One crucial aspect of this spatial foundation may be the ability to use space to make sense of number (Hubbard et al, 2005). Spatial representations of number could ground the highly abstract notion of numerical magnitude in the more basic, experiential notion of location. More complex forms of mathematics could then build on this foundation, from algebra to calculus and beyond (Núñez \& Marghetis, 2015). The current study tests this account by examining whether spatial representations are activated during one canonical case of complex mathematical activity: solving equations.

## Mixed evidence for spatial-numerical associations in higher mathematics

There is considerable evidence that spatial representations of number are ubiquitous and automatic, at least during simple numerical tasks (Hubbard et al, 2005; Winter, Marghetis, \& Matlock, 2015). These spatial representations involve both the horizontal and vertical axes. Among literate adults in Western cultures, for instance, processing lesser numbers facilitates subsequent responses on the left, while processing greater numbers facilitates responses on the right (Dehaene et al, 1993). Similarly, when German adults generate random numbers while undergoing upward and downward motion, they produce numbers that are significantly greater when moving upward and lesser when moving downward (Hartmann et al, 2011). In adults, these spatial representations have been shaped considerably by culture. The association between numerical magnitudes and horizontal locations, for instance, is reversed among Palestinians who read both words and numbers from right-to-left (Shaki et al, 2009). When we encounter a number, therefore, we automatically activate spatial representations of its magnitude.
But do these implicit spatial representations play any role in mathematics beyond the domain of simple numbers? The evidence is rather mixed. One point in favor of such a role is that the correlation between early spatial abilities and later school success in mathematics is mediated by the ability to map numbers to a linear path (Gunderson et al, 2012). Causal evidence comes from the finding that training students to map numbers to linear path improves calculation (Siegler \& Ramani, 2009). There is also evidence that spatial representations of number play a role in mathematical communication. Mathematical experts produce gestures that express numbers as locations, even
when their speech does not contain any mention of space (Marghetis \& Núñez, 2013).
On the other hand, there have been a number of failures to find any relation between spatial-numerical associations and higher mathematical ability (e.g., Cipora \& Nuerk, 2013; Cipora, Patro, \& Nuerk, 2015). Indeed, there is little evidence that spatial representations of number are activated at all during mathematical activities that are more complex than simple numerical judgments - judging a number's relative magnitude, or determining whether it is even or odd. In contrast to these simple tasks, real mathematical activity seldom involves single numerals in isolation. Algebra, in particular, is often the first time that students begin to think about numbers, not just in terms of their magnitudes, but also in terms of their structural interrelations. As these more complex notions come to the fore, spatial representations of numerical magnitude may fade into the background.
Moreover, many of these more complex notions may also have a spatial underpinning. During mental calculation, for instance, subtraction and addition are associated with leftward and rightward motion, respectively (Knops et al, 2009; Marghetis, Núñez, and Bergen, 2014); and during algebraic reasoning, space is used to represent the hierarchical syntax of algebraic expressions (Landy \& Goldstone, 2007). If space is playing these other roles, then the association between space and number might reasonably be expected to fade. The neural circuitry responsible for representing spatial location cannot be all things at once. On this account, as space is co-opted for new roles arithmetic, algebraic syntax - its association with numerical magnitude might diminish. Number-space associations may be limited to simple numerical judgments, disappearing as mathematical complexity increases.

## The present study

The current literature, therefore, appears to support conflicting accounts. On one hand, associations between number and space are activated automatically during a variety of simple tasks, and spatial processing more generally has been implicated in higher-level mathematical thinking. On the other hand, individual differences in spatial representations of number do not appear to correlate with mathematical expertise. This presents a puzzle. What is happening to these spatial representations of number as people transition from simple judgments of isolated numerals to more complex mathematical activities?

To resolve this puzzle, we analyzed the spatial dynamics of individuals' manipulations of algebraic equations, using a methodology that we have dubbed Dense Recording of Algebraic Manipulations (DREAM). In this approach, participants manipulate equations using click-and-drag dynamic algebra software; we record the moment-tomoment details of these manipulations, including the precise mouse trajectories used to rearranging equations.

In the current study, algebraic equations were displayed on a computer screen (e.g., $x+3=7$ ), and participants could rearrange these equations by clicking and dragging symbols as if they were physical objects. We also manipulated whether participants performed a task that was focused on magnitude ("Click and drag the greatest/least number") or algebraic structure ("Solve for x"). Throughout, we recorded the fine-grained details of these interactions, including the precise spatial locations at which individual numbers were clicked ${ }^{1}$. By varying the numbers in the equations, we could see whether numerical magnitude had a systematic effect on the location of symbolic manipulations.
We foresaw several possible outcomes. If spatial representations of number play no role in higher mathematics - or play a role only in development - then spatial representations might not be activated at all while equations are manipulated, particularly if the goal is to solve the equation. If, on the other hand, spatial representations of number continue to play a functional role in algebra perhaps by grounding the meaning of otherwise arcane symbolic manipulations - then we might find traces of spatial-numerical associations in the fine details of how equations are manipulated. In particular, greater numbers might be clicked higher or more rightward, while lesser numbers might be clicked lower or more leftward.

## Methods

## Design

Participants manipulated equations with a computer mouse, moving terms as if they were virtual objects. This was implemented with the Graspable Math software (www.graspablemath.com). Think of files and folders on a computer desktop, which can be reorganized and rearranged by clicking and dragging. Graspable Math offers the same functionality but for equations. In response to these manipulations, the software automatically adjusts the equation to maintain its validity. For instance, given the equation ' $x+2=4$,' as the 2 is dragged to the far side of the 4 , the + symbol changes automatically into the - symbol as it crosses the equal sign, so that the final state of the equation would be ' $x=4-2$ ' (Fig. 1a). This allows users to focus on how and why they want to rearrange equations. In addition, clicking on the equals sign flips an equation (e.g., $\mathrm{x}=2 \rightarrow 2=\mathrm{x}$ ), and clicking on an operation performs that operation (e.g., $x=4-2 \rightarrow x=2$; Fig. 1b).

The full system is quite powerful and can be explored online (www.graspablemath.com). The current study used a simplified version that included only the dragging and clicking interactions described above. We recorded where
${ }^{1}$ Technically, participants clicked numerals that denoted numbers, and it was the numerals' denotations that had magnitude. For simplicity of presentation, however, we shall conflate numerals with their denotations and refer to them as numbers.
and when interactions occurred, including $x, y$ coordinates of the mouse cursor. Here we focus on where, exactly, participants clicked on numbers, to investigate whether this spatial behavior was affected by the numbers' magnitude.

Figure 1. Manipulating equations using Graspable Math. (a) As an equation is rearranged, it's updated automatically to remain valid. Here, ' +2 ' is dragged from left to right; the sign is switched as it crosses the equals sign. (b) Operations are triggered by clicking the operator.

On each trial, an algebraic equation appeared on the screen (e.g., ' $x+3=5$ '). Participants performed one of two tasks, assigned between-subjects.
In the Algebra task, participants had to solve for the variable by clicking and dragging to simplify the equation (Fig. 1). For instance, given $x+3=5$, one might start by dragging the 3 to the other side of the equation. Note that this does not require attention to numerical magnitude, only to the algebraic relations between the terms.

In the Magnitude task, participants were presented with the exact same equations, but their task was to find the least number - or the greatest number, depending on the block - and indicate their selection by dragging it to other side of the equation. This click-and-drag response was chosen so that the two tasks involved comparable interactions with identical stimuli.

## Participants

Volunteers participated in exchange for partial course credit ( $N=69, M_{\text {age }}=19$ years, 51 women, 18 men). A target sample size of 68 was determined in advance on the basis of similar studies of number and space (e.g., $n=44$ in Fischer et al, 2010).

## Materials

For both tasks, items consisted of equations in the form $x$ $\pm b=c(N=112)$. Values of $b$ and $c$ ranged from 1 to 9,
excluding 5. The value of $b$ was always different from $c$, so one number was always greater than the other, producing 56 combinations of values for $b$ and $c$. Each combination was used to create two equations: one with addition (e.g., $x+2=$ 3 ) and one with subtraction (e.g., $x-2=3$ ).

## Procedure

Participants gave informed consent, completed a brief tutorial on how to manipulate equations with the mouse, and read task instructions. This was followed by practice trials chosen randomly from the full list of items $(n=4)$. They then completed the experimental trials $(n=224)$. Each item appeared twice, ordered randomly across four blocks. For the Magnitude task, initial target magnitude (greater, lesser) was assigned randomly and switched halfway through.
Each trial began with the appearance of a fixation symbol at the top-center of the screen. Clicking on this fixation symbol triggered the appearance of an equation toward the bottom of the monitor. The equation appeared either on the left or right of the screen and with the variable either on the left or right of the equal sign (i.e., ' $x+2=3$ ' or ' $3=x+2$ '), assigned randomly. Participants were then free to manipulate the equation using the computer mouse. Trials in the Magnitude task ended automatically when a number was dragged across the equal sign and released. In the Algebra task, trials ended automatically when participants had solved for $x$. Participants finished by answering a series of standard demographic questions along with four questions about mathematical experience: Did they study calculus in high school? In college? What was their grade? And what was their SAT score? No other measures were collected.

## Analysis

We focused on where numbers were clicked, specifically the first number manipulated during each trial. Our primary measure was the deflection of these locations, relative to where the participant would click typically (i.e., standardized by participant). A value of zero thus indicated no deflection; negative values, deflections downward or leftward; and positive values, deflections upward or rightward. Analyses used linear mixed-effects models, with centered predictors and the maximal converging effects structure justified by the design (Barr et al, 2013).

## Results

One participant was removed for poor accuracy (72\%). Accuracy was high among remaining participants ( $M=$ $96 \%, 95 \%$ CI $[86 \%, 100 \%]$ ). One additional participant was removed for corrupted data. Before analysis, we removed trials where the participant did not arrive at the correct response ( $4 \%$ of trials), followed by those that were three standard deviations faster or slower than each participant's mean (1.4\% of trials).

## Overall spatial deflection due to numerical magnitude

We first investigated whether numerical magnitude caused systematic spatial deflections in click locations. For each trial, we calculated a measure of overall spatial deflection by summing the deflection along the vertical and horizontal axis (i.e., a signed Manhattan distance). On this measure, positive values indicate deflections that are, overall, congruent with our predictions for greater numerical magnitudes (i.e., rightward and upward), and negative values indicate deflections congruent with predictions for lesser magnitudes (i.e., leftward and downward). This spatial deflection was analyzed with a model that included fixed effects of Relative Magnitude (i..e, whether the selected number was greater or less than the equation's other number), Task (Algebra vs. Magnitude), and their interaction; and random intercepts and slopes for both participants and items.
There was no effect of Task (p > .9). As predicted, interactions with numerals were deflected spatially by their magnitude, $b=.25 \pm .03 \mathrm{SEM}, t=8.8, \mathrm{p}<.0001$. These deflections were congruent with canonical spatial representations of numerical magnitude. When participants manipulated the lesser number in an equation, they clicked a location that was deflected in the congruent left-downward direction ( $M=-0.09$ ); when they manipulated the greater number, they clicked more right-upward $(M=0.11)$.

The size of this spatial deflection, moreover, was moderated by the task, $b=-0.14 \pm 0.06$ SEM, $t=-2.4 p=$ .02. The size of the magnitude-based spatial deflection in the Magnitude task ( $b=0.30 \pm 0.03$ SEM) was significantly larger than in the Algebra task $(b=.18 \pm .04$ SEM $)$, even though the magnitude-based deflection was significant in both tasks (both $p \mathrm{~s}<.0001$ ). Thus, magnitude induced an overall spatial deflection of numeral manipulations, and the size of this deflection was task-dependent.

## Axis-specific spatial deflections

We next investigated whether this task-sensitive spatial deflection was specific to either the vertical or horizontal axis. Along the vertical axis, there was no evidence that responses differed by Task, $b=0.001 \pm .02 \mathrm{SEM}, p>9$. By contrast, a number's relative magnitude had a systematic impact on where it was clicked, $b=.18 \pm .02 \mathrm{SEM}, t=7.7$, $p<.0001$. When the selected number was greater than the other number in the equation, it was clicked 0.18 standard deviations higher than when it was less than the other number. This spatial-numerical deflection was moderated by the task, as revealed by a significant interaction, $b=-0.14 \pm$ $.05 \mathrm{SEM}, t=-2.3, p=.02$. Additional analyses confirmed that a spatial-numerical deflection occurred for both tasks, and differed only in size. In the Magnitude task, greater numbers were clicked higher than lesser numbers, $b=0.23$
$\pm 0.04$ SEM, $p<.0001$. In the Algebra task, greater numbers were still clicked significantly higher, but the deflection was dampened, $b=0.12 \pm .03$ SEM, $p=.0001$. Thus, there was spatial-numerical deflection in both tasks, but the amount of deflection was greater with explicit attention to magnitude.
On the horizontal axis, the effect of Magnitude was smaller but still significant ( $b=0.06 \pm 0.02 \mathrm{SEM}, t=2.9, p$ $<.01$ ). While there was no evidence that this magnitudebased deflection was moderated significantly by the Task ( $b$ $=-0.02 \pm 0.04 \mathrm{SEM}, t=-0.5, \mathrm{p}>.6$ ), additional analysis revealed that the magnitude-based horizontal deflection was only reliable in the Magnitude task, $b=0.07 \pm .03$ SEM, $\mathrm{p}=$ .01. In the Algebra task, by contrast, there was no evidence of a magnitude-based deflection along the horizontal axis, $b$ $=0.05 \pm 0.04$ SEM, $p=.17$.

Figure 2: Magnitude-based spatial deflection while manipulating equations. The vertical axis indicates mean spatial deflection, normalized for each subject (i.e., zscored). Interactions with greater numbers (red squares) were deflected upward and rightward; interactions with lesser numbers (blue circles), downward and leftward. This occurred in both tasks, but it was significantly more pronounced in the Magnitude task. (Error lines = SEM.)

## Discussion

We investigated whether symbol-mediated algebraic reasoning activates spatial representations of number, using dense recordings of algebraic manipulations (DREAM). Manipulations of algebraic equations were deflected upward and rightward when interacting with greater numbers, and downward and leftward when interacting with lesser numbers. The strength of this magnitude-based deflection, however, was moderated by the task. Spatial deflection was greatest when the task required explicit attention to numerical magnitude, and was dampened when the task
required algebraic reasoning. This was true even though the two tasks involved interacting with identical equations using comparable movements. In sum, when manipulating equations, people automatically activate a spatial representation of numerical magnitude, and the strength of this activation depends on the task's mathematical demands.

Spatial deflection along the horizontal axis was less pronounced than along the vertical axis. One explanation of this finding is that algebraic notation uses horizontal spacing for another purpose: to indicate syntactic hierarchy. In algebraic notation, higher-precedence operations are often written with little space between operands (e.g., $3 \cdot x \cdot y$ ) or no space at all (e.g., 3xy), while lower-precedence operations often introduce additional space between operands (e.g., $3+$ $\mathrm{x}+\mathrm{y}$ ). Thus, during equation manipulation, the horizontal axis may be co-opted to represent algebraic structure, dampening horizontal representations of numerical magnitude (Landy \& Goldstone, 2007; Landy, Allen, \& Zednik, 2014). By contrast, on purely numerical or arithmetic tasks, numerical magnitude does deflect hand movements along the horizontal axis: to the left for lesser magnitudes, and to the right for greater magnitudes (Marghetis et al, 2014; Faulkenberry, 2016).

## A new DREAM for studying algebraic reasoning

The study reported here is the first to use a methodology that we have dubbed dense recording of algebraic manipulations (DREAM) to gain insight into the cognitive processes at work during algebraic reasoning. Similar computer mousetracking approaches have been used to study the dynamics of simple numerical judgments (e.g., Faulkenberry, 2016; Song \& Nakayama, 2008) and mental arithmetic (e.g., Marghetis et al, 2014). DREAM extends this mousetracking methodology to a domain where manual interaction with external symbols is not just an artificial feature of the experimental design, but an integral part of the mathematical activity itself. One contribution of this study is to introduce this data-rich paradigm, which we hope can open new avenues of inquiry into mathematical cognition.
Algebraic reasoning is powerful because it transforms difficult conceptual tasks into a series of simple, robust physical manipulations of stable external symbols (Hutchins, 1995). Indeed, it is a canonical example of a cognitive accomplishment that depends on distributing the cognitive load across time and space. This requires coordinating skull-internal processes (perception, planning) with external processes like writing and gesturing. At its core, therefore, the practice of algebra demands the skillful use of hands: writing and erasing equations; using a finger to point to some aspect of an equation. DREAM allows us to analyze this distributed 'manual labor' that is a natural part of algebraic activity.

## Soft-assembling space for mathematics

This is the first evidence that spatial representations of number are activated during algebraic reasoning. Previous research, however, has documented other spatial processes that play a role in algebraic reasoning. The conventions of our algebraic notation use horizontal spacing to indicate syntactic hierarchy: higher-precedence operations are compressed (e.g., xy), while lower-precedence operations introduce more space between symbols (e.g., $x+y$ ). Participants are sensitive to these conventions (Landy \& Goldstone, 2007; Landy et al, 2014). Once participants master the basic syntax of algebra, moreover, they retrain their visual system so that they literally see equations as consisting of visual objects that respect the syntactic hierarchy of algebra (e.g., $x \cdot a+y \cdot b$ is perceived as two objects: 'x • a' and 'y •b'; Marghetis, Landy, \& Goldstone, 2016). The current study adds to this list of spatial processes that are deployed to solve algebraic equations.
This menagerie of spatial processes raises the question of how they are all brought into coordination. We favor an account where these different brain-based spatial resources are soft-assembled: they are brought into coordination in a way that is both transient and situated, responding to the demands of the task and the material environment (Clark, 2008). On this account, the development of mathematical expertise is not merely a process of piling new insights on top of old. Instead, the mathematical expert learns to combine, flexibly, a range of spatial processes, sometimes deploying one representation, other times another.
This account raises just as many questions as it answers. First, what is the time course of these processes? Are they all activated at once, or are they brought online sequentially in a cascade of activations? Marghetis and colleagues (2014), for instance, documented how, when individuals perform exact symbolic arithmetic (e.g., $2+7$ ), they first activate a spatial representation of the magnitude of the first number, then of the arithmetic operation, and finally of the solution. A similar cascade may occur in algebra.
Second, given our limited cognitive resources, how do all these mathematical facets-magnitude, arithmetic, algebraic syntax-become coupled to space without conflicting with each other? The spatial impact of relative magnitude was dampened significantly when the goal was to solve the equation rather than to judge relative magnitude. This suggests that spatial representations of number may fade over time, particularly when it comes to mathematical activities, like algebra, that foreground structural relationships over numerical magnitudes.
This fading may occur on multiple timescales, from the developmental to the momentary. On a developmental timescale, mathematical expertise might involve redeploying spatial resources to represent arithmetic or algebraic relations, pushing aside representations of magnitude. On shorter timescales, the activation of spatial
representations may be task-dependent, as it was in this study, or change from moment-to-moment-for instance, as an individual goes from identifying the symbol they intend to manipulate, to actually moving that symbol. Thus, as attention shifts away from magnitude or as other concepts acquire spatial associations, a symbol may become "semantically bleached" of its spatial-numerical content.

Indeed, the current results leave open the question of whether these spatial-numerical associations play a functional role in algebraic reasoning. Taken to the extreme, our results are consistent with an account wherein, for higher mathematics, spatial representations of number are largely epiphenomenal, playing a diminished role as spatial circuits are re-deployed to represent other aspects of the mathematical content (e.g., hierarchical algebraic structure).

## Conclusion

Are spatial representations of number really as ubiquitous as some have assumed, or are they limited to simple numerical tasks? Using dense behavioral recordings of equation manipulations, we found that numerical magnitude did, indeed, cause deflections that suggest a bottom-to-top and left-to-right spatial representation of number. This occurred even when the task was entirely algebraic, though the deflections were more pronounced when the task did require attending to magnitude. Our capacity for algebraic reasoning depends on a host of skills and processes - many of which are spatial - that must be brought in and out of coordination during situated reasoning. This singular ability would be impossible without the capacity to cobble together such processes both flexibly and dynamically.

# Chunking Ability Shapes Sentence Processing at Multiple Levels of Abstraction 

Stewart M. McCauley (Stewart.McCauley@liverpool.ac.uk)<br>Department of Psychological Sciences, University of Liverpool

Erin S. Isbilen (esi6@cornell.edu)<br>Morten H. Christiansen (christiansen@cornell.edu)<br>Department of Psychology, Cornell University

#### Abstract

Several recent empirical findings have reinforced the notion that a basic learning and memory skill-chunking-plays a fundamental role in language processing. Here, we provide evidence that chunking shapes sentence processing at multiple levels of linguistic abstraction, consistent with a recent theoretical proposal by Christiansen and Chater (2016). Individual differences in chunking ability at two different levels is shown to predict on-line sentence processing in separate ways: i) phonological chunking ability, as assessed by a variation on the non-word repetition task, predicts processing of complex sentences featuring phonological overlap; ii) multiword chunking ability, as assessed by a variation on the serial recall task, is shown to predict reading times for sentences featuring long-distance number agreement with locally distracting number-marked nouns. Together, our findings suggest that individual differences in chunking ability shape language processing at multiple levels of abstraction, consistent with the notion of language acquisition as learning to process.

Keywords: sentence processing; chunking; learning; memory; usage-based approach; language

## Introduction

Language takes place in real time; a fairly uncontroversial observation, yet one with far-reaching consequences that are rarely considered. For instance, a typical English speaker produces between 10 and 15 phonemes per second (Studdert-Kennedy, 1986), yet the ability of the auditory system to process discrete sounds is limited to around 10 per second, beyond which the signal is perceived as a single buzz (Miller \& Taylor, 1948). Moreover, the auditory trace is limited to about 100 ms (Remez et al., 2010). Compounding matters even further, human memory for sequences is limited to between 4 and 7 items (e.g., Cowan, 2001; Miller, 1956). Simply put, the sensory signal is so incredibly short-lived, and our memory for it so very limited, that language would seem to stretch the human capacity for information processing beyond its breaking point. We refer to this as the Now-or-Never bottleneck (Christiansen \& Chater, 2016).

How is language learning and processing possible in the face of this real-time constraint? A key piece of the puzzle, we suggest, lies in chunking: through experience with language, we learn to rapidly recode incoming information into chunks which can then be passed to higher levels of representation.

As an intuitive demonstration of the necessity of chunking, imagine being tasked with recalling a string of letters, presented auditorily: uopfmreepoa ecsgnpl $i r$. After a single presentation of the string, very few listeners would be able to recall a sequence consisting of even half of the letters (cf. Cowan, 2001). However, if exposed to the exact same set of letters but re-ordered slightly, virtually any listener would able to recall the entire sequence with ease: frog m o u s e paperpencil. Clearly, such a feat is possible by virtue of the ability to rapidly chunk the sequence into familiar sub-sequences (frog, mouse, paper, pencil).

According to the proposal of Christiansen and Chater (2016), the Now-or-Never Bottleneck requires language users to perform similar chunking operations on speech and text in order to process and learn from the input. This is necessary both due to the fleeting nature of sensory memory and the speed at which information is encountered during processing. Specifically, language users must perform Chunk-and-Pass processing, whereby input is chunked as rapidly as possible and passed to a higher, more abstract level of representation. Information at higher levels must also be chunked before being passed to still higher, increasingly abstract levels of representation.

Thus, in order to communicate in real-time, language users must chunk at multiple levels of abstraction, ranging from the level of the acoustic signal to the level of phonemes or syllables, to words, to multiword units, and beyond. Indeed, mounting empirical evidence supports the notion of chunking at levels higher than that of the individual word: children and adults appear to store and utilize chunks consisting of multiple words in comprehension and production (e.g., Arnon \& Snider, 2010; Bannard \& Matthews, 2008). Moreover, usage-based (e.g., Tomasello, 2003) and generative (e.g., Culicover \& Jackendoff, 2005) theoretical approaches have highlighted the importance of such units in grammatical development and sentence processing alike.

Chunking has been considered a key learning and memory mechanism in mainstream psychology for over half a century (e.g., Miller, 1956), and has been used to understand specific aspects of language acquisition (e.g., Jones, 2012; Jones, Gobet, Freudenthal, \& Pine, 2014). Nevertheless, few have sought to understand how it may shape more complex linguistic skills, such as sentence processing. McCauley and Christiansen (2015) took an initial step in this direction, showing that individual
differences in low-level chunking abilities were predictive of reading times for sentences involving relative clauses, demonstrating the far-reaching impact of basic chunking skills in shaping complex linguistic behaviors.

The present study seeks to evaluate the predictions of the Chunk-and-Pass framework more closely, by examining individual variation in chunking at two different levels of abstraction. Specifically, whereas chunking has previously been treated as a uniform memory ability, we test the novel theoretical prediction that chunking abilities may be relatively independent at different levels of linguistic abstraction. Participants were first asked to take part in a multiword-based serial recall task (Part 1) designed to yield a measure of chunking at the word level. This was followed by a variation on the non-word repetition task (Part 2), designed to yield a measure of phonological chunking ability. Importantly, due to the memory limitations discussed above, participants must utilize chunking in order to recall more than a few discrete words or phonemes in these tasks (e.g., Cowan, 2001; Miller, 1956). Finally, participants took part in an online self-paced reading task (Part 3). The results show that chunking ability at each level predicts different aspects of sentence processing ability: chunking at the phonological level predicts the extent to which low-level phonological information interferes with or facilitates complex sentence processing, while chunking at the multiword level predicts the role of local information in processing sentences with long-distance dependencies.

## Part 1: Measuring Individual Differences in Word Chunking Ability

The first task sought to gain a measure of individual participants' ability to chunk words into multiword units. To this end, we specifically isolate chunking as a mechanism by employing a classic psychological paradigm: the serial recall task. Serial recall has a long history of use in studies of chunking, dating back to some of the earliest relevant work (e.g., Miller, 1956), as well being used to extensively study individuals' chunking abilities (e.g., Ericsson, Chase, \& Faloon, 1980).

Participants were tasked with recalling strings of 12 individual words, with each string consisting of 4 separate word trigrams extracted from a large corpus of English. Importantly, in order to recall more than a few discrete items (as few as 4 in some accounts; e.g., Cowan, 2001), listeners must chunk the words of the input sequence into larger, multiword units. In this case, we expect them to draw upon linguistic experience with the trigrams in the experimental items.

In addition, we included a baseline performance measure: matched control strings, which featured identical functors to the experimental sequences, along with frequency-matched content words (to avoid semantic overlap effects on recall), presented in random order. Thus, comparing recall for experimental and control trials provides a measure of word chunking ability that reflects language experience while
controlling for such factors as attention, motivation, and-to the extent that it is separable-working memory.

## Method

Participants 42 native English speakers from the Cornell undergraduate population ( 17 females; age: $M=19.8$, $S D=1.2$ ) participated for course credit. Of the original 45 subjects, one was excluded due to audio recording errors, while two subjects failed to complete all three tasks.
Materials Experimental stimuli consisted of word trigrams spanning a range of frequencies, extracted from the American National Corpus (Reppen, Ide \& Suderman, 2005) and the Fisher corpus (Cieri, Graff, Kimball, Miller \& Walker, 2004). The combined corpus contained a total of 39 million words of American English. Each item was compositional (non-idiomatic). Item frequencies, per million words, ranged from 40 to .08 , averaging at .73 .

Each word was synthesized independently using the Festival speech synthesizer (Black, Clark, Richmond, King \& Zen, 2004) and concatenated into larger strings consisting of 12 words ( 4 trigrams). Each trigram was matched as closely as possible for frequency with the others occurring in a sequence.

To provide a non-chunk-based control condition, each item was matched to a sequence of words which contained identical functors but random frequency-matched content words (in order to avoid semantic overlap effects on recall, content words were not re-used). The ordering of the words was then randomized. An example of a matched set of sequences is shown below:

1) have to eat good to know don't like them is really nice
2) years got don't to game have she mean to them far is

The final item set consisted of 20 sequences (10 experimental, 10 control).
Procedure Each trial featured a 12-word sequence presented auditorily. Each word was followed by a 250 ms pause. Immediately upon completion of the string, the participant was prompted to verbally recall as much of the sequence as possible. Responses were recorded digitally and later transcribed by a researcher blind to the conditions as well as the purpose of the study.

The presentation order of the sequences was fully randomized. The entire task took approximately 15 minutes.

## Results and Discussion

Participants recalled significantly more words from experimental strings than the frequency-matched control sequences. The overall recall rate for words occurring in experimental items was $74.0 \%$ ( $S E=2.3 \%$ ), while the recall rate for control sequences was just $39.2 \%$ ( $S E=1.1 \%$ ). The difference between conditions was significant $(t(41)=18.8$, $p<0.0001$ ).

As the purpose of Part 1 was to gain an overall measure of chunk sensitivity, we calculated the difference between conditions individually for each subject ( $M=34.8 \%$,
$S E=1.8 \%$ ), which afforded a measure of word-chunking ability that reflects language experience while controlling for factors such as working memory, attention, and motivation. We refer to this difference measure as the Word Chunk Sensitivity score, and it is used as a predictor of sentence processing ability in Part 3.

In addition to bolstering previous empirical support for compositional (non-idiomatic) multiword sequences as linguistic units in their own right (e.g., Bannard \& Matthews, 2008), Part 1 revealed considerable individual differences across participants in word chunking ability. Recall rates for experimental items ranged from as high as $93.3 \%$ to just $30.4 \%$, with difference scores across the conditions ranging from $50.8 \%$ as low as $3.0 \%$.

## Part 2: Measuring Individual Differences in Phonological Chunking Ability

While the first task sought to gain a measure of individual participants' chunking abilities at the level of words, Part 2 sought to gain a measure of chunking ability at the phonological level. To this end, we re-purposed the standard non-word repetition (NWR) task as a chunking task. NWR has been used extensively to study various aspects of language development. Recent studies, however, have suggested that chunking may better account for NWR performance than more nebulous psychological constructs, such as working-memory (e.g., Jones, 2012; Jones et al., 2014). In one sense, the NWR task can be re-conceptualized as a serial recall task, as in Part 1. Following such work, and in keeping with the Now-or-Never perspective outlined above, we propose that individual differences in chunking ability underlie differences in NWR performance. In turn, NWR-with appropriately constructed stimuli-can serve as an additional dimension along which to measure chunking ability at the level of phonological processing.

Participants engaged in a standard NWR task, with each non-word consisting of 4,5 , or 6 syllables. However, the stimuli were designed such that the same set of syllables occurred in two different non-words, but in different orderings: one ordering yielded an item with high "chunkability," according to corpus statistics, while the other was estimated to be less "chunkable." The two items were then counterbalanced across halves of the task.

## Method

Participants The same 42 subjects from Part 1 participated directly afterwards in this task.
Materials Non-words were generated using an algorithm which took a large list ${ }^{1}$ of English syllables and randomly generated syllable combinations that were evaluated according to distributional statistics at the phoneme level. For the purpose of supplying statistics, the combined corpus used in Part 1 was automatically re-transcribed phonetically using the Festival speech synthesizer (Black et al., 2004).

[^407]For each of three different syllable lengths (4-, 5-, and 6syllables), the algorithm extracted item pairs that differed maximally in sequence likelihood (based on phoneme trigram statistics) across two different sequential orderings of the same set of syllables. In other words, pairs were selected in which one ordering of syllables was highly "chunk-like," while the other ordering of the same syllables was less "chunk-like," according to the phoneme statistics of the corpus. Four sets of non-words (the four in which the pair differed most greatly in terms of sequence likelihood) were selected for each syllable length. An example of a highly "chunk-like" 4-syllable item is krew-ih-tie-zuh, which was matched to the less chunk-like tie-zuh-ih-krew.

Thus, the final set of items included 24 non-words, eight in each of three syllable-length conditions (4-, 5-, and 6syllable), with four being highly "chunk-like" and the other four consisting of alternate orderings of the same syllables which were statistically less "chunk-like."
Procedure The task was split into two blocks, with all NWR item pairs counterbalanced between them. The auditory presentation of each non-word was followed by a 1500 ms pause, after which the participant was prompted to recall the item verbally. As with Part 1, responses were recorded digitally and scored offline. The task took approximately 4 minutes to complete.

Correct responses received a score of 1. Responses involving alteration to a single phoneme (usually a vowel substitution, which could easily stem from differences in regional dialect) received a score of 0.5 . All other responses received scores of 0 .

## Results and Discussion

Participants achieved a mean NWR accuracy rate of $54.1 \%$ ( $S E=2.3 \%$ ). While the overall differences between the high chunk-like $(\mathrm{M}=55.2 \%, \quad \mathrm{SE}=2.5 \%)$ and low chunk-like ( $\mathrm{M}=53.1 \%, \mathrm{SE}=2.5 \%$ ) conditions were in the expected direction, they were subtle, with a mean difference of $2.1 \%$ (non-significant: $t(41)=1.12, p>0.1$ ). However, there was considerable individual variation in the size of this difference across participants ( $S E=1.9 \%$ ), ranging from $29.2 \%$ to less than $0 \%$, at $-16.6 \%$. Therefore, in Part 3, we assess both the overall NWR performance score as well as the difference between the conditions (which we refer to as the Phonological Chunk Sensitivity score) as predictors of sentence processing.

Importantly, neither the overall raw task performance ( $\beta=-0.03, p=0.9$ ) nor the Chunk Sensitivity scores $(\beta=-0.19$, $\mathrm{p}=0.22$ ) from Parts 1 and 2 correlated with one another, consistent with the notion that chunking at each level may have different consequences for sentence processing.

## Part 3: Measuring Individual Differences in Sentence Processing and Chunking

In Part 1, we sought to gain a measure of individual participants' ability to chunk words together, while Part 2 aimed to provide a measure of phonological chunking ability. In Part 3, the same subjects from the first two parts
participated in a self-paced reading task designed to: i) assess on-line sentence processing across two different sentence types which were hypothesized to involve chunking at the word and phonological levels, but to different extents; ii) determine the extent to which chunking ability, as assessed in the first two tasks, predicted processing difficulties for each sentence type.

The first sentence type featured long distance subject-verb number agreement with locally distracting number-marked nouns, exemplified by (1):

1. The key to the cabinets was rusty from many years of disuse.

Previous work (Pearlmutter, Garnsey, \& Bock, 1999) has shown that readers are slower to process the verb when the number of the local noun (cabinets) does not match that of the head noun (key), resulting in the sequence (cabinets was). Reading times are compared to sentences in which the number marking matches, as exemplified by (2):

## 2. The key to the cabinet was rusty from many years of disuse.

In other words, reading times are higher at the verb when the local information is distracting. Following the finding that text-chunking ability predicts decreased difficulty with complex sentences involving long-distance dependencies (McCauley \& Christiansen, 2015), we hypothesized that participants with higher Word Chunk Sensitivity scores (Part 1) would be less susceptible to interference from local information in sentences such as (1). Subjects that are better able to rapidly chunk words together and pass them to higher levels of representation should not only experience decreased computational burden from long-distance dependencies, but should be less affected by locally distracting information.

The second sentence type featured object-relative (OR) clauses, which have been shown to be processed with greater ease by good text chunkers (McCauley \& Christiansen, 2015). However, in the present study we added an element of phonological interference: two pairs of words in each sentence exhibited phonological overlap. Previous work has shown that low-level phonological overlap can interfere with the processing of sentences featuring relative clauses (Acheson \& MacDonald, 2011). An experimental item and its matched control are shown in (3) and (4):
3. The cook that the crook consoles controls the politician. 4. The prince that the crook comforts controls the politician.

In line with the Chunk-and-Pass framework, we predicted that better phonological chunkers, as assessed in Part 2, would be less susceptible to phonological interference, by virtue of their ability to more rapidly chunk and pass phonological information to a higher level of representation.

Thus, participants' resilience to phonological interference was hypothesized to be better predicted by Phonological Chunk Sensitivity (Part 2), while participants' susceptibility to local number mismatch was expected to be better predicted by Word Chunk Sensitivity (Part 1).

## Method

Participants The same 42 subjects from Parts 1 and 2 participated in Part 3 immediately afterwards.
Materials There were two sentence lists-counterbalanced across subjects-each consisting of 9 practice items, 20 experimental items, 20 matched control items, and 68 filler items. There were two experimental conditions, each with 20 items; the first consisted of the OR sentences featuring phonological overlap (the first 20 items from Acheson \& MacDonald, 2011). The second experimental condition consisted of grammatical sentences featuring long-distance number agreement with locally distracting number-marked nouns (the 16 items from Pearlmutter et al., 1999, plus four additional sentences with the same properties).

Each list included, for each condition, 10 of the items in their experimental form and 10 of the items in their control form (without rhymes in the case of the OR sentences; without locally distracting nouns in the case of the number agreement sentences). The lists were counterbalanced such half of the subjects saw the experimental versions of sentences the other half saw in their control form.
Procedure Materials were presented in random order using a self-paced, word-by-word moving window display (Just, Carpenter, \& Woolley, 1982). At the beginning of each trial, a series of dashes appeared (one corresponding to each nonspace character in the sentence). The first press of a marked button caused the first word to appear, while subsequent button presses caused each following word to appear. The previous word would return once more to dashes. Reaction times were recorded for each button press. Following each sentence, subjects answered a yes/no comprehension question using buttons marked "Y" and "N." The task took approximately 10 minutes.

## Results and Discussion

Only trials with correct answers to comprehension questions were analyzed. Accuracy for the number agreement condition was $88.3 \%$; for the object-relatives it was $80.0 \%$. Following Acheson \& MacDonald (2011), raw reaction times over 3000 ms were excluded. Prior to analysis, raw reaction times (RTs) were log-transformed.
Mean RTs for the main verb in the number agreement and phonological overlap sentences were comparable to those in the corresponding original studies (respectively: Pearlmutter et al., 1999; Acheson \& MacDonald, 2011), as was the size of the mean difference between conditions. In the number agreement condition, the verb in experimental items ( $\mathrm{M}=361.1$, $\mathrm{SE}=19.9$ ) was processed more slowly than in controls ( $\mathrm{M}=316.7$, $\mathrm{SE}=13.9$ ), a mean difference of 44 ms (F1[1,41]=12.7, $p<0.001 ; F 2[1,18]=10.2, p<0.01)$. There was a fair amount of individual variation in the difference

Fig. 1: Correlation between Word Chunk Sensitivity (derived from recall scores in Part 1) and the difference in main verb RTs between sentences with locally distracting number information vs. control sentences.
between conditions ( $\mathrm{SD}=79.4$ ).
The critical main verb in OR sentences featuring phonological overlap was processed more slowly ( $\mathrm{M}=605.1$, $\mathrm{SE}=70.6$ ) than in matched controls ( $\mathrm{M}=546.3$, $\mathrm{SE}=42.2$ ), a mean difference of 58.8 which was non-significant ( $F 1[1,41]=1.21, \quad p=0.28 ; \quad F 2[1,18]=0.04, \quad p=0.8 ; \quad$ see discussion). There was, however, considerable individual variation in the difference between conditions ( $\mathrm{SD}=343.7$ ), especially relative to the size of group mean difference.

We were primarily interested in the extent to which differences in RTs between experimental and control sentences could be predicted by the Chunk Sensitivity measures collected in Parts 1 and 2. Below, we analyze these relationships using multiple linear regression, with Word Chunk Sensitivity and Phonological Chunk Sensitivity scores as predictors of RT differences between conditions (recall that the two metrics were not correlated). ${ }^{2}$

For the difference between sentences featuring locally distracting number information and their control counterparts, we found that Word Chunk Sensitivity was a significant predictor of RT difference at the verb ( $\beta=-0.79$, $t=-3.19, p<0.01$ ), while Phonological Chunk Sensitivity and the interaction term did not reach significance. The model for the significant main effect had an $R$ value of 0.42 . The correlation between Word Chunk Sensitivity and the RT difference is depicted in Figure 1. As can be seen, subjects with higher Word Chunk Sensitivity scores appear less susceptible to interference from the locally distracting number information, as reflected by lower differences between verb RTs for experimental vs. control sentences.

With regard to the difference between OR sentences with and without phonological overlap, we found that Phonological Chunk Sensitivity was a significant predictor of RT differences at the main verb ( $\beta=-3.49, t=-2.43$, $p<0.05$ ), while Word Chunk Sensitivity and the interaction

[^408]

Fig. 2: Correlation between Phonological Chunk Sensitivity (derived from repetition scores in Part 2) and the difference in main verb RTs for OR sentences with and without phonological overlap between words.
term did not reach significance. The model for the significant main effect had an $R$ value of 0.36. A scatterplot showing the correlation between Phonological Chunk Sensitivity and the RT difference is shown in Figure 2: better chunking ability resulted in less phonological interference.

Thus, consistent with the predictions of the Chunk-andPass framework, we find evidence for the notion that chunking ability shapes sentence processing differently at two separate levels of abstraction: participants who were more sensitive to word chunk information better processed long-distance dependencies in the face of conflicting local information, while those with higher phonological chunk sensitivity better processed complex sentences with phonological overlap between words. That the two chunk sensitivity measures did not correlate with one another further underscores the notion of chunking taking place at multiple levels of abstraction.

While we failed to find the same effect of phonological overlap on processing as did Acheson and MacDonald (2011), it is likely that our subjects (Cornell undergraduates) had more reading experience than subjects at UW-Madison, and experienced less interference overall. Nonetheless, our measure of phonological chunk sensitivity was sensitive enough to pick up individual differences that predicted sentence processing in the face of phonological interference.

Intriguingly, participants with very high Phonological Chunk Sensitivity appeared to experience an advantage for OR sentences featuring phonological overlap. This raises the possibility that such subjects benefitted from phonologically-based priming of subsequent rhyme words in sentences such as (3). Further work will be necessary to evaluate this possibility.

## General Discussion

In the present study, we show that individual differences in chunking ability predict on-line sentence processing at multiple levels of abstraction: chunking at the phonological level is shown to predict the way phonological information
is used during complex sentence processing, while chunking at the multiword level is shown to predict the ease with which long-distance dependencies are processed in the face of conflicting local syntactic information. In Part 1, we adapted the serial recall task-a paradigm used for over half a century to study memory, including chunking phenomena-in order to gain a measure of individual variation in subjects' ability to chunk word sequences into multiword units. In Part 2, subjects participated in a NWR task with non-words designed to vary according to the ease with which their phonemes could be chunked. The difference in correct repetition rates between highly chunkable and less chunk-able items provided a measure of individual variation in chunking ability at the phonological level. Finally, in Part 3 we showed that chunking at the multiword level was predictive of processing for sentences with long-distance dependencies and distracting local information, while chunking at the phonological level was predictive of complex sentence processing in the presence of phonological overlap between words.

Expanding on the findings of a previous study that showed low-level chunking of sub-lexical letter sequences to predict sentence processing abilities (McCauley \& Christiansen, 2015), the present study supports the notion that chunking not only takes place at multiple levels of abstraction, but that individuals' processing abilities may be differently shaped by chunking at each level. Moreover, chunking at lower levels (e.g., the phonological level) may have serious consequences for processing at higher levels (e.g., sentence processing).

