adding causal diagrams improves text comprehension because "they provide an explicit visual representation of a text's causal structure that helps the reader understand the text's causal structure". Analyzing causal relationships between text fragments is cognitively demanding. Presenting a causal diagram can help readers to construct a mental model of the text and hence leave more room for inference drawing and consequently a deeper comprehension of the text.

McCrudden et al. (2009, p. 81) present four reasons why the use of adjunct displays boosts understanding of causal relationships. First, a saliency issue: the relevant causal steps are brought to the fore. Their second reason refers to the reduction of cognitive effort. Third, a holistic understanding of the causal structure of the text is more easily achieved. A last reason is concerned with spreading the information via different channels: "it is possible that an adjunct display distributes the information across verbal and spatial working memory stores, functionally increasing its capacity" (McCrudden et al., 2009, p. 81).

Apart from causal diagrams, images are also often added to text. The visual "argument hypothesis" and "picture superiority effect" state that adding images is effective because they are more easily processed than text. In that respect, reference is often made to the "dual coding theory" (Paivio, 1990) that attributes these benefits to the assumption that there are two different codes for visual information (stemming from pictures or words). The dual coding theory postulates that there are two distinct cognitive
systems for information processing and retrieval. "Imagens" stores nonverbal information in mental images, whereas "logogens" stores verbal information in word-like codes (see also Vekiri, 2002). The dual coding theory had been called into question by Johnson-Laird (1998) claiming that information from both verbal and image cues is represented in a single amodal form (see also Vekiri, 2002). These challenges have received recent support from neurological studies. Specifically, recent neural evidence has shown (Shinkareva, Malave, Mason, Mitchell, \& Just, 2011) that patterns of brain activity when thinking about concrete objects are independent of the stimulus presentation format (i.e. words or pictures). Neural states could be identified that are common to pictorial and verbal input referring to objects categories. Not only could they find this effect within participants, but regions of brain activity could also be predicted across participants. "The category of a noun that a person reads or thinks about can be identified solely on the basis of activation patterns obtained from other individuals" (Shinkareva et al. 2011, p. 2422). This evidence at least suggests that the dual coding theory and the picture superiority effect need rethinking.

## Influence of causal diagrams on comprehension

In this section, we address the question whether causal diagrams bring specific advantages for text interpretation. Several studies with undergraduate students have revealed the beneficial nature of adding causal diagrams to texts.

McCrudden et al. (2007) present participants with texts accompanied or unaccompanied by a causal diagram (i.e. a type of visual display that explicitly represents cause-effect relationships, McCrudden 2007, p. 367) summarizing the main ideas and causal sequences of the text. Their results showed that participants who studied both text and causal diagram understood better the five causal sequences in the text. In a second experiment, in which participants studied either the text or the causal diagram, no differences could be found for recall of main ideas or causal sequences between the two conditions. They conclude that causal diagrams are not merely redundant with text.

McCrudden, Schraw, and Lehman (2009) set up two experiments in which participants read a text, either followed by the task to study a causal diagram, to study a list, or to reread the text. After that, participants were asked a range of questions focusing on the steps in the causal sequences and the transitive relationships between causes and effects. Participants in the reread condition performed worse than participants in the other conditions. On the basis of similar results in the two experiments they conducted, McCrudden, Schraw, and Lehman (2009, p. 80) conclude that explicating the steps in a causal chain improves comprehension of the text and learning of causal relationships.

In another study McCrudden, Magliano and Schraw (2011) investigated the online reading processes of participants while they were reading a text or studying a diagram. In their first experiment participants either studied
the causal diagram before reading the text or did not study the causal diagram before reading the text. Participants who studied a diagram before reading the text had faster overall reading times than participants who did not. Moreover, participants in the diagram condition recalled more information than participants in the no-diagram condition. In a second experiment, participants in the no-diagram condition had to read the text twice in order to make the experiment similar for the two groups, and in order to preclude the fact that the effect from the first experiment was due to the repetition of content (2011, p. 78). Again they conclude that "exposure to the diagram had a beneficial effect on comprehension over and above simple repetition" (2011, p. 81). Reading time data showed that reading times of the text of participants who first studied a causal diagram were longer than those of participants who simply reread the text. After that they compared text reading times of participants in the diagram condition with text reading times of participants (of the first reading of the text) in the reread condition. No differences could be found between them. In a third experiment participants were asked to "think aloud" while studying the texts or diagrams. It was shown that presence of a diagram improved the participants' recognition of causal relations.

## Experiment: the contributions of text, images and causal diagrams for recall

We investigate the effects of images and visual displays on recall of information from expository science texts. As in McCrudden et al. (2007) we included conditions with text only, text and diagram, and diagram only. The diagram consists of key terms of the text; relations and sequences are expressed by means of arrows.

Our study diverged from the one by McCrudden et al. (2007) in five important respects. First, we added a condition with text and images. We wanted to find out whether visual displays aided recall of ideas and causal sequences and if they did, which kind of visual display was most beneficial for a thorough understanding and recall. Do causal diagrams entail a bigger advantage because they explicate causal relations? Or do images contribute equally to the comprehension process because they visually represent the content? Second, we did not include a reread condition in our experiment because we think this condition is not straightforwardly comparable to the other conditions. Participants who were asked to reread the text probably invested less effort than participants who received slightly new materials summarizing the main ideas of the text they had just read. In our opinion, rereading a text that is exactly the same as the one you have just read is bound to go a lot faster. Third, we opted for a direct comparison between all four conditions in one experiment. Fourth, participants were given less time to study the causal diagram than in the study by McCrudden et al. (2007). Less information needs to be processed and we wanted to find out whether similar results could be achieved with less studying time. Fifth, we decided
to recruit pupils from secondary schools because the lion's share of research has been carried out with university students and elementary school children, and little attention has been paid to pupils in the last years of secondary school (see also: Mason, Tornatora, \& Pluchino, 2013). Because pupils in this age category are studying many different subjects, are getting acquainted with studying larger chunks of information and need to make important decisions about their future study and career orientations, they are a very interesting group to look into in more detail.

In the experiment participants were allocated to one of four conditions: study a text combined with images, a text combined with a causal diagram, only the causal diagram, or only the text. Participants were tested for their recall of main ideas and for their recall of steps from a causal chain. As in McCrudden et al. (2007) we expect no differences for recall of the main ideas, because their understanding does not rely on participants' ability to link information. We do expect differences for recall of causal sequences because these require participants to build a mental model of the text with causal links, which burdens cognitive resources (Graesser \& Bertus, 1998). If the participants in the text only condition outperform the other conditions, this provides evidence that accompanying materials are redundant. If on the other hand, participants in the condition of text accompanied by causal diagram or causal diagram alone outperform the other conditions, it provides evidence in favour of the causal explication hypothesis: explicating causal relations in a diagram helps processing. If the condition of text combined with images is better than the rest, this supports the visual argument hypothesis.

On the basis of the literature, we hypothesize that participants will perform better in the conditions where text is accompanied by a visual aid, be it a causal diagram or an image.

## Method

Participants 91 pupils from the fifth and sixth grade secondary education (mean age $=17.05, S D=0.85$ ) took part in the experiment. The participants' mother tongue was Dutch.

Design The materials were manipulated between subjects. Participants were randomly attributed to one of four conditions: text and images, text and diagram, text only, or diagram only.

Materials The materials varied in the four conditions. Basis in all cases was an explanatory scientific text about space travel. In the 'text only' condition participants read a text of 1171 words. The text was taken from McCrudden et al. (2007) ${ }^{1}$ and translated into Dutch. A few minor

[^536]adaptations were made in order to make the text more easily readable in Dutch. In the 'text and images' condition the same text was used, but now accompanied by six images. Every image highlighted a particular step from one of the five causal sequences. Three images illustrated a step from the causal sequence (osteoporosis, an excess of bodily fluids in the upper regions of the body, contradictory signals in the brain about the body's orientation). The other three images illustrated a consequence or danger of the causal sequence (kidney stones, muscle loss, heart shrink). In the 'text and diagram' condition, the text was accompanied by a causal diagram. Text and diagram were presented simultaneously. The causal diagram was taken from McCrudden et al. (2007) and translated into Dutch. The causal diagram consists of five cause-consequence relations originating from a common cause: lack of gravity during space travel. In the 'diagram only' condition participants only studied the diagram. In the 'text and diagram' condition and 'diagram only' condition, the materials were preceded by a few lines instructing the participants how to read and interpret the diagram.

Test materials consisted of a questionnaire consisting of two parts. The first part contained three questions. The first asked about participants' prior knowledge about space travel ( $1=$ knew nothing $-6=$ already knew everything). The second question asked participants to write a short text about their willingness to become a space traveler after having read about the dangers of space traveling. This question was inserted in order to create a time buffer between reading the text and answering recall questions. The third question enquired about the "main ideas": participants were asked to name parts of the body that were affected by space travel, and the associated risks (e.g. lack of gravity influenced bone structure, which augmented the risk of kidney stones). The second part of the questionnaire focused on the causal sequences. A particular risk was given (e.g. space travel may cause kidney stones) and participants were asked to list as many causal steps as they could remember. They were invited to explain why the risk existed and to name as many causes and consequences as possible.

Procedure The experiment was conducted in a large study room. Participants in the 'text only', 'text and images', and 'text and diagram' conditions were given 8 minutes to study the materials, participants in the 'diagram only' condition were given 4 minutes to study the materials. (Time needed was determined on the basis of a small pretest.) The 8 minutes group was told after four minutes that four minutes remained. All groups were informed one minute before the end that one minute remained. The materials were collected
site for NASA: When Space Makes You Dizzy (Phillips \& Hullander, 2002) and Mixed up in Space (Phillips \& Hullander, 2001), and one Web-page from an educational Web site for the National Space Biomedical Research Institute: Human Physiology in Space (Lujan \& White, 2002)." (McCrudden et al., 2007, p. 373)
and the first part of the questionnaires was handed out. When participants had finished the first part of the questionnaire, they raised their hands, handed in the first part and received the second part of the questionnaire. No time limits were imposed to fill in the questionnaires. The experiment took the participants approximately 45 minutes.

## Results

Preliminary questions: On the question how well acquainted participants were with the subject of space travel on a scale from 1 (=knew nothing) to 6 (=knew everything already), an average of 2.3 was reached ( 23 participants chose 1 on the scale, 34 chose 2,19 chose 3,12 chose 4,3 chose 5 , none chose 6 ). Correlations were checked between overall recall of main ideas and prior knowledge and between overall recall of causal sequences and prior knowledge but no significant correlations were found.