This work is highly relevant to the study of language acquisition. The Now-or-Never bottleneck imposes incremental, on-line processing constraints on language learning, suggesting a key role for chunking. Indeed, a number of recent computational modeling studies have demonstrated that chunking can account for key empirical findings on children's phonological development and word learning abilities (Jones, 2012; Jones et al., 2014), while other work has captured a role for chunking in learning to comprehend and produce sentences (McCauley \& Christiansen, 2011, 2014). There exists a clear need for further developmental behavioral studies-including longitudinal studies-examining individual differences in chunking as they pertain to specific stages of language development as well as more general language learning outcomes.

#### Abstract

Success in Algebra I often predicts whether or not a student will pursue higher levels of mathematics and science. However, many students enter algebra holding persistent misconceptions that are difficult to eliminate, thus, hindering their ability to succeed in algebra. One way to address these misconceptions is to implement worked-examples and selfexplanation prompts, which have been shown to improve students' conceptual knowledge. However this effect seems to be greater after a delay. The current study sought to explore such time-related effects on algebra conceptual knowledge. In a year-long random-assignment study, students either studied worked-examples and answered self-explanation prompts ( $\mathrm{n}=$ 132) or solved typical isomorphic problems $(\mathrm{n}=140)$. A three-way mixed ANCOVA (pre-algebra knowledge $x$ condition x time) found a significant condition by time effect. The growth of algebra conceptual knowledge was greater for students studying worked-examples than for those solving typical problems.

Keywords: worked-examples; self-explanation prompts; algebra; conceptual knowledge

## Introduction

Algebra I is often considered to be a gate-keeper course, meaning that a student's success in the course often determines whether he or she will continue on to a higher level mathematics or science course (U.S. Department of Education, 1997). Furthermore, students in the United States tend to struggle mastering algebra concepts, potentially contributing to the lower enrollment of U.S. college students in mathematics and science related majors compared to competing countries.

The newly implemented Common Core State Standards (CCSSI, 2010) stresses the importance of both procedural and conceptual knowledge of mathematics content. However, especially when it comes to algebra, students hold persistent misconceptions, which hinder their ability to master the content. In fact, students often enter Algebra I holding strong misconceptions that may impact their success mastering algebra content (Brown, 1992; Chiu \& Liu, 2004; Kendeou \& van den Broek, 2005). For instance,
misconceptions such as believing that the equals sign is an indicator of operations to be performed (Baroody \& Ginsburg, 1983; Kieran, 1981; Knuth Stephens, McNeils, \& Alibali, 2006), that the negative sign represents only the subtraction operation and does not modify terms (Vlassis, 2004), that subtraction is commutative (Warren, 2003), and that variables cannot take on multiple values (Booth, 1984; Knuth et al., Kuchemann, 1978) are all thought to be critical. Holding such misconceptions have been shown to hinder students' success in problem solving (Booth \& Koedinger, 2008).

A large body of research supports the notion that eliminating mathematics misconceptions is not an easy task. In fact, many students continue to hold these misconceptions after traditional classroom instruction (Booth, Koedinger \& Siegler, 2007; Vlassis, 2004). Often in order to challenge a student's misconception, one must directly draw out and confront the faulty thinking (Donovan \& Bransford, 2005). A combination of worked-examples and self-explanation prompts has been used to do just that.

Worked-examples, which are mathematics problems with worked-out solutions, provide the opportunity to point out common misconceptions to students. Some textbooks offer a small number of worked-examples, often at the beginning of a chapter or section. However, research indicates that interleaved worked-examples, alternating between workedexamples and problems for students to solve, are more beneficial to learning (Clark \& Mayer, 2003; Sweller \& Cooper, 1985).

Furthermore, the benefit of worked-examples can be improved with the inclusion of self-explanation prompts, which are questions that prompt students to explain their reasoning. When students self-explain, they are able to integrate various pieces of knowledge, fill gaps in their own knowledge, and make new knowledge explicit (Chi, 2000; Roy and Chi, 2005). Students at all ability levels who are
prompted to self-explain learn more than those who do not self-explain (Chi, de Leeuw, Chiu \& Lavancher, 1994).

Often if a textbook uses a worked-example, it displays a correct problem solution. However, incorrect workedexamples have also shown benefits to learning. In empirical laboratory students, students who are asked to explain the errors in incorrect solutions, as well as explain effective strategies in correct examples, learn more than students who are asked to only explain correct examples (Durkin \& RittleJohnson, 2009; Siegler \& Chen, 2008).

While the use of worked-examples and self-explanation prompts have been shown to improve learning, often there is a delayed-effect, meaning that the effect is larger on a delayed post-test rather than immediately after the intervention. For instance, Adams and colleagues (2014) found that while students solving isomorphic problems with feedback and students studying incorrect examples did not differ significantly at immediate posttest, students in the incorrect example group scored significantly better on a delayed posttest compared to the problem-solving group. This suggests that the worked-example/self-explanation effect may improve over time.

## Current Study

This study applies previous laboratory research supporting the use of both correct and incorrect worked-examples paired with self-explanation prompts to the classroom. While highly controlled laboratory studies are necessary when developing theories, applied studies are needed in order to investigate the limits of generalization.

We explore the effects of studying worked-examples and answering self-explanation prompts compared to solving typical isomorphic problems on students' algebra conceptual knowledge. We hypothesize that students who study worked examples and answer self-explanation prompts will have less algebra misconceptions and, therefore, will have higher conceptual knowledge compared to those who solve traditional isomeric problems.

Finally, the current study will explore students' conceptual knowledge growth over the course of a full school year, extending the evidence to support a delayed effect by providing longitudinal evidence from repeated interventions.

## Methods

## Participants

Participants included 562 Algebra I students from 28 classrooms ( 12 teachers) from five school districts across the United States. The sample was $49 \%$ female. Students were classified as underrepresented minority (URM; Black, Hispanic, biracial) or non-URM (White, Asian); 65\% of the students were classified as URM. Participants were also
socioeconomically diverse, with $52 \%$ coming from families who qualified for the Free or Reduced Lunch program (FRL).

Due to the restrictions of repeated-measures ANOVA, only students who completed all four quarterly exams were included in the analysis. Due to natural attrition (i.e. students leaving the school or absence on the day of the quarterly exam) the sample was reduced to $272 ; 51 \%$ female, $61 \%$ URM, $50 \%$ FRL.

Classrooms were randomly selected to either complete problem- or example-based worksheets yielding 14 problem-based $(\mathrm{n}=140)$ and 14 example-based ( $\mathrm{n}=132$ ) classrooms. Of the 12 teachers, eight taught one class of each condition; however, two teachers instructed two classes of the problem-based condition and one class of the example-based condition, while two others instructed two example-based classes and one of the problem-based class.

## Procedure

Intervention During the school year, teachers taught the algebra content using their own typically teaching methods; however, they were asked to sporadically assign the 42 study-worksheets at times they deemed appropriate during the year. Teachers did not have to assign the worksheets if they did not cover that material in their curriculum. On average, teachers assigned 27 worksheets (ranging from 15 to 40) throughout the year. There was no significant difference in the number of worksheets assigned between groups, with the problem-based group completing an average of 28 worksheets and the example-based group completing an average of 26 worksheets, $p>.05$. Teachers were given the freedom to assign the worksheets in any order and were told to treat the assignments as they would any other assignment in their class; however they were instructed to have students complete the assignments during the class period, not for homework. Students were allowed to work together if the teacher typically permitted that behavior. Each assignment took about 20 minutes to complete.

The worksheets of both conditions contained four problemsets (with two math problems similar to each other per set). The problem-based worksheets contained four regular problem-sets where students were asked to simply solve each problem, similar to a typical math worksheet. The example-based worksheets replaced one math problem within each set with a worked-example and self-explanation prompt(s). Students in this group were instructed to study the worked-example, answer the self-explanation prompt, and complete the second math problem on their own. Each example-based worksheet contained two correct workedexamples and two incorrect worked-examples. See Figure 1 for sample problem- and example-based problem sets.

Figure 1. Sample problem- and example-based problem sets.
Assessment At the beginning of the school year, all students were given a pre-test assessing their pre-algebra knowledge. Throughout the school year, students were given four quarterly exams. The four exams contained the same 18 items, however teachers were asked to only assign the test items taught to date; therefore, students were not answering items containing content they were not already taught. This exam assessed both procedural and conceptual algebra knowledge. At the conclusion of the year, students were given a post-test, consisting of 10 Algebra I standardizedtest release items.

At the end of the school year, each school provided the researchers with student demographic information, such as gender, ethnicity, and free or reduced lunch qualification. Finally, teachers completed a survey answering questions about their use of the worksheets. The survey contained questions such as "How often did you review the worksheets with the students after completion?"

## Measures

Algebra Conceptual Knowledge The quarterly benchmark exams consisted of 18 items, each of which had multiple parts, yielding a total of 71 sub-items. Of these 71 subitems, 46 measured students' conceptual knowledge of algebra content. We operationally define conceptual knowledge as an understanding of the core features in problems for a given topic (e.g. Booth, 2011). Algebra conceptual knowledge scores were calculated for each quarter by dividing the number of correctly answered items by 46 . This score does not take into account the number of items attempted since each teacher assigned a different number of items each quarter.

Pre-algebra Knowledge The pre-algebra exam was given at the start of the school year before students completed any
study-worksheets. This exam covered content necessary for the success in an algebra course, such as the understanding of equality and difference between coefficient and constant. This exam consisted of 11 items with 71 sub-items. Prealgebra knowledge scores were calculated by dividing the total number of correctly answered items by 71 .

Teacher Reports At the end of the year, teachers were administered a survey about their experience in the study. In one item, they were asked about the frequency with which they reviewed study assignments in class. Teachers responded by selecting one of the following options: $0-20 \%$ of the time, $20-40 \%$ of the time, $40-60 \%$ of the time, $60-$ $80 \%$ of the time or $80-100 \%$ of the time. Teachers' responses were recoded into a $1(0-20 \%)$ to $5(80-100 \%)$ scale.

All measures were scored and coded by two researchers, checking for internal and external consistency.

## Results

The following analysis explores the effects of time, prealgebra knowledge and condition on students' algebra conceptual knowledge. Pre-algebra knowledge was included in the model because student' prior-knowledge is known to greatly influence their future learning. While other outcome measures (i.e. procedural knowledge and standardized test release items) were collected, they are beyond the scope of this study focused on conceptual knowledge growth. The other measures will or are presented in other reports. Finally, URM status and rate of teacher review were included as covariates because differences were found between conditions.

A three-way mixed ANCOVA was run to understand the effects of pre-algebra knowledge, condition, and time on algebra conceptual knowledge. The rate of review and minority status were included as covariates. Using Greenhouse-Geisser estimates, the interaction between condition, pre-algebra knowledge and time was not statistically significant; however, there was a statistically significant two-way interaction between time and all between-subject variables. See Table 1 for results.

Table 1. Greenhouse-Geisser estimates for 3-way ANCOVA for algebra conceptual knowledge.

|  |  |  |  | partial |

## Discussion

Due to the nature of the quarterly exams, it was expected that students would score better over time. As mentioned in the procedure section, the conceptual knowledge portion of the quarterly exam consisted of 46 sub-items. However, students only attempted to answer the items in which they were familiar with. Therefore, students attempted to answer more items as they covered additional content over the course of the school year, leading to potential increased scores over time. However, we were more interested in the interaction between treatment and time. It was hypothesized that there would be differences in the rate of algebra conceptual knowledge growth between the example-based and problem-based groups.

As predicted, this analysis revealed a significant condition by time interaction. At the end of quarter 1, students solving typical algebra problems, in the problem-based group, scored slightly better than students in the example-based condition. However by the end of quarter 2, the opposite occurred. Students studying worked-examples and answering self-explanation prompts scored slightly higher than those in the problem-based group. This gap continued to widen throughout the remainder of the school year. By quarter 4, example-based students scored an average of 5 percentage points higher on the algebra conceptual knowledge test than the problem-based students, which is supported by previous studies finding a delayed effect (i.e. Adams et al., 2014).

The limitations of this study include a sample restricted to those present for all four quarterly exams. In addition, although a within-teacher design controlled for teacher-
related variables, it is possible that there was some contamination across classrooms. For instance, some teachers reported using a few of their own worked-examples with their problem-based classroom. The current analysis was based on linear growth; further studies should consider using a more robust analysis in order to account for possible quadratic or cubic growth curves.

This analysis adds to the current body of research by providing evidence from the classroom to support laboratory findings. It also extends our understanding of the short-term benefits of worked-examples and self-explanation prompts by offering longitudinal data. Our findings emphasize the need to measure learning over longer time intervals.

Based on these findings, it is suggested that teachers interleave worked-examples and self-explanation prompts with traditional algebra problems. In order to receive maximum benefit, students should be exposed to this approach consistently throughout the entire school year, not just in a single instance. Furthermore, such interventions should be interleaved in algebra textbooks, rather than simply displaying a few correct worked-examples at the beginning of a section. Finally, both correct and incorrect worked-examples should be used in the classroom to promote maximum benefit.

As previously noted, success in Algebra $I$ is a known gatekeeper to later mathematics and science success. However, many students enter algebra with persistent misconceptions that obstruct their achievement in algebra. The findings from this study suggest that using workedexamples combined with self-explanation prompts as classroom practice materials can improve student's conceptual knowledge, consequently decreasing their misconceptions. The findings from this study are particularly exciting as they come from a study that took place in actual classrooms and not research laboratories. Due to the setting of the current study, our findings illustrate that even when precision, like that provided in a laboratory, cannot be guaranteed the positive effect of using workedexamples paired with self-explanation prompts is still seen.

## Acknowledgments

Thanks are due to the participating school districts; without their interest this type of applied research would not be possible. The research reported here was supported by the Institute of Education Sciences, U.S. Department of Education, through Grant R305A150456 to the Strategic Education Research Partnership (SERP) Institute. The opinions expressed are those of the authors and do not represent views of the Institute or the U.S. Department of Education.

# Semantic Ambiguity Effects: A Matter of Time? 

Joyse Medeiros (j.medeiros@bcbl.eu)<br>BCBL. Basque Center on Cognition, Brain, and Language<br>UPV. University of the Basque Country<br>Blair C. Armstrong (blair.armstrong@utoronto.ca)<br>Department of Psychology \& Centre for French \& Linguistics at Scarborough, University of Toronto<br>BCBL. Basque Center on Cognition, Brain, and Language

#### Abstract

Are different amounts of semantic processing associated with different semantic ambiguity effects? Could this explain some discrepant ambiguity effects observed between and across tasks? Armstrong and Plaut (2016) provided an initial set of neural network simulations indicating this is indeed the case. However, their empirical findings using a lexical decision task were not clear-cut. Here, we use improved methods and five different experimental manipulations to slow responding---and the presumed amount of semantic processing---to evaluate their account more rigorously. We also expanded the empirical horizon to another language: Spanish. The results are partially consistent with the predictions of the neural network and differ in several important ways from English data. Potential causes of these discrepancies are discussed in relation to theories of ambiguity resolution and cross-linguistic differences.

Keywords: semantic ambiguity; slow vs. fast lexical decision; semantic settling dynamics, neural networks.

Understanding how the meaning of ambiguous words is resolved is critical because the meaning of most words depends on context (e.g., cricket can refer either to a game or to an insect). Developing an account of ambiguity resolution has, however, been challenged by two complications: 1) the complex and often apparently contradictory effects of ambiguity observed between and sometimes even within a given experimental task, discussed below, and 2) the often inconsistent effects observed for polysemes with related senses (e.g., chicken can refer to an animal or its meat) vs. homonyms with unrelated meanings (e.g., cricket) compared to (relatively) unambiguous control words (e.g., chalk).

Recently, Armstrong and Plaut (2016) reported neural network simulations suggesting that many apparently inconsistent effects can be reconciled as a function of (a) how the number and relatedness of a word's meanings are activated over time, (b) the amount of processing that takes place before a response can be generated in a given task (see Figure 1). This semantic settling dynamics (SSD) account posits that early processing is dominated by excitatory/cooperative neural dynamics that would facilitate the processing of polysemes. In contrast, later processing would be dominated by inhibitory/competitive neural dynamics that would impair the processing of homonyms. Thus, "fast" tasks like typical lexical decision, in which
participants must decide whether a letter string forms a word (e.g., cricket) or not (e.g., blicket), would show a polysemy advantage (e.g., e.g., Armstrong \& Plaut, 2016; Beretta, Fiorentino, \& Poeppel, 2005; Rodd, Gaskell, \& Marslen-Wilson, 2002). In contrast, "slow" tasks like typical semantic categorization, in which participants must determine whether a word refers to a member of a particular category (e.g., does cricket refer to a vegetable?), would show a homonymy disadvantage (e.g., Hino, Pexman, \& Lupker., 2006).

The SSD account offers both a contrasting and a complementary explanation to an account positing that different ambiguity effects are due to task-specific configurations of the decision system (Hino et al., 2006). In contrast to the decision system account, the SSD hypothesis stresses how dynamics within semantics can critically shape the ambiguity effects observed in a given task. The decision system should, however, play an important role in determining "when" sufficient evidence has accumulated to generate a response---and thus which portion of semantics is being tapped (for a broader discussion, see Armstrong \& Plaut, 2016).

-     - Homonymous . . . . Polysemous - Unambiguous

Figure 1. Semantic activity as a function of processing time for homonyms, polysemes, and unambiguous controls in the neural network simulation reported by Armstrong and Plaut (2016). Slices A-D highlight how sampling these trajectories at different time points aligns with different behavioural and neural effects reported in the literature, such as typical lexical decision (Slice A) and semantic categorization (Slice C).

Armstrong and Plaut (2016) also put the SSD account to the test in an empirical setting. In their experiments, the overall task (lexical decision) was held constant. They then
manipulated additional properties of the task to slow responses (manipulations of nonword difficulty and/or the brightness of the letters on the screen). Insofar as these slow-downs enabled additional semantic processing to take place, the SSD account predicts this would lead to a shift from a polysemy advantage in the easy/fast conditions (Figure 1, Slice A) and a homonymy disadvantage in the slow/hard conditions (Figure 1, Slice C).

The results were generally---although not perfectly--consistent with these predictions. A polysemy advantage was typically observed in the easy/fast condition, but evidence for this advantage in the harder conditions was more limited. Similarly, there was evidence that a homonymy disadvantage was present in some (but not all) of the hard/slow conditions, but, critically, not in the easy/fast conditions. One possible interpretation of these results is that they are attributable to a slight increase in semantic processing and thus reflect only a small step along the predicted semantic settling dynamics (e.g., Figure 1, Slice A to Slice B, rather than Slice A to Slice C). Additional investigations are needed, however, to better explore this possibility and the validity of the SSD account more broadly.

The present work is a major extension of Armstrong and Plaut's (2016) initial empirical studies. From a theoretical perspective, it follows the abductive reasoning: if a range of different manipulations designed to slow responding all yield the same changes in ambiguity effects, this will provide broad convergent support for the SSD account. Our work also builds upon past work in several important ways: First, for all but one condition, it uses within-participant manipulations to boost statistical power. Second, the experiments were run in Spanish, a language in which it is easier to control for several potential confounding variables (e.g., with few exceptions, each Spanish letter maps to a single sound and vice versa, so matching word lengths in number of letters also matches word lengths in number of phonemes). Doing so also allows for the evaluation of the robustness of particular ambiguity effects and facilitates the development of general as opposed to Anglocentric theories (Share, 2008). Further, recent Spanish homonym meaning frequency norms (Armstrong et al., 2015) allow us to select homonyms with balanced meaning frequencies. This should boost the competitive dynamics assumed to be associated with homonyms during late processing.

## Behavioral Studies of Lexical Decision

We evaluated whether slowing participants' lexical decision responses using several different manipulations reproduced the different semantic ambiguity effects predicted by the SSD account. If these different manipulations produce the anticipated effects, this would support the notion that the time-point at which the response was made---and the corresponding amount of semantic settling---is a critical component of any theory of semantic ambiguity resolution. (Without denying that these dynamics interact and are further shaped by other systems; e.g., the response system.) If the results do not produce the predicted effects, this would
support claims that qualitative differences in the configuration of the response system, as opposed to semantic settling dynamics, explain many discrepant ambiguity effects.

We applied the following manipulations to a standard visual and/or auditory lexical decision task, which we describe in detail subsequently. The first two manipulations relate closely to those in Armstrong \& Plaut (2016) for comparison purposes, whereas the remaining three have never been used in studies of semantic ambiguity.

1. Visual Lexical Decision: Nonword Wordlikeness: "Easy" nonwords with lower bigram frequencies and higher Orthographic Levenshtein distances (OLD; Yarkoni, Balota, \& Yap, 2008) than the word stimuli were used in the baseline; "Hard" nonwords with higher bigram frequencies and lower OLDs than the words were used in the slowed condition. This was the only between-participant manipulation because previous experiments have found carry-over effects when nonword difficulty is blocked within participants (Armstrong, 2012). All other manipulations were within participants and used easy nonwords to avoid potential ceiling effects on how slow lexical decision can be pushed.
2. Visual Lexical Decision: Visual Noise: Standard text was presented in the baseline; visual noise ( 950 3px dots) was superimposed to degrade the text in the slowed condition. This condition is similar to the contrast reduction manipulation in Armstrong \& Plaut (2016).
3. Intermodal Lexical Decision: Visual lexical decision served as the baseline, auditory lexical decision as the slowed condition. This experiment was motivated by different ambiguity effects observed in audio vs. visual lexical decision in Rodd et al. (2002).
4. Auditory Lexical Decision: Auditory Noise: Clear sound recordings were presented in the baseline; noisy recordings---created by replacing $75 \%$ of the auditory signal with signal-correlated noise---were used in the slowed condition.
5. Auditory Lexical Decision: Compression/Expansion: Recordings were played $30 \%$ faster in the baseline and $30 \%$ slower in the slowed condition. The "similarity" time effect in Goldwave ${ }^{\circledR}$ (v6.13) was used to preserve pitch and the naturalness of the vocalization.
Participants. Each experiment was completed by 42 Spanish native speakers (avg. age $=24$ years, $70 \%$ female). All had normal or corrected-to-normal vision and no history of language or psychological disorders. Participants received a monetary payment. Consent was obtained in accordance with the declaration of Helsinki.

Stimuli. Words. The stimuli filled a $2 \times 2$ factorial design that crossed number of unrelated meanings (NoM: one vs. two) with number of related senses (NoS: few [range: 1-5] vs. many [range: 6-14]), similar to past work (Rodd et al., 2002; Armstrong \& Plaut, 2016). NoM and NoS were based on the number of separate entries vs. sub-entries for each word in the Real Academia Española Spanish dictionary (RAE, 2014). For convenience, we will refer to the four
conditions as (relatively) unambiguous words (NoM: 1, NoS: few), homonyms (NoM: 2, NoS: few), polysemes (NoM: 1, NoS: many) and hybrids (NoM: 2, NoS: many).

To maximize the potential for competition between the interpretations of words with two unrelated meanings, we only included homonyms and hybrids with dominant relative meaning frequencies below 0.82 in the Spanish eDom norms (Armstrong et al., 2015). Using the EsPal Spanish word database (Duchon, Perea, Sebastián-Gallés, Martí, \& Carreiras, 2013), the candidate items were also constrained to have no homophones, be between 4 and 10 letters long, have word frequencies between 0.1 and 50 , and have only noun or verb meanings (all had at least one noun meaning). This database also provided information regarding the word's summed bigram frequency, length in phonemes, and length in syllables.

The SOS stimulus optimization software (Armstrong, Watson \& Plaut, 2012) identified 36 items in each cell of the design that were also matched on a range of psycholinguistic covariates (see Table 1). Finally, we collected separate norms for the imageability and familiarity of the words from two groups of 25 native speakers who did not participate in the main experiments.

Nonwords. Candidate nonwords were generated for each of $\sim 80,000$ words sampled from Espal (Duchon et al, 2013) to match the psycholinguistic properties of the experimental words, except for NoM and NoS. Nonwords were generated via the Wuggy nonword generator using the default settings (Keuleers \& Brysbaert, 2010). In total, 144 "easy" nonwords were sampled to have lower bigram frequency and higher OLD than the words, whereas 144 "hard" nonwords were selected to have a higher bigram frequency and lower OLD than the words.

Table 1. Properties of the Word Stimuli

|  | Unambig. | Polyseme | Homonym | Hybrid |
| ---: | :---: | :---: | :---: | :---: |
| Example | tractor | vaina | pinta | pipa |
| \# Meanings | 1 | 1 | 2.1 | 2.4 |
| \# Senses | 3.2 | 9.8 | 3.3 | 9.0 |
| Word Freq. | 5.3 | 5.5 | 5.0 | 6.3 |
| OLD | 1.9 | 1.8 | 1.8 | 1.5 |
| \# Letters | 6.6 | 6.5 | 6.7 | 6.0 |
| \# Phonemes | 6.6 | 6.3 | 6.6 | 5.9 |
| \# Syllables | 2.8 | 2.8 | 2.9 | 2.6 |
| Familiarity | 4.2 | 4.7 | 4.0 | 4.6 |
| Imageability | 4.3 | 5.1 | 4.5 | 4.9 |
| Dom. Freq. | - | - | 0.5 | 0.5 |

Note. Dom. Freq. = Relative Frequency of dominant meaning.
Table 2. Properties of the Word and Nonword Stimuli

|  | Words | Easy Nonwords | Hard Nonwords |
| ---: | :---: | :---: | :---: |
| Bigram Freq. | 1602 | 445 | 2782 |
| OLD | 2.0 | 2.9 | 1.5 |

Audio Recordings. Audio recordings were produced by a male native speaker. Volume was normalized to half the dynamic range. Auditory stimuli were pre-processed using Audacity (Mazzoni, 2013).

Procedure. The experiments were run on a desktop computer with a CRT monitor using Psychopy (Peirce, 2007). Auditory stimuli were presented over headphones.

Each experiment began with 4 practice trials. Participants then completed four blocks of 72 experimental trials, each of which began with 4 unanalyzed warm-up trials. An equal number of words from each cell of the design were presented in each block. The order of the stimuli was pseudorandom, with the constraint that no more than three words or nonwords could be presented in a row.

Each trial began with blank screen for 250 ms , followed by a fixation cross (+) for 750 ms , which was briefly replaced by a blank screen again for 50 ms before the presentation of the word or nonword. In the visual conditions, text was presented in the center of the screen. In the auditory conditions, the recording was played, instead. Response latency was measured from stimulus onset, and the next trial began automatically after a response. A message was displayed if no response was made within 2500 ms . Participants responded by pressing the left and right control keys with their right and left index fingers. Word responses were always made with the dominant hand. The experiment took about 20 minutes to complete.

## Results

Data screening. Participants and items were screened for outliers using the Mahalanobis Distance Statistic and a critical p-value of .001 . This eliminated no more than two participants in each experiment and no more than two words of any type. Trials with latencies < 200 ms or $>2000 \mathrm{~ms}$ were also discarded ( $0.66 \%$ of trials).
Analytical approach. The analyses reported here focused on the critical effects of homonymy and polysemy relative to unambiguous controls, as well as how these variables were affected by the slowing manipulations. We also report exploratory analyses of the hybrids, which should be affected by both cooperative and competitive dynamics.

All of the word data were analyzed with linear mixedeffect models (Bates, Maechler, Bolker \& Walker, 2015) using R (R Core Team, 2016). The models included the key fixed effects of manipulation (with the faster/easier condition used as the baseline) and item type (with separate contrasts between an unambiguous baseline and homonyms, polysemes, and hybrids). To address potential confounds, the models also included fixed effects of imageability, residual familiarity ${ }^{1}$, log-transformed word frequency, OLD, length in letters, and bigram frequency. All of the aforementioned fixed effects were allowed to interact with the effect of manipulation. Further, to reduce autocorrelation effects from the previous trials (Baayen, \& Milin, 2010), the models included fixed effects of stimulus type repetition, previous trial accuracy, previous trial lexicality, previous trial latency, and trial rank. All continuous variables were centered and normalized. Additionally, the models included random intercepts for

[^409]

Figure 2. Correct latency [left] and accuracy [right] for the experiments. H=homonym, U=unambiguous, $\mathrm{P}=\mathrm{Polysemous}$, $\mathrm{Y}=\mathrm{Hybrid}$. Error bars = SEM.
item and participant. Random slopes were omitted because these models did not always converge. Latency was modeled with a Gaussian distribution, whereas accuracy was modeled with a binomial distribution. Effects were considered significant if $\mathrm{p} \leq .05$, and trends are considered marginal if $\mathrm{p} \leq .15$. All tests were two-tailed.

Correct Latency. The latency data are presented in the left panel of Figure 2. Slowing Manipulations. All five manipulations slowed overall response speed (all $p \mathrm{~s} \leq .02$ ). Homonyms. A main effect indicating a homonymy disadvantage was observed in the intermodal and auditory noise manipulations ( $b=24.0, \mathrm{SE}=10.3, t=2.4, p=.02$ and $b=34.0, \mathrm{SE}=15.0, t=2.3, p=.03$, respectively). The homonymy by slowing manipulation interaction produced a significant increase in the homonymy disadvantage in the slower condition of the auditory compression/expansion experiment ( $b=29.1, \mathrm{SE}=13.3, t=2.2, p=.03$ ). A similar marginal trend was observed in the nonword wordlikeness experiment ( $b=13.2$, $\mathrm{SE}=8.2, t=1.6, p=.11$ ). Polysemes. A main effect indicating a polysemy advantage was only detected in the baseline condition of the nonword wordlikeness manipulation $(b=-19.8, \mathrm{SE}=9.4, t=-2.1, p$ $=.04$ ). The polysemy by slowing manipulation interaction indicated that the polysemy advantage marginally decreased in the visual noise experiment $(b=30.7, \mathrm{SE}=16.3, t=1.9$,
$p$ =.06). Hybrids. There were no significant effects involving hybrids in any experiment. Imageability. There was always a marginal or significant facilitatory main effect of imageability (all $p \mathrm{~s} \leq .06$ ). The imageability by slowing manipulation interaction indicated this effect increased marginally in the slowed conditions of the intermodal ( $b=-$ $6.1, \mathrm{SE}=4.0, t=-1.5, p=.12$ ), visual noise ( $b=-9.3, \mathrm{SE}=$ 5.9, $t=-1.6, p=.12$ ), and audio compression/expansion experiments ( $b=-9.2$, $\mathrm{SE}=4.9, t=-1.9, p=.06$ ).
Accuracy. The accuracy data are presented in the right panel of Figure 2. Slowing Manipulations. The slowing manipulation decreased overall accuracy in the visual noise condition ( $b=-2.1, \mathrm{SE}=0.3, z=-8.2, p<.001$ ), whereas it increased overall accuracy in the audio expansion condition ( $b=2.0, \mathrm{SE}=0.3, z=7.0, p<.001$ ). Homonyms. The homonymy by slowing manipulation interaction in the compression/expansion experiment indicated that there was a marginal decrease in homonym accuracy after slowing ( $b$ $=-0.6, \mathrm{SE}=0.4, z=-1.7, p=.10$ ). Polysemes. A marginal main effect indicating a polysemy advantage was observed in the nonword wordlikeness experiment ( $b=0.4, \mathrm{SE}=0.2$, $z=1.7, p$ <.09). There were also marginal polysemy by slowing manipulation interactions in the nonword wordlikeness and audio compression/expansion experiments, indicating that there was decrease in polyseme
accuracy relative to the unambiguous baseline in the slowed conditions ( $b=-0.6, \mathrm{SE}=0.4, z=-1.8, p=.09$ ). Hybrids. As in the latency data, no significant effects involving the hybrids were observed. Imageability. The facilitatory main effect of imageability was always significant (all $p \mathrm{~s} \leq .02$ ), except for in the case of auditory noise (the model did not converge) and in the audio compression/expansion experiment, where the effect was marginal ( $p=.15$ ). There was a marginal interaction between imageability and the slowing manipulation in the visual noise experiment indicating differentially decreased facilitation after slowing ( $b=-0.2, \mathrm{SE}=0.1, z=-1.6, p=.11$ ), whereas in the compression/ extension experiment $(b=0.2, \mathrm{SE}=0.1, z=$ $1.5, p=.14$ ) there was increased facilitation.
Summary. A significant or marginal homonymy disadvantage, or an increased homonymy disadvantage in the slowed condition, was observed in all but the visual noise experiment. A main effect of polysemy was only detected in one experiment and the polysemy advantage marginally decreased in two experiments. Hybrid items were never significantly different from the unambiguous controls, which is likely due, at least in part, to difficulties matching these rare items on other covariates. The facilitatory effect of imageability was significant or marginal in all experiments. The magnitude of these facilitation effects increased marginally in three experiments (intermodal, visual noise, compression /expansion).

## Discussion

The aim of our study was to evaluate whether a range of different manipulations designed to slow responses would lead to different ambiguity effects, as predicted by the SSD account. At first glance, except for speed-accuracy tradeoffs, virtually all of the effects that were significant or marginal were consistent with the SSD account. Additionally, most of non-significant results showed the predicted trends numerically. Thus, this collective body of work does add some additional support to the notion that processing time---and the presumed amount of semantic settling---plays a role in explaining many ambiguity effects. These results also suggest that some broad ambiguity effects transcend different languages.

Additionally, taking a more critical view of the observed effects promises to reveal additional aspects of how and why discrepant ambiguity effects are observed within and between tasks. To begin, our ideal a priori aim was to reproduce a polysemy advantage only in the easiest/fastest tasks (Figure 1, Slice A) and observe a homonymy disadvantage only in the hardest/fastest tasks (Figure 1, Slice C). The overall pattern of results, however, would appear to be more consistent with the easiest task beginning closer to Slice B, where both a weaker homonymy disadvantage and polysemy advantage are predicted. This result is surprising for several reasons. First, Armstrong and Plaut (2016) went to great lengths to make their lexical task as difficult as possible, and yet their results were consistent with earlier processing dynamics (primarily Figure 1, Slice

A-B). Their overall latencies were also approximately 100 ms faster than in the analogous conditions in the present work. The present work did use words with slightly lower frequencies, but it also used considerably easier nonwords, so there is no clear explanation for this large discrepancy. Further, we have conducted an additional experiment with "very easy" nonwords (nonwords with extremely low bigram frequencies and neighborhood sizes) and still not been able to increase overall performance by a substantial degree. These results are also inconsistent with Jager, Green, \& Cleland's (2016) prediction that a polysemy advantage should be strongest for low frequency words because their meanings overlap more.

Another possibility worth considering is that whereas past research has typically struggled to produce a homonymy disadvantage and had more success in obtaining a polysemy advantage, the present work may have experienced the opposite difficulties. This may be due to having used atypically large set of balanced homonyms. This was accomplished by sampling from a database of subjective meaning frequency norms (Armstrong et al., 2015) and may have differentially boosted the power of the homonymy effects. This more powerful manipulation of homonymy may also have coincided with a less powerful manipulation of polysemy based on the recent results of Fraga, Padrón, Perea, \& Comesaña (2016). They found that although the number of senses provided in a subjective meaning norming study and those available in the RAE dictionary (the source of our polysemy counts) correlated highly, only the subjective norms were significant predictors of latencies in lexical decision and naming tasks. Unfortunately, there was insufficient overlap between our items and theirs to corroborate their findings in our own data. However, this recent observation clearly stresses the importance of how polysemy is measured. In English, several studies have used dictionary counts to predict polysemy successfully (e.g., Armstrong et al., 2016; Rodd et al., 2002 both used counts from Wordsmyth; Parks, 1999). Thus, our findings in Spanish suggests that the lexographers administering the RAE dictionary use a different classification scheme for ambiguity, and/or English and Spanish vary in their distributions of polysemes in ways that shape performance to a substantial degree. The latter possibility gains support from the Armstrong et al. (2015) homonym norming study. They observed that despite Spanish and English having similar total numbers of homonyms, Spanish homonyms are much more likely to have a strongly dominant meaning. (This also posed challenges for us finding balanced and well matched hybrids.) Clearly, a more extensive set of polyseme norms with high external validity must be collected in both languages to evaluate these possibilities.

The prior discussion has focused primarily on potential differences in objective or subjective measures of ambiguity. However, is also possible that broader properties of the language and/or of our participants may have contributed to the aforementioned discrepancies. Our use of

Spanish, an orthographically transparent language, may have been advantageous when controlling for orthographic and phonological confounds. However, it may also have allowed for the rapid spreading of activation between orthography and phonology. This could have, in turn, allowed these representations, as opposed to semantics, to be the primary drivers of the response system. Although the significant effects of imageability indicate that semantics did always influence responses, it is possible that semantic effects may have been attenuated such that only the strong effect of homonymy could be detected.

On a related front, the participants tested by Armstrong and Plaut (2016) were all native English speakers in the USA and presumably had limited exposure to other languages. In contrast, the participant population in the Basque Country is bilingual and all participants reported proficiency in one or more other languages that share at least a partially overlapping phonology and/or orthography (e.g., Basque, French, English). Bilingualism in and of itself has been reported to slow responses in some tasks (e.g., Luo, Luk, \& Bialystok, 2010). These results have typically been explained by focusing on dynamics at the (sub)lexical level, however (e.g., in the Bilingual Interactive Activation model; Dijkstra \& van Heuven, 1998). Our results suggest that some of these differences could also be attributable to processing differences at a semantic level. Consistent with this hypothesis, Taler, Zunini, and Kousaiev (2016) found that monolinguals exhibited greater facilitation as a function of increased NoS than bilinguals in a lexical decision task. This was true both in response latency and in EEG measures of the N400, which is known to index semantic processing. Collectively, these results suggest that semantic settling dynamics and ambiguity resolution could be impacted by knowledge of multiple languages. The field would therefore benefit from additional carefully matched experiments across a broad span of languages.

Returning to the initial question that motived our work, does processing time play a critical role in shaping some ambiguity effects? Our results provide partial support that this is, indeed the case. However, the cases in which such support did not materialize are perhaps just as theoretically relevant. These cases highlight how certain core effects in the semantic ambiguity literature may vary as a function of the language in which the test is conducted, and/or as a function of knowledge of a second language. They also point to important methodological issues that remain to be addressed, such as how to classify and compare polysemy across languages. Taken together, the present work therefore serves not only advances our understanding of the semantic settling dynamics in ambiguity resolution. It also highlights the value of cross linguistic comparisons in developing a general as opposed to a language-specific understanding of semantic ambiguity.

## Acknowledgments

# Inferring Intentional Agents From Violation of Randomness 

Yuan Meng (yuan_meng@berkeley.edu)<br>Thomas L. Griffiths (tom_griffiths@berkeley.edu)<br>Fei Xu (fei_xu@berkeley.edu)<br>Department of Psychology, University of California, Berkeley<br>Berkeley, CA 94720 USA

#### Abstract

Humans have a strong "cognitive compulsion" to infer intentional agents from violation of randomness and such an agency-nonrandomness link emerges early in development. In two studies, we directly quantified, formalized, and compared both ends of this link for the first time. In Experiment 1, two groups of participants viewed the same 256 binary sequences (e.g., AABAAABA) and classified each as generated by agents/non-agents or by nonrandom/random processes. We found a strong correlation between two judgments: sequences viewed as more agentive also tended to be judged as less random. In Experiment 2, another two groups were asked to produce sequences that others might appreciate as agentive or nonrandom. Participant-generated sequences in the two conditions had a substantial overlap, indicating common guiding principles of agency and nonrandomness generation. Taken together, the present studies provide evidence for a shared cognitive basis of agency detection and subjective randomness.

Keywords: agency; subjective randomness; agencynonrandomness link; animate-inanimate distinction

## Introduction

We can accept a certain amount of luck in our explanations, but not too much. The question is, how much?

- Richard Dawkins, The Blind Watchmaker (1996)

When we look at something as delicate and orderly as the eye, it is only natural to believe that such a work of art must be designed by someone, an intentional agent with a purpose in mind. In contrast, it takes "a very large leap of the imagination to think the other way around" (Dawkins, 1996, p.7).

This cognitive compulsion to infer agents from order may have given birth to thousands of religions shared by the vast majority of people on Earth (Barrett, 2000; Keil \& Newman, 2015) and it dates back to early childhood (Friedman, 2001) and infancy (Ma \& Xu, 2013; Ma, Berthiaume, Hoch, \& Xu, under revision; Newman, Keil, Kuhlmeier, \& Wynn, 2010). By 10 and 12.5 months of age respectively, infants appreciate that only agents can create regular visual (e.g., YYRYYRYYR, $Y$ and $R$ stand for yellow and red balls; Ma \& Xu, 2013) and auditory (e.g., TTTCTTTTCTTTCTTTC, T and C stand for tambourine and cowbell sounds; Ma et al., under revision) sequences. Similar appreciation has been found in different tasks. For instance, 12-month-olds expect agents (e.g., a ball) but not inanimate objects (e.g., a perceptually similar ball with eyes) to bring order to a disorderly pile of blocks.

Keil and Newman (2015) used these findings to argue that during the first few months of life, infants observe a bulk of ordering and disordering events together with their causes and come to "associate only agents but not non-agents with many kinds of ordered and nonrandom sequences" (p.132).

Notwithstanding counterexamples such as molecular selfassembly or evolution, this association is often true in our universe where entropy tends to increase over time; in contrast, it takes energy, information, and goal-direction to go against the force of nature, all of which strongly indicate agentive causes even to the youngest humans (see Baillargeon, Scott, \& Bian, 2016, for a review). Based on these experiences and intuitive theories, deviation from randomness often indicates nonrandom generation processes behind the scenes (Griffiths \& Tenenbaum, 2001, 2003, 2004, 2007; Sim \& Xu, 2013; Williams \& Griffiths, 2013). When the specifics are unknown, people often default to agents as the "causal placeholders", thinking that they did it somehow (Saxe, Tenenbaum, \& Carey, 2005; Wu, Muentener, \& Schulz, 2015).

If the above line of reasoning holds true, people's judgment of agency should align with their judgment of nonrandomness-the less random something looks, the more agentive it strikes us as. This prediction might be hinted by Kushnir, Xu, and Wellman's (2010) finding that 20-montholds use violation of random sampling to infer the preference of an agent ("She always picked this toy despite its rarity, so she must really like it."). It is possible that nonrandomness not only indicates the psychological states of an already known agent, but also cues its very existence. Imagine if you see a haystack in the middle of a desert (which apparently violates the surrounding vegetation distribution)-you may well conclude that someone must have been there apart from that she is very fond of hay. Alternatively, as Feldman and Tremoulet $(2008)^{1}$ suggested, the intermediate level of nonrandomness is the strongest cue of agency: "Too simple-a simple periodic noise burst, say-and it's an inanimate source, say, a rotating pulsar. Too complex-a totally patternless sequenceand it's just random electromagnetic interference. To seem intelligent it has to be somewhere in between: patterned, but neither perfectly periodic nor completely chaotic" (p.22).

Empirical evidence is needed to test the two possibilities. To the best of our knowledge, there is no research directly examining the relationship between human intuitions about agency and randomness. The closest work to date (Ma \& Xu, 2013; Ma et al., under revision), for instance, lacks a measure of the regularity of the stimuli. Without quantifying

[^410]subjective agency and subjective nonrandomness, however, it is hard to tell whether or not they go hand in hand. In addition, without an independent measure of regularity, one may find herself trapped in circular reasoning-"What is regularity?" "It's the evidence from which people infer intentional agents." "How do people infer intentional agents?" "From regularity." Also, past studies only looked at a small subset of all possible binary sequences of equal length ( 9 digits in Ma \& Xu, 2013; 12 digits in Ma et al., under revision). Chances are that regular sequences in those studies happened to look both regular to the researchers (which is most likely why they were chosen in the first place) and agentive to the infants. We cannot rule out the possibility that there exist a considerable amount of "irregular" sequences that look like the work of an agent, or reversely, "regular" sequences that only call for an inanimate cause. Therefore, to systematically investigate the agency-nonrandomness link, we need to include a wide range of sequences rather than a selected few.

## Linking agency and randomness

To shed light upon the agency-nonrandomness link, we conducted two experiments. In Experiment 1, one group of participants viewed 256 binary sequences of length 8 (e.g., $\Lambda \Lambda \Gamma \Lambda \Gamma \Lambda \Lambda \Lambda)$ and classified the source of each sequence into agentive or non-agentive entities while another group classified the source of each as random or nonrandom processes ${ }^{2}$. Should agency detection be tightly related to subjective randomness, we would expect a high correlation between ratings from the two groups. Sometimes, we not only need to detect other agents, but also wish to be detected by others. For instance, if we are abducted and locked in a truck, flashing the taillight in a "meaningful" way may attract the police and save our lives. Do we actually have such a good intuition about what kind of sequences others may appreciate as agentive? Is it related to our intuition of what others will view as nonrandom? We looked into these questions in Experiment 2 by asking another two groups of participants to generate an 8 -digit binary sequence that they thought might receive the highest agency or nonrandomness score. We examined whether the mean scores of participant-generated sequences were higher than that of all 256 in Experiment 1, as well as the overlap between sequences generated by the two groups.

If people indeed make similar judgments about agency and nonrandomness, then the question is whether they solve the two problems in a similar way. In the last decade, Griffiths and Tenenbaum (2001, 2003, 2004, 2007) formalized the problem of randomness detection as a statistical inference of the data generation process given the data: that is, when judging if a given sequence $X$ is random, people are comparing the probability that $X$ was generated by a random process ( $P($ random $\mid X)$ ) against the probability that $X$ was generated by a regular process $(P($ regular $\mid X))$. The ratio of these two

[^411]probabilities, or "posterior odds", is given by Bayes' theorem (below is the log-odds form):
\[

$$
\begin{equation*}
\log \frac{P(\text { random } \mid X)}{P(\text { regular } \mid X)}=\log \frac{P(X \mid \text { random })}{P(X \mid \text { regular })}+\log \frac{P(\text { random })}{P(\text { regular })} \tag{1}
\end{equation*}
$$

\]

The subjective randomness of sequence $X$ is defined as the only part that depends on $X$-the log-likelihood ratio:

$$
\begin{equation*}
\operatorname{randomness}(X)=\log \frac{P(X \mid \text { random })}{P(X \mid \text { regular })} \tag{2}
\end{equation*}
$$

If $X$ results from flipping a fair coin or the equivalent, then $P(X \mid$ random $)$ is simply $\frac{1}{2}^{l(X)}(l(X)$ is the length of $X)$-the heart of the problem thus becomes evaluating $P(X \mid$ regular $)$. Griffiths and Tenenbaum $(2003,2004)$ specified $P(X \mid$ regular $)$ using a hidden Markov model (HMM) that associates each symbol $x_{i}$ (e.g., H) in $X$ with a hidden state $z_{i}$ (e.g., repeating H). The probability that $X$ is generated by a certain HHM is obtained by summing over the probability that $X$ is generated by each of all possible states $Z$ under this model:

$$
\begin{equation*}
P(X)=\sum_{Z} P(X, Z) \tag{3}
\end{equation*}
$$

Knowing that each $x_{i}$ solely depends on $z_{i}$ and each $z_{i}$ is determined by $z_{i-1}$, we can rewrite Equation 3 as below:

$$
\begin{equation*}
P(X, Z)=P\left(z_{0}\right) \prod_{i=2}^{n} P\left(z_{i} \mid z_{i-1}\right) \prod_{i=1}^{n} P\left(x_{i} \mid z_{i}\right) \tag{4}
\end{equation*}
$$

In this study, the regular generation process is defined by 22 repeating "motifs" of length 1 (repeating H or T ) to 4 (e.g., repeating HTHH, TTHH, etc.). Each symbol in the 22 motifs corresponds to a hidden state, which amounts to 72 . The prior of each motif is $\alpha^{k}$ ( $k$ is the length of a motif) and the probability of continuing with a motif is $\delta$. Using this HMM, we can estimate the subjective randomness of all 256 sequences.

## Experiment 1: Judging sequences

## Method

Participants Seventy-four participants with a United States IP address took part in Experiment 1 on Amazon Mechanical Turk (http://www.mturk.com/, "MTurk") for a payment of $\$ 3.5$. A past acceptance rate equal to or greater than $93 \%$ was required for participation. 40 participants ( 20 women; mean age $=37.15, S D=12.63$, range: $19-70$ years) were randomly assigned to the agency judgment task and 34 (17 women; mean age $=33.98, S D=10.45$, range: $23-67$ years) to the nonrandomness judgment task. Another 36 were excluded for failing one or both instruction check questions.

Stimuli and procedure To begin, participants read a cover story corresponding to their task:

Agency condition. "Welcome to year 3017! Imagine you are a space rescuer whose job is to search for astronauts lost in deep space. These days spaceships are all equipped with a radio transmitter. To call for help, astronauts can use it
to send out sequences made of two types of radio wavesLambda ( $\Lambda$ ) and Gamma ( $\Gamma$ ). However, both types of waves may also be produced by natural phenomena such as celestial body activities-in this case, $\Lambda$ and $\Gamma$ are equally likely to appear. Everyone in space knows that by current technical standard, radio receivers can only pick up 8 waves in a rowthat is, you can only detect sequences that have 8 waves (as mentioned before, each wave is either $\Lambda$ or $\Gamma$ ). If you receive a sequence and think it was produced by natural phenomena, you will ignore it and stay on course. If you think it came from humans, then you will go to them. In this study, you will see about 250 sequences. Your task is to decide whether each sequence was generated by a natural phenomenon or by a human astronaut. Please answer as quickly and accurately as possible!"

Nonrandomness condition. "You're about to see some sequences made of 8 symbols. Each symbol is either Lambda ( $\Lambda$ ) or Gamma ( $\Gamma$ )—which may represent heads or tails, even or odd digits, successes or failures, or other event outcomes. For instance, the sequence $\Lambda Г \Gamma \Lambda$ could stand for "tails, heads, heads, tails", "even, odd, odd, even", etc. Some of these sequences were created by tossing an actual fair coin, which means they are random series-in this case, $\Lambda$ and $\Gamma$ are equally likely to appear. However, other sequences may be generated by nonrandom processes, such as computer programs, successes and losses of a basketball team, and so on. In this study, you will see about 250 sequences. Your task is to decide whether each sequence was generated by a random process or by a nonrandom process. Please answer as quickly and accurately as possible!"

Two quizzes immediately followed to test participants on the sources of sequences as well as the chance of two symbols appearing in the natural phenomenon or the random processs scenario. Images (pixel resolution: $700 \times 525$ ) of 256 binary sequences of length 8 were then displayed on the screen. In the agency judgment task, participants were asked to classify the source of each sequence into "human astronaut" or "natural phenomenon", and in the nonrandomness judgment task, into "nonrandom process" or "random process". The display order was randomized and the relative location of choices counterbalanced between participants. The whole process was self-paced and took an average of 20 minutes.

## Results

An alpha level of .05 was used for all statistical analyses. Each sequence received an agency score (the proportion of participants classifying its source as "human astronaut") as well as a nonrandomness score (the proportion of participants classifying its source as "nonrandom process").

To examine the stability of participants' judgments, we looked at the scores of 128 sequences (e.g., $\Lambda \Lambda Г Г \Lambda \Lambda Г \Lambda$ ) and their complements (e.g., $Г Г \Lambda \Lambda Г Г \Lambda \Gamma)$-in theory, they should be the same. Indeed, the sequence-complement correlation was high in the agency condition, $r(126)=.84,95 \% \mathrm{CI}$ [.78, .89], $p<.001$, adjusted $R^{2}=.71$, and even higher in the nonrandomness condition, $r(126)=.93,95 \% \mathrm{CI}[.91, .95], p$

Figure 1: The agency-nonrandomness link in Experiment 1.
$<.001$, adjusted $R^{2}=.87$, suggesting that participants were making reliable judgments during the task.

Of central interest to Experiment 1 was the correlation between agency and nonrandomness scores. We found a strong positive correlation between the two, $r(254)=.84,95 \%$ CI [.81, .88], $p<.001$, adjusted $R^{2}=.72$ (see Figure 1a).

To see whether detecting agents was a similar problem to detecting deviation from randomness, we tested if the same model (as specified earlier) fit data from both tasks reasonably well. Since our models predicted subjective randomness, we recoded agency scores into non-agency scores (1-agency score) and nonrandomness scores into randomness scores (1 - nonrandomness score). Fitting the non-agency data gave $\delta$ $=.44$ and $\alpha=.11$, with correlation $r(254)=.72, p<.001$, and fitting the randomness data gave $\delta=.45, \alpha=.12$, with correlation $r(254)=.75, p<.001$. Model predictions in the two conditions were strongly correlated, $r(254)=.96,95 \%$ CI [.95, .97],$p<.001$, adjusted $R^{2}=.92$ (see Figure 1b).

## Discussion

In Experiment 1, we found a strong correlation between participants' agency and nonrandomness judgments-that is, sequences viewed as less random were rated as more agentive. A hidden Markov model fit human data in both tasks reasonably well and produced highly overlapping predictions for subjective non-agency and subjective randomness, which suggests that people are solving highly similar problems when detecting agents and violation of randomness.

At the beginning of this paper, we discussed two possible forms the agency-nonrandomness link. Feldman and Tremoulet (2008) suggested that mid-level randomness is most agentive, according to which we should find a reverse $U$ -shaped/U-shaped relation between the degree of agency/nonagency and the degree of randomness. However, this was neither the case in human judgments (Figure 1a) nor model predictions (Figure 1b). Instead, the findings in Experiment 1 provided evidence for a linear agency-nonrandomness link.

## Experiment 2: Generating sequences

Participants A total of 212 participants with a United States IP address who did not participate before took part in Experiment 2 on MTurk for a payment of $\$ 0.5$. A past acceptance rate equal to or greater than $93 \%$ was required for participation. 105 participants ( 38 women; mean age $=35.59$, $S D=10.54$, range: $18-67$ years) were randomly assigned to the agency generation task and 107 ( 34 women, 1 other; mean age $=36.36, S D=11.63$, range: $19-65$ years) to the nonrandomness generation task. Another 78 were excluded for failing one or both instruction check questions or generating sequences that were not binary or of length 8 .

## Method

Stimuli and procedure To begin, participants read a cover story corresponding to their task:

Agency condition. "Welcome to year 3017! Imagine you are an astronaut who is lost in deep space after an accident. These days spaceships are all equipped with a radio transmitter. To call for help, you can use it to send out sequences made of two types of radio waves-Lambda ( $\Lambda$ ) and Gamma $(\Gamma)$. However, both types of waves may also be produced by natural phenomena such as celestial body activities-in this case, $\Lambda$ and $\Gamma$ are equally likely to appear. Everyone in space knows that by current technical standard, radio receivers can only pick up 8 waves in a row-that is, you should only send sequences that have 8 waves (as mentioned before, each wave is either $\Lambda$ or $\Gamma$ ). If space rescuers receive your sequence and thinks it was produced by natural phenomena, they will ignore it and stay on course. If they think it came from humans, then they will come to you.I $n$ order to save yourself, what sequence will you send to space?"

Nonrandomness condition. "You're about to write down a sequence made of 8 symbols. Each symbol is either Lambda ( $\Lambda$ ) or Gamma ( $\Gamma$ )—which may represent heads or tails, even or odd digits, successes or failures, or other event outcomes.

For instance, the sequence $\Lambda \Gamma \Gamma \Lambda$ could stand for 'tails, heads, heads, tails', 'even, odd, odd, even', etc. Sequences like this could be created by tossing an actual fair coin, which means they are random series. However, they could also be generated by nonrandom processes, such as computer programs, successes and losses of a basketball team, and so on. In this study, you will come up with one sequence. Your task is to make it look least random-that is, this sequence should NOT look like the product of a random process; instead, it should look like it's generated by a nonrandom process. In order to fulfill your task, what sequence will you write down?"

Two quizzes immediately followed to test participants on what kind of sequence they should generate and the chance of two symbols appearing in the natural phenomenon or the random processs scenario. Then they entered a sequence in 8 text entry cells (the task requirement was visible). The whole process was self-paced and took about 2-3 minutes.

## Results

Since symbols have no inherent meanings, sequences (e.g., $\Lambda Г \Lambda \Lambda Г \Gamma \Lambda \Gamma)$ and their complements (e.g., $Г \Lambda Г Г \Lambda \Lambda Г \Lambda)$ were coded as the same form (e.g., ABAABBAB). Participants in the agency condition generated 31 unique sequences while those in the nonrandomness condition generated a total of 35 . Table 1 summarized unique sequences generated in both conditions ( 16 overlapping sequences are marked in yellow).

To begin, we looked at whether participants were able to generate good sequences with respect to the task requirement. To do so, we assigned agency and nonrandomness scores in Experiment 1 to participant-generated sequences in Experiment 2 (e.g., the score of ABAABBAB would be the mean score of $\Lambda \Gamma \Lambda \Lambda \Gamma \Gamma \Lambda \Gamma$ and $Г \Lambda Г Г \Lambda \Lambda Г \Lambda)$. In the agency condition, participant-generated sequences had higher scores ( $M$ $=.56, S D=.19)$ compared to all 256 sequences $(M=.43, S D$ $=.14)$, mean difference $=.13,95 \% \mathrm{CI}[.08, .16], t(154.56)=$ $6.58, p<.001, d=.86$. Participant-generated sequences ( $M$ $=.62, S D=.22$ ) also received higher nonrandomness scores than that of the whole set $(M=.50, S D=.23)$, mean difference $=.12,95 \%$ CI [.09, .17], $t(286.11)=5.87, p<.001, d=$ .58. In both the agency and the nonrandomness condition, the frequency of sequences being generated was positively correlated with their scores, $r(103)=.75,95 \%$ CI [.66, .83], $p<$ .001 , adjusted $R^{2}=.56, r(105)=.53,95 \%$ CI $[.38, .65], p<$ .001 , adjusted $R^{2}=.27$, respectively.

To see if the agency-nonrandomness link exists in sequence generation, we examined the overlap of participantgenerated sequences in the two conditions. First, 87 out of 105 "agentive" sequences were also generated in the nonrandomness condition and a similarly large proprotion of "nonrandom" sequences- 83 out of 107 -were found in the agency condition as well. Among the 31 unique agentive sequences and 35 unique nonrandom sequences, 16 were shared by both. The question is whether this overlap was due to chance, a problem that is often faced by bioinformatics scientists when deciding given a genome with $N$ genes, whether one gene list with $a$ genes overlaps with another with $b$ genes

Table 1: Participant-generated sequences in Experiment 2.

| nonrandom | freq. | score | agentive | freq. | score |
| :---: | :---: | :---: | :---: | :---: | :---: |
| ABABABAB | 21 | 0.60 | AAAAAAAA | 40 | 0.76 |
| AAAAAAAA | 17 | 0.90 | ABABABAB | 20 | 0.40 |
| AAAABBBB | 15 | 0.85 | AAAAAAAB | 3 | 0.65 |
| AABBAABB | 14 | 0.56 | AAABBBAA | 3 | 0.50 |

| ABBABAAB | 1 | 0.19 | ABBAAABB | 1 | 0.34 |
| ABBABBAA | 1 | 0.30 | ABBBAABB | 1 | 0.31 |
| ABBABBBA | 1 | 0.40 | ABBBBBBA | 1 | 0.66 |
| ABBBAABA | 1 | 0.20 |  |  |  |
| ABBBAABB | 1 | 0.35 |  |  |  |
| ABBBABAA | 1 | 0.24 |  |  |  |
| AbBbBBBA | 1 | 0.90 |  |  |  |

if they have an intersection of $t$ genes. In our study, the "genome" was all 128 unique sequences while participantgenerated agentive and nonrandom sequences were the two "gene lists". Using Fisher's exact test implemented by the GeneOverlap R package (Version 1.12.0; Shen \& Sinai, 2013), we found that the 16 -sequence overlap between two conditions was unlikely to arise by mere chance, $p<.001$.

## Discussion

Participants in Experiment 2 showed a good sense of what sequences may strike others as agentive or nonrandom: in both the agency and the nonrandomness condition, they generated sequences with higher scores than all 256 sequences. Crucially, we found a statistically meaningful overlap between agentive and nonrandom sequences, indicating that people not only make similar judgments about agency and nonran-
domness, but may also be guide by similar intuitions when generating stimuli that are agentive or nonrandom.

## General Discussion

The present studies provide evidence for a shared cognitive basis of agency detection and subjective randomness. In Experiment 1, participants made similar judgments about agency and nonrandomness: sequences viewed as more agentive also tended to be judged as less random. A hidden Markov model with 72 states and 22 motifs fitted human performance in both tasks equally well and produced identical predictions regarding the degree to which people should view each sequence as agentive or nonrandom. In Experiment 2, participants did a good job generating sequences that others might see as agentive or nonrandom. Sequences in these two conditions had a substantial overlap, indicating common guiding principles of agency and nonrandomness generation.

Our work contributes to a growing body of literature on the perceived link between order and agency (e.g., Barrett, 2000; Friedman, 2001; Ma \& Xu, 2013; Ma et al., under revision; Newman et al., 2010) by directly quantifying, formalizing, and comparing both ends of this link for the first time.

As Williams and Griffiths (2013) pointed out, randomness judgments often boil down to relative frequency (Are two equally likely events equally frequent?) and sequential dependence (Do earlier events influence subsequent events?). However, past researchers studied the link between these two apsects of randomness (or lack thereof) and agency sepa-rately-for instance, Kushnir et al. (2010) focused on the former while Ma and Xu (2013) the latter. In our study, both biased frequency (e.g., AAAAAAAB) and high sequential dependence (e.g., AAABBAAA) lead to high agency ratings, which may help unify past findings. Future work will look at how differently or similarly frequency and dependence are weighted in our nonrandomness and agency judgments.

Although violation of randomness plays an important role in agency detection, we do not claim that it is the only cue to agency or always linked to the latter. Given certain background knowledge or context ${ }^{3}$, "irregular" stimuli may look agentive-a seemingly chaotic drip painting still looks like the work of a human, and "regular" stimuli can appear non-agentive-we would not necessarily think a mechanical watch is alive because it tick-tocks every second. Without such information, however, intentional agents are perhaps the best guess for a nonrandom outcome. Follow-up studies should take a closer look at how rich knowledge may be integrated into the way we reason about agents and randomness.

Another question is whether the current findings generalize to other types of stimuli, such as matrices, numbers, geometric shapes, etc. Answering this question requires us to understand and formalize randomness in these domains, on which there are increasingly more studies in recent years (e.g., Griffiths \& Tenenbaum, 2007; Hsu, Griffiths, \& Schreiber, 2010). We plan to investigate the agency-nonrandomness link us-

[^412]ing new types of stimuli. Even for binary sequences, it is worth looking at if what we found applies to longer sequences where more interesting regularities may emerge, such as the repeating triads in Ma and Xu's (2013) study. Also, as the length extends, it may become difficult to find a global pattern and one may have to focus on local patterns. How will these factor into our agency and nonrandomness judgments?

On the computational level, our study is the first step towards formalizing how people perceive agency. A more precise account requires us to directly estimate the probability distribution of a certain stimulus being generated by an agent, $P(X \mid$ agent $)$, which can be achieved by using a much larger sample size (e.g., the Big Bell Test invited more than 100,000 people from all over the world to generate random responses; see http://thebigbelltest.org/ for details) as well as applying sampling methods such as Markov chain Monte Carlo with People ("MCMCP", Sanborn, Griffiths, \& Shiffrin, 2010).

MCMCP is also able to capture each person's judgment. What looks agentive to some may look inanimate to others; understanding individual differences may allow us to appreciate the complexity of human agency perception and on top of that, explain far-reaching psychological and societal consequences, such as the endorsement of Intelligent Design, the denial of natural selection in favor of creationism, and so on. In regards to other social phenomena, past studies explored the relationship between randomness and perceived efficacy of rituals (Legare \& Souza, 2014), belief in conspiracy theories (Dieguez, Wagner-Egger, \& Gauvrit, 2015), etc.. We wonder whether people's agency intuition plays a similar or a different role in these situations, especially using the more intricate characterization of agency that MCMCP provides.

In his book Scienceblind, Shtulman (2017) argued that many misconceptions of science stick not just because of ideology or the media, but also because they have deep roots in our intuitive theories. As mentioned before, our agencynonrandomness link may be one such root. For science educators, the question at hand is, how malleable is it? Given the right kind and amount of evidence, will we update our belief? For instance, by understanding causal mechanisms by which nonrandomness could arise from non-agentive sources (e.g., a ball rolling down a xylophone produces orderly sounds, but it is not viewed as an agent by adults or even infants, Schachner, Carey, \& Kelemen, 2013), can we weaken or break this link?

## Acknowledgments

We thank Shaun O'Grady for suggesting a critical change in the stimuli and Fred Callaway for helpful discussions.

# Does Presentation Format Modulate Adults'Automatic Processing of Proportions? 

Rui Meng (rmeng5@wisc.edu)<br>Department of Educational Psychology, 1025 W. Johnson Street Madison, WI 53706 USA<br>Percival G. Matthews (pmatthews@wisc.edu)<br>Department of Educational Psychology, 1025 W. Johnson Street<br>Madison, WI 53706 USA

#### Abstract

Whereas much is known about how humans categorize and reason based on absolute quantities, research investigating the processing of relative quantities, such as proportions, is comparatively limited. The current study used a Stroop-like paradigm to examine adults' automatic processing of nonsymbolic proportions and how presentation formats modulate this processing. Participants were asked to compare individual components across proportions in six different presentation formats. Congruity between component size and overall proportion affected accuracy of comparison, such that participants were less accurate when proportion (the irrelevant dimension) was incongruent with absolute quantity (the relevant) dimension. Moreover, the congruity effect was modulated by the presentation format. These findings serve as evidence that humans automatically access relative quantity when presented in nonsymbolic formats and provide evidence that the strength of this processing is modulated by the format of presentation.

Keywords: automatic processing; congruity effect; relative quantity; proportions; presentation format

## Introduction

Humans share with many species a non-verbal system to estimate absolute quantity (Dehaene, 1997). The invention of number symbols allows humans to precisely represent absolute quantity instead of mere approximate estimation. However, simple absolute quantification is often not sufficient to guide behavior. We frequently need to relate two quantities to generate a new construct: proportion or ratio. Although much is known about the processing of absolute quantity (either symbolic or nonsymbolic), comparatively little is known about how the brain encodes relative quantity.

To represent relative quantity accurately, humans exploit their symbolic numerical competence by using number fractions. However, children and adults often experience great challenges and difficulties in learning and using fractions (Ni \& Zhou, 2005). Furthermore, research on symbolic fractions suggest that the numerical magnitudes represented by symbolic fractions are not automatically activated (Kallai and Tzelgov, 2009), and that the holistic processing of symbolic fractions depends on the stimuli and task contexts (Meert et al., 2009; Meert et al., 2010; Schneider \& Siegler, 2010). For example, Meert and colleagues (2009) observed that access to the magnitude of
symbolic fractions was affected by the congruity or incongruity between the value of the single components and the value of whole fraction. Schneider and Siegler (2010) found that adults process fraction magnitudes holistically when the task does not allow them to use any shortcut strategies that would enable separate processing of the numerator and denominator magnitudes.

Similar to absolute quantity, which can be judged approximately without symbols, proportion (relative quantity) can also be determined non-verbally. Studies have suggested that even by a young age, humans can understand proportion information when presented nonsymbolically (McCrink \& Wynn, 2007; Jacob, Vallentin, \& Nieder, 2012; Matthews, Lewis, \& Hubbard, 2015). For instance, infants can discriminate between two ratios long before the concept of proportionality is introduced during formal schooling (McCrink \& Wynn, 2007).

Research even suggests that the magnitudes of proportions are automatically activated (Duffy, Huttenlocher, Levine, 2005; Duffy, Huttenlocher, Levine, \& Duffy, 2005; Fabbri et al., 2012; Yang et al., 2015; Matthews \& Lewis 2016). Six-month-olds dishabituated when the relation between a dowel and its container changed but not when the absolute size of both object changed while the relation was held constant (Duffy, Huttenlocher, Levine, \& Duffy, 2005). Moreover, 4-yearolds chose the dowel which had the same dowel-container relation as the original display rather than the one with the same absolute dowel size (Duffy, Huttenlocher, Levine, 2005). Fabbri et al. (2012) found that the magnitude of proportions can be automatically and holistically processed by adults using a congruity manipulation in which the greater numerosity of white dots co-occurred with a lower proportion. Yang et al. (2015) found that proportion interfered with preschool children's area comparison performance.

It is acknowledged that the cognitive processes involved in proportion processing vary depending on the type of proportional relation involved (i.e., part-to-part vs. part-towhole) (Sophian \& Wood, 1997; Spinillo \& Bryant, 1999; Möhring, Newcombe, Levine, \& Frick, 2016), and display types (i.e., continuous, discretized, discrete) (Spinillo \& Bryant, 1999; Jeong, Levine, \& Huttenlocher, 2007; Boyer, Levine, \& Huttenlocher, 2008).

Proportions can be presented as either part-to-part relations or part-to-whole relations. Previous research suggested that part-to-part presentation is easier for 6- to 8-year-old children (Spinillo \& Bryant, 1999). However, other study provided evidence that children performed better for problems involving part-to-whole presentation (Sophian \& Wood, 1997; Möhring, Newcombe, Levine, \& Frick, 2016). There is no evidence yet for if and how adults would perform differently for these two relations presentation.

Proportions can also be displayed as continuous, discrete, or discretized (see Figure 1). Previous studies generally agreed that continuous display encourages perceptual approximate measurement of the intensive quantity, while discrete (and discretized) display would lead to exact counting strategy (e.g., Boyer, Levine, \& Huttenlocher, 2008; DeWolf, Bassok, \& Holyoak, 2015). This was underlined by findings that children showed greater and earlier success in judging proportions displayed as continuous quantities than in judging proportions displayed as discrete quantities even if other variables were controlled to be constant (Spinillo \& Bryant, 1999; Jeong, Levine, \& Huttenlocher, 2007; Boyer, Levine, \& Huttenlocher, 2008). For adults, we do not know yet whether they are still influenced by the display format.

These results suggest that presentation format might influence proportions processing. Fabbri and Yang's results are actually different as for the level of automaticity. It is probably due to the fact that they used different presentation format. Fabbri et al. (2012) used arrays of dots and part-topart proportion judgment, while Yang et al., (2015) asked participants to compare the areas of two sectors that were designed in part-to-whole relation. Therefore, the present study aims to systematically investigate how the level of automaticity will change for different presentation formats.

The current study used a Stroop-like paradigm to examine the processing level of proportions. In a Stroop-like task, participants are asked to make judgments on one dimension while there are other dimensions that may agree or conflict with the one to be judged. Participants' performance can suggest the automatic activation of the irrelevant dimensions. Higher error rate and longer reaction times will be observed for incongruent trials than for congruent trials if the irrelevant dimensions are accessed automatically. For example, people tend to spend more time and make more errors when they are asked to compare the magnitudes of two numbers that have incongruent physical sizes than the pairs that have congruent physical size with corresponding magnitudes (Henik \& Tzelgov, 1982).

In the present study, absolute quantity will be treated as the relevant dimension and relative quantity (proportion) as the irrelevant dimension. For congruent trials, the larger proportion also has the larger components. For incongruent trials, the larger proportion would have the smaller components. If participants' performance is worse in the incongruent condition, it would provide evidence that the representation about proportions is automatically activated.

We aim to investigate whether presentation format of proportions would be automatically activated in different levels and thus have different effects to the absolute quantity comparisons. The size of interference in Strooplike tasks is proposed to be a function of degree of the irrelevant dimension's automaticity (MacLeod \& Dunbar, 1988). Therefore, we focus on the size of interference to see whether the automatic accessing level of proportions will differ.

## Method

## Participants

33 undergraduate students from a large Midwestern university participated for course credit (31 females; ages 18 -22).

## Stimuli

Presentation formats were designed to be all possible combinations of display types and relation types.

Three display types were designed: continuous, discrete, and discretized (see Figure 1). The discrete items were arrays of white and black squares with width of 20 pixels. The discretized items were displays composed of these squares stacked to form line segments, except that they were lined together with 1 pixel distance between them. The continuous items were identical to the discretized displays except that there was no space in between.

We examined both part-to-part and part-to-whole relations. For all three displays, we varied the presentation such that half of the proportions were presented in part-topart relation, and half were presented in part-to-whole relation. The part-to-part relation was defined as the white portion to the black portion; the part-to-whole relation was defined as the white portion to the total portion.

Each proportion was presented in one of the six presentation formats depicted in Figure 1 below.

Figure 1: Example of six presentation formats used in the experiment, all represent proportion of $1 / 3$.

Each stimulus pair consisted of two proportions displayed side by side. The center-to-center distance between the two proportions was 800 pixels.

There were two conditions differing by congruity. In congruent pairs, the stimulus which had the larger white portion also had a larger proportion value of white portion relative to either black portion or total (white plus black) portion. In incongruent pairs, the stimulus which had larger white portion had a smaller proportion value of white portion relative to either black portion or total (white plus black) portion. Table 1 showed all the stimuli used.

Table 1 Stimuli used in the present study

|  | Prop. 1 | Prop. 2 | Absolute <br> Distance | Relative <br> Distance |
| :--- | :--- | :--- | :--- | :--- |
|  | $2 / 8$ | $3 / 9$ | 1 | $1 / 12$ |
|  | $1 / 4$ | $2 / 6$ | 1 | $1 / 12$ |
|  | $1 / 6$ | $2 / 8$ | 1 | $1 / 12$ |
|  | $2 / 3$ | $3 / 4$ | 1 | $1 / 12$ |
|  | $4 / 12$ | $5 / 12$ | 1 | $1 / 12$ |
|  | $7 / 12$ | $8 / 12$ | 1 | $1 / 12$ |
|  | $2 / 12$ | $3 / 9$ | 1 | $1 / 6$ |
|  | $1 / 6$ | $2 / 6$ | 1 | $1 / 6$ |
| congruent | $1 / 12$ | $2 / 8$ | 1 | $1 / 6$ |
|  | $3 / 9$ | $4 / 8$ | 1 | $1 / 6$ |
|  | $4 / 6$ | $5 / 6$ | 1 | $1 / 6$ |
|  | $5 / 10$ | $6 / 9$ | 1 | $1 / 6$ |
|  | $4 / 8$ | $6 / 9$ | 2 | $1 / 6$ |
|  | $2 / 4$ | $4 / 6$ | 2 | $1 / 6$ |
|  | $1 / 6$ | $3 / 9$ | 2 | $1 / 6$ |
|  | $3 / 9$ | $5 / 10$ | 2 | $1 / 6$ |
|  | $2 / 6$ | $4 / 8$ | 2 | $1 / 6$ |
|  | $1 / 3$ | $3 / 6$ | 2 | $1 / 6$ |
|  | $1 / 3$ | $2 / 8$ | 1 | $1 / 12$ |
|  | $2 / 6$ | $3 / 12$ | 1 | $1 / 12$ |
|  | $1 / 4$ | $2 / 12$ | 1 | $1 / 12$ |
|  | $3 / 4$ | $4 / 6$ | 1 | $1 / 12$ |
|  | $5 / 6$ | $6 / 8$ | 1 | $1 / 12$ |
|  | $6 / 9$ | $7 / 12$ | 1 | $1 / 12$ |
|  | $6 / 8$ | $7 / 12$ | 1 | $1 / 6$ |
| $1 / 3$ | $2 / 12$ | 1 | $1 / 6$ |  |
| incongruent | $5 / 6$ | $6 / 9$ | 1 | $1 / 6$ |
|  | $4 / 6$ | $5 / 10$ | 1 | $1 / 6$ |
| $2 / 3$ | $3 / 6$ | 1 | $1 / 6$ |  |
| $2 / 4$ | $3 / 9$ | 1 | $1 / 6$ |  |
| $4 / 6$ | $6 / 12$ | 2 | $1 / 6$ |  |
| $2 / 3$ | $4 / 8$ | 2 | $1 / 6$ |  |
|  | $1 / 2$ | $3 / 9$ | 2 | $1 / 6$ |
| $2 / 4$ | $4 / 12$ | 2 | $1 / 6$ |  |

Note. Prop. 1 means the first proportion value; Prop. 2 means the second proportion value. Absolute Distance means the absolute quantity distance, which is the difference for the white portions of the pair; Relative Distance means the relative quantity distance, which is the difference for the proportion values of white portion relative to either black portion or total (white plus black) portion.

## Procedure

Participants were instructed to select the stimulus which had larger white portion. Participants were asked to press "d"
when they judged the left stimulus had larger white portion and to press " j " when they judged the right stimulus had larger white portion. Both speed and accuracy were emphasized in instructions.

Each trial began with a 500 ms presentation of a fixation cross in the center of the screen, immediately followed by the stimulus pair. The pair stayed on the screen until participants submitted a response or timed out at 3000 ms .

In each block, each of these 34 proportion pairs was presented twice, either with the larger proportion to the left or to the right, giving 68 trials in each block. The stimuli in each block were presented in a random order. There were six different blocks, and the presentation order of these six blocks was counterbalanced, resulting a total of 408 trials.

## Results

Accuracy and mean reaction time (RT) were computed for each condition for each participant and used as the primary outcome variables. Only correct RTs were used in the analysis. We conducted separate repeated-measures ANOVAs using accuracy and RT.

The repeated-measure ANOVA on the accuracy with congruity and presentation format as within-subject factors was calculated. Results revealed that the main effect of congruity was significant, $F(1,32)=15.827, p=0.000$, $\eta_{p}^{2}=0.331$. Participants made more mistakes in the incongruent condition ( $M=77.1 \%, S E=4.6 \%$ ) than in the congruent condition ( $M=92.0 \%, S E=1.3 \%$ ). The main effect of presentation format, however, was not significant, $F(5,160)=0.184, p=0.671, \eta_{p}^{2}=0.006$. This indicated that adults' overall accuracy was not affected by presentation formats. Figure 2 depicted the pattern of accuracy for congruent and incongruent conditions for each presentation format.

Figure 2: Congruity effect on accuracy for each presentation format. "pcn" means part-to-part relation with continuous display; "pdd" means part-to-part relation with discretized display; "pds" means part-to-part relation with discrete display; "wen" means part-to-whole relation with continuous display; "wdd" means part-to-whole relation with discretized display; "wds" means part-to-whole relation with discrete display.

The two-way interaction of presentation format with congruity was significant, $F(5,160)=2.319, p=0.046$, $\eta_{p}^{2}=0.068$. The result indicated that the effect of congruity was modulated by presentation format.

We also analyzed reaction times in the same way as accuracy. Figure 3 displays the pattern of mean correct reaction times across conditions. Only the main effect of presentation format was significant, $F(5,105)=7.575, p=$ $0.000, \eta_{p}^{2}=0.265$. The main effect of congruity and the twoway interaction of congruity and presentation format were not significant, $p \mathrm{~s}>0.05$.

Figure 3: Congruity effect on response times for each presentation format.

## Discussion

The results of current experiment showed that adults made more mistakes making judgments in the incongruent conditions than in congruent conditions. And the size of congruity effect varied by different presentation formats. But response time did not show such a clear pattern as accuracy. Participants seemed to spend about same time comparing congruent and incongruent trials. Overall, the current study suggested that adults can automatically process the magnitudes of proportions even though it was irrelevant and disturbing to the absolute quantity comparison task, and that the congruity effect was modulated by the presentation format.

Even though more and more effort has been made to explore human's understanding of proportions, very little is known about the specific processing level of them. Consistent with previous findings that human have an intuitive understanding of proportion and represent them perceptually (e.g., Jacob, Vallentin, \& Nieder, 2012; Matthews, Lewis, \& Hubbard, 2015), our study demonstrated that proportions can be automatically processed. The observation of the congruity effect confirmed the findings of previous studies that showed the same automatic processing of proportion (e.g., Fabbri et al., 2012; Yang et al., 2015; Matthews \& Lewis 2016). The
study also provided evidence to the fact that humans, at least adults, can process proportion automatically no matter what kind of formats the proportion is presented.

Moreover, based on previous findings that presentation format can influence proportion processing, the present study found that the level of automatic processing of proportion varied for different presentation formats. The size of congruity effect of automatic processing of proportion was modulated by presentation format. Proportions presented as discretized part-to-part display seemed to show the largest difference of accuracy for congruent trials and incongruent trials. This finding was a little bit surprising, because previous studies suggested that continuous display promotes greatest success for proportion processing at least for children (Boyer, Levine, \& Huttenlocher, 2008). It is possible that adults adopt different processing strategies or preference than children. It would be interesting to see whether children shown different congruity effect pattern for these presentation formats. Another possibility is that the task in the current experiment was an implicit and unintentional task for proportion processing, while previous studies showing presentation differences were all explicit and intentional tasks for proportion processing (Sophian \& Wood, 1997; Spinillo \& Bryant, 1999; Jeong, Levine, \& Huttenlocher, 2007; Boyer, Levine, \& Huttenlocher, 2008). Humans might perform differently during two task scenarios. Further studies will be needed to address these issues.

Theorists generally have two different explanations to account for the mechanism of automaticity phenomenon. Some focus on the learned automatic processes and emphasize the learning mechanism (Anderson, 1992). Others believe there are innate automatic processes that humans are born with (Hasher \& Zacks, 1979). The current study cannot tell whether the mechanism of the automatic processing of proportion is natured or nurtured. 5-year-old children have been found to show similar congruity effect for accuracy but not response time in a sector comparison task, which provided some hint that the automatic processing of proportion is not acquired by learning or instruction (Yang et al., 2015). However, more evidence considering culture, education and intelligence, is required to reach final conclusions about the mechanism of automatic processing of proportion.

# Utilizing simple cues to informational dependency 

Hugo Mercier<br>CNRS

## Helena Miton

CEU

#### Abstract

Participants can adequately take into account several cues regarding the weight they should grant majority opinions, but that they do not consistently take into account cues regarding whether the members of the majority have formed their opinions independently of each other. We suggest that these conflicting results can be explained by hypothesizing that some cues are evolutionarily valid (i.e. they were present and reliable during human evolution), and others not. Using this framework we derive and test hypotheses about two facets of informational dependency. The first 3 experiments show that participants adequately take into account cues to informational dependency when they are presented in a simple, evolutionarily valid way. Experiments 4 to 7 show that people consistently take into account shared motivation, but not shared cognitive traits, as a source of potential dependency, as predicted by the likely greater importance of differences in motivation during our evolutionary history.

# Children's EEG Indices of Directed Attention during Somatosensory Anticipation: Relations with Executive Function 

Staci Meredith Weiss (SWeiss@ Temple.edu)<br>Department of Psychology, 1701 N. 13th Street<br>Philadelphia, PA USA<br>Peter J. Marshall (PJMarsh@Temple.edu)<br>Department of Psychology, 1701 N. 13th Street<br>Philadelphia, PA USA

#### Abstract

Children's ability to direct attention to salient stimuli is a key aspect of cognitive functioning. Here we examined the magnitude and lateralization of EEG indices during somatosensory anticipation elicited by a left or right directional cue indicating the bodily location of an upcoming tactile stimulus. In 50 children aged 6-8 years, somatosensory anticipation was accompanied by anticipatory negativity and alpha mu rhythm desynchronization at contralateral central electrode sites ( C 3 and C 4 ) overlying the hand area of the somatosensory cortex. Individual differences in these contralateral brain responses during somatosensory anticipation were associated with scores on a flanker task of executive function. The results suggest that processes involved in directing attention in the tactile modality may overlap with those involved in broader executive function abilities.

## Introduction

The ability to direct attention in a focused and efficient manner is crucial to cognitive performance and decisionmaking (Posner and Fan, 2008). Directed attention is the heightened monitoring of spatial location prior to presentation of a target stimulus, and is known to facilitate heightened perception, shorter reaction time and improved inhibition in adults (Rothbart, Posner and Kieras, 2006). Introduction of preparatory cues relevant for upcoming target stimuli allows study of neural activity or behavior during anticipation, prior to subsequent attention and perception of stimuli (Anderson and Ding, 2012). Anticipation is the goal-directed monitoring of sensation in expectation of a stimulus. Within a sensorimotor contingency framework, anticipatory brain responses can be viewed as 'pragmatic' in that they prepare for expected action (Engel et al., 2013), reflecting the reciprocal nature of prior experience, cognition and action (O'Reagen, 2011). In directed attention tasks with children, individual differences in post-stimulus neural activity to target stimuli (Stevens and Bavelier, 2012) are associated with cognitive skills and school achievement, but pre-stimulus anticipatory neural activity is rarely examined as an index of cognitive ability.

Directed attention paradigms investigate how manipulation of endogenous (top-down) attention facilitates subsequent exogenous (bottom-up) stimuli-driven attention, perception, and neural responses to target stimuli. Neural activity in the region that encodes target stimuli features are
modulated not only in response to stimuli, but also during anticipation (Corbetta and Shulman, 20012). This effect is present even when the preparatory cue is presented in a different sensory modality from that of the expected target, allowing temporal and spatial differentiation of anticipatory activity in the target sensory cortex from cue encoding (Zanto and Gazzley, 2009). During anticipatory attention, preparatory cues uniquely engage the intra-parietal sulcus (IPS) to apply a filter on attention, which is not active in subsequent target perception (Corbetta and Shulman, 2002).

Emerging research accounts for neural activity unique to anticipation as filtering the focus of attention in expectation of an upcoming target (Zhang and Ding, 2010). To examine this account, we study how the magnitude of anticipatory neural activity during a somatosensory directed attention task relates to performance on the flanker task, which demands conflict monitoring, or a focus on single target stimuli among distractors competing for attention (Rothbart, Posner and Kieras, 2006). The flanker task requires participants to respond to the direction of a central target arrow amidst congruent or incongruent flanking distractor arrows: incongruent conditions are associated with slower reaction times, explained as resolving the conflict between the target and distractors. The flanker task taps into endogenous attentional abilities measured by executive function (EF). Our understanding of EF is informed by relational-systems theory, with EF defined as the goaldirected regulation of behavior, aligning action with topdown attention (Dick and Overton, 2011). We are concerned with the relations between flanker task performance and individual differences in the neural indices during somatosensory anticipation, elicited in a directed attention paradigm in which a visual cue directs children's attention to the expected spatial location of an upcoming tactile stimulus. Associating neural indices of somatosensory anticipation with EF facilitates study of inter-sensory attention, with potential for linking sensory-specific attentional processes to cognitive skills.