Main ideas: An ANOVA was conducted with text type (causal diagram only - text only - text and diagram - text and images) as the independent variable and main ideas as the dependent variable. No main effect of text type could be found: $F(3,87)=.739, p=.53$. Recall of main ideas did not differ significantly whether participants read the 'text only', 'text and diagram', 'text and images' or the 'causal diagram only'.

Causal sequences: As for recall of the causal sequences, we conducted an ANOVA with text type as between subjects variable and causal sequence as within subjects variable (repeated measures). To allow for comparisons across causal steps, scores were converted to proportions. I.e. per causal sequence, the number of causal steps remembered was divided by the total number of causal steps for that particular sequence.

There was a main effect of text type $F(3,87)=3.93$, $p=.011$. Causal diagram $(M=0.52)$ led to greater recall than any of the other text types (text only $M=0.34$ - text and diagram $M=0.39$ - text and images $M=0.33$ ). Planned comparisons revealed that 'diagram only' differed significantly from 'text and diagram' $F(1,87)=4.91$, $p=.0015$, which was the second best condition for recall.

There was a main effect of specific topic of the causal sequences: $\quad F(4,348)=18.80, \quad p=.00001$. Planned comparisons revealed that the causal sequence of 'muscle loss' was significantly more recalled than the other four causal sequences ('muscle loss' $M=0.57$ - kidney stones $M=0.43 ; F(1,87)=10.66, p=.002)$. No difference was found between the causal sequence 'kidney stones' and 'motionsickness' ( $M=0.42$ ), but these two causal sequences were better recalled than the causal sequence 'infections' (infections $M=0.31$ - kidney stones; $F(1,87)=4.61, p=.035$ ), which was in turn more recalled than the causal sequence about 'heart shrink' (heart shrink $M=0.25$ - infections $F(1$, 87) $=3.97, p=.049$ ).

The interaction between text type and causal sequence almost reached significance level: $F(12,348)=1.66, p=.07$. The causal sequence that was easiest to remember (muscle loss) did not differ between the different text types. For the more difficult causal sequences, planned comparisons revealed that the participants in the "diagram only" condition always scored best (motion-sickness $F(1,87)=6.96, p=.009$; kidney stones $F(1,87)=9.32, p=.003$ infections $F(1,87)=8.25, \quad p=.005$, and heart shrink $F(1,87)=7.59, p=.007)$.

## Discussion

As in McCrudden et al. (2007) no differences were found between the groups for recall of the main ideas.

The results for the causal sequences show that participants had higher recall rates when they studied a causal diagram only than any of the other types of materials (text only - text and diagram - text and images). No differences were found between the other conditions. Moreover, participants in the 'diagram only' condition only had four minutes to study the diagram, whereas the participants in the other conditions could study the materials for eight minutes. The fact that participants were able to achieve better comprehension in a shorter period of time, is surprising. This result runs counter to the results obtained in McCrudden et al. (2007) where no differences in recall of causal sequences between diagram and text could be found.

A straightforward explanation is the fact that the diagram only contained information that was relevant for the questions participants would receive (cf. the saliency issue discussed in the introduction). The other conditions with text also contained secondary information. A more in-depth explanation for these results might reside in the fact that participants need to invest more processing effort in understanding the diagram and this leads to deeper processing and hence a better retention of the studied materials in the brain. Ainsworth and Loizou (2003) and Moore and Scevak (1997) show that students make more inferences in diagrams than in running text. McCrudden, Magliano, and Schraw (2011) show that studying a diagram led to higher recall of information compared to text reading.

This experiment provides evidence that studying a diagram leads to a better retention in memory. When participants study texts, they may opt for the easy way out: the text reads smoothly, deep processing is not necessary for superficial text comprehension. Additional evidence for this claim can be found in the fact that, similar to the results of McCrudden et al. (2007), the more complex the causal sequence, the better participants could recall the causal sequences when they had studied a diagram compared to the other conditions. Difficult causal sequences may not have been understood profoundly enough in the text condition, whereas the diagram condition made sure the more difficult causal sequences were studied thoroughly. This fits in with the finding by Cromley et al. (2010, p. 69) that "students used a significantly higher proportion of inferences and high-level strategies and a significantly lower proportion of
low-level strategies in diagrams than in text. (...) diagrams seemed to promote more high-level, integrative activity and seemed to discourage low-level superficial strategies."

An explanation why the 'text and diagram' condition did not have higher recall rates than the 'text only' condition, is to be found in the fact that students often skip diagrams or skim only parts of the diagram (see e.g. Schmidt-Weigand et al., 2010). Schmidt-Weigand et al. (2010) also showed that the time participants took to inspect visualizations of the text was considerably lower than the time participants took to read the text. Participants might find the information in the text sufficient and find the diagrams superfluous. When their expectations of relevance were met, they did not take the effort to study the diagrams in detail. This could be overcome in future research by presenting the diagram before the text.

Another surprising finding is that our results fail to support the so called "picture superiority effect" since the condition in which participants studied text and images had the lowest averages of all conditions (but not significantly lower than text only and text and diagram). It has been suggested that when words are processed meaningfully, memory for them may be comparable to that of pictures (Weldon \& Coyote, 1996, p. 671). Processing of information (words, pictures, ...) is optimized according to task requirements (Job \& Tenconi, 2002). Once that purpose is defined, "the processing of information seems to proceed to levels that satisfy the task requirements" (Miller, 2011, p. 719). So in our experiment, adding pictures did not lead to better recall because the information present in the text was sufficient to the participants. Adding pictures did not entail any additional benefits. Apparently participants thought that the information was processed satisfactorily for the current purposes. While Levin \& Mayer, 1993 and Marcus et al., 1996 (as cited in Pike et al. 2010) provided evidence that the use of illustrations reduces the demands on working memory and hence leaves more resources for higher order processing of the text, no evidence for this could be found in our results.

## General Discussion

Here we will situate our results with regard to the causal explication, verbal redundancy, and picture superiority hypothesis. We will also discuss the implications for devising course materials.

## Causal explication hypothesis

McCrudden et al. (2007) provided evidence in favour of the causal explication hypothesis, when text and causal diagram were presented together, because participants in the condition text and causal diagram outperformed the ones in the text only condition. On the basis of our results, we can say that our results tilt toward a redundancy effect when two sources of information are presented together. Even though it is claimed in McCrudden et al. (2007) that causal diagrams are not merely redundant with texts, this seems to be the case in our study. When adding a causal diagram to
text, recall rates drop to levels similar to those of text only. This may be due to the fact that participants only had a look at the diagrams after having already processed the text and hence devoted less attention to it than when they first would have had a look at the causal diagram instead of vice versa.

However, when a causal diagram is presented on its own, recall for causal sequences improves. These results underpin the causal explication hypothesis. When implicit causal relations are made explicit in a causal diagram, recall significantly improves. Whether the effect is due to the fact that only the relevant information for the recall questions was summarized in the causal diagrams or whether it is actually due to their structure or both factors combined, will have to be left unresolved for the time being. However, there can be little doubt as to the role causal diagrams play in alleviating the strains put on our cognitive capacity. The resources made available in this way can then be devoted to storing the information and the links between bits of information more firmly in memory.

## Verbal redundancy

The effect of redundant information has been studied on various levels. Many studies have been conducted investigating "verbal redundancy". When similar information is simultaneously given via different channels (i.e. spoken and written information), comprehension and recall are not necessarily better than when the information is only given in one form. These studies have often been carried out in multimedia environments. The overall conclusion is that when redundant information is given, learning becomes impaired. Rey and Buchwald (2011), Sweller (2005a, 2005b) have shown that offering redundant material often interferes with learning rather than facilitating it (see Sweller, 2005b, p. 159). This redundancy effect is attributed to the fact that working memory capacity is burdened excessively with integrating identical information received via different sources. The results of the experiment are in accordance with the aforementioned studies. When the information is twice presented (causal diagram and text, or text and pictures) learning does not improve compared to the text only condition. So the fact that the information is given in two versions does not hinder learning but neither does it improve learning.

## Picture superiority

As we have argued in the discussion, we fail to find evidence for the picture superiority effect. When pictures are added to text, recall does not improve. The positive effect of a causal diagram cannot be interpreted in terms of picture superiority, because causal diagrams are not pictures, but they are small summaries of causal information in the text.

## Suggestions for study materials

In conclusion, we can say that causal diagrams turn out to be a very convenient study aid, when a deeper understanding of relations is aimed for. It is even the case
that causal diagrams appear to be the principal matter to study for students instead of texts when recall of causal relations is at stake. Participants who studied the causal diagram alone, outperformed the participants in any of the other conditions. So, we can recommend students to draw causal diagrams of the materials they have to study and authors of school and college books to add causal diagrams whenever possible summarizing the main ideas and the relations between them. Making the structure of the text more insightful is a vital characteristic of causal diagrams.

In short, our findings hints towards the need to elucidate course material with diagrams in order to boost memory.

#### Abstract

Accounts of abstract word learning suggest that learning these words relies primarily on access to linguistic cues, such as the statistical co-occurrence of words with similar semantic properties. Thus, children with language impairment (LI), who by definition have impoverished access to linguistic context, should have disproportionate impairments in abstract word knowledge. Here, we compared verbal definitions and lexical decisions to both abstract and concrete words of children with LI (ages 8 to 13) and both age-matched and vocabulary-matched typically developing (TD) peers. Relative to age-matched peers, children with LI had significant deficits in both tasks. Crucially, however, there was not greater impairment of abstract words. We conclude that that linguistic knowledge is not a sine qua non to learning abstract words and concepts and other mechanisms, which are not specifically impaired in LI, are at play.

Keywords: abstract concepts; semantic representation; distributional semantics; lexical decision; specific language impairment (SLI); vocabulary development.

## Introduction

Children learn thousands of words quickly and efficiently, often without any formal training, and even in impoverished environments. Learning words is hard because even when the referent is present in the physical environment, rarely it is isolated in the visual scene (Medina, Snedeker, Trueswell \& Gleitman, 2011). To make the situation worse, referents are not always present in the physical environment, either because they are spatially and/or temporally displaced (e.g., talk about past or future events), or because they are abstract and have no tangible referent. Most theories of vocabulary acquisition focus on the mechanisms by which words referring to concrete concepts (i.e. objects, actions and other events that can be experienced with our senses and through our own actions) can be learnt; it is less clear how a child learns abstract concepts, which are not perceivable by the senses.

It has been argued that children learn the meaning of concrete words such as "cat" or "run" by observing the statistical contingencies between the words and the objects,
people and actions occurring in the physical environment (e.g., Yu and Smith, 2007). In addition, such contingencies could be enhanced by the use of social communicative cues, such as eye-gaze, or pointing, through which caregiver directs attention to the correct referent (Baldwin, 1991) or by infants actively isolating intended referents from the visual background by picking them up (Morse, Benitez, Belpaeme, Cangelosi \& Smith, 2015).

Word meanings, however, can also be learnt from the linguistic context in which the words occur (Firth, 1957). Recent work has demonstrated how models of semantic memory, based on co-occurrences of words in text (also called Distributional Semantic Models), can predict a variety of semantic effects in adults and children (e.g., Andrews, Vigliocco \& Vinson, 2009; Bruni, Tran \& Baroni, 2014; Landauer \& Dumais, 1997; Griffiths, Steyvers \& Tenenbaum, 2007). This strategy could complement, at least for concrete words, other social-cognitive strategies. For abstract words, distributional information may provide a powerful, if not the most important, mechanism for learning (e.g., Andrews et al., 2009; Johns \& Jones, 2012).

In line with distributional semantic models, abstract words are acquired late in development (Kousta, Vigliocco, Vinson, Andrews \& Del Campo, 2011; Ponari, Norbury \& Vigliocco, in press; Schwanenflugel, 1991). Early studies of children's language production (Brown, 1957, reported in Schwanenflugel, 1991) suggested that $75 \%$ of the words most frequently produced by school-aged children (6-12 years of age) were concrete; in contrast, only $28 \%$ of the words used most commonly by adults were concrete. Schwanenflugel (1991) further reported that, while 6-yearold children have already mastered the majority of concrete words most frequently used by adults, it is not until adolescence that children have mastered the majority of abstract words used by adults. These facts align well with the idea that a sufficient amount of linguistic input is necessary to extract meaning for abstract words.

Thus, if the ability to learn meaning from co-occurrences in the input is critical for learning abstract concepts and words, abstract words should be especially challenging for
children with developmental language impairments (LI). Language impairment is a neurodevelopmental disorder affecting approximately $7.5 \%$ of children at school entry (Norbury et al. 2016, Tomblin et al. 1997). Children with LI have language abilities significantly below expectations for age in the absence of obvious social, sensory or neurodevelopmental explanations. Children with LI typically present with severe deficits in morphosyntax and other aspects of grammar (Rice, 2013), accompanied by vocabulary that is reduced in both breadth and depth relative to typically-developing peers (McGregor, Oleson, Bahnsen \& Duff, 2013). Unfortunately there is a dearth of empirical investigation into the acquisition of abstract words by children with LI.

Here, we investigate implicit and explicit knowledge of abstract and concrete words in children with Language Impairment (LI). Target words were selected at different age of acquisition bands and controlled for variables that are known to affect adult processing, including frequency, number of letters and valence. Lexical decision was used to test implicit knowledge, while verbal definitions were used to test explicit knowledge.

## Methods

## Participants

Eighteen children with an existing diagnosis of Language Impairment (LI; 14 males; mean age $=10.03, \mathrm{SD}=1.76$ ) were recruited from schools in Southeast England. Children in the TD groups were selected from a pool of 73 children who completed both tasks and were matched to the children with LI on age and gender ( $\mathrm{TD}_{\text {age }} ; \mathrm{n}=18,14$ males; mean age $=10.34, \mathrm{SD}=1.44$ ) or by raw scores on the British Picture Vocabulary Scale (BPVS; Dunn, Dunn, Whetton, \& Burley, 1997) ( $\mathrm{TD}_{\text {vocab }} ; \mathrm{n}=18,14$ males; mean age $=8.16$, $\mathrm{SD}=2.12$ ). TD children were recruited from local schools and did not have any reported special educational needs, or history of language delay. Children's non-verbal cognitive abilities were assessed using the Matrix Reasoning test of the Wechsler Abbreviated Scale of Intelligence (WASI, Wechsler, 1999). LI children were also administered the Recall Sentences subtest of the Clinical Evaluation of Language Fundamentals: Core Language Scales (CELF; Semel, Wiig, \& Secord, 2006), see Table 1. The same children participated in both tasks.

## Materials

Thirty-six abstract and 36 concrete words were selected from a pool of 3,505 words for which normative data on a range of lexical variables could be obtained. These variables included: Age of Acquisition (AoA; Kuperman, Stadthagen-Gonzalez \& Brysbaert, 2012), concreteness, familiarity (Coltheart, 1981), valence (Warriner, Kuperman \& Brysbaert, 2013), and frequency (Balota et al., 2007). AoA ratings were used to ensure the items selected were appropriate for our participants' age: words were divided into Age of Acquisition bands (1: words acquired at 4-5
years of age; 2: words acquired at 6-7 years; 3: words acquired at 8-9 years; 4: words acquired at 10-11 years). Within each AoA band, triplets of negative (valence ratings $<4.0$ ), positive (valence ratings $>6.0$ ) and neutral (valence ratings of 4.5-5.5) words matched on length (number of letters), concreteness, log frequency and familiarity were created. Triplets of abstract words were then paired to concrete triplets matching for average length, frequency and familiarity. Among these 72 words, 24 ( 12 abstract and 12 concrete) were shared between the two tasks; 24 ( 12 abstract and 12 concrete) were used for the definitions task only, and the remaining 24 were used for the lexical decision task only. Additionally, for the lexical decision task, forty-eight pronounceable non-words were created by changing one phoneme from 48 words matched to the experimental words on length, AoA, valence and concreteness. All words and non-words were recorded by a native English speaker using Audacity v. 1.2.2.

## Procedure

All children were tested in a quiet room in their school and received stickers for participation. Stimuli were presented acoustically using E-Prime version 2.0 software (Psychology Software Tools, Pittsburgh, PA) running on a Dell Latitude E6320 laptop with a touchscreen display. Children were presented with short computer games in which they were asked to help a cartoon alien learn English. The Definitions task was always presented before the Lexical Decision task, in a single session.
Definitions. After wearing the headset (which included a microphone), children were presented with a practice trial (the concrete noun: "rose") before the experiment. They were encouraged to provide an accurate and comprehensive definition, including as much information as they could on the meaning of each word. Each trial included the presentation of the alien in the center of the computer screen, along with the auditory presentation of an English word. Children's responses were audio-recorded using EPrime and then scored off-line. The 48 words were presented in four blocks of 12-items arranged in AoA blocks (block 1: words acquired at 4-5; block 2: words acquired at 6-7; block 3: words acquired at 8-9; block 4: words acquired at 10-11); words within each block were presented in random order. The task ended when the subject was unable
to define three words within a single AoA block or responded to all 48 words.

Scoring of definitions We used a 0 to 4 scale. Four points were awarded if an answer showed complete semantic understanding of the word; 3 points if an answer showed a good understanding of the word (e.g., one or more features of the concept); 2 points if the answer provided correct but generic information that doesn't help to identify the element in an unequivocal way (e.g., giraffe = animal; anger $=$ a feeling); 1 point if the answer was not wrong, but poor in content (e.g., evening $=$ is when we dine); 0 point if the answer was wrong; no answer was given; or the concept was repeated (e.g. Photo $=$ to take a photo). Scoring was performed by two independent researchers who were blind to the identity or diagnosis of the children. Interclass correlation coefficient (ICC) was computed to determine the level of agreement between the two scorers, yielding a high degree of reliability, ICC $=.86$ ( $95 \% \mathrm{CI}$ : . $845-.879$ ), $p<$ .001. A third independent researcher moderated instances in which the scores differed by more than 1 point ( $12.6 \%$ of all definitions), and the instances in which only one scorer awarded a score of 0 ; all other scores were averaged.
Lexical decision. Children were presented with six practice trials (three non-words and three words that were not used in the experiment). In each trial, a cartoon alien was presented in the middle of the screen for 1000 ms , followed by the auditory presentation of either a real English word or a nonword. Immediately after the offset of the word (average stimulus duration $=830 \mathrm{~ms}$ ), two touch screen buttons appeared at the bottom left (a red thumbs-down icon) or the bottom right (a green thumbs-up icon) of the screen (see Figure 1).

Figure 1 - Lexical decision task. Trial timeline.
Children were instructed to press the green button when they heard a word they knew, or the red button if they heard a "funny, made-up" word. After the six practice items, participants completed all 96 items ( 24 abstract and 24 concrete words, plus 48 non-words) presented in a randomised order.
Data analysis Separate mixed-design ANOVAs with concreteness (abstract, concrete) as within-subject factor and
group (LI, TD) as between-subject factor were used to analyse average rating (in the definition task) and accuracy (in the lexical decision task), for both age-matched groups and vocabulary-matched groups.

We further assessed the individual performance of children with LI on abstract and concrete words against the difference in those conditions exhibited by matched TD controls, using the Revised Standardized Difference Test (RSDT) (Crawford and Garthwaite, 2005a, 2005b). This test was developed in neuropsychology research to test for dissociation between patient performance on two or more tasks. Here, the two concreteness sets (abstract, concrete) are treated as the two different 'tasks', and the difference in performance between them is evaluated against TD averages. The RSDT controls for Type I error rates when there are correlations between the tasks under study; we entered simple correlations between abstract and concrete raw scores from the TD groups.

## Results

## Definitions

Only $13.4 \%$ of our TD children could provide any definition for words of AoA block 4 (words acquired at 1011); therefore, we excluded block 4 from further analyses, thus reducing the total number of items to 36 words (18 abstract and 18 concrete).
LI vs TD ${ }_{\text {age. }}$ Average accuracy ratings for definitions provided by children with LI and matched $\mathrm{TD}_{\text {age }}$ children for concrete and abstract words are shown on Figure 2 (topleft). A mixed ANOVA yielded a significant main effect of concreteness, $\mathrm{F}(1,34)=9.277, \mathrm{p}=.004, \eta_{p}^{2}=.214$, with concrete words (1.31) attracting more complete and accurate definitions than abstract words ( 0.80 ). The main effect of group was also significant, $\mathrm{F}(1,34)=20.314, \mathrm{p}<.001, \eta_{p}^{2}$ $=.374$; definitions provided by children with LI $(0.80)$ were rated as significantly poorer in quality than those given by their age-matched TD peers (1.63). However, the group $\times$ concreteness interaction was not significant ( $\mathrm{p}=.427$ ), indicating that poor quality definitions were provided for both abstract and concrete words by children with LI.
LI vs TD vocab. One $\mathrm{TD}_{\text {vocab }}$ child did not complete the task and his definitions were excluded along with data from the matched child with LI. Average ratings of definitions provided by LI and matched $\mathrm{TD}_{\text {vocab }}$ children ( $\mathrm{n}=17$ per group) for concrete and abstract words are shown on Figure 2 (top-right). Analyses demonstrate a significant main effect of concreteness, $\mathrm{F}(1,32)=21.687, \mathrm{p}<.001, \eta_{p}^{2}=.404$, with concrete words (1.31) eliciting more accurate and detailed definitions than abstract words (0.86). Importantly, the group $\times$ concreteness interaction were not significant (all $\mathrm{p}>.170$ ).
Individual LIs vs control group comparisons. Individual performance of LI children against matched $\mathrm{TD}_{\text {age }}$ and $\mathrm{TD}_{\text {vocab }}$ groups is shown on Figure 2 (bottom). For all children with the LI group, the abstract vs concrete
comparison was not significantly different from the pattern shown by both age-matched and vocabulary-matched peers.