## EEG Indices of Somatosensory Anticipatory Attention

Changes in brain responses recorded through the electroencephalogram (EEG) are reliable indicators of attention orienting, sometimes proving more predictive of relevant behavior than reaction time responses to stimuli (Foxe and Snyder, 2011). Brain responses to directed
attention are lateralized, such that there is a modulation of neural activity contralateral to the direction of the spatial cue (Gazzaley and Nobre, 2012). Attention can be indexed by the modulation of EEG signals in the alpha band (8-14 Hz in adults). Alpha band fluctuations are interpreted as a correlate of underlying attentional states, with the magnitude of change in amplitude sensitive to stimuli salience, strength and individual differences. When monitoring stimuli presented to one visual field, to one hand or to one ear, there is typically a disruption of rhythmic alpha activity known as event-related desynchronization (ERD) in the contralateral sensory cortex (Stevens and Bavelier, 2012). Desynchronization of the alpha rhythm appears to reflect an increase in local field potentials of neurons in the region of interest. Heightened alpha band desynchronization is thought to increase the perceptual salience of upcoming stimuli in the target modality (Foxe and Snyder, 2011). In the tactile modality, anticipatory desynchronization of the alpha-range mu rhythm at central electrodes is an index of somatosensory cortex excitability.

Attention-related changes in the EEG during anticipation can also be indexed via event-related potential (ERP) methods. Relevant here is the contingent negative variation (CNV), a negative-going potential occurring during the anticipatory period between a preparatory cue and a target stimulus (Corbetta and Shulman, 2002). The CNV elicited by a preparatory cue can be considered to reflect endogenous anticipatory directed attention, while later potentials (P1, N2, P3) can be considered to reflect exogenous, stimulus-evoked attention.

There is an emerging literature studying pre-stimulus EEG activity during the anticipation of touch. Detection of weak tactile stimuli was predicted by contralateral power of anticipatory alpha desynchronization (Zhang and Ding, 2010) after a cue indicated upcoming stimulation of the right hand. Anticipatory somatosensory selective attention paradigms often include a cue containing relevant spatial information about upcoming tactile stimulation, to examine the lateralization of brain responses or hemispheric asymmetry. Haegens, Luthur and Jensen (2012) demonstrated anticipatory desynchronization of alpha rhythm in central electrodes contralateral to the direction of the spatial cue, and synchronization of the alpha rhythm in the ipsilateral central electrodes. To our knowledge, there is no existing research on the cognitive mechanisms facilitating the association of pre-stimulus alpha mu desynchronization and post-stimulus enhanced perception of tactile stimuli. There are also no studies on the developmental trajectory of neural indices during somatosensory anticipation.

## Development of Directed Attention and EF

Precursors to attention regulation are apparent in infancy, with gaze fixation sensitive to stimulus features, novelty preferences, and prior learning in newborns (Hood, Willen, Driver, 1998; Sheese et al., 2008). Goldberg, Maurer and

Lewis (2001) found age-related differences in children's target discrimination on visual selective attention paradigms when target and non-target stimuli were presented simultaneously. By age 8 years, performance was comparable to adults in anticipatory visual selective attention tasks. The authors suggested discrepant trajectories in the development of distractibility and anticipation.
There is interest in studying the neural indices elicited by selective attention, when distractors presented simultaneous to the target compete for directed attention. Coch, Sanders and Neville (2005) employed a dichotic listening task to examine neural indices in response to target tones in attended and unattended simultaneous auditory streams in children aged 6-8. They found a slow positive ERP peaking around 150 ms in children as opposed to the typical ERPs found in adults: early sensory potentials, followed by an N2 and P3. The amplitude of the ERP was greater in the attended auditory stream than the unattended auditory stream. Isbell, Wray and Neville (2015) found the positivity of auditory-evoked selective attention potentials related to non-verbal IQ scores, such that only higher-IQs preschoolers exhibited significant differences in amplitude distinguishing target tones in the attended stream from tones in the unattended stream. The nature of the dichotic listening task requires the same skills as the tasks involved in non-verbal IQ assessment. A study of anticipatory attention to visual stimuli in 10-year-old children found that CNV magnitude (evoked by preparatory spatial cues) related to visual short-term memory capacity (Shimi et al., 2014). The measure of EF was response to the targets of 'anticipatory attention', so it is difficult to tease apart the relations among task performance, working memory and neural indices of attention.

Prior studies suggest adult executive function relates to brain responses during attention to visual or auditory stimuli. During a dichotic listening task, the amplitude of the contralateral brain responses during auditory selective attention relates to non-verbal working memory (Giuliano et al., 2014). In contrast, a study of visual selective attention found only ipsilateral brain responses to be related to cognitive skills (Zanto \& Gazzaley, 2009). The authors found that the ipsilateral increase in amplitude accounted for greater variation in working memory, when compared to the magnitude typically associated with selective attention, which is reduced alpha power in the contralateral occipital cortex. The current investigation extends the study of anticipatory attention and cognitive skills to the somatosensory domain by examining how EF relates with EEG indices of directed attention to upcoming tactile stimuli.

## Current Study

Studying pre-stimulus attention in the tactile modality contributes to the basic science of bodily awareness and somatosensation. The fundamental, early-developing nature of somatosensory processing (Marshall \& Meltzoff, 2015) make it a compelling domain of study for examining the
development of top-down attentional processes. Furthermore, perception of tactile pulses appears uniquely associated with neural indices of attention, unlike reaction time in response to tactile pulses (Zhang and Ding, 2010): Electrophysiological data can therefore provide insight into the perception of touch, beyond simultaneous behavioral measures. Our study examines how the somatosensory domain adds to the developmental literature on executive function indices of domain-general attention.

The current study examined the magnitude and lateralization of CNV potentials and sensorimotor alpha mu rhythm modulation, as elicited by a directional cue indicating the bodily location of upcoming tactile stimuli. We hypothesized that individual differences in brain responses during somatosensory anticipation would be associated with scores on a flanker task. This potential association between the cognitive state elicited during anticipation and EF was the key focus of the study.

## Methods

## Participants

Sixty children between the ages six to eight years of age participated in the study ( $M=7.2$ years, $S D=.6 ; 27$ male). Families were recruited from a diverse urban environment using commercially available mailing lists and online advertisements. Families were not invited to participate if their child had any medical or psychological diagnoses, was left-handed, or on any long-term medication. A number of children were excluded from analyses because they did not have a sufficient number of artifact-free trials $(n=6)$ or because the child did not tolerate cap preparation ( $n=4$ ). These 10 excluded children did not statistically differ in scores on the flanker from the remaining sample ( $\mathrm{N}=50$.)

## Procedure

Children were read an assent form outlining the protocol in the presence of their caregiver, who also read the consent forms. Children were then fitted with an EEG cap while seated at a table facing a computer screen, with instructions to stay as still as possible with their hands on their lap, out of sight. Research assistants explained the paradigm as a game that required children to pay close attention to the right or left hand, as indicated by the arrow, and respond to the tactile stimuli by pressing a foot pedal once if they felt one tap or twice if they felt two taps. Each of the 120 trials began with a fixation cross baseline for 1500 ms , followed by an arrow displayed for 500 ms , followed by a response screen which read 'Copy with Your Foot!' (Figure 1).

Figure 1. Protocol consisted of 120 trials: a 1500 ms baseline, then an arrow displayed for 500 ms , then tactile stimuli and response.

Tactile stimulation was delivered using a pneumatic simulator controlled by STIM stimulus presentation software (both device and software from James Long Company), with the compressed air delivered during the arrow display and before the response screen. An inflatable membrane mounted in a plastic casing was placed on the middle fingers of children's left and right hands, held in place by a finger clip. The membrane is inflated by a short burst of compressed air delivered via flexible polyurethane tubing ( 3 m length, 3.2 mm outer diameter). The tactile stimulus feels like a light tap on the finger, lasts around 60 ms , and has a peak force of around 2 N .

The NIH Cognition Toolbox flanker task was then administered. Children completed the flanker task on an iPad by selecting the direction of a central target arrow among 4 flanking distractor arrows, which were either congruent or incongruent in direction to the target arrow. Scores were calculated as number of trials with correct response for incongruent trials weighted by reaction time, such that a higher score indicated better EF abilites.

## EEG Collection and Processing

EEG was recorded using a 32-electrode stretch cap (ANT Neuro, Inc.) from the following sites: Fp1, Fpz, Fp2, F3, F4, Fz, F7, F8, C3, C4, CP1, CP2, T7, T8, P3, P4, Pz, P7, P8, $\mathrm{O} 1, \mathrm{Oz}, \mathrm{O} 2$, and the left and right mastoids. Conducting gel was used and scalp electrode impedances were kept under $25 \mathrm{k} \Omega$. The signal from each site was amplified using optically isolated, high input impedance ( $>1 \mathrm{G} \Omega$ ) custom bioamplifiers (SA Instrumentation) and was digitized using a 16 -bit A/D converter ( $+/-5 \mathrm{~V}$ input range). Bioamplifier gain was 4000 and the hardware filter ( 12 dB /octave rolloff) settings were .1 Hz (high-pass) and 100 Hz (low-pass). EEG analysis was performed using the EEGLAB 13.5.4b toolbox (Delorme and Makeig, 2004) implemented in MATLAB. The signal was collected referenced to the vertex $(\mathrm{Cz})$, and EEG signals were re-referenced offline to an average mastoids reference for further analysis. Independent component analysis (ICA) cleared EEG data of ocular and muscle artifact. The ICA procedure was an automation of the method described by Hoffmann \& Falkenstein (2008). Visual inspection of the EEG signal was then used to reject epochs containing movement artifact. The mean number of artifact-free trials per cue direction was 41 ( $\mathrm{SD}=5.71$ ).

## Results

Analyses focused on electrode sites overlying the hand area (the left and right central electrodes; C3 and C4) of sensorimotor cortex. For all ANOVAs, within-subject effects were adjusted using Greenhouse-Geisser correction factors; pairwise t-test comparisons and multiple linear regressions were reported with p-values adjusted for multiple comparisons.

## Anticipatory Negativity

We extracted mean amplitude during the 300 ms immediately preceding tactile stimulation, within the 500 ms window relevant to anticipatory attention. This window
was selected to study the CNV waveform, accounting for a 200 ms delay after the preparatory cue (Shen et al., 2017).

To study lateralization of anticipatory negativity, an ANOVA compared mean CNV amplitude by electrode (C3 or C4) and cue direction (left or right arrow). There was a significant main effect of cue direction, such that cues directing attention to the right hand elicited an enhanced anticipatory negativity $(\mathrm{F}(1,48)=37.06, \mathrm{p}<.019)$. There was a significant main effect of electrode, such that C3 exhibited enhanced anticipatory negativity $(\mathrm{F}(1,48)=$ $37.06, \mathrm{p}<.001$ ). As expected, there was significant interaction between electrode ( C 3 or C 4 ) and cue direction, $\mathrm{F}(1,48)=15.95, \mathrm{p}<.001$, driven by negativity in the electrode contralateral to the stimuli: pairwise comparisons (adjusted with FDR) reveal amplitude in C3 was lower for right cue than left cue, $\mathrm{p}<.001$, while the opposite trend was found for the amplitude of $\mathrm{C} 4, \mathrm{p}<.061$ (see figure 2).

Figure 2. For each trial, an epoch of 1500 ms was extracted: analyses focused on the 300 ms preceding tactile stimulation during the pre-stimulus period, accounting for the average amplitude during a pre-cue $200-\mathrm{ms}$ baseline. The epochs were then filtered at 30 Hz .
I
Anticipatory ERPs and Flanker. To examine the relations between flanker and anticipatory negativity, regressions were conducted predicting flanker scores from lateralization of CNV amplitude and its interactions with electrode and cue direction. We computed lateralization of CNV amplitude by subtracting the mean amplitude at C 3 from mean amplitude at C 4 , for each participant and each hand. There was a trend of lateralized amplitude predicting flanker score, $\mathrm{t}(1,48)=1.72, \mathrm{p}=.090$. Performance on the flanker task was predicted by a significant interaction between lateralized amplitude and cue direction, $t(1,48)=-2.40, \mathrm{p}$ $=.019$. To further probe this interaction, we performed posthoc regressions predicting flanker score by average amplitude for C3 and C4 during right and left cues. The interaction was driven by marginal relations between flanker and amplitude in the contralateral hemisphere: flanker score related with CNV amplitude over C3 elicited by a right directional cue, $\mathrm{t}(1,49)=-1.72, \mathrm{p}=.094$, and over C 4 elicited by a left directional cue, $\mathrm{t}(1,49)=-1.70, \mathrm{p}=.097$. Amplitude in the ipsilateral hemisphere did not relate with flanker score.

## Time Frequency Analysis

Event-related spectral perturbation (ERSP) analyses were conducted on the alpha frequency band at $7-12 \mathrm{~Hz}$ (Berchicci et al., 2011; Marshall, Bar-Haim, \& Fox, 2002), as is appropriate for children, and baseline corrected for the 500 ms prior to cue onset. Event-related desynchronization (ERD) is as an alpha power decrease relative to the baseline. An ANOVA compared pre-stimulus alpha power by electrode ( C 3 or C 4 ) and cue direction (left or right arrow). There was a main effect of cue direction, such that cues directing attention to the right hand elicited greater desynchronization, $\mathrm{F}(1,48)=37.06, \mathrm{p}<.001$. There was no main effect of electrode position. A significant interaction was observed between electrode and cue direction, $\mathrm{F}(1,48)=15.95, \mathrm{p}<.001$ (see figure 3). The interaction was due to greater ERD in the contralateral hemisphere (see figure 4): the mu rhythm showed greater desynchronization over C3 elicited by the right cue, and over C 4 elicited by the left cue.

Figure 3. For each trial, an epoch of 1500 ms was extracted: spectral power was estimated using Gaussiantapered Morlet wavelets, and changes in power were computed as ERSP focused on the 500 ms pre-stimulus period, relative to a 500 ms baseline $(-1000$ to $-500 \mathrm{~ms})$.

Mean Event-Related Desyncronization(-500-0ms)

Figure 4. Mean ERSP for mu rhythm $(7-12 \mathrm{~Hz})$ in $\mathrm{C} 3 / \mathrm{C} 4$ for left/ right cues from -500 ms to 0 ms . Negative values reflect a reduction in mu power (ERD) relative to a 500 ms pre-cue baseline ( -1000 to -500 ms ).

Anticipatory ERSP and Flanker. To examine the relation of flanker task scores with ERD during somatosensory anticipation, regressions were conducted predicting scores on flanker task by ERD and its interactions with electrode position and cue direction, controlling for within-participant variability. There were no significant main effects or twoway interactions. However, performance on the flanker task was significantly predicted by a three-way interaction between alpha power, electrode position and cue direction, t (46) $=2.33, \mathrm{p}=.012$. Post-hoc regressions (with p-values adjusted for the false discovery rate) further probed the relations, revealing ERD in the hemisphere contralateral to the direction of the cue was inversely related to the scores on the Flanker task: for right cue over C3, $\mathrm{t}(1,49)=-2.65$, $\mathrm{p}=.014$, and for left cue over $\mathrm{C} 4, \mathrm{t}(1,49)=-2.50, \mathrm{p}=.021$. ERD in the ipsilateral hemisphere was not related with flanker score (see Table 1). Refer to Figure 5 for inverse correlations between flanker score and contralateral ERD.

Table 1. Flanker predicted by ERD, Cue, \& Electrode

| Overall Regression | $B$ | Std Error | t value | $p$ |
| :--- | :---: | :---: | ---: | :--- |
| ERD | -3.51 | 2.53 | -1.39 | .16 |
| Electrode | -.627 | 2.49 | -.252 | .80 |
| Cue | 2.44 | 2.45 | .977 | .32 |
| Power*Cue*Electrode | 2.33 | .021 | 2.33 | $.01^{*}$ |
| Post-Hoc Regression | $B$ | Std Error | t value |  |$\quad p$.

*Significant at less than $\mathrm{p}=.05$; p-values of post-hoc corrected for FDR

Figure 5. Correlations of Flanker scores with ERD: significant correlations were found for pre-stimulus ERSP contralateral to cue direction. For right cue over C3, r= .395; for left cue over $\mathrm{C} 4, \mathrm{r}=-.377$. There was no relation between flanker scores and ipsilateral ERSP; right cue over $\mathrm{C} 4, \mathrm{r}=.106$; left over $\mathrm{C} 4, \mathrm{r}=-.021$.

## Discussion

The current study investigated somatosensory anticipation in children, and if anticipatory EEG responses in amplitude and alpha mu rhythm were related with individual differences in flanker scores. Just as seen in adults, we found a preparatory spatial cue directing attention to the bodily location of upcoming tactile stimulation modulated the activity of the alpha mu rhythm. Children's contralateral alpha band activity (in C3 - Right Cue and C4 - Left Cue) during anticipation was inversely associated with performance on a flanker task, while ipsilateral responses had no relation to flanker scores. Anticipatory negativity (i.e., the CNV response) was lateralized, with more negative amplitudes in the hemisphere contralateral to cue direction. The degree of lateralization, computed as mean amplitude at $\mathrm{C} 4-\mathrm{C} 3$, was related to participants' flanker scores, which subsequent analyses demonstrated were driven by contralateral negativity. Children's ability to modulate attention in preparation for tactile stimulation appears to be related to individual differences in EF, as codified by their scores on the flanker task.
Our findings of an association between flanker and neural indices of tactile attention should be interpreted with caution, as our sample is small for a study of individual differences. Studies linking neural indices of somatosensory anticipation and attention with other EF tasks should be conducted, to parallel research in other sensory modalities (Isbell, Wray and Neville, 2015). Other studies of anticipation in adults suggest that ipsilateral EEG activity suppresses responses to distractors (Hagens, Luthur, and Jensen, 2012; Zanto \& Gazzaley, 2009), but our paradigm did not include distractor stimuli; our study observed only a trending alpha power increase in the ipsilateral hemisphere, elicited by stimuli to the left hand. Further investigations can examine whether introducing simultaneous, competing stimuli in the somatosensory domain elicits an ipsilateral increase in alpha mu rhythm, as observed during anticipatory somatosensory selective attention in adults. A paradigm with simultaneous tactile stimulation to both hands would be more parallel to developmental research on the relations of cognitive skills and children's somatosensory selective attention rather than our study of somatosensory directed attention. First, we believed it crucial to replicate modulation in EEG indices during the anticipation of tactile stimuli in children, and further investigation is needed to assess how preparatory cues influence anticipation, attention and perception when distractors are introduced. Our results support that shared processes are involved in sensory-specific directed attention and domain-general EF, but continued study of attention in different modalities will address theories of inter-sensory attentional mechanisms (Gazzaley and Nobre, 2012). Study of brain responses to tactile stimuli uniquely informs models of action-oriented representation, wherein internal (cognitive and physiological) states reflect the environment and prescribe action (Clark, 1998; Engel et al., 2013).

Research on bodily awareness and representation would benefit by studying how the associated neural indices of somatosensation are influenced by attention and related cognitive processes. Children's neural indices during directed attention to bodily sensation appear similar to those in adults, when compared to ERP responses evoked during visual and auditory attention (Stevens and Bavelier, 2012). This could be interpreted as signaling the importance of somatosensory attention in development, although further work is needed to establish whether tactile attention is more predictive than attention in other modalities (e.g. vision). Future studies of the neural indices of somatosensory attention could lay the foundation for interventions that train attention or executive function in children.

# Modeling Unsupervised Event Segmentation: Learning Event Boundaries from Prediction Errors 

Katherine Metcalf (metcalka@indiana.edu)<br>Department of Computer Science, 901 E. 10th St. Bloomington, IN 47408 USA<br>David Leake (leake@indiana.edu)<br>Department of Computer Science, 901 E. 10th St. Bloomington, IN 47408 USA

#### Abstract

Segmenting observations from an input stream is an important capability of human cognition. Evidence suggests that humans refine this ability through experiences with the world. However, few models address the unsupervised development of event segmentation in artificial agents. This paper presents work towards developing a computational model of how an intelligent agent can independently learn to recognize meaningful events in continuous observations. In this model, the agent's segmentation mechanism starts from a simple state and is refined. The agent's interactions with the environment are unsupervised and driven by its expectation failures. Reinforcement learning drives the mechanism that identifies event boundaries by reasoning over a gated-recurrent neural network's expectation failures. The learning task is to reduce prediction error by identifying when one event transitions into another. Our experimental results support that reinforcement learning can enable detecting event boundaries in continuous observations based on a gated-recurrent neural network's prediction error and that this is possible with a simple set of features.

Keywords: Event Cognition; Unsupervised Segmentation; Expectation-based Failures; Reinforcement Learning

## Introduction

The ability to derive meaning from complex observations is a skill that has been recognized as vital for "growing" an intelligent agent from a simple starting state through interactions with a complex environment (Brooks, 1995; Cohen, Oates, Atkin, \& Beal, 1996). Before the agent is able to reason over a world model, it must first develop one. We present an approach in which an agent, exposed to patterns with temporal dependencies, develops a predictive model of its environment. The agent's expectation failures (i.e. prediction errors) are then used as the basis of its event segmentation mechanism. The resulting segments form the foundation of event representations.

The research we present in this paper builds on the work by Reynolds, Zacks, and Braver (2007) to build a computational model of event segmentation. We extend their model by incorporating a reinforcement learning agent to handle the detection of event boundary locations and trigger the subsequent event segmentation. The prediction mechanism is the gated-recurrent neural network (GRNN) model outlined by Reynolds et al. We evaluated several variations on the state representation presented to the reinforcement learning agent. The representations leverage information about the GRNN's
prediction error through time. The first representation evaluated is a simple state representation composed of the ratio of the predictive model's current error to its average error. This simple representation is then expanded to include a measure of input change, the amount of time since the gate was last opened, and the type of event that is expected next. Each state representation we evaluated contained the prediction ratio. We tested the GRNN-RL pair and the state represations on a motion captures dataset representing people executing 13 distinct tasks. Our results support the idea that information about the GRNN's prediction error is sufficient to allow a learned RL policy to appropriately identify event boundaries.

## Motivation

People are able to unconsciously and effortlessly perceive sequences of discrete events from dynamic and continuous sensory input (Radvansky \& Zacks, 2014; Ross \& Baldwin, 2015). People's ability to recognize temporal structure and patterns frequently observed across environmental contexts facilitates their partitioning of continuous activities into discrete events (Elman, 1990; Cleeremans \& McClelland, 1991; Cohen \& Adams, 2001; Reynolds et al., 2007). Therefore, people must learn the sequential dependencies that allow them to reason about sequences of observations as single, individual events. Reasoning about both observed events and their associated spatiotemporal patterns allows humans to reason about the underlying cause of the change in sensory observations (Radvansky \& Zacks, 2014). Evidence suggests that when people use an inferred event (i.e., spatiotemporal pattern) to guide their sensory expectations, they are able to recognize when transitions between events occur because their observations no longer match that of the current, hypothesized spatiotemporal pattern (Braver \& Cohen, 2000; Rougier, Noelle, Braver, Cohen, \& O’Reilly, 2005). We model how agents develop spatiotemporal models and use them to to interpret continuous observations as discrete events.

## Background

The task of this paper is related to previous works such as the Neo project (Cohen et al., 1996). Neo is a simulated infant that implements a computational model of the perceptual analysis by image-schema theory of complex concept formation (Johnson, 1987; Mandler, 1988, 1992; Lakoff \& John-
son, 2008). Neo begins with relatively simple configurations and develops/learns complex concepts through interactions with a simulated, complex world, by analyzing occurrences of discrete, symbolic tokens. We agree on the importance of developing complex agents able to learn via a process of perceptual analysis, representations of objects, states, and activities as its foundation for learning conceptual categories. However, a precondition for systems such as Neo is a process for transforming continuous sensory observations of the world into meaningful, discrete units (i.e., "unitization"). Our work addresses the unitization problems.

Reynolds et al. (2007) propose a relatively simple mechanism for event segmentation. Using its experiences with the world, their mechanism refines and hones the way it segments continuous observations without prior knowledge about the events or about the locations of event boundaries. Their mechanism is an implementation of the first component of Event Segmentation Theory (EST), a theory of event schema/model creation (Zacks, Speer, Swallow, Braver, \& Reynolds, 2007; Kurby \& Zacks, 2008). While previous approaches to event segmentation focused on the degree of change between subsequent observations as the key predictive feature (Newtson, 1976; Gibson, 1979), EST emphasizes the role of prediction failures. The importance of prediction error during event segmentation is based on data suggesting that people attempt to predict what they will observe next (Rao \& Ballard, 1999; Enns \& Lleras, 2008; Niv \& Schoenbaum, 2008).

People maintain working models, dynamic representations that facilitate event comprehension and incorporate predictions about what will be observed next, of the events they are observing (Radvansky \& Zacks, 2014). Evidence suggests that working models are the result of the segmentation and chunking of experience that are triggered by transient increases in prediction error (i.e., expectation failure driven event segmentation). When an event boundary is detected, people update their working model, thus changing their expectations about what will be observed next. However, there is a key limitation in the approach taken by Reynolds et al. when implementing this process, as their system depends on externally set thresholds to determine when one event ends and another begins. The work we present here extends their prediction model by removing externally set thresholds and examining the impact of incorporating higher-level expectations.

## Modeling Prediction Error-based Segmentation

## Reynolds, Braver, and Zack's Segmentation Model

Reynolds et al. (2007) used a gated-recurrent neural network, with the architecture depicted on the left in Figure 1, to model how people might learn sequential dependencies and perceive discrete event categories from continuous observations. The GRNN identified points at which one activity transitioned into another via an expectation failure based heuristic. They selected the GRNN because they considered it the most bio-

Figure 1: GRNN Model Architecture (Reynolds et al., 2007) on the left. Unsupervised Event Segmentation Model Architecture on the right.
logically plausible model available for capturing how people might learn sequential dependencies with the ability to store a representation of the current event in memory based, on contemporary work in behavioral and neuropsychological correlates of event structure and computational studies of sequential domains (for an extensive literature review see Reynolds et al. (2007)). The GRNN adjusted its event representation by triggering a gating mechanism that allowed the event representation to be directly updated based on the GRNN's observations. The gating mechanism controlled the extent to which the event representation was updated by each new observation and, combined with the network's recurrence, allowed the GRNN to maintain representations of the events through time (Elman, 1990; Hochreiter \& Schmidhuber, 1997). In their simulations, the gate was operated either: (1) by ground truth knowledge about the location of event boundaries or (2) by an externally set threshold on the ratio of the model's current sum squared error (SSE) and its average SSE. Their model attempted to predict its next observation; expectation failures were measured as SSE in the model's prediction and the true next observation. Based on the distribution of SSE observed within events versus at event boundaries, the authors concluded that a GRNN with an expectation failure-based gating mechanism is a reasonable approximation of how people might segment sequences of observations into meaningful units.

We built on Reynolds et al.'s (2007) work by extending their GRNN to include a RL agent that learns a policy for controlling the gating mechanism.

## A New Approach to Unsupervised, Self-Regulating Event Segmentation

We incorporated a RL agent that learned a policy for controlling the gating mechanism that Reynolds et al. (2007) created for their final simulation (Simulation IIIB), with the architecture depicted on the right in Figure 1. In Simulation IIIB, the gating mechanism was controlled by a simple mathematical function that evaluated whether the ratio of the models' last observed prediction error relative to the observed average error exceeded a threshold (1.5). Before modifying Simulation IIIB to include the RL agent, we tested our implementation in order to replicate their the experimental results, and we observed the same relations between the within event and
boundary observations. Reproducing the author's results (1) allowed us to evaluate the reproducibility of their work before using it as the basis of our system and (2) allowed us to build our model on one already reviewed and evaluated by the scientific community.

In our model, the gating function from Simulation IIIB was replaced with a RL agent that learned a policy for controlling the gating mechanism. An Expected-Sarsa learning algorithm with a linear function approximator (Sutton \& Barto, 2015) was used to learn the policy for controlling the gating mechanism. Our GRNN and RL combination is only able to build low-level expectations about what it will observe next. However, it could be used as a component in a larger system to build higher-level expectations that could be used to help guide the actions of the RL agent. In our experiments, while our model only directly builds expectations at the lower level, we incorporate information at higher levels of expectation in the the RL agent's state representation. We distinguish between lower and higher level information based on whether or not the information stems from the RL agent's immediately available observations about the state of the GRNN. Lowerlevel information is information that is readily available to the RL agent, whereas higher level information is not immediately available. For instance, the degree to which there is change between two subsequent observations is readily observable, whereas knowledge about the likelihood of a the next event transition being from sitting to standing is not.

In our experiments, the combined GRNN and RL agent was presented with a sequence of frames of motion captures of activities carried out by people (i.e. sitting,standing,jumping,etc.). Each activity constituted a single event and contained some number of frames. The frames are what the GRNN observed. The experiments varied the information presented to the RL agent. The RL agent's state representations consisted of both lower and higher level information about the state of the GRNN and RL agent. The lower-level information included a measure of the GRNN's prediction error (as in Reynolds et al. (2007)), the degree of change in the system's subsequent observations (inspired by Newtson (1976); Gibson (1979)), and the amount of time since the RL agent last updated the event representation. The higher level information included was a representation of the next event the agent expected to observe.

## The Models

The GRNN was constructed with the same parameters used by Reynolds et al.: 54 input units, 100 hidden units, 100 event units, 100 recurrent units, and 54 output units. The input and the hidden units had sigmoidal activation functions. The weights were initialized randomly within the range $[-0.5,0.5]$ and during back-propagation the learning rate was 0.001 . When comparing our implementation of the GRNN to that of Reynolds et al. we trained it to asymptotic performance, roughly 20,020 events, and evaluated it on 900 events. For further specifics about how the GRNN
was configured, please refer to details about Simulation IIIB in Reynolds et al. (2007). The GRNN was trained on 50, 000 events with a perfect gating signal prior to incorporating the RL agent as the gating mechanism.

The RL agent was construction according to an $\varepsilon$-greedy Expected-Sarsa with replacing traces policy learning algorithm. The specific state representations the agent learned to operate over can be seen in the experiments section below. Each of the state representations contained at least one continuous feature, therefore a linear function approximator was used to estimate the value of each state-action pair. Tile coding was used to convert the continuous states into binary feature vectors consisting of 32 layers of tilings with 4 tiles for each feature.

The agent had two possible actions: (1) flip the gate and (2) do not flip the gate. The policies were learned according to -SSE computed from the SSE observed in the GRNN's predictions after each action by the RL agent. We chose this reward, because it allows for unsupervised to control the gating mechanism and it is aligned with event segmentation theory (Radvansky \& Zacks, 2014). Table 1 shows the learning parameters used to learn the policies for each of the state representation experiments.

## Experiments

Experiments evaluated the performance of the RL agent at detecting when the GRNN's event representation should be updated. In each experiment, the RL learning algorithm described above was evaluated according to the quality of the policy it was able to learn given the different state representations. The different state representations incorporated different amounts of low and high-level information. The low-level information described the state of the GRNN and the state of the RL agent. The high-level information described expectations about the next event that would be observed. The RL agent learned over the course of 2,000 episodes. During each episode, the RL agent was exposed to 100 randomly ordered events. For the first 20 events, a perfect gating signal was used before the RL agent began learning. This allowed a reasonable average SSE to be computed before it was used as part of the RL agent's state representation. An overview of the experimental state representations and the learning parameters used by the RL agent to learn a policy for the given state representation can be seen in Table 1.

Each state representation consisted of between 1 and 4 features and always contained a feature describing the GRNN's current prediction error with respect to its historical prediction error, i.e. SSE_Ratio. Each dimension represented different information about the state of the overall system (Table 2):

- SSE_Ratio - the GRNN's current prediction error (i.e. SSE) with respect to a windowed average of the GRNN's historical SSE;
- Obs_Dist - the euclidean distance between two subsequent observations, $X_{t-1}$ and $X_{t}$;

Table 1: State Representations and Learning Parameters.

| State Representation | Learning Parameters |
| :--- | :--- |
| SSE_Ratio | $(\alpha=0.005 ; \gamma=0.95 ; \lambda=0.9)$ |
| SSE_Ratio+Obs_Dist | $(\alpha=0.005 ; \gamma=0.9 ; \lambda=1.00)$ |
| SSE_Ratio+Next_Event | $(\alpha=0.001 ; \gamma=0.9 ; \lambda=0.75)$ |
| SSE_Ratio+Last_Gate | $(\alpha=0.005 ; \gamma=0.95 ; \lambda=0.8)$ |
| SSE_Ratio+Obs_Dist+Last_Gate | $(\alpha=0.005 ; \gamma=0.9 ; \lambda=0.8)$ |

## The Data

The training data set for the GRNN and, subsequently, the RL agent was the motion capture data used by Reynolds et al. (2007), which can be found at http://dcl.wustl.edu/stimuli.html.

The data set contains 3-dimensional motion captures of people performing 13 distinct tasks. Each motion capture lasted 3-4 seconds and contained between 10 and 13 observations. Each motion capture activity was considered to be one event. Each event observation consisted of 18 (x, y, z) points on the body. We preprocessed each observation following Reynolds et al. (2007); the origin of the coordinate frame was transformed such that the points corresponding to person's hip was the origin, all values were scaled to the range $[-1,1]$, and the orientation of each figure was altered such that it was the same across all events.

Following Reynolds et al. (2007), before each training run for the GRNN or the RL agent, the training set was created by randomly ordering the events from the set of 13 events. A new event was randomly selected and added to the training set until the GRNN reached asymptotic performance. This allowed the GRNN and the RL agent to observe each event multiple times and learn a good predictive model for the frames that fell within a given event. The random ordering of the events provided the learning algorithm with a large variety of transition examples. The same process was used to create the training set of the RL agent, but with a stopping condition of the combined GRNN and RL agent having observed a prespecified number of events.

## Results

The results show that it is possible to use reinforcement learning to identify true event boundaries. Furthermore, it is possible to learn a policy for controlling the GRNN gating mechanism without encoding any knowledge within the reward function about where event boundaries actually exist. This is important, because it provides evidence demonstrating that it is possible for an artificial agent to take the first steps towards learning complex concepts using a bottom-up approach. Additionally, it provides evidence that it is possible for an artificial agent to learn on its own without requiring the painstaking process of handcoding thresholds and decision boundaries on the part of a human.

Table 3 shows the results from training the RL agent with the eight different state representations. Dist. describes the average distance between when the RL agent chose to update the event representation and the closest true event boundary. Reward is the total reward received by the agent during the episode. Err. describes the GRNN's average SSE over the course of the episode. Each value in Table 3 is averaged across 50 independent runs.

For each state representation, it was possible to learn a policy by which the RL agent could control the GRNN's gating mechanism. The learning curves for each state representation can be seen in Figure 2. Each of the state representations was

Table 3: Experimental results after 1000 episodes averaged over 50 runs.

| State | Dist. | Reward | Err. |
| :--- | :--- | :--- | :--- |
| SSE_Ratio | 0.2 | -12.0 | 0.15 |
| SSE_Ratio+Obs_Dist | 0.13 | -30.72 | 0.18 |
| SSE_Ratio+Next_Event | 0.52 | -31.44 | 0.18 |
| SSE_Ratio+Last_Gate | 1.22 | -65.78 | 0.38 |
| SSE_Ratio+Obs_Dist+Last_Gate | 1.16 | -42.31 | 0.25 |
| SSE_Ratio+Obs_Dist+Next_Event | 0.76 | -48.69 | 0.28 |
| SSE_Ratio+Last_Gate+Next_Event | 1.1 | -103.07 | 0.3 |
| SSE_Ratio+Obs_Dist+ | 0.32 | -52.56 | 0.5 |
| Last_Gate+Next_Event |  |  |  |

able to achieve an average reward between $0.15-0.5$ over the course of 1000 episodes. When run using a perfect gating function, the GRNN is able to achieve an average prediction error within the same range achieved by the RL agent. It is of note that this improvement in performance over that reported by Reynolds et al. (2007) is due, in part, to advances in deep neural network computing libraries. The state representation SSE_Ratio+Obs_Dist was able to learn a policy best able to maximize its received rewards. This indicates that information about the ratio of the current SSE to the average observed SSE and the degree of change between two subsequent observations are critical features for deciding how and when to update the GRNN's event representation.

Figure 2: GRNN Model Architecture (Reynolds et al., 2007).

The results show that the RL agent was able to learn a policy for each state representation. The agent was able to reach a reasonable average distance from the true event boundary, approximately 1.5 frames for about half of the state representations. We considered the RL agent's ability to identify an event boundary within 0.67 of the true event boundary to be
a reasonable level of performance given that each event lasts for 11 frames on average.

Finding that it is possible for a RL agent to learn when one event ends and another begins using GRNN's the SSE_Ratio alone, while surprising, is encouraging, as an initial step towards learning to unitize continuous observations without the use of higher level information (i.e. Next_Event). It is possible that the SSE_Ratio feature was so powerful on its own because it is correlated with and related to the other lowerlevel features (i.e. Obs_Dist and Last_Gate). However, it is not surprising that the SSE_Ratio+Obs_Dist both resulted in a high performing policy and the best performaning policy given the evidence in the literature suggesting that the degree of change between two subsquent observations plays a large role in segmenting continuous events and detecting boundary points on physical objects (Newtson, 1976; Gibson, 1979) is considered.

The ability to correctly identify event boundaries does not always have a consistent effect on the GRNNs observed prediction error. This finding indicates that it is not the number of boundaries that are correctly identified that is important, but rather which boundaries are correctly identified. Appropriately handling sub-event boundaries could drive down error in the GRNN while causing the RL agent to trigger gates at non-event boundaries, thus increasing the average distance measure. For example, the SSE_Ratio state representation results in an agent that is better able to detect event boundaries than the SSE_Ratio+Next_Event state represention, but the SSE_Ratio+Next_Event results in more rewards and lower average prediction errors in the GRNN.

## Future Work

That the RL agent was able to learn a policy for controlling the gating mechanism based solely on the GRNN's prediction error supports the potential for prediction error to play a primary role in event segmentation. We hypothesize that prediction error is likely to play an important role in other aspects of complex event segmentation and, possibly, event cognition. For example, if a person is unable to predict the event he/she will observe, then the higher level expectation failures might be propagated back to the segmentation gating mechanism and alter how it is identifying event boundaries. The ability of the agent to learn a gate controlling policy given a state representation that includes higher level expectations (i.e. the likelihood that the current event will transition into a standing event), indicates that the combined GRNN and RL agent model should be able to segment continuous observations into discrete events such that the discrete events are maximally predictive based on higher level expectation errors. We intend to study this in future work.

The research in this paper represents a step towards modeling how an intelligent agent can reason about and manipulate its model of the world in order to develop meaningful representations in an unsupervised way. Given that our system can recognize event boundaries, the next step is to develop a
system that is able to recognize sub-events. We believe that extending our approach to learning a policy for segmenting an event into sub-events will depend on two parts: (1) allowing the RL agent to more finely control the amount of influence each observation has on the subsequent event representation and (2) learning prototypical representations of the events. Giving the RL agent more fine-grained control over the influence incoming observations have on the current event representation should allow the agent to account for sub-events within longer, more complex events. Additionally, by learning the sequential dependencies among the event representations, it should be possible to go beyond identifying event boundaries to predicting which event will be observed next. For example, given an observation that a person is currently seated, represented in the form of the GRNN+RL agents event representation and the learned prototypical agent, it should be possible to predict the likelihood that the person will stand up.

## Conclusion

This paper has presented a model for learning to segment continuous observations into event units. Additionally, our model is able to learn to identify boundary points without any prior knowledge. The combined GRNN and RL agent proposed in this paper represents an approach to modeling event segmentation that removes the limitation of externally set thresholds and is able to operate in continuous domains. Experimental results support our conclusion that it is possible to use RL to learn a gate controlling mechanism that is able to accurately identify event boundaries independently without incorporating knowledge about the location of event boundaries in the reward function.

# Objections to Computationalism. A Short Survey 

Marcin Miłkowski (mmilkows@ifispan.waw.pl)<br>Instytut Filozofii i Socjologii PAN, ul. Nowy Świat 72, 00-330 Warszawa, Poland

#### Abstract

In this paper, I review the objections against the claim that brains are computers, or, to be precise, informationprocessing mechanisms. By showing that practically all the popular objections are based on uncharitable (or simply incorrect) interpretations of the claim, I argue that the claim is likely to be true, relevant to contemporary cognitive (neuro)science, and non-trivial.

Keywords: computationalism; computational theory of mind; representation; computation; modeling

## Computationalism and Objections

The computational theory of mind, or computationalism, has been fruitful in cognitive research. The main tenet of the computational theory of mind is that the brain is a kind of information-processing mechanism, and that informationprocessing is necessary for cognition; it is non-trivial and is generally accepted in cognitive science. The positive view will not be developed here, in particular the account of physical computation, because it has already been elucidated in book-length accounts (Fresco, 2014; Miłkowski, 2013; Piccinini, 2015). Instead, a review of objections is offered here, as no comprehensive survey is available.

The survey suggests that the majority of objections fail just because they make computationalism a straw man. Some of them, however, have shown that stronger versions of the computational theory of mind are untenable, as well. Historically, they have helped to shape the theory and methodology of computational modeling. In particular, a number of objections show that cognitive systems are not only computers, or that computation is not the sole condition of cognition; no objection, however, establishes that there might be cognition without computation.

## Computer metaphor is just a metaphor

Computational descriptions are sometimes described as $a$ computer metaphor (cf., e.g., Ekman, 2003; Karl, 2012, p. 2101). The use of the term suggests that the proposed description is rough and highly idealized, and cannot be treated literally. However, by using the term, others suggest that no computational model may be treated seriously; all are mere metaphors (Daugman, 1990).

A defender of computationalism might concede this and weaken their position. But the position is also tenable in the stronger version. This is because computer metaphors cannot really be tested and rejected, whereas computational models can. For this reason, in this paper, I will adopt, along with other theorists (Newell \& Simon, 1972, p. 5; Pylyshyn,

1984, pp. xiv-xvi), a stronger version of computationalism, which claims that cognition literally involves computation.

## Software is not in the head

This objection is that there is no simple way to understand the notions of software and hardware as applied to biological brains. But the software/hardware distinction, popular as in the slogan "the mind to the brain is like the software to hardware" (Block, 1995; Piccinini, 2010), need not be applicable to brains at all for computationalism to be true. There are non-program-controllable computers: they do not load programs from external memory to internal memory in order to execute them. A mundane example of such a computer is a logical AND gate. In other words, while it may be interesting to inquire whether there is software in the brain, even if there were none, computationalism could still be true.

## Computers are just for number-crunching

Another intuitive objection, already stated (and defeated) in the 1950 s , is that brains are not engaged in numbercrunching, while computers compute over numbers. But if this is all computers do, then they don't control missiles or send documents to printers. After all, printing is not just number crunching. The objection rests therefore on a mistaken assumption that computers can only compute numerical functions. Computer functions can be defined not only of integer numbers but also of arbitrary symbols (Newell, 1980), and as physical mechanisms, computers can also control other physical processes.

## Computers are abstract entities

Some claim that because symbols in computers are, in some sense, abstract and formal, computers-or at least computer programs-are abstract as well (Barrett, 2015; Barrett, Pollet, \& Stulp, 2014; Lakoff, 1987). In other words, the opponents of computationalism claim that it implies ontological dualism (Searle, 1990). However, computers are physical mechanisms, and they can be broken, set on fire etc. These things may be difficult to accomplish with a collection of abstract entities. Computers are not just symbol-manipulators. They do things, and some of the things computers do are not computational. In this minimal sense, computers are physically embodied, not unlike mammal brains. It is, however, a completely different matter whether the symbols in computers mean anything.