Figure 2 - Top: Average score (on a 0-4 scale) of definitions to abstract and concrete words, comparing performance of LI with $\mathrm{TD}_{\text {age }}\left(\mathrm{N}=18\right.$; left), and with $\mathrm{TD}_{\text {vocab }}(\mathrm{N}=17$; right) children. Error bars indicate standard error of the mean. Bottom: Proportion of errors for individual LI children and the $\mathrm{TD}_{\text {age }}$ and $\mathrm{TD}_{\text {vocab }}$ groups in defining abstract and concrete words. ${ }^{\wedge}$ Child LI4 was not included in the comparison with the $\mathrm{TD}_{\text {vocab }}$ group. Error bars for the TD groups data indicate standard error of the mean.

Lexical decision. In order to ensure children attention and compliance to task instructions, the examiner controlled stimulus presentation and did not ask the children to respond quickly, but rather as accurately as possible. Reaction times are therefore not reliable and our analyses are limited to accuracy (proportion of correct responses).
Pre-processing. We checked the children's overall performance with words and non-words to determine whether some of the children showed a bias toward either answering "word" or "non-word". We computed the response bias (or criterion, c), calculated by multiplying the sum of the normalised hit rate (correctly identifying a word) and the normalised false alarm rate (incorrectly claiming that a non-word was a word) by -0.5 (e.g., Fox, 2004). The average criterion bias was $-0.002(\mathrm{SD}=0.33)$ for TD children, and $-0.02(\mathrm{SD}=0.50)$ for children with LI. Children who showed a criterion bias higher than 1.5 standard deviations above their group mean (indicating a strong bias toward "non-word" responses) or lower than 1.5 standard deviations below their group mean (indicating a strong bias toward "word" responses) were excluded from further analyses. Using these criteria, 3 children were excluded from the LI group (LI9: $c=-0.97$; LI12: $c=-0.74$; LI17: $c=-0.97$ ); to maintain the matching between the LI and TD groups, we also excluded the corresponding TD children.
$\mathbf{L I}_{\text {age }} \mathbf{v s} \mathbf{T D}_{\text {age. }}$. Proportion of correct responses of the 14 LI and matched $\mathrm{TD}_{\text {age }}$ children for concrete and abstract words is shown on Figure 3 (top-left). There was no main effect of concreteness, $F(1,26)=1.203, p=.283$; but the main effect of group was significant, $\mathrm{F}(1,26)=7.971, \mathrm{p}=.009, \eta_{p}^{2}=$ .235 , indicating that $\mathrm{TD}_{\text {age }}$ children (.85) were more accurate overall than children with $\mathrm{LI}_{\text {age }}$ (.72). Crucially, the group $\times$ concreteness interaction was not significant.
$\mathbf{L I}_{\text {vocab }}$ vs $\mathbf{T D}_{\text {vocab. }}$. Two $\mathrm{TD}_{\text {vocab }}$ children did not complete the task; therefore they were excluded along with their matched LI partner. This left 12 children per group for the LI - $\mathrm{TD}_{\text {vocab }}$ comparison. The proportion of correct responses of LI and $\mathrm{TD}_{\text {vocab }}$ children for concrete and abstract words is shown on Figure 2 (top-right). In this analysis, there were no significant main effects of concreteness, $F(1,22)=1.234, p=.279$, or valence, $F(2$, 44) $=.376, p=.689$. Crucially, the main effect of group and the group $\times$ concreteness interaction were also not significant (all $\mathrm{p}>.330$ ).

Figure 3 - Top: Proportion of correct responses to abstract and concrete words, comparing performance of LI with $\mathrm{TD}_{\text {age }}\left(\mathrm{N}=14\right.$; left), and LI with $\mathrm{TD}_{\text {vocab }}(\mathrm{N}=12$; right) children. Bottom: Proportion of correct responses of individual LI children and the $\mathrm{TD}_{\text {age }}$ and $\mathrm{TD}_{\text {vocab }}$ groups for recognition of abstract and concrete words. Children LI3 and LI7 were not included in the comparison with the $\mathrm{TD}_{\text {vocab }}$ group. The asterisk indicate one child who showed a greater difference between abstract and concrete words when compared against $\mathrm{TD}_{\text {age }}$ data ( $\mathrm{p}<0.05$, two-tailed). Error bars indicate standard error of the mean.
Individual LIs vs control group comparisons. Individual performance of LI children against matched $\mathrm{TD}_{\text {age }}$ and $\mathrm{TD}_{\text {vocab }}$ groups is shown on Figure 3 (bottom). In general, the discrepancy between abstract and concrete words was not significantly different from the discrepancy pattern shown by both age-matched and vocabulary-matched TD children. Only one child with LI (LI8) showed a
significantly larger difference between abstract and concrete words when compared to $\mathrm{TD}_{\text {age }}$ peers, $\mathrm{t}(13)=3.342, \mathrm{p}=$ .005. This difference reflected an advantage for concrete (.79) over abstract (.42) words. In all other children, the abstract vs concrete comparison was not significantly different from either $\mathrm{TD}_{\text {age }}$ or $\mathrm{TD}_{\text {vocab }}$ matched controls.

## Discussion

We compared performance of children with LI to that of age-matched or vocabulary-matched TD peers on two tasks: the first, a verbal definitions task, provided an explicit measure of children's semantic knowledge of abstract and concrete words. The second, a lexical decision task, did not require linguistic output and served as implicit measure of word processing. Both tasks used concrete and abstract words that were matched on a number of variables known to affect word processing in adults, such as frequency, valence, age of acquisition and length.

In the definition task, we found a significant effect of concreteness, indicating that concrete words were easier to define by both children with LI and their age- and vocabulary-matched peers. This may be because to define abstract words, children need to retrieve other abstract words and these latter may be more difficult (not just because of their abstractness but also because they may be longer, less familiar etc) than the concrete words they need to retrieve for defining the concrete stimuli. Importantly, we found that children with LI were significantly worse than their age-matched peers in defining all words, both concrete and abstract. When compared with younger TD children matched for receptive vocabulary, no difference was found between the two groups. There were no significant interactions between concreteness and group, indicating that even when LI children are worse overall than TD peers in defining words, they do not have disproportionate difficulties defining abstract words. By analysing the performance of individual LI children against the difference between abstract and concrete words shown by the two TD comparison groups, we further demonstrated that this is a finding consistent across the whole sample. No individual child with LI showed a greater impairment defining abstract words relative to concrete words.

In the lexical decision task, there was no significant effect of concreteness, which is consistent with findings in the adult literature that, when all lexical variables that have been shown to favour concrete words (such as length and familiarity) are tightly controlled, the concreteness advantage disappears (see Kousta et al., 2011). Critically, we again found that children with LI were significantly less accurate overall in making decisions about words relative to their age-matched TD peers, but there was no interaction between group and concreteness. In other words, even on this implicit task, children with LI were not disproportionately impaired in their processing of abstract words compared to concrete words. The case-series analyses comparing individual LI children with their age- or vocabulary-matched controls once again confirmed that
even at an individual level, children with LI responded to abstract and concrete words in a similar manner to that of TD children, for all but one child (LI8).

These findings challenge any theory that posits linguistic competence as a necessary prerequisite for acquiring abstract words. Children with LI do not have the same vocabulary competence as typically developing children (McGregor et al., 2013), moreover it has been shown that they do not take advantage of correlational information to the same extent as their typically developing peers (Evans, Saffran \& Robe-Torres, 2009). For all these reasons, learning abstract words should present an almost insurmountable challenge for them. However, children with LI in the current study, despite their language limitations, did not show any evidence of disproportionate deficits in abstract word knowledge.

Distributional Semantics models offer a powerful mechanistic account of how word meanings can be acquired from language. On the basis of the linguistic contexts in which a word is used, children could make inferences about word meaning (e.g., Landauer \& Dumais, 1997, Griffiths et al., 2007; Andrews, Vinson \& Vigliocco, 2009). Such a mechanism would be at play for both concrete and abstract words, although it could play a greater role for abstract words. Our results indicate that whereas these mechanisms can be at play, there is no evidence for them to have a different role for concrete and abstract words. Our results may also be considered to be problematic (especially if replicated with argument bearing verbs) for the "syntactic bootstrapping hypothesis (e.g., Gleitman et al., 2005), according to which phrasal and syntactic information is used to constrain possible word meanings. Gleitman et al. (2005) specifically discuss how this information may be especially important in learning verbs (which are more abstract than nouns). Under the plausible assumption that our children with LI have a history of problems in processing sentencelevel linguistic structure, our results suggest that such a strategy may not be the only manner in which children learn abstract vocabulary.

Thus, other mechanisms are also at play. Ponari, Norbury, and Vigliocco (in press) presented initial evidence that learning abstract words could be based on multiple strategies and, at least in the earlier stages of acquisition, take advantage of the strong association between abstractness and emotional valence (Kousta et al., 2011). Emotional valence could support the establishment of the distinction between concrete and abstract domains of knowledge because, while concrete words would refer to observable entities and actions that we can experience with our senses and act upon, abstract words would refer to internal states of self and others that trigger embodied emotional reactions and experiences. These emotional reactions could come about from interactions with caregivers in which children associate words heard with emotions expressed by the caregivers or by the child themselves. Such a view posits that communicative social interaction would play a central role in language acquisition,
along the lines proposed by recent social-cognitive theories of lexical development (e.g., Tomasello, 2000). To this end, it is important to note that children with LI do not show evidence of fundamental socio-cognitive deficits. It is interesting to note that emotion, however, does not seem to have a privileged role abstract vocabulary after the age of 9 (cf. Ponari et al., 2017). It is likely that by this age, strategies grounded in basic socio-cognitive processes (e.g., ability to make inferences on others intentions) or emotional experience become insufficient to differentiate among the meanings of an increasingly larger number of abstract words in the child's vocabulary and language-based strategies may become more important.