## People are organisms, computers are not

Barrett (2015), among others, also presses the point that people are organisms. It's trivially true but irrelevant:
physical computers are physical, and they may be built in various ways. A computer may be built of DNA strands (Zauner \& Conrad, 1996), so why claim that it's metaphysically impossible to have a biological computer?

## Symbols in computers mean nothing

One of the most powerful objections formulated against the possibility of Artificial Intelligence is associated with John Searle's Chinese Room thought experiment (Searle, 1980). Searle claimed to show that running a computer program is not sufficient for semantic properties to arise, and this was in clear contradiction to what was advanced by proponents of Artificial Intelligence, who assumed that it was sufficient to simulate the syntactic structure of representations for the semantic properties to appear. As John Haugeland quipped: "if you take care of syntax, the semantics will take care of itself" (Haugeland, 1985, p. 106). But Searle replied: one can easily imagine a person with a special set of instructions in English who could manipulate Chinese symbols and answer questions in Chinese without understanding it at all. Hence, understanding is not reducible to syntactic manipulation. While the discussion around this thought experiment is hardly conclusive (Preston \& Bishop, 2002), the problem was soon reformulated by Stevan Harnad (1990) as "the symbol grounding problem" (SGP): How can symbols in computational machines mean anything?

If the SGP makes sense, then one cannot simply assume that symbols in computers mean something just by being parts of computers, or at least they cannot mean anything outside the computer so easily (even if they contain instructional information (Fresco \& Wolf, 2013)). Representational properties do not necessarily exist in physical computational mechanisms (Egan, 1995; Fresco, 2010; Miłkowski, 2013; Piccinini, 2008). So, even if Searle is right and there is no semantics in computers, the brain might still be a computer, as computers need no semantics to be computers. Perhaps something additional to computation is required for semantics.

There is an important connection between the computational theory of mind and the representational account of cognition: they are more attractive when both are embraced. Cognitive science frequently explains cognitive phenomena by referring to semantic properties of mechanisms capable of information-processing (Shagrir, 2010a). Brains are assumed to model reality, and these models can be utilized in computations. While this seems plausible to many, one can remain computationalist without assuming representationalism (the claim that cognition requires cognitive representation). At the same time, a plausible account of cognitive representation cannot be couched merely in computational terms as long as one assumes that the symbol grounding problem makes sense at least for some computers. To make the account plausible, most theorists appeal to notions of teleological function and semantic information (Bickhard, 2008; Cummins \& Roth, 2012; Dretske, 1986; Millikan, 1984), which are not
technical terms of computability theory, neither can they be reduced to such. However, processing of semantic information is still processing of information; hence, computation is necessary for manipulation of cognitive representation.

Computationalism was strongly connected to cognitive representations by the fact that it offered a solution to the problem of what makes meaning causally relevant. Many theorists claim that because the syntax in computer programs is causally relevant (or efficacious), so is the meaning. While the wholesale reduction of meaning to syntax is implausible, the computational theory of mind makes it clear that the answer to the question includes the causal role of the syntax of computational vehicles. Still, the fact that it does not offer a naturalistic account of meaning is not an objection to computationalism itself. That would indeed be too much. At the same time, at least some naturalistic accounts, such as Millikan's and Dretske's, can be used to solve the SGP (see Miłkowski 2013, chap. 4).

## Computers can only represent with all detail

The debate over meaning in computers and animals abounds in red herrings, however. One recent example is Robert Epstein's (2016) popular essay. His most striking mistake is the assumption that computers always represent everything with arbitrary accuracy. Epstein cites the example of how people remember a dollar bill, and assumes that computers would represent it in a photographic manner with all available detail. This is an obvious mistake: representation is useful mostly when it does not convey information about all properties of the represented target. If Epstein is correct, then there are no JPEG files in computers, as they are not accurate, because they are based on lossy compression. Moreover, no assumption of the computational theory of mind says that memory should be understood in terms of the von Neumann architecture, and it is controversial to suggest that it should (Gallistel \& King, 2010).

## People don't process information

Ecological psychologists stress that people do not process information, they just pick it up from the environment (cf. Chemero, 2003; Gibson, 1986). Thus, to understand this, one should make more explicit the meaning of information processing in the computational theory of mind. What kind of information is processed? The information in question need not be semantic, as not all symbols in computers are about something. The minimal notion that could suffice for our purposes is one of structural information: a vehicle can bear structural information in the event that it has at least one degree of freedom, that is, it may vary its state (MacKay, 1969). The number of degrees of freedom, or yesno questions required to exactly describe its current state, is the amount of structural information. As long as there are vehicles with multiple degrees of freedom and they are part of causal processes that cause some other vehicles-just like some models of computation describe these processes
(Miłkowski, 2014)-there is information processing. This is a very broad notion, as all physical causation implies information transfer and processing in this sense (Collier, 1999).

The Gibsonian notion of information pickup requires vehicles of structural information as well. There needs to be some information out there to be picked up, and organisms have to be structured so as to be able to change their state in response to information. Gibsonians could, however, claim that the information is not processed. It is unclear what is meant by this: for example, Chemero seems to imply that processing amounts to adding more and more layers of information, like in Marr's account of vision (Chemero, 2003, p. 584; cf. Marr, 1982). But information processing need not require multiple stages of adding more information. To sum up: the Gibsonian account does not invalidate computationalism at all.

## Consciousness is not computational

Some find (some kinds of) consciousness to be utterly incompatible with computationalism, or at least, unexplainable in purely computational terms (Chalmers, 1996). The argument is probably due to Leibniz's thought experiment in Monadology (Leibniz, 1991). Imagine a brain as huge as a mill, and enter it. Nowhere in the interplay of gears could you find perceptions, or qualitative consciousness. Hence, you cannot explain perception mechanically. Of course, this Leibnizian argument appeals only to some physical features of mechanisms, but some still seem to think that causation has nothing to do with qualitative consciousness.

The argument, if cogent, is applicable more broadly, not just to computationalism; it is supposed to defeat reductive physicalism or materialism. For this reason, this objection might be dismissed as attacking any scientific project that explains consciousness reductively.

Virtually all current theories of consciousness are computational, even the ones that appeal to quantum processes (Hameroff, 2007). For example, Bernard Baars offers a computational account in terms of the global workspace theory (Baars, 1988; cf. also Dennett, 2005), David Rosenthal gives an account in terms of higher-level states (cf. Cleeremans, 2005; Rosenthal, 2005), and Giulio Tononi explains in terms of minimal information integration (Tononi, 2004). Is there any theory of consciousness that is not already computational?

John Searle, however, suggests that only a noncomputational theory of consciousness can succeed. His claim is that consciousness is utterly biological (Searle, 1992). How does this contradict computationalism given that there might be biological computers? Moreover, Searle fails to identify the specific biological powers of brains that make them conscious. He just passes the buck to neuroscience, which often offers computational accounts.

## Computer models ignore time

Proponents of dynamical accounts of cognition stress that Turing machines do not operate in real time. This means that this classical model of computation does not appeal to real time; instead, it operates with the abstract notion of a computation step. There is no continuous time flow, just discrete clock ticks in a Turing Machine (Bickhard \& Terveen, 1995; Wheeler, 2005). This is true. But is this an objection against computationalism?

First, some models of computation appeal to real time (Nagy \& Akl, 2011), so one could use such a formalism. Second, the objection seems to confuse the formal model of computation with its physical realization. Physical computers operate in real time, and not all models of computation are made equal; some will be relevant to the explanation of cognition, and some may only be useful for computability theory. A mechanistically-adequate model of computation that describes all relevant causal processes in the mechanism is required for explanatory purposes (Miłkowski, 2014).

## Brains are not digital computers

Universal Turing machines are crucial to computability theory. One could, however, maintain that brains are not digital computers (Edelman, 1992; Lupyan, 2013).

But computationalism can appeal to models of analog computation (e.g., Siegelmann, 1994), or even more complex kinds of computation (Piccinini \& Bahar, 2013), if required. These models are still understood as computational in computability theory, and some theorists indeed claim that the brain is an analog computer, which is supposed to allow them to compute Turing-incomputable functions. Thus, one cannot dismiss all kinds of computationalism by saying that the brain is not a digital computer. There are analog computers, and an early model of a neural network, Perceptron, was analog (Rosenblatt, 1958). The contention that computers have to be digital is just dogmatic.

## Genuine artificial intelligence is impossible

There are a number of arguments of a form:
People $\psi$.
Computers will never $\psi$.
So, artificial intelligence is impossible (or computationalism is false).

This argument is enthymematic, but the conclusion follows with a third assumption: if artificial intelligence is possible, then computers will $\psi$. The plausibility of the argument varies from case to case, depending on what you fill for $\psi$. For years, it was argued that winning in chess is $\psi$ (Dreyfus, 1979), but it turned out to be false. So, unless there is a formal proof, it's difficult to treat premise 2 seriously.

What could be plausibly substituted for $\psi$ ? There are many properties of biological organisms that simply seem irrelevant to this argument, including exactly the same energy consumption, having proper names, spatiotemporal location, etc. The plausible candidate for substitution is some capacity for information-processing. If there is such a human capacity that computers do not possess, then the argument is indeed cogent.
Only people can see the truth A classical anticomputational argument points to the human ability to recognize the truth of logical statements that cannot be proven by a computer (Lucas, 1961; Penrose, 1989). It is based on the alleged ability of human beings to understand that some statements are true, which is purportedly impossible for machines (this argument is based on the Gödel proof of incompleteness of the first-order predicate calculus with basic arithmetic). The problem is that this human understanding has to be non-contradictory and certain. But Gödel has shown that in general it cannot be decided whether a given system is contradictory or not. So either it's mathematically certain that human understanding of mathematics is non-contradictory, which makes the argument inconsistent as it cannot be mathematically certain because it's undecidable; or the argument just assumes noncontradiction of human understanding, which makes the argument unsound because people make contradictions unknowingly (Krajewski, 2007; Putnam, 1960).

Common sense cannot be formalized Another similar argument points to common sense, which is a particularly difficult capacity. The trouble with implementing common sense on machines is sometimes called (somewhat misleadingly, cf. (Shanahan, 1997)) the frame problem (Dreyfus, 1972, 1979; Wheeler, 2005). Inferential capacities of standard AI programs do not seem to follow the practices known to humans, and that was supposed to hinder progress in such fields as high-quality machine translation (BarHillel, 1964), speech recognition (held to be immoral to fund (Weizenbaum, 1976)), and so on. Even if IBM Watson wins in Jeopardy!, one may still think it's not enough. Admittedly, common sense is a plausible candidate in this argument.

Even if the proponent of computationalism need not require that genuine AI be based on a computer simulation of human cognitive processes, he or she still must show that human common sense can be simulated on a computer. Whether it can or not is still a matter of debate.

## Computers are everywhere

At least some plausible theories of physical implementation of computation lead to the conclusion that all physical entities are computational (this stance is called pancomputationalism, (cf. Müller, 2009)). If this is the case, then the computational theory of mind is indeed trivial, as not only brains are computational, but also cows, black holes, cheese sandwiches etc. are all computers. However, a pancomputationalist may reply by saying that there are
different kinds (and levels) of computation, and brains do not execute all kinds of computation at the same time (Miłkowski, 2007). So not just any computation but some non-trivial kind of computation is specific to brains. Only the kind of pancomputationalism that assumes that everything computes all kinds of functions at the same time is catastrophic, as it makes physical computation indeed trivial (Putnam, 1991; Searle, 1992).

## There are no computers

Another more radical move is to say that computers do not really exist; they are just in the eyes of beholder. According to John Searle, the beholder decides whether a given physical system is computational, and therefore may make this decision for virtually everything. Nothing intrinsically is a computer. But the body of work on physical computation in the last decade or so has been focused on showing why Putnam and Searle were wrong in some sense (Chalmers, 2011; Chrisley, 1994; Copeland, 1996; Miłkowski, 2013; Piccinini, 2015; Scheutz, 1996; Shagrir, 2010b). The contemporary consensus is that computational models can be used to adequately describe causal connections in physical systems, and that these models can also be falsely ascribed. In other words, computational models are not different in kind from any mathematical model used in science. If they are mere subjective metaphors and don't describe reality, then mathematical models in physics are subjective as well (McDermott, 2001).

Intuitively, arguments presented by Searle and Putnam are wrong for a very simple reason: why buy a new computer instead of ascribing new software to the old one? We know that such ascriptions would be extremely cumbersome. Therefore, there must be a flaw in such arguments, and even if the technicalities involved are indeed interesting, they fail to establish a conclusion.

## Conclusion

In this paper, I have listed and summarized a number of arguments against computationalism. The only objection that seems to be plausible at first glance is the one stating that common sense is impossible or extremely difficult to implement on a machine. However, more and more commonsensical capacities are being implemented on machines.

The point is that there's no good reason to think that the brain is not a computer. But it isn't a mere computer: It is physically embedded in its environment and interacts physically with its body, and for that, it also needs a peripheral nervous system (Aranyosi, 2013) and cognitive representations. Yet there's nothing that denies computationalism here. Most criticisms of computationalism therefore fail, and sticking to them is probably a matter of ideology rather than rational debate.

## Acknowledgments

The work on this paper was funded by a National Science Centre (Poland) research grant under the decision DEC2014/14/E/HS1/00803. The author wishes to thank Tomasz Korbak, Martin Hughes, Panu Raatikainen, Błażej Skrzypulec, and anonymous reviewers for their comments.

#### Abstract

This study aimed to assess how specific components of an action could be selected by a simple computational system. We performed an experiment to test associations between grasps (precision or power grip) and several objects. We then ran simulations using a naive bayes classifier to study to what extent it could reproduce participants' choice. This classifier had two learning matrices containing objects' size associated with a grip by means of our experiment. When receiving a new object' size it computed the probability for each grip to be adapted. The highest probability was considered to represent which grip was associated with the object by the classifier. Results show that the classifier can reproduce participants' choice depending on the size of its learning matrices, and can quickly select the right type of grip for a majority of trials, showing that micro-affordances (Ellis \& Tucker, 2000) can be reproduced through naive bayesian classification.

Keywords: affordance; grip; bayesian method; classifier

## Introduction

As Leonard de Vinci said : "movement is principle of life". The way people interact with the world through body movements is indeed a corner stone of psychology, and especially of embodied psychology. As embodied psychology postulates that high-level cognitive processes are bodily rooted, or at least that their result depends on bodily states (Wilson, 2002), movements of the living body is a crucial point to attend. Yet how adapted body movements occur is not well determined and several propositions are made, one of them being particularly attractive for embodied cognitivists: theory of affordances (Gibson, 1979).

Affordance is a concept coined by Gibson (1979) that relies on direct perception. Although it has many interpretations, we will rely on the definition of Chemero (2003) in which affordances represent the relations between an animal's capacities and features of its environment. Abilities of an animal are functional properties, that depends on this animal's history.

This theory highlights the fact that voluntary actions are products of our perception of the situation, our abilities, and what we have learned. Moreover, this theory predicts that
action is part of objects' memories and perception, as it is now established (Brouillet et al., 2015), which is of interest for psychology and for robotics as they permit to gain insight into the perception-action loop (Montesano et al., 2007, 2008).

Yet, the link between perception and affordances needs further investigation, as clues, or features, need to be extracted from, or constructed on the basis of the environment. Such clues would facilitate the link between a rich perception and an adapted movement, and permit on line adaptation.

Our purpose was to test how adapted voluntary movements could be selected, by a very simple computational system, on the basis of clues extracted from perception. To do this we chose to test some specific components of an action: grasping movements (Koester, Schack, \& Westerholz, 2016). A lot of our interactions with the world depend on our ability to grasp things around us in a proper way, for example using a power or a precision grip (i.e. with all fingers of the hand or with the thumb and index, respectively, see Figure 1). These specific components of action (that doesn't include walking, reaching etc...) are termed micro-affordances by Ellis and Tucker (2000). These micro-affordances are supposed to emerge while looking at an object, and to facilitate a specific grasp. We selected object size to be the feature of the environment that could be associated to a specific grasp, in order to create a model that simulates a perceptually based motor activity.

The computational system we used to infer specific grasps rely on bayesian probability (Jones \& Love, 2011; Pearl, 1985). The bayesian approach appears to be promising when studying how humans can interact with the world in presence of uncertainty (Perfors et al., 2011). It can apply to motor planning and control, estimation of context and motor learning (Wolpert \& Ghahramani, 2000; Wolpert, Ghahramani, \& Flanagan, 2001), and can be easily used in its simplest ways (Robert, 2000). This approach rely on conditional probability and allows to determine the probability of a certain event (for example a particular grasp) knowing some information :
past experiences (e.g. earlier grasp in presence of an object) or sensory inputs (e.g. object size) (Naïm et al., 2007).

The particular model we chose is a naive bayes classifier. This model has two learning matrices : one containing the size of objects graspable with a power grip, and one containing the size of objects graspable with a precision grip, size being represented by three parameters $x, y$, and $z$. Once it has computed these matrices, it receives the size of a novel object to be classified as graspable with a power grip or with a precision grip. In order to do so, it selects the most probable grasp, knowing the object size, to be the grasp to produce in presence of this particular object.

This approach of micro-affordances as naive bayesian classification can be of interest for psychologists and roboticians, as it can reduce the size of ontology, or databases, needed for an adapted system, and permits to infer micro-affordances in a very simple way.

In a first part we present the experiment to test microaffordances with human beings and select objects that can be associated with a precision or a power grip. In a second part we explain how the model categorizes objects as being graspable with a precision or a power grip by means of naive bayesian classification, and show the results obtained with this model. We then compare human's and classifier's performances and discuss the possible developments of such applications.

## Selection and association of objects with a precision or a power grip

## Participants

Sixteen students were recruited for a pre-experiment in order to select the objects used in our experiment and simulation. Eighty students, different from the previous ones, were then recruited in order to select the appropriate grasp for each object (seven of them were not taken into account as they changed their grasping for the same objects between trials and differed drastically from the others). All participants freely signed a letter of consent, were right-handed, had normal or corrected to normal vision and over 18 years old, none had problems of motricity.

## Materials

Forty-four pictures of objects were used. Each picture was modified to have the object being centered, vertically oriented, and a half of their real size when displayed on the computer screen.

These images were presented to sixteen students in a preexperiment, with a hand near the object either making a power grip or a precision grip (see Figure 1). Participants had to indicate their level of agreement with the grip being displayed with the object. A high level of agreement with a grip meant that it was a reasonable grip to pick up and use the object.As a result, twenty objects were selected for the experiment, ten being graspable with a power grip and ten with a precision grip.

Figure 1: A hand making a power grip (left picture), and a precision grip (right picture).

## Procedure

All of eighty participants were received one by one in an experimentation room, and sat in front of a computer Lenovo 17.3" with graphics card AMD radeon HD 8500M. They were asked to grab, with their right hand, a device that constrained them to make either a power or a precision grip. They were instructed to look at the computer screen and make the more appropriate grip on the device when seeing an object displayed on the screen. The twenty objects were then displayed randomly. When the twenty objects had been exposed, a second random presentation was made, in order to ensure the grip selected by participants for each object.

## Results

Overall, the grips selected by means of the pre-experiment were respected, as shown in Table 1 and Table 2, and participants showed stable grip for each object. All of which allowed us to classify each object as associated with a precision or a power grip.

Table 1: Percentage of responses for objects associated with a precision grip, a number was attributed to each object for further comparison.

| Objects | N | \% power grip | \%precision grip |
| :--- | :---: | :---: | :---: |
| grain of wheat | 1 | 0.68 | 99.32 |
| tweezers | 2 | 3.42 | 96.58 |
| nut | 3 | 0.68 | 99.32 |
| radish | 4 | 10.96 | 89.04 |
| smart card | 5 | 1.37 | 98.63 |
| screw | 6 | 0.00 | 100.00 |
| paper clip | 7 | 0.00 | 100.00 |
| strawberry | 8 | 6.85 | 93.15 |
| french beans | 9 | 1.37 | 98.63 |
| key | 10 | 2.74 | 97.26 |

## Simulation with a naive bayes classifier

## The naive bayes classifier

The second step of this work was to put the naive bayes classifier to the test. To do so, we had to implement the size of objects used in our experiment. We chose to represent size in

Table 2: Percentage of responses for objects associated with a power grip, a number was attributed to each object for further comparison.

| Objects | N | \% power grip | \%precision grip |
| :--- | :---: | :---: | :---: |
| glass | 11 | 97.26 | 2.74 |
| hair clipper | 12 | 91.10 | 8.90 |
| coconut | 13 | 100.00 | 0.00 |
| apple | 14 | 99.32 | 0.68 |
| corn | 15 | 95.89 | 4.11 |
| computer mouse | 16 | 89.73 | 10.27 |
| board wiper | 17 | 92.47 | 7.53 |
| universal pliers | 18 | 95.21 | 4.79 |
| pepper | 19 | 95.21 | 4.79 |
| deodorant | 20 | 91.78 | 8.22 |

a three dimensional cartesian coordinate system, representing height, width, and depth.

Figure 2: A computer mouse mesured on $x, y$ and $z$.

Table 3: Mean and Variance for objects associated with a precision grip or a power grip.

| Objects | $x$ | Mean (Variance) |  |
| :--- | :---: | :---: | :---: |
|  | $x$ | $y$ | $z$ |
| precision | 1.265 | 0.62 | 4.87 |
|  | $(0.422)$ | $(0.291)$ | $(11.72)$ |
| power | 6.76 | 5.27 | 13.92 |
|  | $(3.83)$ | $(8.58)$ | $(22.94)$ |

We defined a rule to mesure our objects : z axis for the longest axis of the object, $y$ axis for the shortest axis of the object, and x the last one, following the right hand rule (e.g. mesure of a computer mouse in centimeter: $x=6, y=1.65$, $z=11.50$, see Figure 2). These rules were followed in order to satisfy the concept of axis for grasping proposed in Michel (2006), we simplified Michel's studies to reduce the natural axis of prehension of an object to its longest side. Mean and variance of objects associated with a precision grip and objects associated with a power grip are presented in Table 3.

## Procedure

The model received an unknown object to be classified as graspable with a power grip or a precision grip. This ob-
ject, represented by a vector $\left(x_{n}, y_{n}, z_{n}\right)$, was associated by the model to probabilities $P\left(\operatorname{grip}_{i} \mid x_{n}, y_{n}, z_{n}\right)$ for $i=1$ the precision grip $\left(\right.$ grip $\left._{1}=G_{1}\right)$ and $i=2$ the power grip $\left(\right.$ grip $\left._{2}=G_{2}\right)$.

The Bayes' theorem permits to decompose these probabilities :

$$
\begin{equation*}
P\left(\text { grip }_{i} \mid x_{n}, y_{n}, z_{n}\right)=\frac{P\left(\text { grip }_{i}, x_{n}, y_{n}, z_{n}\right)}{P\left(x_{n}, y_{n}, z_{n}\right)} \tag{1}
\end{equation*}
$$

The probability $P\left(\operatorname{grip}_{i}, x_{n}, y_{n}, z_{n}\right)$ can be written as :

$$
\begin{gather*}
P\left(\text { grip }_{i}, x_{n}, y_{n}, z_{n}\right)=P\left(x_{n}, y_{n}, z_{n}, \text { grip }_{i}\right) \\
=P\left(x_{n} \mid y_{n}, z_{n}, \text { grip }_{i}\right) \times P\left(y_{n}, z_{n}, \text { grip }_{i}\right) \\
=P\left(x_{n} \mid y_{n}, z_{n}, \text { grip }_{i}\right) \times P\left(y_{n} \mid z_{n}, \text { grip }_{i}\right) \times P\left(z_{n}, \text { grip }_{i}\right) \\
=P\left(x_{n} \mid y_{n}, z_{n}, \text { grip }_{i}\right) \times P\left(y_{n} \mid z_{n}, \text { grip }_{i}\right) \times P\left(z_{n} \mid \text { grip }_{i}\right) \times P\left(\text { grip }_{i}\right) \tag{2}
\end{gather*}
$$

Here, the naive assumption of conditional independence assumes that given the category $\operatorname{grip}_{i}, x_{n}, y_{n}$ and $z_{n}$ are independent, so that :

$$
\begin{equation*}
P\left(x_{n} \mid y_{n}, z_{n}, \text { grip }_{i}\right)=P\left(x_{n} \mid \text { grip }_{i}\right) \tag{3}
\end{equation*}
$$

and

$$
\begin{equation*}
P\left(y_{n} \mid z_{n}, \text { grip }_{i}\right)=P\left(y_{n} \mid \text { grip }_{i}\right) \tag{4}
\end{equation*}
$$

Thus, using equations (1) (2) (3) and (4)

$$
\begin{align*}
& P\left(\text { grip }_{i} \mid x_{n}, y_{n}, z_{n}\right)= \\
& \frac{P\left(x_{n} \mid \operatorname{grip}_{i}\right) \times P\left(y_{n} \mid \text { grip }_{i}\right) \times P\left(z_{n} \mid \text { grip }_{i}\right) \times P\left(\text { grip }_{i}\right)}{P\left(x_{n}, y_{n}, z_{n}\right)} \tag{5}
\end{align*}
$$

The model then selected the adapted grip for the object $\left(x_{n}, y_{n}, z_{n}\right)$ using :

$$
\begin{equation*}
\operatorname{argmax}\left[P\left(G_{1} \mid x_{n}, y_{n}, z_{n}\right) ; P\left(G_{2} \mid x_{n}, y_{n}, z_{n}\right)\right] \tag{6}
\end{equation*}
$$

In concrete terms the naive bayes classifier had two learning matrices of size $(j, 3), j$ being the number of objects in the learning matrices, represented by their three coordinates $\left(x_{j}, y_{j}, z_{j}\right)$. One matrix included the objects classified as graspable with a precision grip $\left(G_{1}\right)$, the other included the objects classified as graspable with a power grip $\left(G_{2}\right)$.

The following calculations were applied similarly for $G_{1}$ and $G_{2}$, we will only present the calculations for parameter $x$ in $G_{1}$ for the sake of clarity. The classifier computed the probability for an object to be graspable with a precision grip $\left(P\left(G_{1}\right)=\frac{j}{2 j}=\frac{1}{2}\right)$.

And the mean and variance of each parameter $x, y$, and $z$ for a precision grip : $\mu_{G_{1}}(x), \mu_{G_{1}}(y), \mu_{G_{1}}(z)$ and $\sigma_{G_{1}}^{2}(x), \sigma_{G_{1}}^{2}(y), \sigma_{G_{1}}^{2}(z)$; and for a power grip, resulting in $\mu_{G_{2}}(x), \mu_{G_{2}}(y), \mu_{G_{2}}(z)$ and $\sigma_{G_{2}}^{2}(x), \sigma_{G_{2}}^{2}(y), \sigma_{G_{2}}^{2}(z)$.

When a novel object with parameters $\left(x_{n}, y_{n}, z_{n}\right)$ was presented to the model, the classifier had to compute the probabilities $P\left(G_{1} \mid x_{n}, y_{n}, z_{n}\right)$ and $P\left(G_{2} \mid x_{n}, y_{n}, z_{n}\right)$, using (5).

As measurements were on continuous variables, the new parameters were computed given the known parameters
of the model using a gaussian probability density function, in order to calculate $P\left(x_{n} \mid G_{1}\right), P\left(y_{n} \mid G_{1}\right), P\left(z_{n} \mid G_{1}\right)$ and $P\left(x_{n} \mid G_{2}\right), P\left(y_{n} \mid G_{2}\right), P\left(z_{n} \mid G_{2}\right)$ with:

$$
P\left(x_{n} \mid G_{1}\right)=\frac{1}{\sqrt{2 \pi \sigma_{G_{1}}^{2}(x)}} e^{-\frac{\left[x_{n}-\mu_{G_{1}}(x)\right]^{2}}{2 \sigma_{G_{1}}^{2}(x)}}
$$

Then the model selected the highest probability (the appropriate grip), using (6).

As gaussian probability density function could return 0 for the probability of a parameter given a class grip $_{i}$, we distinguished two cases. In the first case only one parameter of the novel object had a probability equal to zero, in this case we did not change anything (we show in discussion why this case is a limit for this type of classification). In the second case two parameters of the novel object, one for each class, had a probability equal to zero (for example $P\left(y_{n} \mid G_{1}\right)=0$ and $P\left(z_{n} \mid G_{2}\right)=0$ ), we changed these probabilities to $\varepsilon$ close to zero , this changed $P\left(G_{1} \mid x_{n}, y_{n}, z_{n}\right)$ and $P\left(G_{2} \mid x_{n}, y_{n}, z_{n}\right)$ to

$$
\begin{equation*}
P\left(G_{1} \mid x_{n}, y_{n}, z_{n}\right)=\lim _{\varepsilon \rightarrow 0} \frac{P\left(x_{n} \mid G_{1}\right) \times \varepsilon \times P\left(z_{n} \mid G_{1}\right) \times P\left(G_{1}\right)}{P\left(x_{n}, y_{n}, z_{n}\right)} \tag{7}
\end{equation*}
$$

and

$$
\begin{align*}
& P\left(G_{2} \mid x_{n}, y_{n}, z_{n}\right)=\lim _{\varepsilon \rightarrow 0} \frac{P\left(x_{n} \mid G_{2}\right) \times P\left(y_{n} \mid G_{2}\right) \times \varepsilon \times P\left(G_{2}\right)}{P\left(x_{n}, y_{n}, z_{n}\right)} \\
& \begin{aligned}
& \text { As } P\left(x_{n}, y_{x}, z_{n}\right)=P\left(x_{n}, y_{n}, z_{n}, G_{1}\right)+P\left(x_{n}, y_{n}, z_{n}, G_{2}\right) \\
& P\left(x_{n}, y_{n}, z_{n}\right)= \\
& P\left(x_{n} \mid G_{1}\right) \times \varepsilon \times P\left(z_{n} \mid G_{1}\right) \times P\left(G_{1}\right)+ \\
& P\left(x_{n} \mid G_{2}\right) \times P\left(y_{n} \mid G_{2}\right) \times \varepsilon \times P\left(G_{2}\right) \\
&=\varepsilon \times\left[P\left(x_{n}, z_{n}, G_{1}\right)+P\left(x_{n}, y_{n}, G_{2}\right)\right]
\end{aligned}
\end{align*}
$$

So that, using (7) and (8):

$$
P\left(G_{1} \mid x_{n}, y_{n}, z_{n}\right)=\frac{P\left(x_{n} \mid G_{1}\right) \times P\left(z_{n} \mid G_{1}\right) \times P\left(G_{1}\right)}{P\left(x_{n}, z_{n}, G_{1}\right)+P\left(x_{n}, y_{n}, G_{2}\right)}
$$

Thus the probability of a grip given the three parameters of the novel object became the probability of a grip given the two parameters of the novel object for which probability was not changed by $\varepsilon$, as the changes operated cancelled each other out.

## Simulation

Simulation was performed using Matlab R2015a with a computer running on Windows 7 with a CPU Intel Core i5-4258U 2.10 GHz .

We aimed at assessing naive bayes classification by analysing classifier's performance with different learning matrices (different learned objects and number of objects
learned). In addition we compared the results of the classifier to the results obtained with human participants.

Simulation ran using $j=1$ to 7 learned objects for each category (we always used the same number of learned objects in the two categories: objects associated with a precision grip and objects associated with a power grip).

Objects that were not used in learning matrices were categorized using the method described earlier.

As learning order did not have any impact on classification, number of trials was defined using the binomial coefficient $\binom{N}{j}$ with $N=10$ the total number of objects in each category and $j$ the number of objects learned in each category. This binomial coefficient gives the number of combination of learned objects without taking into account possibilities of permutation (learning order). The classifier was tested for every possible combination of learning: for each combination of precision grip's learning, we tested all combinations of power grip's learning. This way the results presented in Table 4 and Table 5 show the proportion of correct classification for every object over all possible learnings of our material.

For each object and each $j$ we verified the grip selected by the classifier within each trial. For objects associated with a precision grip by means of our experiment (see Table 1), classification was recorded as right when the classifier calculates a higher probability for precision grip than for power grip. The reverse was made for objects previously associated with a power grip (see Table 2). If probabilities for a precision grip and for a power grip were equal, we considered that classification was incorrect.

## Results

Overall it took 1397.71 seconds ( 23 minutes and 29 seconds) for the program to select learning matrices and make 1837440 classification. The classification of one object took in average $7.61 \times 10^{-1} \mathrm{~ms}$.

When more than one parameter for one class was equal to zero ( 33 cases), or when $P\left(x_{n}, y_{n}, z_{n}\right)$ was considered equal to zero due to very small probabilities ( 82 cases), classification was impossible. These particular numeric cases happened rarely ( 115 objects impossible to classify over 1837440 classified objects).

We computed the percentage of right classification for each object and each $j$ (number of learned objects before classification). The percentages of right classification are shown in Table 4 (the percentage of right classification for objects considered as associated with a precision grip), and Table 5 (the percentage of right classification for objects considered as associated with a power grip).

A few things are to be discussed here. First, we can see that overall the classifier returned the right grip most of the time, in all the conditions ( $92.86 \%$ of right classification).

Secondly we can see that classification was better for objects that were considered associated with a power grip than for the others.

Thirdly, we see that classification performance increased as number of learned objects increased. This is because pa-

| Mean | 93.45 | 98.67 | 99.81 | 99.98 | 100 | 100 |

rameters $\mu$ and $\sigma$ were more representative of a class (power or precision grip) as number of learned objects increased.

What is counterintuitive is that classification of object number 4 got worse and worse, it is because we put more objects different from object 4 in the precision grip's learning matrice as the simulation went on. Object 4 had its three parameters close to boundaries of the precision grip space (represented by its mean and variance for each parameter $x, y$ and $z)$. Thus, depending on the objects learned, increasing the number of learned objects put object 4 out of the boundaries: the more learned objects associated with a precision grip had parameters close to the parameters of object 4, the more object 4 was classified as part of precision grip's objects. Conversely the more learned objects associated with a precision grip had parameters distant from object 4, the more it was classified as part of power grip's object. Compared to object 4, other precision grip's objects had one of their parameter close to the boundaries of precision grip's space, but not all of their parameters, which made them easier to classify cor-
rectly.
The fact that object 4 was hardly well classified, instead of being a real issue for naive bayesian classification, could be an advantage when comparing the classifier's performance and human classification: in our experiment object 4 reveals the higher percentage of selection for the competing grip (see Table 1).

## Comparison of human and classifier's performance

To compare human's and classifier's performance we used a $\chi^{2}$ test of independence between variable object (object 1 to object 20) and variable responding entity (human participants or naive bayes classifier).

When three, four, five and six objects of each category were put in the classifier's learning matrices, we found that the two variables were independent $\left(\chi^{2}(19)=25.22, p=\right.$ $0.15 ; \chi^{2}(19)=23.06, \quad p=0.23 ; \quad \chi^{2}(19)=21.69, \quad p=$ $0.30 ; \chi^{2}(19)=22.71, p=0.25$, respectively), this meaning that classifier's performance and human grip's choice were not significantly different.

When two objects of each category were put in the classifier's learning matrices, we found that variables object and responding entity were independent, but with a greater difference between human's and classifier's performance $\left(\chi^{2}(19)=29.26, p=0.06\right)$.

Finally, when seven objects of each category were put in the classifier's learning matrices, it appeared that the two variables were not independent anymore $\left(\chi^{2}(19)=33.01, p<\right.$ 0.05 ), human's and classifier's performance became significantly different.

## Discussion

The results we obtained reveal that naive bayesian classification can reproduce the grip's choice made by human participants.

A good association of a novel object and its adapted grip can be accomplished with a reduced database and few parameters. This may permit to determine quickly a subclass of grips belonging to the precision or power grip classes when looking at an object, in other words to detect the possible nested micro-affordances associated with the object (for example a precision grip could comprise several nested microaffordances: a grip with the thumb and the index, a grip with the thumb, the index and the middle finger, with more or less strenght etc...). Quickness of the categorisation in precision or power grip classes could then be an advantage for real-time adaptation.

But some limitations are to be exposed. The calculation of conditional probabilities through gaussian probability density function implies that a parameter could have a zero probability given a certain grip class. This pulled the probability of this grip to zero, while the probability of the competing grip automatically became one, biasing the classification of the object. A second limitation is the ad hoc hypothesis that parameters are independent, which could induce errors for other parameters than the ones we used.

When seven objects of each category were learned by the classifier, the selection made by the classifier and human choice became significantly different probably because classifier's selection only account for a calculation made on the basis of mean and variance of the three parameters representing the objects. This calculation is always the same and as long as enough objects are learned the mean and variance of each class' parameter began to show little variability no matter the learning matrices. This shows that the algorithm used with this classifier produces a rigid classification, and cannot, at some point, reproduce the diversity created both by the complexity of our cerebral structures and the variations of embodiment between different human beings.

Yet this classifier can reproduce, in the majority of cases, human grip's choice in a small amount of time, and with few parameters needed to be taken into account. This shows that micro-affordances could be reproduced in some way with a simple computational system using naive bayesian classification, suggesting that some early stages of the processes linked to human micro-affordance could be performed by some simple probabilistic mechanisms.

Future studies should take more parameters for an object by cutting up the objects in three parts in order to determine the type of grip and the position of the grip on the object (Faria et al., 2014), and introduce action's consequences (Hommel, 2015; Shin, Proctor, \& Capaldi, 2010) through tactilo-kinesthetic parameters (Pfister et al., 2014), like pressure induced by the weight of the object, or muscle tension, in order to permit an efficient grip with a simple classification algorithm. We should also investigate the classifier's performance when an increased number of objects are learned and classified.

## Acknowledgments

We would like to thank Johan Briglia, Jean-Pierre Rivet and Firas Kaddachi for their contributions to this work. We also thank Epsylon's DynaCSE team and LIRMM's IDH team for welcoming us during our thesis, and Paul Valery University for funding this thesis.

#### Abstract

The standard approach posits that analogical inferences are generated by copying unmapped base relations, substituting base entities by their corresponding target ones, and generating slots for unmapped base entities. Contra this account, results from Experiment 1 revealed that analogical inferences seldom include relations that resemble the base relation from which they were derived. Most of the inferences, however, could be categorized as exemplars of a schema-governed category capable of characterizing the base information to be projected. To gather further precision about the criteria that guide inference generation, in Experiment 2 we showed that analogical inferences tend to match the base information from which they are derived in values of salient dimensions of the relational category to which they belonged. Our results suggest that the relational constructs employed in modeling analogical inference should move beyond one-term multiplace predicates so as to include more complex relational structures.

Keywords: analogy; inference; relational category.

## Introduction

Analogical thinking is a central mechanism in human cognition (Gentner, 2003; Hofstadter \& FARG, 1995; Holyoak \& Thagard, 1995), playing an important role in activities as diverse as categorization, problem solving, scientific discovery, decision making, and argumentation (Gentner, Holyoak, \& Kokinov, 2001). In all these activities, analogy involves establishing a mapping between the compared situations and transferring new knowledge from a more familiar situation (base analog) to a less familiar one (target analog).

Almost all current theories of analogy agree that the alignment that takes place during mapping should satisfy the constraints of one-to-one mapping and parallel connectivity, (e.g., Falkenhainer, Forbus, \& Gentner, 1989; Gentner, 1989, Holyoak \& Thagard, 1989; Hummel \& Holyoak, 1997). While one-to-one mapping requires that each element in one situation maps to at most one element in the other situation, parallel connectivity entails that if two predicates are matched, their arguments must be placed in correspondence according to their roles. The following analogy illustrates these constraints:

> Base analog: John loved Mary and this made John give Mary a perfume

> Target analog: Peter loved Susan

While one-to-one mapping implies that pairing John with Peter should prevent pairing John with Susan, parallel connectivity dictates that if love has been paired with want, John must be placed in correspondence with Peter and Mary with Susan, as agents and patients, respectively, of the previous matched relations.

Theories of analogy also agree in that base assertions that are connected to the collection of mapped elements but which do not have a counterpart in the target will be brought over as candidate inferences. To formulate these inferences, the cognitive system would apply some variant of a copy with substitution and generation mechanism (CWSG; e.g., Falkenhainer et al., 1989; Holyoak, Novick, \& Melz, 1994; Hummel \& Holyoak, 2003). In our example, after projecting the base higher order relation cause to the target, the cognitive system would generate and transfer a "template" proposition like "Peter [give or a similar action"] Susan [something like a perfume]" into the target. This template proposition is generated from "John gave Mary a perfume", via copying give, substituting John by Peter and Mary by Susan (matched during mapping), and generating a slot for the entity perfume.

[^413]Supporting the postulations of the dominant theories of inference generation, there is some evidence that people tend to apply the syntactic constraints of one-to-one mapping (i.e., previous correspondences will dictate substitutions in CWSG) and systematicity (i.e., people are more likely to import an inference from base to target when the fact is causally connected to other matching facts) (e.g., Clement \& Gentner, 1991; Gentner, Ratterman, \& Forbus, 1993; Markman, 1997). There is also evidence that people tend to apply pragmatic criteria to derive their inferences (Spellman \& Holyoak, 1996). The application of these principles would be in the service of guaranteeing some minimal initial plausibility and relevance for the generated inferences (see, e.g., Holyoak et al., 1994).

As a pattern-completion process that takes maximal advantage of the mapping process, CWSG can be regarded as fast and computationally inexpensive. As most theories agree, analogical inference mechanisms should not be required to provide an adequate content to the produced inferences, something that should allegedly rely on post-inference stages of analogical reasoning such as evaluation and adaptation (Holyoak et al., 1994). The question arises as to whether the information conveyed by the templates obtained via CWSG can adequately guide post-inference generation processes in filling them in a semantically appropriate way.

In our example, if we repeat give, there is some probability of generating semantically appropriate inferences from the template "Peter gave [something like a perfume] to Susan" simply by replacing perfume by another exemplar of toiletry. However, while substituting perfume with spa set gives rise to a somewhat adequate inference, substituting perfume with deodorant would be inappropriate. It seems that combining give with an exemplar of toiletry will be adequate only if it gives rise to an instance of say, "manifestations of love". In this sense, the strategy of repeating the base relation and searching for a new exemplar of the base entity categories seems insufficient to guarantee some minimal semantic appropriateness of analogical inferences, to the extent that it requires some kind of "semantic supervision" from more complex category structures that the analogizer should keep in mind during the process. Combining substitutes (similar relations) of the relation give with substitutes of the entity perfume so as to obtain cases of "manifestations of love" would require even more thoughtful control. Just to exemplify, if we replace give by lend, no toiletry seems appropriate to generate a demonstration of love, although we can generate an exemplar of this category via replacing perfume by "his new car" or by "his weekend house at the beach".

The second problem with the CWSG strategy is that it can lead to inconvenient fixations, since many combinations of non similar verbs and objects could result in manifestations of love: write her a poem, prepare her favorite meal, or pick some wildflowers. Searching for cases of manifestations of love without the semantic restrictions imposed by the mechanism of CWSG seems to be a more flexible and productive strategy.

Based on the above considerations, we propose an alternative to CWSG which consists in categorizing the base analog information from which the inference will be derived as an exemplar of a schema-governed relational category (SGC), and searching for new exemplars for this category. Members of SGCs such as murder share a structure that can be instantiated by very different exemplars (Gentner \& Kurtz, 2005; Goldwater, Markman, \& Stilwell, 2011; Markman \& Stilwell, 2001), such as "Fred thrust a knife into Gina’s heart", "Mary had Bob drink poison", or "The offender disconnected the patient's oxygen supply". When the situations in an analogical comparison are exemplars of a SGC, the similarity between the relations and entities of the compared events is no longer necessary to have a good analogy (Minervino, Oberholzer, \& Trench, 2013). The analogical relatedness between "John gave Mary a perfume" and "Peter wrote Susan a poem" is not based on semantic resemblances between give and write or perfume and poem, but rather on the fact that both acts represent exemplars of the SGC "manifestation of love". In this sense, the limitation of CWSG seems to stem from treating analogical inference as an element-by-element pattern replacement guided by isolated similarities, and from not considering the broader meaning of the facts described by propositions. When this broader meaning is taken into account, the cognitive system can do away with element-to-element similarities.

With the aim of determining which of these alternative mechanisms constitutes a better account of how analogical inferences are generated, one of the conditions of Experiment 1 served to document the extent to which analogical inferences produced by participants involve relations that are similar to those of the base analog (as posited by dominant theories), as well as the extent to which they involve facts that pertain to the same schema-governed category as the base effect. In order to confirm that participants' inferences took into account the analogical relation between the target and the source-as opposed to representing plausible consequences of the target analog considered in isolation-, the inferences generated by the abovementioned group were contrasted to the inferences produced by a second group of participants who had to propose likely consequences of the target situations, but without having previously received an analogous source.

## Experiment 1

## Method

Participants and Design Fifty students of psychology at the University of Comahue (mean age $=22.86$ years, $S D=$ 3.42 volunteered to participate in the experiment. They were randomly assigned in equal number to the analogy and the target-only groups. The dependent variables were (1) the similarity between the relation of the base effect and that of the inferred situation, and (2) whether or not the inferred situation belonged to the same SCG as the base effect on which it was inspired.

Materials Ten sets of stimuli were built, each one comprising a base and a target analog. The base analog consisted of a base cause that engenders a base effect. The base causes consisted in three-place predicates in which an agent exerts an action over an object, and directed to a patient. The base effects were predicates in which the former patient exerted another action to another object, but which is directed to the former agent. Participants were tasked with generating a consequence of the target cause that they deemed analogous to that of the base analog. Table 1 displays a sample of the experimental materials.

Table 1: Sample of experimental materials, Experiment 1

| Set \# | Category | Situation |

Procedure Participants in the analogy condition received a brief written explanation about the potential of analogical comparisons to infer new information about a target situation. The instructions presented the main activity as one in which they were going to receive a first situation comprising a cause and its associated effect, followed by a second situation for which they had to proposed an effect that could be considered analogous to that of the original fact. Participants of the target-only group received a brief written explanation about how people hypothesize effects for
certain facts. The instructions presented the main activity as one in which participants were going to receive a simple situation, with the task of proposing a likely effect. Participants received the stimuli in random order. The experimental stimuli were presented on a computer screen, with participants typing their answers within prespecified fields. The administration took place in groups ranging from two to five participants, with each participant working individually. Participants were allotted a maximum of 30 min to complete the trials at their own pace.

Coding Each of the inferences proposed by participants was analyzed along two key dimensions: (1) the extent to which the action included in an inference was semantically similar to that of the base effect of the corresponding set of materials-a central prediction of the CWSG approach-, and (2) whether o not the inferred fact and its corresponding base effect belonged to the same schema-governed category. To carry out the first analysis, two judges unfamiliar with the purpose of the study received a ten-page table in which the verbs of the critical base effects (one from each set of materials) were matched against the verbs of all the inferences generated by participants for that particular set. Judges were asked to rate the similarity of the verb-pairs using a 5 -point scale ( $1=$ highly dissimilar; $5=$ highly similar). They worked independently of one other, and the scores given by the two judges to each of the verb-pairs were averaged. Judges' scores were found to be reasonably reliable, Cronbach's $\alpha=$.797. While verbs yielding an average score of three or more were classified as "similar", those obtaining an average score of less than three were sorted as "dissimilar". In order to perform the second analysis, two additional judges received each of the inferences proposed by participants preceded by its corresponding target cause and followed by a list of four words or brief descriptors representing SGCs, with the instruction to draw a mark next to any of the descriptions that could be used to categorize the target effect (they could mark as many as they wanted, or leave all of them unchecked in case they considered that none of them applied). For all inferences corresponding to a given set of materials, the list of event categories comprised two SGCs that corresponded to the base effect and two SGCs that did not correspond to the base effect, all presented in random order. For example, for Set 1 (see Table 1), one of the participants generated the inference "The grandson played with the stove". In order to determine whether this inference could be encompassed by the same SGC as the base analog in which it was inspired, judges received the target cause plus the inference at stake, coupled with the following event descriptions: (1) revenge, (2) dangerous situation (3) jealousy reaction, and (4) risky situation. Inferences were scored as sharing a SGC with the base effect in all those cases where the two judges checked at least one of the two "correct" event descriptors (danger and/or risk), regardless of whether they agreed on which of the correct descriptors was checked.

## Results and Discussion

The verbs of the inferences generated by participants of the analogy group resembled those of their corresponding base effect in $31.6 \%$ of the cases. It should be noted, however, that $12.7 \%$ of the inferences generated in response to the target analog alone (i.e., those of the target-only group) involved verbs that resembled those of the base effect received by participants of the analogy group. More fine-grained analyses using chi-square statistics revealed that the rate of utilization of similar verbs by the analogy group differed from the rate of spontaneous utilization of those same verbs by the target-only group in 4 of the 10 sets of materials (see Table 1).

With regards to SGC similarity, judges' analyses showed that while the inferences generated by the analogy group involved the SGC of the base effect in $88 \%$ of the cases, the inferences produced in response to the target analog alone belonged to these same categories in $34.4 \%$ of the cases. Chi- square tests revealed that for all 10 sets of materials the probability of generating an inference that pertains to the SGC of the base effect by participants of the analogy group was higher than the proportion of inferences pertaining to those same SGCs within the target-only condition (See Table 1).

The low proportion of semantically similar relations among the inferences produced by the analogy group suggests that the mechanism of postulating target relations that resemble their counterparts in the base analog, as dictated by CWSG, cannot adequately account for how analogical inferences are derived. In contrast, the fact that the vast majority of the inferences belonged to the same SGC as the causal consequent of the base analog suggests that the dominant mechanism involved in the generation of analogical inferences consists in analyzing the SGCs to which the base effect belongs, and generating further exemplars of such categories.

[^414]Having documented that the majority of inferences were exemplars of a relational category that was readily applicable to the base analog effect, a sensible research question concerned whether inclusion to such relational category suffices as a criterion for generating analogical inferences. As suggested by data obtained by Minervino et al. (2013), a factor that seems to influence the perception of analogical resemblance between exemplars of a SGC has to do with whether the target situation matches the base situation along the most salient dimensions of the relational category to which they belong. Taking the category robbery as an example, the analogability of two exemplars depends on whether they match in central dimensions such its importance, violence or planning. Experiment 2 was aimed at determining whether the observed sensitivity to this constraint generalizes to analogical inference.

As in Experiment 1, participants received a base analog comprising two causally related situations, followed by the presentation of a target situation that was virtually identical to the causal consequent of the base analog and by the task of completing the target situation with a consequence that they deemed analogous to that of the base. The main difference with Experiment 1, however, was that the exemplars of SGCs that were employed as the effects of the base situations were chosen to instantiate either a high or a low value along a central dimension of the relational category to which they belonged. The purpose of the experiment was to assess the extent to which the exemplars of SGCs included in participants' inferences matched the consequent of the base situation in terms of its values along the manipulated dimension.

## Experiment 2

## Method

Participants Twenty-four students of psychology at the University of Comahue (mean age $=21.1$ years, $S D=3.36$ ) volunteered to participate in the study.

Materials and Procedure Ten new sets of materials were built. The sets had the same general structure as those of Experiment 1, with the main difference being that for each base cause we derived two possible base consequences instead of one. These two consequences belonged to the same SGC, but differed from each other in that they scored differently along a central dimension of such category. As an example, the base cause $A$ paleontologist brought fossils to the Trelew Museum was followed either by the base effect The museum commissioned a statue of the paleontologist (an instance of reward with a high value in the dimension "magnitude") or by The museum issued a diploma to the paleontologist (low value in the dimension "magnitude"). Table 3 displays a sample of the experimental materials.
To ensure that participants encoded the base consequences as members of the SGC whose critical dimension was being manipulated, participants were explicitly informed about the specific category to which the base consequence belonged (see Table 3).

Table 3: Sample of experimental materials, Experiment 2

| Set | Category | Base and target situations |
| :---: | :---: | :---: |
| 1 | REWARD | BC : A paleontologist brought fossils to the Trelew Museum $\mathrm{BE}_{\mathrm{hv}}$ : The Museum commissioned a statue of the paleontologist $\mathrm{BE}_{\mathrm{lv}}$ : The Museum issued a diploma to the paleontologist TC: Another paleontologist brought important fossils to the Rawson Museum |
| 2 | ROBBERY | BC: The old lady trusted her house's keys to her nanny <br> $\mathrm{BE}_{\mathrm{hv}}$ : The nanny sold the old lady's jewelry <br> $\mathrm{BE}_{\mathrm{lv}}$ : The nanny took a book from the old lady's house TC: Another old lady trusted her house's keys to her nanny |
| 5 | CONTRI- <br> BUTION | BC : A young man was invited to a barbecue by his friends $\mathrm{BE}_{\mathrm{hv}}$ : He volunteered to pay the meat to his friends <br> $\mathrm{BE}_{\mathrm{lv}}$ : He volunteered to bring matches to his friends <br> TC: Another young man was invited to a barbecue by his friends |

Note. BC: Base Cause; $\mathrm{BE}_{\mathrm{hv}}$ : Base effect with high values on a key dimension of the relational category; $\mathrm{BE}_{\mathrm{lv}}$ : Base effect with low values on such dimension; TC: Target Cause.

Two complementary booklets of materials were built. In each version half of the sets were coupled with consequences instantiating low values along the manipulated dimension of the SGC to which they belonged, and half with consequences embodying high values along such dimensions. The procedure was identical to that on Experiment 1.

Coding Two new judges received each of the inferences generated by participants coupled with the critical dimension that corresponded to that set of materials. They were asked to rate how it fared along such dimension using a 5-point scale ranging from the minimum to the maximum possible levels along the manipulated dimension (e.g., for the reward example, they had to rate the magnitude of the reward from $1=$ very small, to $5=$ huge). The scores given by the two judges to each of the inferences were averaged. Judges' scores were found to be reliable, Cronbach' $\alpha=.823$.

## Results and Discussion

The inferences generated out of base facts ranking high along the manipulated dimensions obtained higher scores than those generated out of base facts displaying lower levels along that dimension $(M=3.18, S D=0.40$ vs. $M=2.18, S D=$ $0.36, t(25)=-10.05, p<.001$.

These results demonstrate that the way in which the base effect fares along a critical dimension of the SGC to which it belongs constrains the way analogical inferences will fare along such dimension. In order to gather a subtler estimate of the strength of this association, judges were also required to score the base effects along the manipulated dimensions. The correlation between the scores assigned to the base effects and those of their associated inferences was strong, $r$ $=.476, n=260, p<.001$. Furthermore, in $71.54 \%$ of the cases the scores of the generated inferences along the manipulated dimension were no farther than one point away from those of the base analogs on which they were inspired.

## General Discussion

A key prediction of the CWSG approach to analogical inference consists in that people will tend to construct their inferences repeating the base relations from which the inferences will be derived or replacing them by similar ones. Against this position, Experiment 1 showed that people do not care much about preserving similarity to base relations but instead focus on generating new exemplars of the SGC applied to the base information from which inferences are derived. In Experiment 2 we collected data favoring a further hypothesis associated to our category-based perspective, namely, that when proposing new exemplars of SGCs people tend to generate cases that fare closer to the base exemplar along critical dimensions of the category to which they pertain.

We have argued that the templates generated by CWSG could sometimes be insufficient to guide the analogizer in generating semantically sensible inferences during the post inference stages of evaluation and adaptation. Returning to the example presented in the Introduction, the chances of generating semantically appropriate inference from the template "Peter [give or a similar action] Susan [something like a perfume] seems rather low. We speculated that while some toiletries could perhaps result in a sensible inference, others do not, and that post-inference generation mechanisms have no semantic basis to distinguish between them.

The standard approach to analogical inference generation could argue that "something like a perfume" should not be interpreted as "an exemplar of toiletry", and that this interpretation is to some extent caricaturizing CWSG, since an intelligent system operating in an analogical mode will not be guided by superficial similarities such as membership to a same category, but would rather interpret it as, say, "give + things that a woman finds romantic". In this sense, the system would promote the search for new exemplars of this ad hoc category (e.g., a teddy, necklace or a bouquet). The problem with this argument is that the very consideration of this ad hoc category supposes the prior conceptualization of the template as a "manifestation of love", something that the analogical machinery has not generated. It is possible that the generalized support that the CWSG approach has received comes in part from the fact that programmers inadvertently read far more understanding than is warranted into the templates produced by this mechanism, as an effect of projecting the SGC that they apply to capture the whole meaning of the template.

The standard approach could also argue that the analogical machinery was not meant to deal with the activity of comprehending the analogs, but rather to start operating once the analogs have been fully comprehended (see, e.g., Morrison \& Dietrich, 1995). In this vein, the analogical engine would receive the fact that John gave Mary a perfume already interpreted as a case of "carrying out a very romantic manifestation of love" (i.e., as a case of this category, and with some specific properties). A problem with this argument is that this conceptualization cannot be captured by a relation-defined as one-term multiplace predicates. The execution of a very romantic demonstration of love would be propositionally represented, stricto sensu, as CARRY OUT [John, ((VERY) ROMANTIC (manifestation of love)), Mary]. The essential information to be transferred is located in an argument represented as a noun (manifestation of love) and its property (VERY ROMANTIC), and not in the one-term predicate outside the brackets (CARRY OUT).

We are far from calling into question the importance of relational aspects in analogical thinking, but we believe it is necessary to discuss and amplify the meaning of "relational", so as to avoid reducing it to one-term multiplace predicates. It should be broadened to include, for example, relational structures as those captured by SGCs. In these structures, relations are only a constituent, being other thematic roles (e.g., agents, patients, objects or instruments) just as important. For example, if an instance of the category "manifestation of love" includes the relation give, the agent's intention should be to awake certain emotions in a person, the patient has to be a candidate for being emotionally affected by the agent at stake, and the object should be pleasant to the patient. The complex interdependency of the constituents of a fact that make it pertain to a SGC makes it proper to talk about these categories as "relational" structures, but the sense of the term is broader than the one employed in computational models of analogy (i.e., a one-term multiplace predicate). The relational character of these categories is also evident in the extremely different situations that can constitute exemplars of a SGC, which could differ even in their relations defined in the traditional way.

## Acknowledgments

We thank Micah Goldwater for suggesting how to operationalize whether participants' inferences belonged to the SCG of the source. This work was supported by the National Agency for Scientific and Technical Research (ANPCyT) under Grants PICT 2352 and PICT 2650, by the University of Comahue under Grants B213, C123 and C134, and by the National Council for Scientific and Technical Research (CONICET) under Grant PIP 0567.

# An Investigation of Factors that Influence Resource Allocation Decisions 

Percy K. Mistry (pkmistry@uci.edu)<br>Department of Cognitive Sciences, University of California Irvine, Irvine, CA 92697-5100 USA<br>Jennifer S. Trueblood (jennifer.s.trueblood@ vanderbilt.edu)<br>Department of Psychology, Vanderbilt University, 111 21st Ave S Nashville, TN 37240 USA

#### Abstract

We investigate how people allocate a limited set of resources between multiple risky prospects. We found that only a small percentage of decisions followed some form of naive diversification or mean-variance optimization. In general, people were less mean-variance optimal than a naive $1 / \mathrm{N}$ heuristic. Aspects of choice sets, such as domain, skew, and second order stochastic dominance, affected resource allocation decisions in a similar manner to their influence on single choice gambles. Individual traits traditionally linked to risk propensity seem to manifest in terms of the degree to which people are inclined to diversify. Lower risk aversion and higher risk seeking traits are linked to increasing diversification. Risk congruency, the degree to which peoples' self-reported and elicited risk aversion matches, moderates how susceptible people are to cost framing nudges. We find evidence for heterogeneous clusters where people either under-weight or over-weight segregated costs, leading to the same nudge producing opposite behavioral results within two risk incongruent groups.

Keywords: resource allocation; risk tolerance; risky choice; individual differences; nudges

## Introduction

There are many instances where people have to distribute a limited set of resources between multiple choice options. These can be personal (e.g. investment in a set of retirement funds; constructing a stock portfolio; budgeting household expenses) or institutionalized (e.g. capital allocation, bank lending decisions, government budgets) monetary decisions. These could also be non-monetary decisions such as distribution of labor, time, bandwidth, etc. The choice options often vary in terms of their potential costs and benefits, which are probabilistic in nature. Each choice option may thus be represented as a risky prospect which has some probabilistic distribution of outcomes. There is a large amount of literature that examines the decision making process when people have to select only one out of 2 or more risky prospects, that is, where all resources are invested in a single prospect.

There are limited studies however, that extend this to a resource allocation paradigm, namely, how do people distribute a limited set of resources between 2 or more such risky prospects? Some studies suggest that people follow the $1 / \mathrm{N}$ heuristic, which proposes that people tend to naively diversify allocation across the available prospects (Benartzi \& Thaler, 2001; Bardolet, Fox, \& Lovallo, 2011), although this is often the case only for a subset of the people making these decisions. The normative version of this problem is extensively studied in economics - what optimal strategies should people adopt? However there is limited research examining whether people come close to adopting such optimal strategies.

It is important to understand how people deviate from optimality, and to understand what aspects of choice sets influ-
ence the resource allocation process. We highlight that measuring optimality and sensitivity to choice sets is more complex in resource allocation tasks compared to simple choice gambles. For simple choice gambles, a cognitive account will typically entail valuation of different prospects, and specification of a deterministic or probabilistic decision rule to compare these valuations. The decision rule for resource allocation needs to be more complex to allow for allocation weights to be placed for each gamble. It needs to take into account aspects such as choice bracketing - whether the valuation of choices is performed at an aggregate portfolio or segregated choice level. These aspects may influence whether drivers of decision making that explain single choice behavior can also explain resource allocation decisions. Further, choice bracketing may also affect how sensitive people are to cost framing nudges, where outcomes are re-framed into a gross higher outcome, set-off by a corresponding cost element. We report an experimental study on resource allocation and show how manipulation of different design factors affects the allocation behavior. The main questions we ask are (1) do people naively diversify?, (2) how sensitive are people to choice set manipulations?, (3) how well do measures of risk traits explain individual differences in resource allocation behavior?, (4) how sensitive are people to cost framing nudges?and (5) how optimal (or sub-optimal) is allocation behavior?

## Experiment

In this experiment we test people's preferences for distributing a fixed set of resources between multiple risky prospects. 50 undergraduate students from Vanderbilt University participated in the experiment. The cover story for the task was that participants had to play the role of the head of a company that had the opportunity to invest a fixed amount of money (hypothetical $\$ 100,000$ ) into one or more of 4 possible projects. Participants were advised that all projects had the same expected time to completion and their objective was to maximize the return on the invested amount. They were required to invest all the money, but could distribute this in any proportion between the 4 projects, including allocating no resources to one or more projects. Each project had two possible outcomes - success or failure. They were provided with the probability of success $\left(p_{S}\right)$ and failure ( $p_{F}=1-p_{S}$ ) for each project, as well as the percentage returns on their investment depending on whether a project succeeded or failed. A successful project always had a positive return, whereas a failed project resulted in either a lower positive or a negative return. The 4 projects always varied in terms of the variability (standard deviation) of return outcomes. Participants were given

Figure 1: Example interface where participants allocate a fixed set of resources between 4 risky prospects using either text inputs or a moving slider scale.

Figure 2: Example interface of how participants receive feedback for each individual prospect after each trial. The proportion of green to red balls is based on the ratio of probability of success to failure. One of the balls is chosen at random to generate a realized outcome.
an example and a practice trial to familiarize themselves with the interface (see Figure 1). After each trial, participants were provided feedback on the outcome. The outcome was based on the described probability of success and dynamically (randomly) picked by the computer program. The process of realization of the outcome for each project was graphically displayed to the participants. For each project they were shown a box containing $100 \mathrm{X} p_{S}$ green balls and $100 \mathrm{X} p_{F}$ red balls. The computer program randomly traversed the box space and eventually picked one of the balls. A green ball implied success and a red ball implied failure (see Figure 2). The returns on the investment for each project were updated based on these outcomes before moving on to the next trial.

## (A) Between-subjects conditions

Participants were split into 2 groups of 25 students each. The between subjects design entailed different rewards, with the rest of the design factors being identical between the two groups. Group 1 participated for course credit, and group 2 for financial compensation. This between-subjects condition tests whether financial incentives affect resource allocation behavior. There is mixed evidence for this in tasks involv-
ing risky choices (Beattie \& Loomes, 1997). Participants in group 2 received a fixed payout of $\$ 5$ plus an incentive ranging from $\$ 0$ to $\$ 10$ that was linked to their performance on the task. For group 2, at the end of the experiment, one of the trials was randomly selected. The incentive component was calculated as $\$ 5$ plus or minus $\$ 0.10$ times the \%returns achieved on that trial, but limited to the range $\$ 0-\$ 10$. For example, achieving a loss of $20 \%$ resulted in an incentive of $\$ 5-0.1(20)=\$ 3$, and achieving a gain of $20 \%$ resulted in an incentive of $\$ 5+0.1(20)=\$ 7$. This allowed for the incentive to be framed as reductions for losses and increments for gains. The total payout including fixed and incentive components ranged between \$5-\$15.

## (B) Within-subjects factorial design

Each participant completed 36 portfolio choice decisions. There were 12 unique decisions based on a 2 (second order stochastic dominance - present vs absent) X 2 (domain - gains vs mixed) X 3 (skew - none, positive, negative) within-subject factorial design. Each of these 12 decisions was repeated in 3 blocks, with the order randomized within blocks. Although the underlying decision remained equivalent across blocks, the three blocks varied in terms of a cost framing effect. The details of the choice set manipulation are given below:
Second order stochastic dominance (SOSD; 2 levels): In the first level, all prospects in a trial had equal expected value, but the 4 prospects had progressively higher standard deviation. As a result, each prospect had SOSD over the subsequent riskier prospects. In the second level, the prospects were not mean preserving, and riskier prospects (higher standard deviation) also had higher expected values. Thus there was no SOSD. Any behavioral account that is based on a weakly increasing concave utility function, or mean-variance optimization, predicts that prospects with SOSD over other prospects will be a dominated preference. Accordingly, optimal resource allocation under such an assumption would imply allocating $100 \%$ of the resources to the safest prospect. SOSD present choice sets allow a parameter free estimation of deviation from mean-variance optimal allocation. On the other hand, choice sets that do not involve SOSD choices allow measuring the level of risk tolerance within a meanvariance optimization framework.

Domain (DM; 2 levels): In the first level, all-gain domain, all outcomes including project failures resulted in positive returns. In the second, mixed domain, the average returns across prospects on failure were negative. Domain manipulation allows us to test for the effects of asymmetric gain-loss utilities within the portfolio choice framework.

Skew (SK, 3 levels): In the first level, all prospects had zero skew, that is, success and failure were equally likely. In the second, all except the safest prospect had negative skew, that is, failure outcomes were more likely. In the third, all except the safest prospect had positive skew, that is, success outcomes were more likely. Symmonds, Wright, Bach, and

Dolan (2011) showed that risk and skewness are differently encoded in the brain. People have been shown to be relatively averse to negatively skewed gambles (Deck \& Schlesinger, 2010). Manipulation of skew allows us to test whether these effects extend to the portfolio choice paradigm.

Purchase cost framing nudges (PC, 3 levels): In the first level, there are no extraneous purchase costs. In the second and third levels, the outcomes from the first level were translated and re-framed into higher gross outcomes accompanied by an appropriate purchase cost. This re-framing led to prospects that were expected-value-equivalent to the prospects presented in the first level. In the second level, the amount of re-framing was increasingly higher with increasing variability (risk) of prospects outcomes. In the third, the re-framing decreased with increasing variability (risk). The trials were presented in a blocked design with three blocks corresponding to the 3 purchase costs conditions, with the order of the 12 problems in each being randomized. The theory of mental accounting suggests that people may account for re-framed outcomes and corresponding costs in a segregated manner, including under or over weighting the cost component relative to the outcomes. The re-framing thus can act as a nudge, pushing people towards allocation to riskier prospects in the second level and safer in the third level if they underweigh the re-framed costs. The direction of the nudge would be reversed if people over-weigh re-framed costs.

## (C) Testing for risk traits

After the allocation task, participants were required to complete one set of paired lottery choices (Holt \& Laury, 2002), summarized as $H L$, with a higher score indicating greater elicited risk aversion. They also completed the DOSPERT financial risk-taking $(D F)$ subscale (Blais, 2006), with a higher $D F$ score indicating higher self-reported risk seeking behavior, and a locus of control (SL) scale (Rotter, 1966), with higher $S L$ scores indicating a higher self-reported external locus of control. All of these influence risky decision making in single choice tasks.

## (D) Defining the dependent variables

The simplest way of measuring a resource allocation decision is to look at the allocation weights $\left(w_{i}\right)$ for each $\left(i^{\text {th }}\right)$ prospect, where $\Sigma_{i=1}^{N} w_{i}=1$, and $N$ is the total number of choices available. Lopes and Oden (1999) proposed that there are individual differences in whether people approach risky decision making from a perspective of security (protecting low outcomes) or potential (maximizing high outcomes). A simplistic measure of people's security and aspiration levels are measured by the weight allocated to the two extreme prospects - safest $(S)$ and riskiest $(R)$ respectively. In addition, the Herfindahl index $(H)=\sum_{i=1}^{N} w_{i}^{2}$, where $N$ is the total number of prospects in the choice set, measures the degree of diversification (Rhoades, 1993). When all weights are equal, $H$ takes the minimum value of $1 / \mathrm{N}$ (maximum diversification) and when all resources are allocated to a single prospect,
$H=1$. For $\mathrm{N}=4$, values close to 0.25 indicate naive diversification, values close to 0.5 indicate some form of conditional diversification (equal allocation to 2 of 4 prospects), and values close to 1 indicate concentration in a single prospect. These measures $S, R$, and $H$ reflect segregated measures based on attention paid to individual prospects.

Often, the emergent characteristics of the aggregated portfolio are of greater interest than the individual choices. Most normative theories of portfolio choice are based on optimizing some function of the portfolio characteristics. Since a portfolio can be represented as a probability distribution over outcomes, the most common characteristics are derived from the moments of the resulting portfolio. We calculate the expected value $(V)$, and the standard deviation $(D)$ of the aggregate portfolio.

Finally, we test for differences between the 2 cost framing conditions. The framing conditions are setup so that correctly accounting for the costs and translation of outcomes should result in no difference between behavior across the three conditions. However, discounting of the costs framed separately would result in a preference for prospects with a higher degree of framing. In one condition, riskier prospects are subject to higher framing (we denote this condition as $F_{1}$ ), and in the other, safer prospects are subject to higher framing, denoted as $F_{2}$. Discounting the costs would result in higher selection of riskier prospects in the first and safer in the second framing condition. We calculate susceptibility to nudges as, $N=\operatorname{mean}\left[\left(S_{F_{2}}-S_{F_{1}}\right),\left(R_{F_{1}}-R_{F_{2}}\right)\right]$. A value of $N$ close to 0 indicates that people are not susceptible to cost framing nudges. A high positive value indicates that people underweight separately framed costs, and thus are nudged towards options with higher framing (larger translation of outcomes). A high negative value indicates that people over-weight separately framed costs, and thus are nudged towards options with lower framing (smaller translation of outcomes).

## Results

## (1) Is there evidence for naive diversification?

Diversification is directly measured using the Herfindahl index (H). The left panel in Figure 3 shows the distribution of $H$

Figure 3: Distribution of Herfindahl index across participants and trials. The color shading shows the number of unique prospects (1 to 4) selected on each trial.

Table 1: Mean values of dependent behavioral measures by design factor. Differences are tested using a Bayesian repeated measures ANOVA for main effects of design factors. Significant differences, measured by log Bayes factors (LBF) $\geq 2.3$ are highlighted in bold.

|  | SOSD |  | Domain |  | Skew |  |  | Cost framing |  |  |

| Risk tolerance ( $Q_{\varepsilon}$ ) | - | 63.7 | 19.9 | 107.5 | 64.7 | 52.4 | 73.9 | 67.0 | 76.1 | 48.0 |

across participants and trials. The color shading also shows the distribution of the number of unique prospects selected on any trial. A naive diversification strategy would indicate a value of $\mathrm{H}=0.25$. A large mass of the distribution lies between the range of 0.25 and 0.5 , with further peaks at 0.5 and 1.0 indicating choices where people selected 2 of the 4 prospects equally, or invested all their resources in a single prospect, respectively. The $1 / \mathrm{N}$ heuristic (naive diversification), proposes that people tend to split allocations evenly between available choices. A variant of this strategy called the conditional 1/N heuristic (Huberman \& Jiang, 2006) proposes that people split allocations evenly across a small number of choices rather than the total number of choices available. Using thresholds suggested by Huberman and Jiang (2006), 11\% of the choices can be summarized as single prospect concentration, $7 \%$ as a conditional diversification into 2 prospects, and $4 \%$ as naive diversification into all 4 prospects.

## (2) Sensitivity to choice set manipulations:

The mean values of the dependent behavioral variables grouped by experimental factors (which define the type of choice sets) are summarized in Table 1. We conduct a Bayesian repeated measures ANOVA analysis (JASP-Team, 2016) testing for main effects of these design factors. A log Bayes factor, $\mathrm{LBF} \geq 2.3$ is considered significant, and highlighted in bold in Table 1. There is no evidence that the incentive condition had any effect on $S, R, H, V$, or $D$, hence the remainder of the analysis combined data from the course credit and financial incentive conditions. There is no evidence that the level of diversification as measured by $H$ is affected by the domain, skew, or SOSD manipulations. There is evidence for a main effect of domain (LBF 28.1), SOSD (LBF 12.8), and skew (LBF 3.2) on $S$. Allocation to $S$ is higher in the mixed domain (mean $39 \%$ ) than in the gains domain (mean 29\%), higher in the SOSD (mean 37\%) compared to non-SOSD (mean $31 \%$ ) condition, and higher in negative skew (mean $37 \%$ ) than positive skew (mean $31 \%$ ) conditions. There is evidence for a main effect of domain (LBF 9.6) and SOSD (LBF 4.3) on $R$. Allocation to $R$ is higher in the gains domain (mean 30\%) than in the mixed domain (mean 24\%), and higher in the non-SOSD (mean $29 \%$ ) compared to the SOSD (mean $25 \%$ ) condition. $V$ and $D$ are expected vary
with domain and SOSD by design. There is no evidence for a main effect of skew on $V$, but there is evidence (LBF 6.9) for a main effect of skew on $D$. Participants exhibit the lowest $D$ (mean 3.6) in the negative skew condition and highest $D$ (mean 4.39) in the positive skew condition, indicating a marked preference for lower variability in the negative skew condition.

## (3) Trait-based individual differences

To test if the measured traits influence behavior in the portfolio allocation task, we use a Bayesian ANCOVA analysis treating the between and within subject choice manipulation factors as random effects and testing for the effects of covariates locus of control (SL), risk aversion (HL), and financial risk seeking (DF). We find evidence of an effect of HL (LBF 5.7) and DF (LBF 2.9) on $S$, and an effect of HL (LBF 13.2) on $R$. These indicate that higher risk aversion (higher HL and lower DF scores) are linked to higher allocation to the safest prospect and lower allocation to the riskiest prospect, as might be expected. Testing for effects of the locus of control (SL), we find evidence of an effect on $S$ (LBF 3.7), and on $R$ (LBF 6.2). These indicate that increasing external locus of control is also linked to higher allocation to safest and lower to the riskiest prospect. Directionally, this is in contrast to findings based on risky gambles (Rotter, 1966) which showed that increasing external locus of control was associated with waging more money on riskier bets.

Figure 4 shows the joint density of \% allocations to $R$ and $S$. The color coding in the three panels shows the mean level of trait scores. Areas in the centre indicate diversificationlike behavior. Interestingly, all 3 mean scores are pretty similar for both extreme decisions ( $\mathrm{R}=100 \%$ and $\mathrm{S}=100 \%$ ), but are different for the central areas representing diversification (lower HL scores and higher DF scores). It seems that risk aversion and risk seeking measures are more indicative of how extreme (concentration vs diversification) people are in their allocations, rather than whether they prefer safer or riskier prospects. We find evidence of an effect of HL (LBF 1.4) and DF (LBF 13.4) on $H$. These indicate that higher risk aversion is linked to lower diversification. This behavior is however contrary to the popular notion that diversification leads to reduced risk.

Figure 4: Joint density of $\%$ allocation to safest vs aspirational prospects. The size indicates the $\%$ of all trials. The 3 panels plot the same density data, with the color coding in the 3 panels showing the mean level fo risk trait scores ( $S L, H L$, and $D F$ respectively).

## (4) Sensitivity to cost framing nudges:

Testing for differences between the framing and no framing conditions, we find a significant effect (LBF 10.3) of whether or not there is some cost framing on $H$, so that framing of either type reduces diversification, with mean H increasing from 0.44 in the no framing condition to 0.49 in both the cost framing conditions. One hypothesis is that the introduction of an additional cognitive element induces people to reduce their diversification. This is supported by the observation that in the no framing condition, people selected all 4 prospects on $55 \%$ and either 1 or 2 prospects on $22 \%$ of the trials. Compared to this, in the framing conditions (combined), people selected all 4 prospects on $45 \%$ and either 1 or 2 prospects on $33 \%$ of the trials.

Testing for differences between the two cost framing conditions $F_{1}$ (higher risk framing) and $F_{2}$ (higher safety framing), a Bayesian repeated measures ANOVA shows evidence that there is no effect on $H$ (LBF -2.7), $S$ (LBF -0.4) or $R$ (LBF -1.9) . Similarly, there is no effect of choice set conditions on $N$. This seems to indicate that people are not susceptible to differential cost framing effects and adequately account for segregated costs and translation of outcomes. However, we find that risk traits are significant moderators of susceptibility to nudges. We have two measures of risk aversion, a self-reported $D F$ and elicited $H L$. When these two are congruent, that is, people show both high (low) self-reported and elicited risk aversion, the susceptibility to nudges is lowest, at 0.04 . When these are incongruent, and people selfreport higher risk aversion but elicited preferences show riskseeking behavior, the susceptibility to nudges is higher, at 0.06 , showing a higher discounting of segregated costs. Most interestingly, when these are incongruent, and people selfreport lower risk aversion but elicited preference show higher risk aversion, the susceptibility to nudges is in the reverse direction, at -0.11 . This can be interpreted as an over-weighting of segregated costs, leading to a nudge away from choices that had a higher framing effect. The combination of risk congruency and self-reported risk aversion have a significant (LBF 4.7) effect on susceptibility to nudges, and represents a source of significant heterogeneity.

## (5) How optimal is allocation behavior?

One of the most popular normative theories of resource allocation is modern portfolio theory (MPT), characterized by mean-variance optimization (Markowitz, 1952). It states that people should select weights that optimize the balance between the expected value and standard deviation of the resulting portfolio. The optimization is a function of a risk tolerance factor $Q$, with lower values of $Q$ indicating preference for safer portfolios and high values of $Q$ indicating preference for riskier portfolios. Given a set of prospects, the theory proposes an efficient frontier of possible weight allocations that result in optimization between the desired portfolio mean $(V)$ and variance (standard deviation $D$ ). Given an implicit objective to maximize $V$ and minimize $D$, the frontier represents portfolio choices such that no other combination of weights can result in an increase in $V$ without an increase in $D$, or a decrease in $D$ without a decrease in $V$. Note that the efficient frontier does not depend on risk preference $Q$, but where the selected portfolio lies along the efficient frontier is dependent on the individual preference parameter $Q$. The set of weights $(x)$ on the efficient frontier for a particular value of $Q$ can be found by minimizing the expression : $x^{T} \Sigma x-Q E^{T} x$. Here $E$ is a vector of expected returns on the individual prospects and $\Sigma$ is the covariance matrix for the returns on the prospects.

Actual portfolios constructed by participants may not lie on the efficient frontier. For any observed portfolio allocation we can calculate the minimum distance of the observed portfolio characteristics from the efficient frontier, which gives the smallest distance to optimality. This distance is dependent on the mean and SD values of individual prospects within a choice set. To enable comparison across choice sets and analyze the impact of factors we calculate the ratio of minimum distance to optimality for the observed portfolio to the largest possible minimum distance to optimality for any combination of weights in the choice set. This is denoted as MPT-error, $d_{\varepsilon}$. The risk tolerance value corresponding to the closest point on the efficient frontier is denoted $Q_{\varepsilon}$, and can be inferred to be the risk tolerance level for that choice. Note that in SOSD trials, all prospects have the same EV, and the efficient frontier is a single point that coincides with $100 \%$ allocation to the
safest prospect. Thus, SOSD trials provide a parameter free estimate of $d_{\mathcal{\varepsilon}}$, but do not allow an estimate for $Q_{\varepsilon}$.

Table 1 provides the mean MPT-error and risk tolerance levels by design factor levels. Conducting a Bayesian ANOVA analysis and comparing against a null model that included participants as random effects, we find evidence for the effect of SOSD (LBF $\infty$ ), domain (LBF $\infty$ ), and skew (LBF 2.3) on $d_{\varepsilon}$. We find evidence for the effect of domain (LBF 36.7) and cost framing (LBF 1.1) on $Q_{\varepsilon}$. The distance to optimality $d_{\varepsilon}$ measured as a percentage of the largest possible distance to optimality has a mean of $(31 \% ; 18 \%)$ for SOSD and non-SOSD choice sets; $(31 \% ; 18 \%)$ for gains and mixed domains; and ( $24 \%$; 22\%; 27\%) for no skew, negative skew and positive skew choice sets. As a comparison, $d_{\varepsilon}$ for a $1 / \mathrm{N}$ portfolio would be $(28 \% ; 13 \%)$ for SOSD and nonSOSD sets, $(25 \% ; 16 \%)$ for gains and mixed domains, and $20 \%$ for all skew sets. On an average, the actual allocations that people make are less optimal from a mean-variance optimization standpoint than what a simple $1 / \mathrm{N}$ heuristic would result in. The mean $d_{\varepsilon}$ is $(22 \% ; 26 \% ; 25 \%)$ in the no-framing, and 2 framing conditions. Although the differences are not statistically significant, directionally, framing conditions lead people further away from mean-variance optimality.

The mean inferred risk tolerance $Q_{\varepsilon}$ is 20 in the gains domain and 107 in the mixed domain, indicating that risk tolerance is highly contextual, rather than a stable trait. The mean inferred value of risk tolerance $Q_{\varepsilon}$ is 67 in the no-framing condition, 76 in the higher-riskier-framing condition, and 48 in the higher-safer-framing condition, reflecting sensitivity of risk tolerance to framing effects. Measures of risk traits (SL, HL, DF) do not have any effect on the closest distance to optimality. Evidence is inconclusive (LBF 0.9) for the effect of SL on $Q_{\varepsilon}$.

## Conclusion

The key findings can be summarized as: (1) Only a very small subset of participants follow a naive diversification or $1 / \mathrm{N}$ heuristic. (2) Design factors such as domain, skew and SOSD across options influence the allocation that people make in extreme (safest or riskiest) prospects, directionally similar to the effect that these factors have in single choice gambles. (3) We show that individual traits traditionally linked to risk propensity seem to manifest in terms of the degree to which people are inclined to diversify. Lower risk aversion and higher risk seeking traits are linked to increasing diversification. These traits do not seem to be consistently linked to risk tolerance when measured within the MPT framework, and do not seem to influence the relative levels of risk and safety observed in resource allocation behavior. The results are counter-intuitive to the popular notion that diversification is linked to a reduction of risk. (4) We find that cost framing nudges affect the level of diversification. While the effect of nudges seems insignificant at an overall level, a deeper analysis shows traitbased clusters. We find that risk congruency, whether peo-
ples' elicited and self-reported risk aversion are congruent, is a strong moderator for susceptibility to nudges. We find evidence for heterogeneous clusters where people either underweight or over-weight segregated costs leading to the same nudge producing opposite behavioral results in the two risk incongruent groups. (5) We find that people are not optimal under a mean-variance optimization objective, and that on an average, a $1 / \mathrm{N}$ heuristic is closer to mean-variance optimization than the actual observed behavior.

# Predicting Individual Differences in Working Memory Training Gain: A Machine Learning Approach 

Shafee Mohammed<br>University of California Irvine, Irvine, California, United States<br>Benjamin Katz<br>University of Michigan<br>Chelsea Parlett<br>University of California, Irvine<br>Martin Buschkuehl<br>MIND Research Institute, Irvine, California, United States<br>Susanne Jaeggi<br>University of California, Irvine

#### Abstract

Working memory (WM) capacity is critically important for the success in school and complex cognitive activities across the lifespan. Training WM skills has shown to lead to improvements in a variety of important cognitive tasks. One's performance on an adaptive and challenging longitudinal WM intervention may serve as an assay of cognitive plasticity. With over 400 participants having completed a minimum of 15 sessions of WM training, we have a rich dataset that allows investigating individual differences and other factors that might determine training outcome using a novel machine learning techniques. Preliminary results suggest that factors such as age, type of n-back, and baseline abilities significantly impact one's ability to improve in training. Other factors such as gender and whether or not training was supervised were not significant. Finally, our model allows prediction of training gain with $78 \%$ accuracy.

# A Longitudinal Study of Differences between Predicted, Actual, and Remembered Personal Change 

Sarah Molouki (smolouki@uchicago.edu)<br>Daniel M. Bartels (bartels@uchicago.edu)<br>Oleg Urminsky (oleg.urminsky@chicagobooth.edu)<br>University of Chicago<br>5807 S. Woodlawn Ave., Chicago, IL 60637

#### Abstract

We investigated people's assessments of their own personal change over time, comparing predicted, actual, and recalled change in personality, values, and performance. On average, participants underestimated the absolute magnitude of their personal change in both prediction and recall. However, people specifically neglected negative future change, resulting in overly optimistic predictions of improvement. In contrast, recall of positive and negative change was relatively more balanced, such that assessments of past improvement were better calibrated on average. Our findings provide insight into how people think about their own identity over time and address disparate theories in the literature regarding predictions of personal stability versus improvement.

Keywords: self-perception; social cognition; future self; past self; identity; time; personal change

## Introduction

Imagine yourself ten years in the future. Will you be nearly the same person you are today, just with grayer hair? Or will you be a significantly changed person with different abilities, values, and personality characteristics? If you will have changed, will you have improved, becoming wiser and kinder, or will you have taken a turn for the worse, ending up lazy and irresponsible?