# Facial Motor Information is Sufficient for Identity Recognition 

Jonathan Vitale, Benjamin Johnston, \& Mary-Anne Williams<br>\{jonathan.vitale, benjamin.johnston, mary-anne.williams\}@uts.edu.au<br>University of Technology Sydney - Centre For Artificial Intelligence<br>Innovation and Enterprise Research Lab (The Magic Lab) - 15 Broadway, Ultimo NSW 2007 - Australia

#### Abstract

The face is a central communication channel providing information about the identities of our interaction partners and their potential mental states expressed by motor configurations. Although it is well known that infants ability to recognise people follows a developmental process, it is still an open question how face identity recognition skills can develop and, in particular, how facial expression and identity processing potentially interact during this developmental process. We propose that by acquiring information of the facial motor configuration observed from face stimuli encountered throughout development would be sufficient to develop a face-space representation. This representation encodes the observed face stimuli as points of a multidimensional psychological space able to assist facial identity and expression recognition. We validate our hypothesis through computational simulations and we suggest potential implications of this understanding with respect to the available findings in face processing.

Keywords: face perception; face processing; face-space; face identity processing; face expression processing; mirroring

## Introduction

Face processing capabilities are of paramount importance for the development of social skills (Grossmann, 2015).

Developmental studies suggest that newborns can match observed facial motor configurations via overt imitative behaviour (Meltzoff \& Moore, 1983, 1992) or covert inner simulation mechanisms (Simpson, Murray, Paukner, \& Ferrari, 2014; Gallese \& Caruana, 2016), even well before the development of early cognitive capabilities (but see Oostenbroek et al., 2016 and Simpson et al., 2016 for a recent discussion on the topic). Hence, it has been suggested that facial expression recognition may be mediated by early neural mechanisms mapping sensory information of the observed facial configuration into a proprioceptive motor format (Gallese \& Caruana, 2016; Iacoboni, 2009) and therefore assisting imitatory mechanisms (Simpson et al., 2014).

On the contrary, face identity processing capabilities follow a developmental process (Grossmann \& Vaish, 2009). Currently, facial identity processing development is not yet well understood. For example, we do not know yet where in the face processing hierarchy representations of invariant (i.e. identity features of the face) and dynamic (i.e. motor features of the face) features interact (Simion \& Di Giorgio, 2015).

According to the 'face-space' framework (Valentine, 1991; Valentine, Lewis, \& Hills, 2015), facial representations are encoded in a multidimensional psychological space. The dimensions of this space are assumed to encode properties of the facial signals that better discriminate one face from another. The distance between two representations underlies their dissimilarity from a psychological perspective. This
framework was initially designed to only account for coding identity-related features, such as sex, distinctiveness, age and attractiveness (Valentine, 1991). Nevertheless, dynamic aspects of faces, such as facial expressions, were neglected. Recently, we developed a computational tool building on top of the face-space framework (Vitale, Williams, \& Jonhston, 2016) and able to exhibit interesting features in agreement with modern understanding in face processing studies. In particular, we demonstrated that this novel face-space can represent both invariant and dynamic features of face stimuli under a shared representation facilitating the recognition of both facial expression and identity exhibited by novel face stimuli (Vitale et al., 2016).

In this paper we offer a new understanding of this facespace, suggesting that facial identity processing capabilities can plausibly develop by interpreting the motor configuration of observed face stimuli.

In particular, from a functional level of analysis, we aim to demonstrate that assuming the existence of an early or innate system $\mathscr{M} \operatorname{otor}\left(x_{i}\right) \Rightarrow \mathscr{E}\left(x_{i}\right)$ able to map perceptual information of the observed face stimulus $x_{i}$ onto a motor interpretation of the exhibited facial expression $\mathscr{E}\left(x_{i}\right)$, it is possible to develop another system Cognitive $\left(X_{\text {new }}\right) \Rightarrow$ $\left\{\mathscr{E}\left(X_{\text {new }}\right), \mathscr{I}\left(X_{\text {new }}\right)\right\}$ assisting the discrimination of facial expressions $\mathscr{E}\left(X_{\text {new }}\right)$ and identities $\mathscr{I}\left(X_{\text {new }}\right)$ exhibited by newly encountered face stimuli $X_{\text {new }}$. Therefore, this paper aims to provide computational evidence supporting the following hypothesis:

Hypothesis: It is possible to generalise the face-space framework to realise a twofold multidimensional space structure able to facilitate facial expression and identity processing capabilities by only interpreting the motor configuration exhibited by the face stimuli encountered during the developmental process.

This work is a significant contribution able to provide a plausible explanation unifying traditional and modern findings in face processing studies, as we will discuss in the remainder of this paper.

## Previous Findings

Recently, we provided a novel understanding of the facespace framework (Vitale et al., 2016). The face-space framework is a widely used tool in face perception and processing research able to explain many of the phenomena underlying facial identity discrimination in both human experimental settings (Lee, Byatt, \& Rhodes, 2000; Rhodes, Jaquet, et

Figure 1: The dual face-space presents a twofold structure: on one side it allows observations with similar motor configurations to lie within close spatial locations $(\uparrow)$, whereas at the same time "repulsing" observations of similar identities away $(\dashv \vdash)$; on the other side, it happens exactly the viceversa. This facilitates respectively facial expression and identity recognition, under common multidimensional codings.
al., 2011) and computational simulations (A. J. Calder, Burton, Miller, Young, \& Akamatsu, 2001). This framework is so important in face studies that it is "virtually impossible to explain the interactions between the computational and cognitive approaches to understanding face recognition without reference to this model. It serves as the glue that binds the theoretical and computational aspects of the problem together" (A. Calder, 2011, page 17).

According to Valentine's face-space, faces are points of a multidimensional space based on their perceived properties. This structure can plausibly account for coding identityrelated features. Unfortunately, dynamic aspects of the face, such as its motor configuration, were neglected in the traditional face-space account. This is a significant limitation, preventing the analysis of the interactions happening between facial expression and facial identity processing.

Therefore, to fill this gap, we introduced a novel hypothesis: the duality hypothesis. This hypothesis suggests that the face-space can plausibly exhibit a twofold structure integrating both dynamic and invariant features of the face into shared codings, although preserving some separation among them to facilitate both facial expression and identity recognition (see Figure 1 for a visual example). We named this understanding with dual face-space and we validated the hypothesis, from a computational perspective, through a mathematical presentation and quantitative results.

## The Dual Face-Space

Given a set of face stimuli shaped as column vectors of a matrix $X$, these stimuli have dimension $\mathscr{D}$ equal to the total number of pixels representing each face stimulus. By submitting the matrix $X$ to a Principal Component Analysis (PCA) (Turk \& Pentland, 1991) it is possible to obtain a mapping matrix $V_{p c a}$ able to map the $\mathscr{D}$-dimensional face stimuli $X$ into compressed d-dimensional representations $\bar{X}$. This process preserves most of the information carried by the face stimuli, but it compresses them in representations having di-

Figure 2: An example of face-space development resulting by applying the mapping function in Equation 2. Face samples belonging to the same identity are on average perceptually closer to each other, thus being a bias for the classification of facial expressions.
mension $d \ll \mathscr{D}$ and it ensures desirable properties in subsequent stages of the model (e.g. positive definiteness, see Vitale et al., 2016):

$$
\begin{equation*}
\bar{X}=V_{p c a}^{\top} X \tag{1}
\end{equation*}
$$

It is important to note that in this paper we do not aim to test the classification performance of the proposed model against other computational models of face recognition, but rather the plausibility of the proposed hypothesis in providing a new understanding of the mechanisms potentially underlying human face processing skills. Therefore, in our studies we used the pixels intensities of static images as input to our models to provide a simplified linear understanding of our theory and related argument. Importantly, the input $\bar{X}$ can be any vector of features extracted by the given face stimuli and able to encode perceptual information of the observed stimuli. Therefore, a viable non-linear alternative of our model can be obtained by pre-processing the input face stimuli $X$ by using an unsupervised deep neural network model trained to preserve invariant and dynamic features of the face in a more compressed and smart representation (Le et al., 2013), instead of the proposed linear PCA. Finally, temporal dynamics can be included by pre-processing a set of consecutive stimuli instead of static images, or by using other techniques improving temporal coherence in the resulting pre-processed representation (Mobahi, Collobert, \& Weston, 2009). These computational pre-processing stages resemble early processing of human visual cortex and are therefore suitable examples for potential future extensions of our theory and related model.

In our previous work (Vitale et al., 2016), we showed that it is possible to implement the dual face-space by solving the following objective function:

$$
\begin{equation*}
V^{\star}=\underset{V \in \mathbf{R}^{d \times d}}{\arg \min } \frac{\operatorname{Tr}\left(V^{\top} \bar{X}\left(I_{N}-W^{\mathscr{E}}\right) \bar{X}^{\top} V\right)}{\operatorname{Tr}\left(V^{\top} \bar{X}\left(I_{N}-W^{\mathscr{I}}\right) \bar{X}^{\top} V\right)} \tag{2}
\end{equation*}
$$

where $W^{\mathscr{E}}$ and $W^{\mathscr{I}}$ are two weight matrices setting desired topological constraints on the face-space via the resulting objective mapping matrix $V^{\star}$. It is possible to obtain the weight
matrix $W^{\mathscr{E}}$ by knowing the facial expressions exhibited by the training samples and, when this matrix is used in Equation 2, it encourages pairs of samples associated with the same facial expression to be in nearby locations in the resulting facespace:

$$
W_{i j}^{\mathscr{E}}= \begin{cases}\frac{1}{n_{\mathscr{E}}}, & \text { if } \mathscr{E}\left(x_{i}\right)=\mathscr{E}\left(x_{j}\right)  \tag{3}\\ 0, & \text { otherwise }\end{cases}
$$

In Equation 3, $n_{\mathscr{E}_{i}}$ is the number of samples in $X$ belonging to the facial expression class $\mathscr{E}\left(x_{i}\right)$ of the face stimulus $x_{i}$ in the column $i$ of matrix $X$.

It is possible to realise the weight matrix $W^{\mathscr{I}}$ by knowing the identities exhibited by the training samples and, when this matrix is used in Equation 2, it promotes repulsive forces between pairs of samples belonging to the same identity, thus reducing misclassification of facial expressions due to the identity bias (Sariyanidi, Gunes, \& Cavallaro, 2015):

$$
W_{i j}^{\mathscr{J}}= \begin{cases}\frac{1}{n_{\mathscr{I}}}, & \text { if } \mathscr{I}\left(x_{i}\right)=\mathscr{I}\left(x_{j}\right)  \tag{4}\\ 0, & \text { otherwise. }\end{cases}
$$

In Equation 4, $n_{\mathscr{I}_{i}}$ is the number of samples in $X$ belonging to the identity class $\mathscr{I}\left(x_{i}\right)$ of the face stimulus $x_{i}$ in the column $i$ of matrix $X$. Figure 1 and Figure 2 show examples of the rationale behind the constraints set by the suggested weight matrices in Equation 2.

Finally, given a generic matrix $M$ and the following permutation function:

$$
\tilde{M}=\sigma(M)=\left(\begin{array}{ccccc}
m^{1} & m^{2} & m^{3} & \ldots & m^{d}  \tag{5}\\
m^{d} & m^{d-1} & m^{d-2} & \ldots & m^{1}
\end{array}\right)
$$

permutating each column vector $m^{i}$ with $i \in[1, \ldots, d]$ of the matrix $M$ in the inverse order ${ }^{1}$ we demonstrated that Equation 2 is sufficient to provide multidimensional representations able to facilitate both facial identity and expression recognition (Vitale et al., 2016).

In fact, given $V^{\star}$ as the optimal solution of the objective function in Equation 2, we demonstrated that the mapping matrix $\tilde{V}^{\star}=\sigma\left(V^{\star}\right)$ is the optimal solution of another objective function promoting facial identity discrimination obtained by inverting Equation 2. The mapping matrix $\tilde{V}^{\star}$ is dual to the mapping matrix $V^{\star}$, since it shares the same components (i.e. column vectors) of $V^{\star}$ but sorted in the opposite order. Therefore, the objective function in Equation 2 realises common codings able to facilitate on one hand facial expression classification $\left(V^{\star}\right)$, and on the other hand facial identity discrimination $\left(\tilde{V}^{\star}\right)$.

## The $\Delta$ Face-Space

To validate our hypothesis, we suggest to approximate the weight matrix $W^{\mathscr{I}}$ with another weight matrix $W^{\Delta}$ implemented without necessarily knowing the identity classes of

[^537]the training face stimuli. In this way the weight matrix $W^{\mathscr{I}}$ in Equation 2 can be replaced by the matrix $W^{\Delta}$, thus realising the following objective function:
\[

$$
\begin{equation*}
V^{\Delta \star}=\underset{V \in \mathbf{R}^{d \times d}}{\arg \min } \frac{\operatorname{Tr}\left(V^{\top} \bar{X}\left(I_{N}-W^{\mathscr{E}}\right) \bar{X}^{\top} V\right)}{\operatorname{Tr}\left(V^{\top} \bar{X}\left(I_{N}-W^{\Delta}\right) \bar{X}^{\top} V\right)} \tag{6}
\end{equation*}
$$

\]

The optimal solution of the objective function in Equation 6 is the mapping matrix $V^{\Delta \star}$. Thus, given a mapping matrix $V_{p c a}$ gathered by submitting the training data $X$ to a PCA, as previously described, it is possible to obtain the final mapping matrix $V_{\text {overall }}^{\Delta}$ realising the $\Delta$ face-space as following:

$$
\begin{equation*}
V_{o v e r a l l}^{\Delta}=V_{p c a} V^{\Delta \star} \tag{7}
\end{equation*}
$$

The mapping matrix $V_{\text {overall }}^{\Delta}$ is able to realise facespace representations facilitating facial expression recognition, whereas the mapping matrix $\tilde{V}_{\text {overall }}^{\Delta}=\sigma\left(V_{\text {overall }}^{\Delta}\right)$, having the same component of $V_{\text {overall }}^{\Delta}$ but permutated in the inverse order, realises representations able to facilitate facial identity discrimination, although without the need of knowing the identities exhibited by the training samples, as suggested by our hypothesis.

## Defining the New Weight Matrix

The purpose of the weight matrix $W^{\mathscr{I}}$ in Equation 2 is to avoid that two face stimuli sharing the same identity, but exhibiting different facial expressions, would get projected to nearby locations of the face-space promoting their misclassification in the same facial expression class (see Figure 2). This misclassification can easily happen since face stimuli of the same identity share most of their perceptual features, and, on average, they are close-by in the perceptual space (Sariyanidi et al., 2015; Turk \& Pentland, 1991). This property exhibited by face stimuli can be used to our advantage to realise the desired weight matrix $W^{\Delta}$.

For each of the $N$ training face stimuli $x_{i}$, shaped as column vectors $i \in[1, \ldots, N]$ of the matrix $X$, we denote with $\Delta_{x_{i}}$ the set containing the perceptual distances $\delta\left(x_{i}, x_{j}\right)$ between the face stimuli $x_{i}$ and the face stimulus $x_{j} \in X$ with $i \neq j$ and exhibiting a different facial expression from the one exhibited by $x_{i}$ :

$$
\begin{equation*}
\Delta_{x_{i}}=\left\{\delta\left(x_{i}, x_{j}\right) \mid x_{j} \in X \wedge x_{i} \neq x_{j} \wedge \mathscr{E}\left(x_{j}\right) \neq \mathscr{E}\left(x_{i}\right)\right\} \tag{8}
\end{equation*}
$$

Since face stimuli of the same identity are perceptually close, their respective distances would be, at least on average, well below their distances from face stimuli with different identities. Then, given the mean $\mu_{\Delta_{x_{i}}}$ and standard deviation $\sigma_{\Delta_{x_{i}}}$ of the distances included in the set $\Delta_{x_{i}}$ it is possible to compute the set $\mathscr{I}_{i} \approx$ described as follow:

$$
\begin{equation*}
\mathscr{I}_{i}^{\approx}=\left\{x_{j} \mid \delta\left(x_{i}, x_{j}\right)<\mu_{\Delta_{x_{i}}}-\beta \sigma_{\Delta_{x_{i}}}\right\} \tag{9}
\end{equation*}
$$

where $\beta$ is a parameter suggesting how many standard deviations below the mean distance would be set the maximum threshold. In this work, $\beta$ was set equal to 2.5 after empirical tests with face stimuli gathered from different datasets
available in face recognition literature. The resulting set $\mathscr{F}_{i} \approx$ includes most of the training samples sharing the same identity of the sample $x_{i}$.

Therefore, the weight matrix $W^{\Delta}$ can be realised as follow:

$$
W_{i j}^{\Delta}= \begin{cases}\frac{1}{n_{\cup i j}}, & \text { if } x_{j} \in \mathscr{I}_{i} \approx x_{i} \in \mathscr{I}_{j} \approx  \tag{10}\\ 0, & \text { otherwise }\end{cases}
$$

where $n_{\cup_{i j}}$ is the number of unique samples in the set $\mathscr{I}_{i} \approx \cup$ $\mathscr{I} \approx$. The realised weight matrix $W^{\Delta}$ is clearly symmetric and the associated Laplacian behaves as a block centring matrix, thus promoting a norm-based space (for in-depth details and mathematical proof refer to Vitale et al. (2016)). The objective function in Equation 6 can be solved through the iterative algorithm proposed by Ngo, Bellalij, and Saad (2012), similarly to our previous contribution (Vitale et al., 2016).

## Experiments

In this paper, we will evaluate the proposed model using the Karolinska Directed Emotional Faces (KDEF) dataset (Lundqvist, Flykt, \& Öhman, 1998), similarly to our previous contribution. The dataset contains static images of 70 subjects- 35 female and 35 male-exhibiting seven different prototypical facial expressions of basic emotions (anger, disgust, fear, happiness, neutral, sadness and surprise). The pictures are taken in various face orientations and in two different sessions (A and B).

We used the frontal pictures taken in session A . We extracted the facial region from the images and reduced their resolution to $80 \times 80$ pixels. Eyes and mouth were at approximately the same position. Illumination variations were reduced by applying a simple equalisation process to the images (using the histeq function available in Matlab software).

We first pre-processed the data by submitting the pixels of the images in input to a PCA as explained previously. We retained the components able to explain $95 \%$ of the variance of the original data resulting in 200 components.

## Procedure

The present experiment tests the ability of the new $\Delta$ facespace, implemented without knowing the identity labels of the training stimuli, to support subsequent processes of identity and facial expression recognition.

In both the two conditions (i.e. facial expression and identity recognition) we used repeated random iterations of the dataset's samples (in this work 35 iterations for both the tasks). In each iteration 25 subjects were randomly selected as the test set among the 70 possible subjects to simulate unfamiliar identities. For each of the 25 selected subjects were randomly chosen 2 facial expressions as probes for the identity recognition task, and the remaining 5 facial expressions as test samples, leading to a total of 125 test samples for each iteration. The images of the other 45 subjects, together with the 50 selected probes, were used as the training set of the current iteration, leading to 365 training samples for each iteration.

With each training data we estimated the mapping matrix $V_{\text {overall }}^{\Delta}$ of the $\Delta$ face-space proposed in this chapter as per Equations 6 and 7. Then, each test sample was mapped onto the $\Delta$ face-space, thus obtaining the encodings $Y^{\Delta \mathscr{E}}=$ $V_{\text {overall }}^{\Delta \top} X$ and $Y^{\Delta \mathscr{\mathscr { I }}}=\tilde{Y}^{\Delta \mathscr{E}}=\tilde{V}_{\text {overall }}^{\Delta \top} X$, respectively used during the expression and identity recognition tasks for the $\Delta$ face-space condition.

For each iteration, we compared the performance of the $\Delta$ face-space against a baseline approach. The baseline approach used all the pixels of the face stimuli to match similar facial expressions or identities. This is a fair methodology considering we pre-processed raw pixels data with a simple PCA. In our previous contribution (Vitale et al., 2016) we showed that the baseline and PCA performance are not differing. Thus, we used this approach as our baseline to demonstrate that matching the expressions and identities of the considered dataset samples in the perceptual space was not a trivial task and that our psychological face-space can indeed facilitate facial expression and identity recognition.

The classification was performed using the nearest neighbour algorithm. For each sample, $x_{i}$, used by the baseline approach, and $y_{i}^{\Delta}$, used by the face-space model, we computed the Euclidean distances from the centroids of each class in the corresponding space, and we selected the class associated with the centroid closer to the sample.

For each test sample during each iteration, the baseline approach provided a single prediction. Instead, our face-space model can use the first $k=[1, \ldots, d]$ components of the mapping matrix $V_{\text {overall }}^{\Delta}$ to map the face stimuli in face-space representations and perform recognition tasks. Thus, our model provided $d$ predictions for each test sample during each iteration. To gather a single prediction, we selected the most frequent class (mode) predicted by the face-space model for each test sample during each iteration, as per a majority voting approach. For each iteration, we then computed the overall recognition rate for the baseline approach and the $\Delta$ facespace in both facial expression and identity recognition conditions. This process led to 35 samples for each considered approach and task.