A large literature on beliefs about personal change suggests that people tend to perceive a trajectory of improvement in their own lives. People claim to possess more desirable characteristics in the present than they did in the past (Wilson \& Ross, 2001), and think they will continue to get even better in the future (Haslam, Bastian, Fox, \& Whelan, 2007; Kanten \& Teigen, 2008). They even expect basic personality traits to improve over most of their lifespan (Krueger \& Heckhausen, 1993), despite some evidence indicating that these traits are mostly unchanging (e.g., Costa \& McCrae, 1989).

Expectations of improvement over time have been associated with people's normative theories about personal identity. For example, Newman, Bloom, \& Knobe (2014) find that when evaluating change in others, people associate improvements, but not declines, with a person's core identity, or "true self." In this view, positive change is a natural part of human development. Other work highlights the finding that people consistently predict greater personal improvement for themselves than for others (e.g., Haslam et al., 2007, Kanten \& Teigen, 2008), suggesting possible self-enhancement motives.

However, separate lines of research suggest that people view their own identity as stable over time. Loewenstein, O'Donoghue, \& Rabin (2003) describe a systematic tendency to overestimate the degree to which one's own preferences will persist into the future. More recently, Quoidbach, Gilbert, \& Wilson (2013) described an "End of History" illusion. In this framework, people reported more change in the past than they anticipated for the future in various domains, possibly due to the difficulty of envisioning new changes in prospect.

It is unclear how to reconcile findings related to belief in self-improvement with research suggesting people underestimate personal change more generally. Do people in fact think that they have stopped changing, or do they believe the biggest improvements are yet to come? Because many studies highlighting people's difficulty in projecting future change have used changes with no obvious direction (e.g., preference change), these have not been directly connected to ideas about improvement or decline. Are these two effects (expectations of improvement and perceptions of stability) in fact conflicting, or do they co-exist? Furthermore, many studies of personal change over time examine either perceptions or actual change, but not both. Are people's predictions and recall of change well-calibrated with their actual change, or do they diverge?

We address these questions by examining both absolute and directional personal change using a repeated measures longitudinal design. Although Quoidbach et al. (2013) found that one sample of people tended to predict less future personal change than the other sample remembered experiencing in the past, the study did not assess actual change in individuals over time. In the current studies, we measure and directly compare predicted, actual, and recalled change within each of our samples of young adults. We use actual change as a baseline to determine whether any observed differences between predicted and remembered change are due to biases in estimating future change, distorted memories of past change, or both. Furthermore, we use measures of personality, values, and ability that allow us to examine change both in magnitude and direction.

Our findings reconcile potentially conflicting viewpoints in the literature by suggesting that although people do underestimate the magnitude of their own change, this finding is moderated by the valence of
change (i.e., whether the change is positive or negative). Averaging across our measures, we find that people are fairly well-calibrated in recall, but specifically underappreciate the potential for future decline. Because people's predictions tend to omit undesirable changes while acknowledging positive change, they simultaneously underestimate absolute change and overestimate (future) improvement on average.

## Methods

We compared predicted, actual, and recalled personal change over time in two panel surveys of young adults, who completed all measures online. Study 1 assessed 155 participants $(60 \%$ female, mean age $=22.1)$ in December 2013 (Time 1) and December 2014 (Time 2), and Study 2 assessed 203 participants ( $73 \%$ female, mean age $=22.6$ ) in May 2016 (Time 1) and September 2016 (Time 2). Study 2 was a conceptual replication that addressed several additional questions raised by the results of Study 1. (Key differences between the two studies are indicated in the "Measures" section). For Study 1, college students (in any year of college) were recruited from across the United States using an online panel. In Study 2, participants were graduating college seniors recruited by the experimenters. Although the time period measured in Study 2 (4 months) was shorter than that in Study 1 (1 year), all participants in Study 2 would be undergoing a major life change (i.e., college graduation) during the study period, making it plausible that significant changes in personality and values could occur between the two assessments.

In both studies, we measured change in personality traits and values, and in Study 2 we also measured change in performance on an objective (knowledge) task. Personality and values are viewed as important psychological determinants of personal identity (Bartels \& Rips, 2010; Chen, Urminsky, \& Bartels, 2016) and have been used in previous research on perceptions of personal change (Quoidbach et al., 2013). We chose these constructs rather than other personal attributes (such as preferences) because change in personality, values, and performance can be measured both directionally (increase vs. decrease) as well as in terms of absolute difference. The performance measure is included to verify that our findings are replicable in a domain where actual change is measured objectively rather than by taking a difference in self-report measures.

Participants provided current measures of personality and values (and performance, in Study 2) at both Time 1 and Time 2. At Time 1, they also predicted what their responses would be at Time 2. At Time 2, they provided their recollection of their responses at Time 1 . Reports of current values were always made before reports of predicted or recalled values.

## Measures

Personality In Study 1, participants completed a 5-item personality assessment that involved reading a short description of each Big Five dimension (i.e., extraversion,
agreeableness, conscientiousness, emotional stability, and openness) and judging how much they thought this trait applied to them. Ratings of current, predicted and remembered personality were reported using a $0-100$ slider scale for each trait. In Study 2, participants again completed this 5 -item personality measure, and also completed a previously validated 10 -item measure with a 7-point response scale (TIPI; Gosling, Rentfrow, \& Swann, 2003; also used in Quoidbach et al., 2013). ${ }^{1}$

Values Values were assessed using a 10 -item version of the Schwartz Value Inventory (Lindeman \& Verkasalo, 2005; also used in Quoidbach et al., 2013), measuring the personal importance of self-direction, stimulation, hedonism, achievement, power, security, conformity, tradition, benevolence, and universalism. Current, predicted, and remembered value importance ratings were measured on a $9-$ point scale.

Performance In Study 2, participants also answered ten factual multiple-choice questions at each time point (e.g., "How many of the world's tallest buildings are located in the United States?"). Both sets of 10 questions were pretested to ensure that they were of similar difficulty and that there were no floor or ceiling effects. At Time 1, participants reported perceptions of their current and future performance, and at Time 2 they reported their perceived current and past performance.

## Pre-Test to Determine Valence of Change

We used a separate online sample ( $N=100 ; 41 \%$ female, mean age $=34.3$ ) to assess how people generally view increases and decreases in the characteristics of interest. For each personality dimension and value, participants used a 0 100 scale to separately report how they would feel ( $0=$ extremely displeased, $50=$ neither pleased nor displeased, 100=extremely pleased) if the given characteristic were to increase and decrease. For each of the five personality dimensions as well as 9 out of 10 values, the average response was significantly greater than 50 for increases (suggesting people consider increases to be desirable) and significantly less than 50 for decreases (suggesting people consider decreases to be undesirable). ${ }^{2}$ Accordingly, for our basic directional analyses, we treat personality and value increases as improvements, and decreases as declines.

In Study 2 (after all other measures were completed), we also asked individual participants to report whether they viewed each personality or value change as an improvement or decline, in order to better account for individual variation in these beliefs. Coding each individual's changes as improvements and declines based on their own assessments

[^415]rather than the mean assessment from the pretest did not change the overall pattern of our results. However, future research can further explore the effect of individual differences in perceptions of valence of these characteristics, as well as perceived differences in the magnitude of their importance.

## Change Calculation

We quantify change in two different ways, looking at both absolute change and directional change. Absolute change (i.e., the absolute difference between an item at Time 2 and Time 1) represents deviation from the present state, ignoring direction. Averaging absolute change across items captures the distinction between variability (high values indicating large changes in any direction) and stability (low values indicating little change). This approach was taken in some prior work, including Quoidbach et al. (2013).

However, looking only at absolute change neglects the fact (confirmed in our valence pre-test) that increases and decreases generally differ in desirability. For example, an increase in creativity might be considered an improvement, but a decrease of equivalent magnitude might be a decline. Measuring only absolute change obscures this distinction.

We therefore also computed measures of directional change (i.e., directional difference in Time 2 minus Time 1 ratings). Averaging across individual items thereby captures the distinction between overall improvement (high positive values indicating net positive change), overall stasis (nearzero values indicating no net change), and overall decline (high negative values indicating net negative change).

In our analyses of personal change, we compare the following: (i) predicted change (difference between future prediction provided at Time 1 and current rating provided at Time 1), (ii) actual change (difference between current rating provided at Time 2 and current rating provided at Time 1), and (iii) remembered change (difference between current rating provided at Time 2 and past recollection provided at Time 2). Using both absolute and directional measures allows us to examine a) whether participants perceive a smaller absolute magnitude of personal change than they actually undergo over time and b) whether participants overestimate their net improvement over time, for both prediction and recall.

## Results

Across our two studies, we have 6 distinct measures for which we examine change over time. For each of these measures, we conducted both an absolute and a directional comparison of the three types of change (predicted, actual, and recalled). Overall, we found that people predicted future improvement, but systematically neglected the possibility of future decline. This resulted in both an overall underestimation of mean absolute future change and an overestimation of mean future improvement. In contrast, people were more balanced in recall, remembering both positive and negative past change. Thus, although people
underestimated the magnitude of past change, they did not express a directional bias in recall.

Although the overall pattern of our results supports this finding, results across measures and studies were highly variable. We report weighted mean effect sizes (Cohen's $d$ ) across all studies in the text of the paper to summarize our overall findings, and present figures depicting the findings of each individual measure to capture the variability across them.

Absolute Change Across our six domains of measurement, we found significant differences in absolute magnitude between predicted, actual, and recalled change. Overall, participants predicted that they would undergo less personal change in the future than they recalled undergoing in the past (mean $d=-0.18, p<.001$ ), which replicates previous findings (Quoidbach et al., 2013). However, this effect was small in comparison to their larger tendency to underestimate the magnitude of both past (mean $d=-0.51$, $p<.001$ ) and future (mean $d=-0.72, p<.001$ ) change relative to actual change. This general pattern was found in all absolute measures except for the 10 -item personality measure used in Study 2 (see left hand side of Figures 1-4).

Figure 1. Absolute and directional change for 5-item personality measure. Error bars represent $95 \%$ CI.
n.s. nonsignificant, $* p<.05, * * p<.01, * * * p<.001$

Figure 2. Absolute and directional change for 10 -item personality measure (Study 2). Error bars represent $95 \%$ CI. n.s. nonsignificant, $* p<.05, * * p<.01, * * * p<.001$

n.s. nonsignificant, $+p<.10, * p<.05,{ }^{* *} p<.01,{ }^{* * *} p<$ . 001

Net Directional Change We conducted a directional analysis that accounts for valence, treating net increases in all measures as improvements and net decreases as declines (based on the results of our pre-test). On average across our measures people predicted more positive future change than they subsequently remembered (mean $d=0.30, p<.001$ ). Our analysis also revealed a tendency to predict more positive net future improvement than actually occurred (mean $d=0.22, p<.001$ ). In contrast, people's recall of past improvement was more variable. Although in Study 1, participants recalled greater improvement in personality and values than they had experienced, recalled improvement was either equal to or less than actual improvement for all measures in Study 2 (right hand side of Figures 1-4). Across all measures in Studies 1 and 2, average recall of past directional change was not significantly different from actual change (mean $d=-0.03, p=.377$ ).

Individual-level "Improvers" and "Decliners" How do we explain the fact that on average, participants simultaneously predicted less absolute change and greater improvement than they actually experienced? To better understand the observed mean-level effects, we separated individuals based on whether they exhibited an overall increase versus decrease in their predicted, remembered, and actual change. For most of our measures across both studies 1 and 2, actual directional change across the sample was near zero. However, this was not because people had remained stable (as evidenced by the large absolute change findings); rather, the sample was evenly split into those who had experienced net improvement and those who had experienced net decline of equal magnitude. ${ }^{3}$ In contrast, predicted change was significantly positive for each measure because fewer individuals predicted that they would decline over the study period, and those that did so reported declines of significantly smaller magnitude than the average decline experienced. Figure 5 illustrates this pattern using the personality and value measures from Study 1.

Figure 5. Decomposing directional change in Study 1 into decline and improvement for a) 5-item personality measure, b) values measure. Column width indicates proportion of participants indicating net improvement or decline and height denotes magnitude of improvement or decline. Error bars represent $95 \%$ CI.

[^416]We then performed separate analyses on those who had actually improved versus those who declined. This revealed that the underestimation of absolute magnitude of change at the sample level in fact comes disproportionately from those participants who are underpredicted their actual decline (rather than from those who underpredicted their actual improvement). Although similar patterns are observed for each of our measures, we describe the 5-item personality measure from Study 1 in detail to illustrate the form of this effect. Participants who experienced an actual net decline in the measured traits over the year $(\mathrm{M}=-12.25, \mathrm{SD}=11.65)$ had instead predicted a mean personality improvement of +3.62 ( $\mathrm{SD}=6.67$ ). The difference between these two numbers reflects a significant directional overprediction of improvement by 15.87 scale points, $t(77)=10.87,95 \%$ CI=[12.96,18.78], $d=1.23, \quad p<.001$. Nevertheless, the absolute magnitude of their predicted change was still smaller than the absolute magnitude of their actual change (i.e., 3.62 vs. $12.25 ; t(77)=5.47,95 \% \quad \mathrm{CI}=[5.48,11.77]$, $d=0.62, p<.001$ ). This yields an underprediction of change when future change is defined only in terms of absolute deviation from zero. In contrast, those who experienced an actual net personality improvement $(\mathrm{M}=+13.07, \mathrm{SD}=11.44)$ had predicted an improvement of +7.73 ( $\mathrm{SD}=7.76$ ). This reflects an underestimation of both their directional improvement and their absolute change by 5.34 scale points, $t(76)=4.05,95 \% \mathrm{CI}=[2.72,7.97], d=0.55, p<.001$.

Comparing the size of these prediction errors reveals that actual decliners made significantly larger errors on average than actual improvers (i.e., 15.87 vs. 5.34 ); $t(152)=5.35$, $95 \% \mathrm{CI}=[6.64,14.42], d=0.86, p<.001$. As a result, we observe an overall improvement bias in the sample, given that the errors made by decliners were biased in the direction of positive change. Figure 6 provides a graphical depiction of this phenomenon.

Figure 6: Comparison of actual (x-axis) versus predicted (yaxis) personality change (Study 1). Each point on this graph represents an individual participant from Study 1, with black dots representing those who actually declined over the period and white circles representing those who improved.

The light gray line represents the line $y=x$ (actual improvement or decline=predicted improvement or decline), which is where each point would fall if predictions were completely accurate. The black line is the regression line relating predicted and actual improvement as fitted from the data. The discrepancy between the black and gray lines to the left of the $y$-axis illustrates the overprediction of improvement in those who actually declined, and the discrepancy on the right side of the graph illustrates the (smaller) underprediction of improvement in those who actually improved.

The finding that those who actually declined underpredicted their decline to a greater extent than improvers underpredicted their improvement was observed across all measures: personality $(t(152)=5.35$, $95 \%$ $\mathrm{CI}=[6.64,14.42], d=0.86, p<.001)$ and values $(t(142)=4.53$, 95\% CI=[0.31, 0.80], $d=0.73, p<.001$ ) in Study 1, and both 5 -item $(t(111)=4.02,95 \% \mathrm{CI}=[3.02,8.88], d=.65 ; p<.001)$ and 10 -item $(t(169)=7.82,95 \% \mathrm{CI}=[0.51,0.86], d=1.17 ; p$ <.001) personality measures, values $(t(182)=2.95,95 \%$ $\mathrm{CI}=[.09, .47], d=.43 ; p=.004)$, and performance $(t(152)=$ $2.56,95 \% \mathrm{CI}=[.14,1.09], d=.40, p=.011)$ in Study 2. However, there was no consistent finding in errors related to recall across studies. In Study 1, those who actually declined made larger errors than those who actually improved for measures of both personality and values. In contrast, across measures in Study 2, actual improvers made errors of equivalent or greater size as actual decliners did in recall.

## Discussion

Overall, the results of our two longitudinal studies reveal that people predict smaller absolute change in personality, values, and performance than they actually experience. However, a directional analysis of the data reveals that this discrepancy is specifically driven by a neglect of negative change. Although on average people experience both improvements and declines over time, they incorrectly predict that their future will consist mainly of improvements. Rather than being the end of their personal trajectory, the present moment represents a watershed of a different sort: the moment when people think a somewhat rocky past resolves into a consistent upward climb. Our findings suggest that looking only at the absolute magnitude of change may obscure important aspects of people's beliefs about their own personal change.

Although people do underestimate the magnitude of their future change, our directional measures reveal that this is not generally caused by expectations of stability in personal characteristics. Rather, at the sample level, those who worsened over our study period were disproportionately likely to have neglected the possibility of decline and instead predicted some smaller level of improvement. Thus, the apparent magnitude effect seems to be driven by a general tendency to overestimate improvement, which is consistent with prior research suggesting that people expect the continued development and emergence of positive
personal characteristics (Haslam et al., 2007; Newman et al., 2014). Previous work also suggests that although people are able to distinguish their future expectations from conceptions of their ideal self, predictions are nonetheless likely to be influenced by aspirations (Molouki \& Bartels, 2017). This may be one mechanism underlying the observed overpredictions of improvement.

Although we found that people overpredicted future improvement, on the whole, we did not find this effect in recall of past change. This may be because past recall is more constrained by reality and episodic facts than future prospection (Kane, McGraw, \& Van Boven, 2009), making people more likely to acknowledge that past decline has occurred even if this was counter to their expectations. However, other research suggests that people do revise their perceptions of the past towards a trajectory of improvement (e.g., Wilson \& Ross, 2001). Although we did find that people overestimated past improvement in Study 1, this pattern did not emerge in Study 2. Further research is needed to explore the source of this heterogeneity (and the large heterogeneity across our measures more broadly), by examining effects of contextual factors such as length of time span, intervening life events, dimension of change, and timing of measurement. In particular, a more careful investigation of our personality measures is needed, as some discrepancies were noted between the 5 -item and 10 -item personality scales used.

In addition to providing a reconciliation of previous findings about perceptions of stability versus improvement, the current work makes an important contribution more broadly to a growing body of literature on people's theories of the nature and persistence of personal identity. Existing research in this area has suggested that people endorse normative theories about a fundamentally good essence that forms the core of one's identity and will be revealed over time (Molouki \& Bartels, 2017; Newman et al., 2014; Newman, De Frietas, \& Knobe, 2015; Strohminger, Knobe, \& Newman, in press; Tobia, 2015). The current research explicitly demonstrates that predictions of personal improvement are more pronounced than actual improvement over time. This finding lends empirical support to the idea that predictions may be influenced by normative beliefs that diverge from a purely descriptive account of personal development. Furthermore, we noted new findings about different patterns of prediction error for those who in fact improved versus declined over the study period. Future research can further explore the interactions between specific developmental trajectories and beliefs about personal identity.

## Acknowledgments

This research was supported by funding from the John Templeton Foundation and the James M. Kilts Center for Marketing at the University of Chicago Booth School of Business. # Visual Data Exploration: How Expert Astronomers Use Flipbook-Style Visual Approaches to Understand New Data 

Fernanda Monteiro Eliott ${ }^{a}$ (fernanda.m.eliott @ vanderbilt.edu)<br>Keivan Stassun ${ }^{b}$ (keivan.stassun@ vanderbilt.edu)<br>Maithilee Kunda ${ }^{a}$ (mkunda@vanderbilt.edu)<br>${ }^{a}$ Department of Electrical Engineering and Computer Science, ${ }^{b}$ Department of Physics and Astronomy Vanderbilt University, PMB 351679, 2301 Vanderbilt Place, Nashville, TN 37235-1679, USA

#### Abstract

What are the cognitive processes in play when someone uses a visualization tool to interactively explore a new dataset? Here, we focus on one particular type of visualization-the scatter plot-which, despite (or perhaps because of) its simplicity, is still one of the most frequently used plot types in many dataintensive disciplines. We conducted a pilot study to investigate how expert astronomers interact with an unfamiliar dataset using a visualization tool called Filtergraph, which supports rapid and easy visualization of large datasets. We present both qualitative and quantitative results, including observations about the temporal dynamics of visual data exploration as well as interesting behavioral patterns that we saw in our participants, such as users taking "circular walks" through the data at various levels of abstraction.

Keywords: Data exploration; graph understanding; information visualization; scatter plots; visualization software.

## Introduction

When astronomer Henry Norris Russell first introduced the now-called Hertzsprung-Russell (H-R) diagram, he wrote, "The appearance of [the figure] suggests the hypothesis that, if we could put on it some thousands of stars, instead of the 300 now available, ...we would find the points representing them clustered principally close to two lines, one descending sharply along the diagonal...the other ...running almost horizontally. ...These two classes of stars were first noticed by Hertzsprung, who has applied to them the excellent names of giant and dwarf stars" (Russell, 1914, p. 287).

In addition to Russell's obvious desire for more data, his wonderfully vivid description conveys the fundamentally visual nature of this discovery. Indeed, the H-R diagram has been called "perhaps the most spectacularly successful example of a simple scatterplot" in all of science (Spence \& Garrison, 1993, p. 1). Today, like many disciplines, astronomy enjoys volumes of data that Russell could only have imagined. However, an astronomer's expertise to make sense out of data-to recognize which patterns represent actual scientific discovery-remains as vital today as it was in 1914.

Most human sense-making with data involves a visuallymediated interaction between the data and the perceptual/cognitive processes of the user-data visualization. Data visualization can be as short and simple as glancing at a printout of a plot on paper, or as lengthy and complex as spending months analyzing and modeling a large dataset. There is an increasing need for interactive data visualization tools that not only leverage the latest in pattern recognition and data mining algorithms, but also place the cognitive needs of the user
front and center-to assist and augment human capabilities in the discovery process (Honavar, Hill, \& Yelick, 2016).

One vital role for data visualization is the open-ended, open-minded exploration of data that leads to unexpected insight, often manifested at first as a "striking" or "interesting" multivariate plot, such as with the H-R diagram. To take a more recent example, an astronomy research team at Vanderbilt University developed a visualization tool called Filtergraph (see Figure 1) designed to allow people to rapidly and easily explore large datasets of up to a few million points (Burger et al., 2013). Using the Filtergraph software to visualize stellar variability data gathered by the Kepler spacecraft resulted in an unexpected and "visually interesting" scatterplot, which in turn led to the discovery of stellar granulation "flicker" and its utility for stellar and exoplanets research, a significant finding that was published in Nature (Bastien, Stassun, Basri, \& Pepper, 2013).

Figure 1: A screenshot of the Filtergraph data visualization interface (Burger et al., 2013), and also the initial view shown to participants in our pilot study.

Here, we report our preliminary results on a pilot study to investigate how expert astronomers interact with an unfamiliar dataset using scatterplots generated by Filtergraph. We use a novel analysis approach that is different from, but complementary to, existing methods that focus on measuring actions or tasks conducted by the data analyst. Instead, our approach measures interactions in terms of dataset attributes: which variables from a large dataset does an analyst look at, when, and why? We present both qualitative and quantitative results from this study, including observations about the temporal dynamics of visual data exploration as well as interesting behavioral patterns that we saw in our participants, such as users taking "circular walks" through the data at various levels of abstraction.

## Related Work

There is a rich foundation of work in HCI (Human Computer Interaction), visual analytics, and infovis that aims to understand the processes by which people interact with and understand data. Sanderson and Fisher (1994) present a widelyused, general framework for thinking about user interactions with an interactive tool in terms of sequences of actions that represent different user functions, such as connecting ideas or introducing comments.

Specifically in relation to data visualization, Yi and colleagues (2007) identify seven modes of interaction with visualization tools, such as select, explore, and filter, that they believe are important for understanding the visual sense-making process. Brehmer and Munzner (2013) present a task typology that bridges low-level interactions with high level tasks and goals during visualization activities. Pirolli and Card (2005) present a detailed cognitive task analysis of visual sensemaking in the domain of intelligence analysis. ElTayeby and Dou (2016) present methods for studying exploratory data visualization that leverage the automated analysis of rich, quantitative interaction $\log$ data to identify and understand underlying patterns of interaction.

Saraiva and colleagues (2005) conducted a very interesting pilot study specifically focused on open-ended, exploratory data analysis in the domain of bioinformatics. They focus on how a visualization tool can complement a dataset in order to facilitate insights that may lead to a discovery. One important issue they addressed was how to define and measure insight. They defined insight based on the context of their work as well as based on characteristics such as time, hypotheses, correctness, and category. Their results show the influence of the visualization tool itself over the processes of human interpretation and insight.

Mayr and colleagues (2016) looked at how mental models parallel a user's use of external visualization tools. They identify key characteristics pertaining to mental models, such as content, structure, coherence, perspectivity, generalizability, and utility, and they review existing empirical methods for conducting user studies to get at these characteristics.

Finally, there is important work being done to understand data visualization and sensemaking in terms of core cognitive capabilities that people bring to bear on such tasks. Healey and Enns (2012) provide a research survey on cognitive theories of attention and perceptual processing as applicable to data visualization. They provide examples of factors that drive visual attention (such as visual feature hierarchies, memory, and prediction) and also factors that impair attention, such as what happens during change blindness, with observations about how improperly designed visualizations can significantly impact a user's mental models of the data.

Tversky (2003) reflects about humans, actions, and space, emphasizing the importance of differences in how people represent space across different spatial reference frames (e.g., in a navigation task versus a graphical understanding task). She includes discussion of the spatial references frames people
use while processing external visualizations of information.

## Methods

We conducted a pilot study to investigate how expert astronomers interact with an unfamiliar dataset using the Filtergraph visualization tool shown in Figure 1. We chose the domain of astronomy as being representative of today's dataintensive disciplines. In designing our study, we wanted to choose a data exploration task that was open-ended enough to provide a realistic challenge to our participants, but also that had at least some constraints so that we could analyze meaningful differences across participants. We decided to invite astronomers to our lab to participate in one-hour sessions, during which they would be instructed to "explore" an astronomy dataset that they had not previously seen. All necessary IRB approvals were obtained prior to the study.

Dataset. We chose a dataset that we believed would not require complex mathematical operations to make sense of, and also that would not be from too specialized a subfield within astronomy. The dataset we chose is described in Berlind et al. (2006) and contains data describing 90, 893 galaxies, which are individually discriminated through 10 attributes (including the galaxy ID), or group separated through 9 attributes (including the group ID), as shown in Table 1.

Table 1: The 19 attributes in the galaxy dataset used for our pilot study (Berlind et al., 2006), along with letter codes used throughout this paper. The last two shaded items represent arithmetic combination of attributes that we observed participants construct on the fly during the study sessions.

| ID_gal | J | AbsMag_g_group-AbsMag_r_group | U |
| RA_gal | K |  |  |

Study protocol. We recruited 7 graduate students in astronomy from the Vanderbilt community, ranging in age from 23 to 28 years old, with 2 identifying their gender as female, 4 as male, and 1 as two-spirited. We ran participants in five sessions: two sessions (S1 and S4) each involved two participants conducting data exploration collaboratively, and the other three sessions (S2, S3, and S5) each involved a single participant. Note that as part of our pilot study design, we decided to include both individual and collaborative sessions to better inform our approaches for future studies.

Participants received gift cards as compensation for their time. Each session proceeded as follows. First, the partici-
pant(s) filled out a short demographic questionnaire. Then, we asked participants to sit down at a computer workstation and use Filtergraph to visualize and explore the galaxy data set. We provided a printout listing all dataset attributes and their semantic descriptions. A member of our study team sat with participants during the session, asking open-ended questions to better understand how the interaction was unfolding. At the end of the session, participants were asked to write down their own impressions about the study, and ideas about what software, tools, catalogs, or other data-related affordances would make their life as an astronomer easier.

Table 2: Session details from our pilot study. $M$ gives the number of major observations in each session, and $N$ gives the number of minor observations.

| Session | \# of participants | Duration (seconds) | M | N |
| :---: | :---: | :---: | :---: | :---: |
| S1 | 2 | 3378 | 12 | 67 |
| S2 | 1 | 3160 | 7 | 47 |
| S3 | 1 | 3289 | 20 | 73 |
| S4 | 2 | 4394 | 19 | 107 |
| S5 | 1 | 2921 | - | - |

Filtergraph settings. To constrain the visualizations used by participants, we asked participants not to change the Filtergraph setting that selects scatterplots as the visualization type. Within the scatterplot setting, Filtergraph offers many interactive options for changing how the dataset is visualized. The attributes assigned to X and Y axes can be changed, and a Z axis attribute can optionally be added. Attributes can also be assigned to the color dimension or used to select or filter out portions of the data. Anywhere individual attributes are used, arbitrary mathematical transformations or combinations of attributes can also be assigned. Additionally, there are options for changing the background plot color as well as the size and shape of data points. When the Z axis is in use, there are options to rotate the plot or change its scale.

All the sessions started from the same home screen, shown in Figure 1, with the X -axis set to attribute A , the Y -axis set to attribute B, and the color set to attribute C (see Table 1).

One concern we had was that participants might get bored or fatigued during the session and generate plots only to fill the time, and not through genuine interest and curiosity in exploring the dataset. Thus, the member of our team who sat with participants tried to be friendly and engaging, to help create a positive session environment. (Note that this member of our team comes from a computer science background, not astronomy, and so we do not believe this "social" aspect of the study sessions introduced significant biases in which parts of the dataset the participants would choose to focus on.)

In addition, after 45 minutes, the participants were informed that they could finish their current activity and end the session, if they wanted to, or they could continue to work for as long as they chose. As it turns out, all of our participants chose to stay past the 45 minute mark, with a minimum session duration of about 48 minutes and a maximum dura-
tion of about 73 minutes; see Table 2.
Analysis approach. We gathered data using a combination of note-taking by study personnel, paper forms, and interaction data collected on the computer workstation through screen recordings of each session. To analyze results, we defined the concepts of major observations and minor observations of the dataset, as illustrated in Figures 2 and 3.

Definition: A major observation is a grouping of contiguously viewed scatterplots within which the attributes assigned to X and Y axes remain constant. When a user changes the attribute assigned to either the X or Y axis (or both), a new major observation begins.

Definition: A minor observation is a grouping of contiguously viewed scatterplots that occurs during a major observation, within which one or more individual, highly related scatterplots are viewed. For example, looking at a 3D scatterplot but rotating the plot to see many different views would constitute a single minor observation of the data.

We used screen recordings to identify major and minor observations within each session. We did not count plots that were generated in the course of defining a single set of plotting parameters (i.e., because Filtergraph redraws plots nearly instantly, while the user might still be typing). Also, sometimes participants assigned the exact same parameters to the current plot, not actually changing the plot at all. We did not count these immediately repeated plots either. Finally, for continuously changing plots, which we saw especially when participants were smoothly rotating or moving 3D plots, we only counted the first and last views as separate plots within the same minor observation.

Exclusions. During session S2, an attribute was plotted by mistake; the participant had intended to plot a different attribute instead and only discovered their mistake after 12 minutes. We do not include these "mistake" plots in our current analysis, though certainly these kinds of mistakes will be considered in future work. In addition, session $S 5$ was qualitatively very different from Sessions S1 through S4. In session $S 5$, the participant appeared to pay very little attention to the semantics of the attributes that were being plotted (even when prompted to consider attribute meanings by our study team member). This participant declared to be selecting attributes randomly, and engaging in a primarily perceptual exploration of the dataset. While we find this pattern of interaction in session S5 extremely interesting, we felt that a different approach would be needed to analyze these data, and so we have left the analysis of session S5 for future work.

## Results and Discussion

Here, we discuss preliminary results from our pilot study. While there is certainly work to be done in analyzing the specific, astronomy-related meanings of participants' data visualization choices, including a detailed criterial analysis on their mental models (Mayr et al., 2016), that type of analysis falls outside the scope of the current paper and will be part of future work. For now, we focus on describing the

Figure 2: For session S1, plots showing the first minor observation for each of the 12 major observations.

Figure 3: For session S2, in chronological order, from left to right: plots showing the 28 minor observations within the fourth major observation. Note the "circular walk": the yellow, red, and blue boundaries indicate 3 different plots that were each observed twice. The six plots with a black background are unclear due to the small number of plotted points.

Figure 4: Number of major observations generated during each session for different combinations of attributes.
general behavioral patterns of data visualization that we observed, including the temporal dynamics of participant interactions with the Filtergraph tool. Table 2 gives details of the five sessions that we ran for this study.

Distribution of major observations by attribute. Consider the 17 data attributes contained in the galaxy dataset (see Table 1). Note that two of the original 19 attributes are ID numbers, for galaxies and groups of galaxies, and so do not capture "meaningful" in the same sense as the other 17. The number of possible major observations that could be made from this data, i.e., possible assignments of attributes to X and $Y$ axes, is $(17$ choose 2$)=272$ possibilities. If we allow mathematical transformations or combinations of attributes, then the number of possible major observations is infinite.

Across all sessions, participants viewed a total of only 38 distinct major observations, as shown in Figure 4. This figure also shows which attributes participants assigned to either the

X or Y axes. Interestingly, only 4 major observations were shared by two or more sessions; this shows the high variability in data exploration paths taken by different individuals.

Attribute I was the only one never assigned to either the X or Y axes. It turns out that this attribute is Boolean; it indicates whether the galaxy is the brightest in its group, and so it makes sense to not be chosen for one of the primary axes. Attributes P (a measure of galaxy morphology) and Q (was there a problem while measuring the galaxy) are the other two categorical variables in the dataset; interestingly, these were assigned to axes at various times during one of the sessions.

The BC combination was the only major observation shared across all four sessions. B gives the longitude of the galaxy group center, and C gives the latitude. So, plotting the BC combination produces what is essentially a spatial "map" of the galaxies represented in the dataset.

Temporal dynamics of data exploration. We are partic-

Figure 5: Distribution of major and minor observations over time, for sessions S1 (top) through S4 (bottom). Each point indicates a group of highly related individual plots (or, for example, a single continuous rotation of the same 3D plot). Major observations repeated within or across sessions are marked by colored labels.
ularly interested in understanding the temporal dynamics of open-ended data exploration. How frequently do our participants switch from one major or minor observation to the next?

Figure 5 illustrates the temporal distributions of major and minor observations for all four sessions. By looking at the blue dots in this figure, we can see the most active periods, the ones in which many plots were quickly generated. We can also see periods in which a single minor observation was studied at some length. (Note also that the large gap early in session S2 is due to data we omitted, as described earlier.) The first point of interest is that participants generally chose to "flip through" the dataset at a fairly brisk pace. Part of this could, of course, be due to the participants knowing they had only one hour to complete the study, but we expect the same to hold in more naturalistic settings as well.

The average duration of minor observations was about 61 seconds, though this distribution has a long tail that falls off fairly consistently and extends to the longest minor observations at around 554 seconds. For major observations, the average duration was about 229 seconds, with a maximum of about 1046 seconds. The durations of major observations seem to show a bimodal tendency, with many major observations falling under the 150 second mark, but another large grouping lying in the 150-400 second range.

Interestingly, participants often returned to the same major observation within the same session. This pattern occurs
not at all in session S 2 , occasionally in session S 1 , and quite a lot in sessions S3 and S4. In sessions S2 and S4, we saw similar "circular walk" patterns within some of the major observations; the participant often returned to the same minor observation that they had started with, before moving on to the next minor or major observation. Figure 3 depicts an example of a "circular walk" within session S2.

Within each major observation, it seems as though participants are directing a type of "movement" from the first to the last plot (depicted via minor observations); a story is being told through the movement of data points across the plots. This notion of movement/story strongly brings to mind the idea of flipbooks. For instance, Figure 3 shows a story regarding the relationship between the attributes $F$ and $E$.

Other qualitative observations. To conclude our presentation of preliminary results, we present a few high-level observations about patterns of data exploration in our study.

Starting point: Participants seemed to choose a starting point to anchor themselves in relation to the dataset. Sessions S1 and S2 began by plotting attributes that involve the spatial position of galaxies, perhaps to let participants establish a mental map of the spatial layout of the galaxy dataset. Sessions S3 and S4 began by looking at attributes like the number of galaxies in each group and the velocity with which each group is moving away from us, perhaps establishing an egocentric reference frame of "us versus the galaxies."

Mouse gestures: Participants frequently used the mouse as a communicative or attention-focusing tool, i.e., to gesture at the visualizations. While some of these were directed at our study team member who was observing the session, many of these mouse gestures also occurred when participants were interacting with Filtergraph and thinking about what to do next. Sessions S1 and S2 exhibited many more mouse gestures than did sessions S3 and S4.

Paper aids: Participants in sessions S1 and S2 relied heavily on the paper printout of attribute details throughout the sessions. Participants in S3 and S4, on the other hand, used the printout at the start, but, during the interaction itself, relied more on the list of attributes provided by Filtergraph.

Collaboration/leadership: In both of the sessions with two participants, we observed that one of the participants seemed to lead the exploratory line of thought. But note that leading does not necessarily means commanding the mouse and directly interacting with the workstation. In one session, the "thought" leader was also the one interacting with Filtergraph, but in the other session, the "thought" leader was not the primary tool interaction person.

Collaboration/corrections: We observed that, in the sessions with two participants, one helped the other to quickly correct mistakenly plotted attributes. In contrast, during session S 2 (which involved a single participant), an attribute was plotted by mistake and not discovered for 12 minutes.

## Conclusion and Future Directions

Our findings highlight a few interesting properties of how domain experts explore an unfamiliar dataset, particularly in terms of temporal and dimensional patterns. The next challenge is to understand how, as people follow exploratory paths through a dataset, they build meaningful cognitive representations of what they see, and how they are able to identify encounters with unexpected, significant data patterns.

We anticipate that temporal patterns are especially important from a cognitive perspective because they describe not just moment-to-moment attentional switches but also serve as a way of marking successive stages at which a person's mental model of a dataset is likely changing. Five minutes spent looking at a single plot, versus five minutes spent "flipping" through multiple plots, are both likely to be equally important modes of exploration. The key is figuring out the cognitive purpose served by each.

We are also intrigued by the frequency of "circular walks" in the exploratory paths taken by our participants. Viewing the same plot twice serves no obvious purpose from a purely statistical or data mining perspective. However, in humans, we predict that these "circular walks" actually serve key roles related to memory, attention, salience, etc.

## Acknowledgments

We would like to thank Dr. Andreas Berlind who generously shared the galaxy dataset we used in our study. This research makes use of Filtergraph, an on-line data visualiza-
tion tool developed at Vanderbilt University through the Vanderbilt Initiative in Data-intensive Astrophysics (VIDA).

#### Abstract

Though most documented sign languages make use of space to denote relationships between predicate arguments, studies of emerging sign languages suggest that spatial reference does not emerge fully-formed but takes time to develop. We present an artificial sign language learning experiment that expands the cultural evolutionary framework to investigate complex linguistic constructions. Our results demonstrate the gradual emergence of consistent devices to distinguish between sentence arguments, some of which rely on iconic spatial contrasts. These findings mirror data from emerging sign languages and point to the cultural mechanisms that facilitate the evolution of complex linguistic structures.

Keywords: language; cultural evolution; learning; communication; sign language; gesture

## Introduction

Sign languages, as manual-visual linguistic systems, are able to represent relationships between a predicate and its arguments using the space around the signer. Though there are differences in exactly how spatial reference is utilised, spatial modulation is attested across most sign languages (Mathur \& Rathmann, 2012). Signers use indexed locations in space to refer to particular arguments, such that a deictic point to an arbitrary location can pronominally refer to the subject or object of a sentence. This mapping can iconically represent a real-word spatial relationship, such that references to arguments in a sentence reflect their orientation in relation to each other in the real world, but that is often not the case and the relationship between referenced locations is primarily grammatical. It has been suggested that the iconic potential of spatial mappings makes the use of space almost inevitable in sign languages (Aronoff, Meir, \& Sandler, 2005), and the beginnings of spatial reference systems have been attested in several emerging sign languages (Senghas, Coppola, Newport, \& Supalla, 1997; Padden, Meir, Aronoff, \& Sandler, 2010).

However, studies on emerging sign languages also suggest that systematic spatial reference is not a property that emerges immediately in a linguistic system, but takes time to evolve over generations of a language (Padden et al., 2010). Spatial agreement systems are used to represent complex relationships between a predicate and its arguments, and as such pose problems for learners. Furthermore, the ability to represent animate agents using the signer's own body may interfere with the development of abstracted spatial reference. Re-
ferring to multiple participants in space requires abstraction away from the signer's body and may therefore take longer to evolve (Padden et al., 2010; Meir, Padden, Aronoff, \& Sandler, 2007). Finally, the use of space is not the only grammatical tool used to denote who does what to whom, and in fact its use is often restricted to particular classes of verbs.

Using a novel experimental method, we ask how systematic spatial reference emerges in a linguistic system, and how the iconic affordances of the manual modality affect the evolution of such a system. Though emerging sign languages provide valuable natural evidence of the early evolution of languages, the experimental research we present here is able to test the particular factors that influence language with a greater degree of control and precision.

Previous experimental research has experimentally demonstrated the importance of cultural evolutionary processes in the emergence of linguistic structure, namely interaction between language users and transmission to new learners of a language (Kirby, Tamariz, Cornish, \& Smith, 2015; Kirby, Cornish, \& Smith, 2008). The gradual development of spatial agreement systems in naturally emerging sign languages similarly points to the impact of interaction and transmission on the evolution of spatial reference. Therefore, we propose a cultural evolutionary stance on the emergence of spatial agreement, and explore the impact of cultural evolutionary processes in a laboratory study. We present a study that investigates the effect of interaction and transmission on the emergence of signals that participants produce to signal complex events with multiple animate arguments. We place silent gesture (where hearing participants with no knowledge of sign language communicate using gesture; GoldinMeadow, So, Ozyürek, and Mylander (2008); Schouwstra and de Swart (2014); So, Coppola, Licciardello, and GoldinMeadow (2005)) within a cultural evolutionary framework that implements interaction between participants, and transmission with an iterated learning model. Pairs of participants communicate about a set of events using only gesture and the gestures they produce are used to train a new pair of participants, who then use what they have learnt to communicate with each other. We provide an experimental account of the evolution of linguistic structure that is informed by data on natural sign languages. The present study offers a more pre-
cise understanding of the cultural evolutionary mechanisms that facilitate the emergence of linguistic structure, and serves to elucidate how modality-specific factors affect the emergence of systematic structure in language.

## Methods

Participants took part in an artificial sign language learning task where they learnt gestures produced by a previous participant in a training stage, before communicating with a partner during testing, using only gesture.

## Participants

50 participants ( 15 male, 35 female, median age $=22$ ) were recruited from the University of Edinburgh's Careers Hub website, and were compensated $£ 7$ for participation in the experiment, which took between 30 and 50 minutes to complete. Participants were self-reported right-handed native English speakers with no knowledge of any sign language.

## Materials

Participants were asked to communicate events, presented orthographically as pairs of sentences in English. Sentences involved two arguments, Hannah and Sarah, who could either be the agent of the sentence, be the goal or recipient of the sentence, or who might not be present in the target sentence at all (see figure 1a for examples). Sentences were presented in pairs at each trial, and pairs of sentences were grouped into blocks of four, where each block comprised a sentence pair of one of four verb types: plain spatial verbs (e.g. to cycle), spatial locative verbs (e.g. to cycle to), physical transfer verbs (e.g. to kick a ball to), and non-physical transfer verbs (e.g. to help; all verbs are shown in table 1 in the appendix). There were four blocks of four pairs in total, giving a total of 16 sentence pairs, and 32 target sentences (figure 1 gives an example of sentences as they would be shown in pairs and blocks). Two blocks consisted of different-agent pairs, such that if Hannah was the agent in the first sentence of a target pair, Sarah would be the agent in the second sentence of that pair, and vice versa. The two remaining blocks consisted of same-agent sentence pairs, such that either Hannah or Sarah was the agent in both sentences in a target pair (e.g. Hannah is walking to Sarah/Hannah is swimming to Sarah). Order of presentation for target sentences was randomised within sentence pairs and within blocks.