## Results

The distribution of the sampled recognition rates was first assessed for normality using a D'Agostino's K-squared test (D'Agostino \& Pearson, 1973) finding that the samples from both facial expression and identity tasks followed a normal distribution ( $p$-values respectively 0.8571 and 0.1382 ). Thus, the effect between the baseline approach and our face-space model were evaluated by a Student's t-test (Keppel, 1991) at a significant level of $\alpha=0.01$. The effect size was assessed by computing Cohen's $d$ (Cohen, 1977).

The results for facial expression and identity recognition are shown in Figure 3a and Figure 3b respectively. From the plots, it is possible to see that the novel $\Delta$ face-space can facilitate both facial expression and identity recognition.

In addition, the t -tests rejected the null hypothesis in both facial expression ( $p$-value $=6.5 \mathrm{e}-19$ ) and facial identity ( $p$ -

Figure 3: Comparative analysis of the performance. (a,b) The recognition rates of the baseline approach and our face-space model respectively during facial expression and facial identity recognition tasks.
value $=1.6 \mathrm{e}-6)$ recognition tasks. The computed effect size suggested a large effect for both the two tasks ( $d=3.03$ for facial expression recognition and $d=0.98$ facial identity recognition). The statistics reached high powers (both $>0.98$ ).

## Potential Implications of the Hypothesis

Although we validated our hypothesis through computational simulations and it is not our aim to suggest that human brain implements the proposed face-space in this way, in this section we will discuss how these results can be of major importance for cognitive science community, at least by focusing at a functional level of analysis.

Modern literature in face perception studies widely suggest interactions between invariant and dynamic features of face stimuli. For instance, it has been shown that women and younger individuals appear to increase cues associated with happiness, whereas men and older people those of anger (Becker, Kenrick, Neuberg, Blackwell, \& Smith, 2007) and studies in face processing broadly suggest that face stimuli can be plausibly represented in multidimensional norm-based spaces (Rhodes \& Jeffery, 2006; Rhodes, Leopold, Calder, \& Rhodes, 2011) and that invariant and dynamic codings of these spaces interact (A. J. Calder et al., 2001).

Interestingly, the proposed hypothesis well integrates with traditional understandings in face studies suggesting distinct routes processing invariant and dynamic features of the face, while still supporting more recent findings suggesting that representations of invariant and dynamic facial features partially overlap (Pell \& Richards, 2013). In fact, Haxby, Hoffman, and Gobbini (2000) suggest that changeable aspects of the face (i.e. eye gaze, expression and lip movement) are processed in the Superior Temporal Sulcus (STS), whereas invariant aspects of the face necessary to classify the exhibited identity are processed in a distinct brain area, the Lateral Fusiform Gyrus (LFG). The STS presents neural connections with the amygdala and other brain areas usually associated
with emotional processing capabilities (Adolphs, 2002) and interactions were observed between the STS and the LFG (Haxby et al., 2000). Recent neuroscience studies suggest that the STS is also related to mirroring mechanisms and imitative capabilities (Buxbaum, Shapiro, \& Coslett, 2014) and Molenberghs, Brander, Mattingley, and Cunnington (2010) provided evidence suggesting that the role of the STS in imitation is not only to passively register observed biological motion, but rather to actively represent sensory-motor correspondences between one's actions and the actions of others. Therefore, the STS, assisted by putative emotional brain areas like the amygdala, can plausibly provide information necessary to interpret the observed facial expression, as suggested in this paper with the assumed system $\mathcal{M}$ otor. This information, in turn, can be then used by the LFG to develop facial identity recognition capabilities, as proposed by the psychological face-space discussed in this paper.

## Conclusions

We provided a new understanding of the face-space framework proposed by Valentine (1991) and able to realise a twofold structure encoding invariant and dynamic features of the face under shared codings and consequently facilitating facial expression and identity recognition capabilities. This face-space can develop by only interpreting motor behaviour exhibited by face stimuli encountered during development. We demonstrated the validity of our claim by providing compelling computational evidence and we discussed the potential implications of this new theoretical understanding in face perception and processing studies. Future works aim in extending the model with non-linear techniques and possibly include temporal features, while at the same time testing the theory by collecting human data from perceptual experiments.

# Forgetting My Memories by Listening to Yours: The Impact of Perspective-Taking on Socially-Triggered Context-Based Prediction Error 

Madalina Vlasceanu<br>Princeton University, Princeton, New Jersey, United States<br>Rae Drach<br>State University of New York Albany<br>Alin Coman<br>Princeton University, Princeton, New Jersey, USA

#### Abstract

The mind is a prediction machine. In most situations in which it finds itself, it has expectations as to what might happen. But when people's expectations are invalidated by experience, the memories that gave rise to these expectations are suppressed. The present research explores the effect of these prediction errors on listener's memories during social interaction. We reasoned that listening to a speaker recounting experiences similar to one's own would trigger prediction errors on the part of the listener that would result in the suppression of his/her memories. Study 1 offers evidence for the effect of socially triggered context based prediction errors on listener's mnemonic representations. Study 2 replicates these findings and shows that this effect is sensitive to a perspective-taking manipulation. Taken together, these findings provide evidence for a yet unrecognized phenomenon by which our conversations shape the memories that we come to hold.

# Rank Aggregation and Belief Revision Dynamics

#### Abstract

In this paper we compare several popular rank aggregation methods by accuracy of finding the true (correct) ranked list. Our research reveals that under most common circumstances simple methods such as the average or majority actually tend to outperform computationally-intensive distance-based methods. We then conduct a study to compare how actual people aggregate ranks in a group setting. Our finding is that individuals tend to adopt the group mean in a third of all revisions, making it the most popular strategy for belief revision.

Keywords: rank aggregation; distance measure; probabilistic model

## Introduction

The problem of rank aggregation, where ranked lists from a diverse set of "judges" are combined into a single "consensus" ranked list, is an active research area in computer science. Particularly, rank aggregation has found successful applications in meta-search (Dwork, Kumar, Naor, \& Sivakumar, 2001; Renda \& Straccia, 2003; Fernández, Vallet, \& Castells, 2006), crowd-sourcing (Niu et al., 2015), and recommender systems (Baltrunas, Makcinskas, \& Ricci, 2010).

Although extensive studies have already been conducted on this topic by computer scientists, these largely concern only the algorithmic issues, i.e., how to produce the "optimal" ranked list, without questioning the very concept of "optimal". Typically, a distance measure is chosen, and the ranked list with the minimum total distance to all the given ranked lists is presumed to be the best one (Dwork et al., 2001). In this paper, we challenge such a view and address the problem from the perspective of cognitive science. Just as importantly, much of the previous research has been theoretical in nature and no empirical work has been conducted to determine how humans actually aggregate ranks. To that end, we went beyond the theoretical models described in section 1 and conducted a group study to better understand real-world rank belief revision. To the best of our knowledge, there has been no similar work to date.

## Modeling

In the first instance, we developed a theoretical simulation to test the accuracy of various rank aggregation methods. The simulation can be thought of in terms of the most preferred order in which to display results of a web search.

Given a set of $m$ items (e.g., web pages), we consider $n$ ranked list of them, $\left\{r_{1}, \ldots, r_{n}\right\}$, each of which is given by a
judge (e.g., search engine). One, and only one, of the possible ranking orders (permutations) $r_{*}$ is deemed to be true (correct).

Each judge is characterised by his "competence" which is defined as the probability of providing the true list.

Our simulation takes the various generated lists and aggregated them into a single list using one of the rules outlined further down in this section.

Unlike in some previous work, such as Fernández et al., for each item in a list we know only its rank position, vis-avis other items, and not any other numeric properties. It is often impossible or unrealistic to obtain the scores of individual items and only their relative positioning to each other is available (Dwork et al., 2001; Renda \& Straccia, 2003). More importantly, a wealth of psychological research suggests that, in many domains, humans represent faithfully only ranking order information and more detailed information is unhelpful (Stewart, Chater, \& Brown, 2006)

For the sake of simplicity our modeling considers that each judge will produce a complete list and no ties are possible. So when ranking items, they will rank all of the choices and will rank them relative to each other in such a way that each item will occupy a unique position. Furthermore, every judge in our model has the same level of competence $c \in[0,1]$. Finally, when a certain rule produces multiple lists that are equally optimal, one of them is selected at random. This work could be generalized straightforwardly in the future by relaxing these constraints.

Following rank aggregation methods have been proposed in previous studies and are widely used in practice, so we will use them in our comparison:

- majority: the consensus list is just the ranked list that appears most frequently.
- average: the consensus list is generated by ranking the items according to their average rank positions, which is essentially same as the Borda's count (Dwork et al., 2001).
- Spearman: the consensus list is the one with the minimum sum of Spearman's footrule to all the given ranked list. Spearman's footrule is defined as the total number of displacements needed to achieve parity between two lists.
- Kendall: the consensus list is the one with the minimum sum of Kendall's tau to all the given ranked list. Kendall's
tau is defined as the total number of inversions required to achieve parity between two lists.
- Kemeny-Snell: the consensus list is the one with the minimum sum of Kemeny-Snell distance to all the given ranked list. The Kemeny-Snell (KS) distance is similar to Kendall's tau, but more robust when dealing with ties.

While the first two methods are simple and easy to compute, the other three that are based on distance measures and have a high computational complexity. It has been shown that finding the optimally ranked list based on Kendall's tau (known as the Kemeney optimal aggregation) is an NP hard problem with just four full lists(Dwork et al., 2001).

Our research question is then: "which rank aggregation method is most accurate?" Here by accuracy, we mean how often the consensus list returned by a rank aggregation method is indeed the true list.

## Computer Simulations

We prepared a simulation in $R$, which samples a number of judges and uses different aggregation methods to determine the list reflective of the group of judges. The generated consensus lists are then compared with the true list to calculate accuracy, which we used as our "performance" measure for the aggregation method. This procedure is repeated across pools of judges of different sizes. In order to smooth out effects of randomness, we performed bootstrapping at each number of judges and took the average value. Therefore each set of judges was simulated several times, before adding additional judges.

Our simulation had a number of parameters that could be altered:

- list size: number of unique items in a list
- competence level: individual probability of picking the correct list
- aggregation method: methods of aggregation described above
- number of runs: each run increased the number of judges in a group by one
- number of simulations: a number of repeats of the same simulation with the same conditions to smooth out any noise due to randomness

We began with a list size of 4 . With no ties there are 24 possible permutations. In the simulation $k$ groups consisting of $n$ number of judges would draw a single list from the full list of permutations. Using one of the aggregation methods, a single list would be selected for each group as the aggregate product, and then compared to the true list. Each group of judges would be re-sampled a number of times to boostrap the results to get a smoother result. Thus, scores reported below are the average results sampled over multiple trials for the same group.

Figure 1: The comparison of aggregation methods in the linear-decay error model.

Error Model One important consideration in the study was the underlying error model that governed a judge's probability of picking the wrong list among all possible permutations. Each judge had a competence measure which reflected the probability of picking the true list. The rest of the probability was distributed among the remaining possible choices. Assuming that judges know anything about the domain in question, the probability of picking a wrong list is likely to be an inverse function of the distance from that list to the true list. Without loss of generality, we used the Kemeny-Snell distance measure $d(\cdot, \cdot)$ to determine the probability of a given list being selected as follows.

$$
\operatorname{Pr}\left[r_{i}\right]= \begin{cases}c & \text { if } r_{i}=r_{*}  \tag{1}\\ (1-c) \frac{1 / d\left(r_{i}, r_{*}\right)}{\sum_{j \neq *}\left(1 / d\left(r_{j}, r_{*}\right)\right)} & \text { otherwise }\end{cases}
$$

In effect, lists that are closer to the true list, would be more likely to be drawn than the lists further away.

We wanted to see relative performance of the various aggregation methods, as the number of judges increased. For all results, we maintained a constant competence level $c=0.1$, which meant a $10 \%$ chance for a judge to pick the true list $r_{*}$. We selected the simulation range from 5 to 100 judges.

## Results

After running several different simulations we produced a number of interesting and insightful results. We present our findings in a series of figures that illustrate the relative performance of the different aggregation methods (see figures $1,2,3$ ).

The majority rule performs significantly worse than the alternatives and does not increase in accuracy as the number of

Figure 2: The comparison of aggregation methods in the fastest-decay error model.
judges increases. On the other hand, the other four methods perform similarly to each other and their accuracy increases as the number of judges goes up, as can be observed in figure 1. It is important to note that the Kemeny-Snell aggregation method does not perform significantly better than the other distance-based methods, despite the fact that the underlying error model is based on the Kemeny-Snell distance! Furthermore, average, which is a very simple method (both computationally and cognitively), performs at least on par with the distance-based methods.

A minor comment regarding high competence is due at this point. When the competence level is above a threshold, e.g., 0.2 , we see a quick rise towards perfect accuracy of all methods, which is not particularly interesting, or informative. Therefore, we kept the competence level low and tried to understand how robust different rank aggregation methods would be under the more challenging condition of lower individual competence.

The above linear-decay error model as described in Eq. (1) is just one way of converting the underlying KS-distance to the targeted true list into a probability of erroneous list selection. Actually any monotonic decaying transformations such as an exponential decay - of those distances could be utilised to pick the non-true lists. To generalise our results we considered two extreme cases of monotonic decay functions of distance: at the one end (fastest-decay), the selection probability drops so rapidly as a function of distance that only the closest lists stand a chance of being selected; at the other end (none-decay), the selection function is flat and the lists of all distances are equally likely to be selected. We have examined both of these extreme cases.

First, let us consider the case where only the ranked lists

Figure 3: The comparison of aggregation methods in the none-decay error model.
closest to the true list had a non-zero selection probability (with each list at that distance equally likely to be picked).

From the results of the simulation we see that the majority method plummets almost immediately towards zero accuracy. This is due to the fact that the competence level, i.e., the probability of picking the true list ( $10 \%$ ), is significantly lower than the probability of picking any of those closest lists (which is $30 \%$ in this example as there are three closest lists in total).

Interestingly, the average method appears to outperform the other methods, and quickly moves towards perfect accuracy as the number of judges increases. There appears to be little difference among the other distance-based methods and they all behave similarly to the average method.

Second, we consider the case where a judge is equally likely to pick any of the wrong lists, regardless of their distance to the true list.

The results of this simulation stand in stark contrast to the other two simulations. The majority method performs significantly better and improves with the number of judges, which is exactly reverse of what was observed in the earlier simulations.

Although the observation was initially quite surprising, the explanation is fairly intuitive. Since the probability of picking the true list is $10 \%$, the remaining probability would be distributed evenly over 23 other possible permutations, which leads to only $3.9 \%$ per permutation. Therefore, the ranked list occurred most frequently is almost guaranteed to be the true list, and the majority method would always perform the best.

Just as importantly, the other aggregation methods appear to falter at this stage. Although there is some improvement along with the increase in the number of judges, the
accuracy stays well below 0.5 , even for groups with 100 judges. Notably, the average method performed the worst, while the Spearman method performed the best among the three distance-based methods.

## Discussion

A few key insights emerge from our modeling efforts. The first and most important one is that there appears to be little benefit of using computationally-expensive distance-based methods to conduct rank aggregation. Secondly, there is clear robustness of adopting the group mean. Accuracy is constantly increases in most scenarios and the method itself is simple enough to calculate and act upon.

The one research question that remains open, however, is what real human subjects would do given a similar task. While it may appear that taking the group mean is advantageous from the accuracy point of view, it is also more difficult to determine than simply adopting the majority opinion for example. To test, this we designed a study that looked at individual rank revision in a group setting.

## Experiment - Rank Revision

This experiment was set up to test what rules, if any, individuals use to revise their beliefs in light of new information. Unlike similar studies on the topic which have mostly looked at absolute answers and estimates, we were interested in applying this in the context of rank revision. In other words, our interest was to understand better how participants revise ranked orders when presented with information from their peers. From the modeling exercises above we knew that adopting the group mean is the most beneficial strategy a person can take in most situations, however, we could not locate any research that corroborated this in an empirical study.

## Method

Participants Participants for this study were volunteers from the University of London community. Participants were paid 5 for taking part in the study. There were 19 participants who took part, which created three panels of five participants and one panel with four participants ( $n=19$ ). Each group of participants took part at the same time and were hosted in the same room. No particular exclusion criteria were used and participants were free to self select which of the time slots worked best for them to attend the study. It did not appear that any participants knew each other prior to the study.

Materials \& Procedure Participants were seated in a computer lab, spaced apart in a way that prevented them from seeing each others' screens. Each participant had a computer in front of them that contained a NetLogo interface that was connected in a network to other computers in the room. See Figure 4 for a sample interface that each participant saw.

Initially, participants were read basic instructions regarding the task. The task involved each participant to rank four cities from the largest to smallest by population size. Each city was presented in a text box and contained a number along with

Figure 4: NetLogo participant interface

Figure 5: NetLogo participant interface

Figure 6: Zoomed in participant view
the name of the city (see example in figure 4). In the drop down box 'City A' they were instructed to put the number of the city they believed to be the largest, 'City B' were to contain the second largest, and so on. After all four boxed were filled, participants had to submit their answers and wait for everyone else in the room to finish. Once, all answers were submitted, participants could see how everyone else had ranked the cities. At this point, everyone had an opportunity to revise their answers in light of additional information (see figure 5 and zoomed in view in figure 6). They repeated this process three times for each question, resulting in four rounds - initial round, plus three revision rounds.

In total, each participant answered 21 questions. There is an initial practice question which participants did in a directed manner, followed by 20 other questions, which were done independently and free from any additional instructions. Each question contained a different set of cities and in different order, but the task was the same. There was only a single experimental condition and all participants were treated the same; they were shown the same set of questions, in the same order.

Figure 7: Number of revisions per Participant

## Results

In the first instance we were interested in individual belief revision. We analyzed how often individuals changed their answers and what rules they have have used to do so.

Individual Revision Discounting the first question, there were 60 opportunities for revision for each participant (20 questions * 3 revision rounds). On average participants changed their answers 10.3 (SD 7.51) times over the course of the simulation, or about $10 \%$ of the time. With some participants changed their answers as little as once, and others changed almost a third of their answers. In total there were 196 revision for all participants. See figure 7 for a visual representation of the number of revisions per participant.

Overall, most revisions occurred in the first round, where almost as many revisions occurred as the subsequent two rounds. Table 1 breaks down revisions by round.

Revisions occurred unevenly between questions. Seven questions had between 13 and 15 revisions, while remaining 13 questions had between five and nine revisions.
The number of revisions made by participants was rather low, but the overall profile of the changes, i.e. mostly in the first round and more for some questions than others, is consistent with some of the other studies in the field of decisionmaking.

Table 1: Round Revisions

| Revision | Revision | Revision |
| :--- | :--- | :--- |
| Round 1 | Round 2 | Round 3 |
| 96 | 58 | 42 |

Models of Revision We fitted several models presented in the first part of the paper trying to predict individual belief revision rules that induced the change (such as mean, median and majority models). We decided to restrict our fitting to two models in particular: mean and majority. As these
models had very interesting properties and were most likely to be available and calculable to participants. Since ranked lists were presented near each other identifying the majority list, or calculating the mean list was a conceivable task that a participant could engage in prior to revising their beliefs.
In order to test whether participants actually behaved in a way predicted by a model, we generated an answer that a participant would pick if they were guided by a model and then compared the predicted answer with the actual answer in a binary fashion. We used two models: mean - using simple Borda count - and majority lists.

Table 2 demonstrates that there were significantly more revisions that moved towards the mean than majority. In fact, of the 196 total revisions, 62 , or $31 \%$ were revisions that adopted the group mean, and 44 or $22 \%$ that adopted the majority list. On average, the mean model was adopted 3.26 times per participant, while majority model was adopted 2.32 times. The rest of the revisions were not accounted by these two models and were being guided by unknown rules.

Naturally, there were instances where both models predicted the same list and the above numbers include revisions where the mean and majority lists coincide. There were 35 revisions where both models predicted the same result.

When removed from the total revision count for each model, there were 27 revisions that adopted the group mean and only 9 revisions that adopted the majority list. This provides strong evidence to suggest that participants in our study adopted the group mean much more readily than the majority list.

Table 2: Model Revision

| Model | Total | Model Only | Average | Revision \% |
| :--- | :--- | :--- | :--- | :--- |
| Mean | 62 | 27 | 3.263 | 31 |
| Majority | 44 | 9 | 2.316 | 22 |

Toward a Model of Rank Belief Revision Our findings suggest that human participants are 3 times more likely to adopt the group mean over the majority list in cases where the two do not coincide. This suggests that computational models that emphasize mean ranks may be closer to the way humans make revisions given additional information in a ranked format.

We did not test other, more complex models on the study dataset. Therefore, it is difficult to say at this point whether adopting the group mean is the most preferred strategy. It should also be noted that revisions represented only $11 \%$ of all choices made by participants and most of the time participants did not change their answers and were not influenced by additional information. However, where revisions did occur, in a third of all cases it was towards the group mean, which is a significant finding. Future models that seek to replicate human behaviour should take these findings into account when constructing more human-like models.

## Conclusions