Participants were placed in individual experiment booths; target sentences were presented on-screen using Psychopy (Peirce, 2007) and video recording and streaming between networked computers was enabled via custom software, Videobox (Kirby, 2016).

## Procedure

Participants were organised into 5 transmission chains of 5 generations, where each generation was made up of a pair of participants, who communicated with each other during testing (see figure 1b). Participants in generations 2-5 took part

Figure 1: Examples of sentence pairs and blocks (a) and diagram illustrating diffusion chain structure (b). Pairs of participants interact at each generation (dotted lines); gestures produced by 1 participant in a pair are transmitted as training to the next generation (solid lines with arrows). A single chain is made up of 5 generations and there were 5 chains in total.
first in a training stage, followed by a testing stage. Participants in the first generation of each chain only took part in the testing stage, and were therefore required to innovate gestures at the beginning of each chain.

Training stage Participants in the training stage were trained on gestures produced by a participant in the previous generation of the chain. The training model was selected at random from one of the two participants in the previous generation, and the full set of gestures produced by that participant were used as training data. At each trial, the participant was shown a video of their model gesturing, and was asked to select the pair of target sentences they were trying to communicate. Whilst the video was playing, participants were shown an array of sentence pairs onscreen, from which to make their choice. The array of sentence pairs comprised the target pair, and three distractors. The distractors differed from the target pair on either the agent configuration, the verb, or both. For instance, a target pair that had Hannah as agent in the first sentence and Sarah as agent in the second, would have a distractor pair with the same verb construction, but as a same-agent pair, with Hannah as the agent of both sentences. Another distractor would keep the agent configuration, but would replace the verbs with other verbs from the same category, and a final distractor would present both different verbs and a different agent configuration. Building the arrays in this way required participants to specify who does what to whom, without necessarily having to describe Hannah and Sarah (i.e., the role is important, not the individual). The position of each pair on the screen was randomised at each trial, and participants could make their guess by pressing the $1,2,3$ or 4 key, depending on the position on the screen.

Participants were given feedback about whether their guess was correct or incorrect, and shown the correct answer. Participants completed 16 training trials, one for each sentence pair. Participants completed the training stage individually, without any interaction with their partner.

Testing stage Participants in the testing stage communicated with a partner, taking turns to be director (the person gesturing) and matcher (the person interpreting). As director, a participant was shown a sentence pair on screen and asked to communicate it to their partner. A three-second countdown prepared them for streaming and recording, when they would produce their gesture to camera. The directing participant saw themselves onscreen whilst they gestured, with their image mirrored. An unmirrored image was streamed to their partner in another booth. Either participant could interrupt the video stream when they had finished their gesture or were ready to make a guess. The matcher's task was very similar to the training task; they watched their partner gesture on screen and had to select the correct target pair from an array of four. Once the matcher had made their guess, both participants were given full feedback, about both the correct answer and the matcher's selection. Participants switched roles after every block (every four trials) and directed and matched for the full set of 16 sentence pairs, giving a total of 32 testing trials. Order of the blocks and target sentence pairs was randomised for each participant.

## Results

## Gesture coding

Gestures were coded for the presence of an agent gesture, a goal (or recipient) gesture and a verb gesture. For each argument, the type of gesture was coded, as well as the location and path of the gesture. The goal or recipient of the target sentence was frequently omitted from gestures; as such, we focus on differentiation between agents across sentence pairs.

## Differentiation strategies

We identified three main strategies participants employed to differentiate between agents in target sentences: the lexical strategy, the body strategy and the indexing strategy (exemplified in figure 2). All strategies make use of iconic representation, and both body and indexing strategies make use of the space around the gesturer to disambiguate target sentences.

Lexical strategies Two out of five chains differentiate sentence arguments based on the gesture type, using a 1- and 2handshape to denote Hannah and Sarah in target sentences. Though this begins as a way to simply distinguish the first sentence in a target pair from the second, these handshapes come to represent individual arguments in later generations.

Body strategies A further two chains rely on differences in body orientation to signal differences between agents in target sentence pairs. Participants use an iconic spatial strategy to represent sentence arguments. For instance, in figure 2b, the participant orients their body to the right to represent Hannah,
and to the left to represent Sarah.
Indexing strategy Finally, one chain developed a strategy in which locations in the space around the gesturer were indexed to refer to different sentence arguments. In the example shown in figure 2 c , the participant points to her left to signal the agent, Hannah. In addition, her verb gesture moves between the indexed locations for agent and recipient.

Participants show a difference based on sentence type (whether same- or different-agent), producing different gestures to represent different agents, and showing divergence between sentence context over generations of the experiment. Figure 3 shows the proportion of gesture sequences that are different across two sentences in a target pair. Rows show the proportion of variation across different aspects: agent gesture type, location of the agent gesture, location of the verb gesture and path of the verb gesture. Variation across these aspects corresponds to different strategies. Chains 1 and 5 primarily vary gestures on agent type, using the lexical strategy (e.g. figure 2a). Chains 2 and 4 vary gestures based on agent location, as well as verb path and location, as they are implementing a body strategy, where agent and verb are simultaneously inferred through the participant's use of their own body (e.g. figure 2b). Finally, chain 3 shows the primary difference on the location of agent gestures, using an indexing strategy to place sentence arguments in difference locations (figure 2c).

We analysed the changes in agent distinctions over generations in the experiment, collapsing the measures shown in figure 3 across features to simply account for whether or not participants create a distinction between agents in the two sentences of a target sentence pair, investigating whether participants structure signals in similar ways across strategies. A binomial mixed effects model analysed the fixed effects of generation and sentence type on the proportion of different agent gestures, as well as their interaction. Chain, target and participant were included as random effects with random intercepts, and random slopes of generation and verb type were implemented for chain and target, respectively. The random effects structure for participant was nested within chains. Comparison of the model revealed a significantly better fit over a reduced model without the interaction term $\left(\chi^{2}=11.51, p<\right.$ 0.001 ). The model indicated a significant effect of the different-agent sentence type in comparison to same-agent sentence pairs ( $\beta=2.73, S E=0.46, z=5.91, p<0.001$ ), as well as a significant interaction between generation and sentence type ( $\beta=0.69, S E=0.22, z=3.12, p=0.002$ ), though no significant effect of generation ( $\beta=0.04, S E=0.12, z=$ $0.29, p=0.77$ ). Participants were more likely to produce gestures that differentiate between agents in different-agent contexts compared to same-agent contexts, and this contrast strengthens over generations in chains of participants.

We also analysed the effect of verb type on the distinctions participants made. Spatial reference in signed languages is not used across all verbs, but usually affects specific sets of verbs. As such, it is possible that participants in the experi-
ment create distinctions based on semantic properties of the verbs they encounter. We ran a binomial mixed effects analysis that examined the effect of verb type on differences between agent gestures. The random effects structure described above was also implemented here. The model showed no improvement over the null model ( $\chi^{2}=1.82, p=0.61$ ), indicating that participants do not condition differences between sentence pairs based on verb type.

## Discussion

Our results demonstrate the evolution of systematic agent distinctions, which emerge over generations of interacting participants. In addition, participants frequently use iconic spatial mappings to create those distinctions, which become increasingly contrastive over generations in the transmission chains. These findings are consistent with data from naturally emerging sign languages that suggest the gradual emergence of systematic spatial mappings.

## Differentiation strategies reflect sign language structure

The three main strategies that participants employ in the present experiment all find comparable forms in natural sign languages: specifically, as lexical signs, role-shift, and spatial agreement. The latter two strategies make use of the space around the gesturer to create distinctions between agents in the target sentences. The body strategy involves movement of the participant's body to represent sentence arguments, and exhibits similarities to role-shift found in natural sign languages, and can be used in natural languages to distinguish between sentence arguments (Padden, 1986; Cormier, Fenlon, \& Schembri, 2015).

The indexing strategy, however, is the strategy that most closely resembles sign language verb agreement, such that locations in the space around the signer are indexed to refer to different sentence arguments (Liddell, 2003; Padden, 1986; Lillo-Martin \& Meier, 2011). The use of indexing in chain 3 begins on the axis perpendicular to the participant's body; for example, the participant points to themselves to denote Hannah, and points directly away from their body to denote Sarah. Over generations of the chain, the use of indices is abstracted away from the body and indexes are contrasted parallel to the gesturer's body, such that Hannah might be indexed to the left of the participant, and Sarah might be indexed to the right. This change mirrors development in two young sign languages, Al-Sayyid Bedouin Sign Language (ABSL) and Israeli Sign Language (ISL). In both ABSL and ISL, early generations of signers demonstrate greater preferences for spatial contrasts that centre around the signer's body, on the perpendicular axis (Padden et al., 2010). However, later generations show an increase in the use of the parallel axis, as demonstrated in the present study. Furthermore, participants in our study made no distinction between verb types, consistent with findings from ABSL that showed spatial mappings were not restricted to any class of verbs in early generations
of the language (Padden et al., 2010). Our findings, consistent with natural language data, indicate that systematic spatial reference does not emerge wholesale, despite the iconic affordances of the modality, but takes time to emerge.

## The evolution of complex constructions

The gestures participants produce support a gradual evolution of systematic linguistic structure, including the use of space; participants indicate a difference between sentence arguments from the first generation, but the mechanisms used to create these distinctions are neither consistent nor systematic early on. Instead, participants converge on particular strategies to make distinctions over generations, and participants show increasing divergence between the same- and different-agent sentence contexts. Participants' reliance on iconic, spatial gestures supports silent gesture research showing that hearing participants can use deictic indexing to track referents (So et al., 2005), though the present results further demonstrate how such a system evolves through use. The increased consistency of these systems supports previous iterated learning experiments (Reali \& Griffiths, 2009; Smith \& Wonnacott, 2010) that suggest learning leads to regularisation. Participants also demonstrate the negotiation of a system that is both expressive and learnable; they minimise the number of strategies used to convey differences in target sentences, settling on one strategy to use in the majority of trials, sufficient to express the differences in the meanings they are trying to convey. Consistent with previous experimental research, the systems participants produce maximise simplicity and informativeness (Kirby et al., 2015; Regier, Kemp, \& Kay, 2015). Participants systematically signal differences between agents in target sentences, producing gestures that allow successful communication within their pair.

## The effects of iconicity on emergent structure

All participants rely on iconic representations to communicate target sentences to their partners. In particular, the use of the gesturer's body and the use of space around the gesturer allow for iconic representations of animate agents. The privileged status of the body is attested in natural sign languages (Meir et al., 2007), and use of the body is attested in the development of spatial grammatical devices (Meir et al., 2007; Padden et al., 2010; Kocab, Pyers, \& Senghas, 2014). Further, consistent with research on emerging sign languages and experimental research (Padden et al., 2010; Theisen, Oberlander, \& Kirby, 2010), our results suggest a movement away from iconic reliance on the body (e.g. the axis change in chain 3 ) as gestures become more consistent and regular across the system.

## Conclusion

We have demonstrated the emergence of systematic signals to communicate complex events, through the cultural evolution of communicative signals, via interaction between users and transmission to new users. Participants make use of different representation tools, all of which have analogues in natural

Figure 3: Proportion of gestures that differentiate agents in target sentences, based on which aspect of the gesture is varied (agent type, agent location, verb location). Coloured lines show proportions for different-agent (blue circles) and same-agent contexts (green triangles). Columns show the proportions for each chain, at each generation. All chains show differences based on context, though they make distinctions in different ways
sign languages. Our findings support data concerning the evolution of spatial reference in emerging sign languages, which suggest that the phenomenon takes time to emerge and systematise. Using an experimental method, we have been able to observe this gradual evolution in a controlled environment, to test more precisely the mechanisms that drive the emergence of spatial reference. Furthermore, these results shed light on modality-specific effects of iconicity, and their influence on the structure of emerging communication systems.

#### Abstract

Successful performance during multimedia learning requires accurate metacognitive judgments. However, little research has investigated the influence of accurate metacognitive judgments for different representations of information (e.g., text and diagram) on performance during multimedia learning. As such, we investigated if participants' metacognitive judgments for text and diagrams (i.e., content evaluations; CEs) were significantly related to increased performance and higher confidence during multimedia learning. Metacognitive judgments and performance measures were collected from 48 undergraduate participants during 18 randomized trials. Results using multilevel modeling indicated that participants' CEs for text-based content were significantly predictive of performance. Results also showed that accurate CEs for diagrams interacted with accurate multiple-choice responses to predict higher retrospective confidence judgments (i.e., higher confidence). Identifying metacognitive judgments predictive of increased performance during multimedia learning has important theoretical, conceptual, and analytical implications.

Keywords: multimedia learning; metacognition; metacognitive judgments; multilevel modeling; performance; science learning

Research indicates learning with multimedia materials (e.g., text and diagram) is more effective than learning through text alone (Butcher, 2014; Mayer, 2014). Successful multimedia learning entails individuals actively and accurately selecting, organizing, and integrating text- and image-based information into a coherent mental model (Mayer, 2014). However, research suggests learners do not always engage in accurate and effective metacognitive monitoring and regulation during learning with multimedia (Azevedo, 2014). Specifically, research has indicated participants often exhibit overconfidence when monitoring their own understanding during multimedia learning (Serra \& Dunlosky, 2010). The multimedia heuristic suggests learners’ own judgments of learning (JOLs; i.e., how well they will remember the information) are largely inflated when compared to their actual performance because individuals perceive multimedia content as being easier to learn than with text alone (Serra \& Dunslosky, 2010).

Research on metacognitive monitoring during multimedia learning has traditionally employed modified metacomprehension paradigms (based on Nelson \& Narens' metamemory framework, 1990), during which participants are asked to make metacognitive judgments (e.g., ease-oflearning [EOL], immediate and delayed JOLs, retrospective confidence judgments [RCJs]) during various stages of multimedia learning (e.g., Burkett \& Azevedo, 2012; Eitel, 2016; Pilegard \& Mayer, 2015). The major assumption of this research is that the timing of metacognitive judgments made during multimedia learning (before learning, during learning, and after learning) will vary in accuracy, selection of cognitive strategies, and subsequent performance, dependent on the specific experimental manipulation (e.g., delayed JOLs are more predictive of performance than EOLs; Burkett \& Azevedo, 2012; Nelson \& Dunlosky, 1991). As this research has identified that most metacognitive judgments for multimedia are often inaccurate (e.g., Serra \& Dunlosky, 2010), much of the literature has focused on ways to improve metacognitive judgments. For example, some research has focused on manipulating the framing of metacognitive judgment prompts to improve judgment accuracy (e.g., Pilegard \& Mayer, 2015; Vössing, Stamov-Roßnagel, \& Heinitz, 2016). Pilegard and Mayer (2015) compared JOLs (i.e., how well do you remember the content) to judgments of understanding (JOUs; i.e., how well do you understand the information) and found JOUs were more predictive of retention and transfer compared to JOLs. These findings suggest that framing metacognitive judgment prompts (e.g., from JOLs to JOUs) significantly impacts the metacognitive processes employed during multimedia learning, potentially indicating there may be other metacognitive judgments participants use that can successfully influence performance. In support of this assertion, research on hypermedia and self-regulated learning (SRL) suggests several other metacognitive processes may be more predictive of multimedia learning outcomes (Greene \& Azevedo, 2009).

Azevedo, Greene, and Moos (2007) developed a classification scheme by which 35 micro-level metacognitive judgments can be evident during successful SRL with hypermedia-based learning environments. One
example of these judgments is a content evaluation (CE). CEs are judgments learners make to assess the relevancy of the content (e.g., multimedia) they are viewing to their current goal (e.g., answering a science question about a human body system; Greene \& Azevedo, 2009). CEs are key metacognitive judgments for successful multimedia learning, such that accurate CEs can direct participants to study more efficiently. For example, if the goal is to answer a science question about the human body system and participants evaluate the text but not the diagram they are viewing to be relevant to their goal, they should invest more effort and time to study the text (as opposed to the diagram), employ the appropriate cognitive strategy (e.g., make an inference), and therefore be more likely to answer the question correctly.

Other research on metacognitive judgments during hypermedia learning has identified the predictive validity of traditional metacomprehension judgments like RCJs. For example, Mengelkamp and Bannert (2010) investigated the stability of participants' RCJs as they learned about operant conditioning with a hypermedia environment. Results indicated that the absolute accuracy (i.e., difference between judgments and performance) was stable throughout the learning session, and relative accuracy (correlation between judgments and performance) was significantly predictive of hypermedia learning outcomes.

Theories of multimedia learning suggest participants cognitively process information from text and diagrams separately and in different ways (Burkett \& Azevedo, 2012; Mayer, 2014). Additionally, researchers have outlined the multimedia effect to indicate that students demonstrate longer periods of recall and higher levels of retention when learning with text and images as opposed to learning only with text (Butcher, 2014). However, evidence suggests learners do not always engage in effective selection, organization, and integration of multiple representations and instead exhibit a bias toward text-based (as opposed to diagram-based) information during multimedia learning (Hegarty \& Just, 1993). Since cognitive processes are different for text and diagrams, it should be expected that metacognitive judgments will also be different.

Accurate metacognitive monitoring and regulation are required during multimedia learning to achieve an increase in learning outcomes (Azevedo, 2014). However, little research has examined the specific processes underlying successful metacognitive monitoring and regulation during multimedia learning. Specifically, few metacognitive judgments have been found to be predictive of successful multimedia learning outcomes (e.g., overconfident JOLs; Serra \& Dunlosky, 2010). We argue that examining other metacognitive judgments (CEs, RCJs) can inform us of monitoring processes that are more indicative of successful learning and performance. In contrast to the limited research on metacognitive judgments during multimedia learning, we focus on different metacognitive judgments and identify how they can contribute to superior learning outcomes.

In this study, we examined participants' text CEs, diagram CEs, multiple-choice responses, and RCJs during multimedia learning to answer the following three questions: (1) Are accurate text and diagram CEs associated with an increase in the likelihood of an accurate multiplechoice response? (2) Is there a significant relationship between text and diagram CE accuracy and RCJs? (3) Is there a significant relationship between the interactions of text and diagram CEs and multiple-choice responses on RCJs?

To address our research questions, we proposed the following hypotheses:

H1: Accurate text and diagram CEs will be significantly associated with an increase in the likelihood of an accurate multiple-choice response.

H2: The relationship between text and diagram CE accuracy and RCJs will be significant.

H3: The relationship between the interactions of text and diagram CEs and multiple-choice responses on RCJs will be significant.

## Method

## Participants

Forty-eight undergraduates ( $69 \%$ female) enrolled at a large mid-Atlantic university participated in this study. Their ages ranged from 18 to $24(M=20.04, S D=1.60)$, and they were compensated up to $\$ 30$ for their participation.

## Experimental Design

This study used a $3 \times 3 \times 2$ within-subjects design (18 trials). Each participant was exposed to three human agent facial expressions: neutral (neutral facial expression), congruent (i.e., joy for facial expressions congruent with the content relevancy), and incongruent (i.e., confusion for facial expressions incongruent with content relevancy). Each participant was also exposed to each type of multimedia content relevancy: fully relevant (text and diagram relevant to the question), text somewhat relevant (but diagram still fully relevant), and diagram somewhat relevant (but text still fully relevant). Additionally, two types of questions were posed: function (regarding the function of a body system) and malfunction (regarding a malfunction of a body system). Based on these manipulations each student completed 18 trials, with different combinations of human agent facial expression, multimedia relevancy type, and question type. For this paper, our analyses focused on metacognitive judgments across the trials and experimental manipulations.

## Materials

The materials used in this study included the following: an informed consent form; a demographic questionnaire; and a researcher-developed, 4-foil, 18-item multiple-choice pretest of basic knowledge of human body systems (e.g., integumentary and nervous systems). Each question on the
pretest specifically related to the content presented in each multimedia science content slide.

Additionally, this study included 18 researcher-developed multimedia science content slides developed with a faculty member in human biology. The relevancy manipulations were created by including information that was related to but not necessary for answering the question.

## MetaTutor Multimedia Learning Environment

The MetaTutor multimedia learning environment is a multimedia-based content presentation tool designed to examine the influence of a human agent's facial expressions on participants' cognitive strategies and metacognitive judgments during learning about human body systems. The environment consists of a human agent capable of facially expressing several emotional states (i.e., neutral, confusion, joy), science questions and corresponding multimedia science content, and metacognitive judgment prompts (EOLs, text and diagram CEs, and RCJs). The multimedia science content consists of three paragraphs (Flesch-Kincaid readability score range: $9.1-12.5 ; M=10.5$ ) and a diagram depicting the concept described in the text.

The environment presents 18 linearly structured, selfpaced trials consisting of metacognitive judgments (e.g., EOLs, CEs, and RCJs), multimedia content presentation, and human agent facial expressions.

The 18 trials have the identical format. In each trial, participants are first presented with a science question and asked to submit an EOL, How easy do you think it will be to learn the information needed to answer this question? Participants made their EOL judgment on a scale from $0 \%$ to $100 \%$, increasing in increments of $20 \%$. Participants were then presented with a content slide containing the text, diagram, science question presented previously, and human agent. After 30 s (to ensure participants had enough time to initially review the material), participants were prompted to assess the relevancy of both the text and diagram, Do you feel the text/diagram on this page is relevant to the question being asked?, by making two CE judgments on a Likerttype scale (ranging from $1-3$ ) on the following statements: The text/diagram is relevant, The text/diagram is somewhat relevant, and The text/diagram is not relevant. Upon making their text and diagram CEs, the human agent expressed a congruent, incongruent, or neutral facial expression based on the relevancy of the content (e.g., a congruent facial expression of joy if the text and diagram were relevant to the question being asked). Following the agent's expression, participants were permitted to reread the text and reinspect the diagram at their own pace. After they re-examined the multimedia content, participants were prompted to answer the science question by choosing the correct response from 4-foil answers. After submitting their answer, participants were prompted to make a RCJ by answering How confident are you that the answer you provided is correct? Participants made their judgment on a scale from $50 \%$ to $100 \%$ increasing in increments of $10 \%$. After submitting their response, participants were required to justify their
answer by typing their response into a text box. Subsequently, participants were asked to make another RCJ based on their justification. This procedure was followed for all 18 trials with each trial randomized across participants.

## Procedure

Once participants entered the lab they were asked to complete an informed consent form. Then the eye tracker was calibrated by the researcher. ${ }^{1}$ Following calibration, participants were asked to complete a computerized demographic questionnaire and an 18-question, 4-foil pretest that assessed their basic science knowledge across the multiple body systems (e.g., urinary, endocrine) presented in the experiment. After the pretest, participants completed the 18 previously described trials. The experimental session lasted approximately 90 min .

## Coding

Text and diagram CE judgments were recorded across the 18 trials (i.e., 18 text +18 diagram $=36$ total CE judgments for each participant). Responses were coded based on their accuracy, such that an accurate CE judgment was given a score of 1 , a partially correct judgment was scored as 0.5 , and an incorrect judgment was scored as 0 . For example, if participants judged the diagram as somewhat relevant and a text as fully relevant during a "diagram somewhat relevant" trial, they were given a score of 1 for each response because the text was still fully relevant to the question being asked, whereas the diagram was only somewhat relevant.

Participants' responses to the 4-foil, multiple-choice questions were coded by correctness. A correct response was coded as 1 and an incorrect response was coded as 0 .

Participants' RCJs were coded on a scale from $50 \%$ to $100 \%$. A score of $50 \%$ indicated participants simply guessed at their answer (indicating they believed they had a 50/50 chance of getting their answer correct), whereas a score of $100 \%$ indicated participants were completely confident in their response.

## Results

## Research Question 1: Are accurate text and diagram CEs associated with an increase in the likelihood of an accurate multiple-choice response?

A fully unconditional model (i.e., with no predictor variables) dichotomous outcomes (i.e., accurate multiplechoice response $=1$, inaccurate $=0$ ), was conducted on multiple-choice accuracy. Results indicated that the average probability of responding to a multiple-choice question correctly was $60 \%$.

A dichotomous outcomes model was conducted on multiple-choice accuracy (i.e., accurate $=1$, inaccurate $=0$ ) with text and diagram CE accuracy as the predictor variables. Results revealed that more accurate text CEs

[^417]$(O R=1.98, t=3.09, p=0.002)$ but not diagram $\mathrm{CEs}(O R=$ $0.98, t=-0.10, p>0.5$ ) were associated with an increase in the likelihood of correctly answering multiple-choice questions. Specifically, as text CE response accuracy increased, there was a $98 \%$ increased chance of responding correctly. That is, if participants were accurate in their text CEs, they were substantially more likely to respond correctly to the multiple-choice questions.

## Research Question 2: Is there a significant relationship between text and diagram CE accuracy and RCJs?

A fully unconditional model conducted on RCJs indicated $29.8 \%$ of the variability was between participants $\left(\tau_{00}=\right.$ 79.61, $z=4.24, p<0.001$ ) and $70.2 \%$ was within participants ( $\sigma^{2}=187.49, z=19.99, p<0.001$ ), justifying further analysis.

An unconstrained multiple level 1 predictor model was run on RCJs using text CE and diagram CE accuracies as the predictor variables. Results revealed that an increase in both text CE accuracy ( $\gamma_{10}=5.70, t=3.95, p<0.001$ ) and diagram CE accuracy ( $\gamma_{20}=6.01, t=4.63, p<0.001$ ) significantly predicted an increase in RCJs. As the accuracies of participants' text and diagram CEs increased, their reported confidence in their performance also increased. This model accounted for $6.2 \%$ of the withinparticipant variance in participants' RCJs.

## Research Question 3: Is there a significant relationship between the interactions of text and diagram CEs and multiple-choice responses on RCJs?

A constrained multiple level 1 predictor model was run on RCJs using text and diagram CE accuracies and their interactions with multiple-choice responses as predictor variables. Results indicated the interaction between text CE accuracy and multiple-choice response accuracy was not significant ( $\gamma_{40}=1.50, t=0.50, p=0.62$ ). However, results did reveal a significant interaction effect between diagram CE accuracy and multiple-choice response ( $\gamma_{40}=-7.21, t=$ $-2.75, p=0.006$ ), such that participants whose diagram CEs were most accurate and who also had more accurate multiple-choice responses also reported more confidence in their answers (see Figure 1). This model accounted for 7.7\% of the within-participant variance in participants' RCJs.

## Discussion

The goal of this study was to examine the relationships between metacognitive judgments and their contributions to increased performance during multimedia learning. Overall, results revealed that when participants made accurate text CEs, they were more likely to respond correctly to multiplechoice questions. Additionally, accurate text and diagram CEs contributed to higher reported confidence in answers. As such, our findings augment current understanding of how different metacognitive judgments, from those

## Diagram Content Evaluation Accuracy

Figure 1: Interaction between diagram CE response accuracy and MC response accuracy on RCJs.
traditionally examined in the multimedia learning literature (e.g., JOLs), can contribute to improved performance and higher confidence.

Results from Research Question 1 indicated accurate text CEs were significantly predictive of an increased chance of responding correctly to multiple-choice questions, whereas diagram CEs were not. These results partially support our hypothesis, demonstrating participants could more accurately assess the relevancy of the text-based (as opposed to diagram-based) material related to answering the science question. Furthermore, these results are consistent with theories of multimedia learning that suggest individuals cognitively process text- and diagram-based material separately (Mayer, 2014; Schnotz, 2014). It is possible that participants not only cognitively process the text and diagrams separately, but also metacognitively monitor the information in text and diagrams separately and with varying levels of accuracy. Given evidence suggesting individuals exhibit a bias toward processing text-based information (at the expense of diagrams; Hegarty \& Just, 1993), in addition to the redundancy of the diagram-based information to the text, participants may have realized the text-based information was sufficient and thus relevant enough to answer the multiple-choice questions correctly.

As hypothesized, results from Research Question 2 demonstrated that text and diagram CEs significantly predicted higher RCJs. Specifically, the more accurate participants' text and diagram CEs were, the more confident they were in their multiple-choice responses. Taken together with the previous finding, these results indicate participants may have relied on their relevancy judgments of both the text and diagram when they made their RCJs (as opposed to answering the question). As such, this finding significantly augments research on metacognitive judgments during multimedia learning by indicating a significant relationship between multiple metacognitive judgments.

Lastly, results from Research Question 3 indicated the interaction between diagram CE accuracy and multiplechoice response accuracy significantly predicted increased RCJs. More specifically, participants who provided more
accurate diagram CEs and responded accurately to multiplechoice questions also reported more confidence in their answers. These results partially support our hypothesis that both text and diagram CEs interact with multiple-choice responses to predict increased RCJs. Additionally, this result is supported by previous literature that suggests a significant relationship between performance and RCJs (e.g., Mengelkamp \& Bannert, 2010). These results also support our assumption that since cognitive processes are different for different representations of information, so too are metacognitive monitoring processes. However, research is limited regarding the metacognitive processes involved when learning with and comprehending diagrams.

Overall, these results suggest that accurately assessing the relevancies of text and diagrams differentially impacts performance and future metacognitive judgments (e.g., accurate CEs related to increased RCJs). Results also indicated that when participants responded to multiplechoice questions, they relied on their metacognitive judgments of the text rather than diagrams. In contrast, participants relied on metacognitive judgments of diagrams and their performance when making RCJs. Previous research has indicated a significant relationship between CEs and performance (e.g., Greene \& Azevedo, 2009). However, unlike previous literature, these results suggest text and diagram CEs differentially impact not only performance, but also reported confidence. Ultimately, these results confirm that other metacognitive judgments for different representations of information can predict greater performance during multimedia learning.

## Limitations

Our study has several limitations. First, as we were primarily interested in the relationship between metacognitive judgments (e.g., CEs, RCJs) and performance across conditions, we did not examine the impact of content relevancy (e.g., fully relevant text and diagram, text less relevant, diagram less relevant) or question type (e.g., function vs. malfunction science question). Furthermore, the information needed to answer the multiple-choice questions correctly was primarily located in the text, which may have influenced participants' CE judgments. Future research should include separate function and malfunction questions based on the information presented in the diagrams. Moreover, we did not examine the accuracies of RCJs as multiple-choice responses were dichotomously coded as correct or incorrect. Future research will include measures of absolute and relative accuracies for RCJs (e.g., Schraw, 2009). Lastly, we can only make limited conclusions regarding the underlying cognitive and metacognitive processes (e.g., multiple fixations on irrelevant diagrams) that contributed to the accuracies of the text and diagram CEs and multiple-choice responses, as multichannel trace data (e.g., eye tracking) were not analyzed. Despite these limitations, this study has several important implications.

## Future Directions and Implications

The results of this study have important implications for future studies examining the influence of metacognitive judgments on performance during multimedia learning. First, future research should include analyses of multichannel trace data (e.g., eye tracking, facial expressions of emotions) that would allow for a more comprehensive depiction of the cognitive, affective, and metacognitive processes that occur when making CEs during multimedia learning (see Azevedo, 2014). Specifically, analyzing eyetracking data can provide a micro-level description of the cognitive processes (e.g., coordination of information sources) contributing to increased performance and accurate text and diagram CEs. For example, does more time spent reading the text contribute to more accurate text CEs? Do specific eye-movement "signatures," as evidenced by scan path analyses, indicate greater integration of multimedia information and subsequently lead to increased performance? Further, examining the influence of participants' affective processes (e.g., emotions) would provide evidence of how they influence cognitive and metacognitive processes. For example, are participants' facial expressions of confusion predictive of decreased CE accuracy? How do participants' facial expressions of frustration influence the quality of their multiple-choice responses? Lastly, as this study was limited to analyzing the accuracy of RCJs, future research should seek to determine how CEs contribute to the accuracy of RCJs. It is possible that participants' CEs were accurate, but they exhibited over- or under-confidence when making their RCJs.

As our results indicated that diagram but not text CEs interacted with multiple-choice responses to predict RCJs, they emphasize the differential impact of multiple representations of information on participants' metacognitive judgments. Future research should examine the specific impact of different representations (e.g., diagrams, graphs, illustrations) on participants' metacognitive judgments to address the gap in the literature and gain better understanding of the metacognitive monitoring processes involved during multimedia learning.

Using a within-subjects design allowed us to examine the differential impact of how accurate metacognitive judgments influenced performance and confidence with reduced error caused by individual differences. Additionally, using multilevel modeling (Raudenbush \& Bryk, 2002) enabled us to accurately assess within-subjects variance without violating traditional statistical assumptions (e.g., independence of observations) that many withinsubjects designs ignore. Despite these benefits, future research should explore other experimental designs that are less controlled (e.g., more naturalistic) to increase the ecological validity of these findings. Due to our sample size, we did not find significant between-subjects variance; future research should replicate these analyses with larger samples to determine individual differences indicative of improved metacognitive judgment accuracy and performance (e.g., prior knowledge of body systems).

Additionally, these results indicate the importance of coordinating multiple sources of information (e.g., text and diagram) and can be used to inform the design of educational training regimens. For example, future research should explore the impact of cognitive (e.g., Bergey, Cromley, \& Newcombe, 2015) and metacognitive (e.g., Azevedo, 2014) instruction that emphasizes how individuals should learn using both text and diagrams. Training can be provided to demonstrate how to accurately judge the relevancy of texts and diagrams, as well as emphasize the importance of accurate metacognitive judgments in relation to increased performance. Furthermore, these results can also inform the design of future intelligent, adaptive multimedia-based learning environments to support and scaffold accurate metacognitive judgments. If participants continuously make inaccurate text CEs, the system can intervene by cueing their attention to the relevant text-based information or by providing additional relevant declarative and conditional knowledge (e.g., how to accurately judge the relevancy of different representations of information).

Lastly, the results from this study suggest accurate metacognitive judgments are required for increased performance and confidence during multimedia learning. Traditionally, metacognitive judgments during multimedia learning have been found to be largely inaccurate. However, our results indicate other metacognitive processes (e.g., CEs) may be more informative of increased performance. For example, future studies could examine the influence of accurate feelings of knowing (i.e., individuals are aware of having read information but are unable to recall it on demand) and how they can contribute to increased performance during multimedia learning. As such, future research examining the influence of other metacognitive judgments will significantly augment our understanding-as well as the contemporary theoretical frameworks of multimedia learning-of the relationship between cognitive and metacognitive processes contributing to increased performance.

## Acknowledgments

The research presented in this paper is supported by funding from the National Science Foundation (DRL 1431532). The authors would like to thank the members of the SMART Lab and the IntelliMedia Group at NCSU for their assistance in this project.

# Interactive Communicative Inference 

Larry Muhlstein (lmuhlstein@ucsd.edu)<br>University of California San Diego<br>Department of Cognitive Science, 9500 Gilman Drive<br>San Diego, CA 92093 USA

#### Abstract

In the search for an understanding of human communication, researchers often try to isolate listener and speaker roles and study them separately. Others claim that it is the intertwinedness of these roles that makes human communication special. This close relationship between listener and speaker has been characterized by concepts such as common ground, backchanneling, and alignment, but they are only part of the picture. Underlying these processes, there must be a mechanism for making inferences about our interlocutors' understanding of words and gestures that allows us to communicate robustly and efficiently without assuming that we take the same words to have the same meaning. In this paper, I explore this relationship between language and concepts and propose an interactive mechanism that can facilitate these latent conceptual inferences. Finally, I show how this proposal paves the way for a more precise account of the role of interaction in communication.

## Introduction

FRIEDA: "I study cognitive science"
FRED: "Cool! The brain is so interesting!"
FRIEDA: "Uh, cognitive science $\neq$ neuroscience..."
Human communication is fraught with misunderstanding, incorrect assumptions, and uncertainty, yet we still manage to make it work. To handle these impediments, we make ample use of processes such as grounding (H. H. Clark \& Brennan, 1991), alignment (Pickering \& Garrod, 2004), repair, and backchanneling (Schegloff, Jefferson, \& Sacks, 1977), all of which are well described in the scientific literature. Because these processes are thought to be somewhat modular, many linguists-especially computationalists-find it useful to remove these processes from their models and experiments and reasonably assume that they can be added back in later when a more complex and complete theory is desired. While it is reasonable to excise details tangential to the core phenomenon of study, to remove these interactive processes underestimates the degree to which they are embedded in human communication and fails to appreciate how indispensable they are to communicative success.

The misunderstanding at hand emerges from the fact that these processes are not fully understood. On one hand, grounding, alignment, repair, and backchanneling allow us to repair inferential errors and to establish tighter conventions, but each of these processes also presupposes the ability to detect misalignments and miscommunications in the first place. While this might not immediately appear to be much of a problem, there is a complete dearth of empirical literature on such inferences and of any theoretical analysis about
their mechanics. The purpose of this paper is to provide a preliminary analysis of the necessary and sufficient properties of these interactive communicative processes and to argue that any reasonably sophisticated understanding of human communication must build upon an epistemologically-sensitive theory of how we detect and repair misalignments and misinferences in order to communicate robustly and veridically.

## Dead reckoning behavior in models of communication

Contemporary models of human communication tend to operate with strong assumptions about what I will call conceptual alignment-the extent to which interlocutors' mappings from surface structure (words, phrases, and actions) to hidden structure (meanings and concepts) align with one another. Conceptual alignment captures how the correspondence ${ }^{1}$ between a speaker's beliefs about the listener's understanding of a situation and the listener's actual understanding affects their ability to communicate ${ }^{2}$. Typically, these models assume that both interlocutors have complete probabilistic conceptual alignment, and therefore that the listener's belief distribution about the meanings the speaker intends to communicate with her utterances is equivalent to the speaker's probability of producing those utterances given her communicative intentions. With this assumption in place, a rich subset of pragmatic behavior including all sorts of implicatures can be fruitfully investigated, and have been with the advent of Bayesian models of pragmatics such as RSA and its many variants (Degen, Tessler, \& Goodman, 2015; Frank \& Goodman, 2012; Goodman \& Lassiter, 2014; Kao, Wu, Bergen, \& Goodman, 2014).

However, if we were to drop this assumption from these models in favor of a more realistic amount of uncertainty, we would notice some problems. For example, if we allow there to be misalignment between the interlocutors' concepts, we would find that any attempt at communication results in a systematic pattern of errors that are not correctable within the scope of the model. A plausible case of this might be if I said the word "justice" intending it to mean something akin to Rawlsian fairness, where all decisions are made from a position of agnosticism about where one falls in society, but my interlocutor thought I was talking about retributive justice, then everything that I said would be misinterpreted, and this would continue indefinitely in the aformentioned mod-

[^418]els because they don't contain any mechanism for detecting conceptual misalignment (instead they assume alignment and proceed from there). An even simpler case could involve a sense/reference mismatch where I use the word "speaker" to refer to a lecturer, but my interlocutor instead interprets it to refer to a sound production device. While it is likely that the vast difference in meaning would cause me or my interlocutor to notice the misinterpretation, a large class of current formal models of conversation would proceed as if I was being properly interpreted at all times.

It is useful to refer to this type of behavior as dead reckoning communication, as it offers the same perils as nautical navigation without taking periodic measurements of location. A ship without instruments, sailing perpetually into the fog, is inevitably bound to stray far from its destination no matter how precisely it was pointed at the beginning of its journey. This happens because of the pervasive uncertainty about the ship's motion, the effects of navigational actions (trimming the sails, hoisting the spinnaker, turning the rudder, etc.), and the environment-which is always changing. Even if a ship's captain plans out a series of actions in advance in order to get the ship to its intended destination and executes these actions flawlessly (without taking interim measurements about the position, speed, and heading of the ship), there is but a tiny chance that the ship will end up in its intended port. So it goes with communication sans feedback. If a speaker wants to convey some concept or scenario to a reader and she develops a series of communicative actions (a communication plan) and executes it without observing the listener's interpretations, then she risks the listener's gross misinterpretation unless she is willing to put in substantially more detail and effort than is typically prudent or even possible in a conversation. Even for the most closely aligned concepts, communication is bound to stray off course if the participants don't continuously probe the state of the discourse and correct its course when necessary. As H. H. Clark and Wilkes-Gibbs (1986) argued, the constraints of conversation restrict us to brief, ad hoc, ephemeral communicative actions, which limits interlocutors' ability to provide the kinds of lengthy descriptions that might be present (and necessary) in a book. However, conversation also affords interaction. As we will see, this offers additional opportunities for coordinated communication between interlocutors by allowing them to make inferences about each others' interpretations. Just like a navigator's instruments allow her to detect the ship's position and velocity and make informed corrections to its course, a speaker's inferences allow her to probe the state of her partner's understanding and choose her successive communicative actions accordingly.

## Response-based inference

To combat this undesirable dead reckoning behavior, we can look both at the necessary properties for any mechanism to handle pervasive uncertainty and misalignment (given the right abstraction of the problem) and at empirical investiga-

(a) Dead reckoning navigation
(b) Navigation with instruments

Figure 1: Dead reckoning vs. instrument-based navigation on a ship. (a) Dead reckoning cannot handle uncertainty and so the ship ends up far from its intended destination. The gray line represents the planned trajectory, while the black line shows the actual trajectory under dead reckoning. (b) Instrument-based navigation allows the captain to correct the ship's course as it goes leading the ship exactly to its intended destination.
tions about how humans specifically seem to handle it in the case of communication.

## Challenge-response authentication

A particularly good formal analogy for the solution I will soon propose is the cryptographic concept of challengeresponse authentication. Challenge-response authentication was developed as a solution to a problem much like the issue of dead reckoning in communication. Imagine that there are two interlocutors, Alice and Bob, each sitting at one end of a digital communication channel (imagine them sitting at desks in separate buildings connected via the internet.) Bob wants to send Alice a secure message, but first Bob needs to know for sure that he is communicating with Alice and not with a malevolent interloper such as their friend Charlie. To verify Alice's identity, Bob needs Alice to say something that only she would know, such as the secret phrase they agreed upon earlier. Bob receives this phrase from the communication channel and concludes that it must have come from Alice. But Charlie, the conniving and generally clever chap that he is, has tapped the communication channel and observes Alice and Bob's secret phrase. The next day, when Bob wants to communicate with Alice, he hears this same phrase, and again believes that it came from Alice. Unbeknownst to him, Alice was sick and wasn't at the computer terminal she normally uses to communicate with Bob. Instead, the secret phrase came from Charlie, who now proceeds to communicate with Bob as if he was Alice.

A natural question then follows: how can Bob and Alice communicate securely without risk of Charlie impersonating Alice? The answer lies in challenge-response authentication. Bob, having discovered the fatal flaw in his authentication system, comes up with a clever alternative. Instead of agree-
ing with Alice upon a secret phrase, they instead come up with a secret relationship between phrases-i.e. a secret function. The next day, when Alice and Bob try to communicate, Bob sends Alice a message called a challenge. When Alice receives this challenge, she feeds it into the secret function and gets an output that she then sends back to Bob as a response. When Bob receives this response, he feeds his challenge into his own copy of the secret function and compares the result with Alice's response. If they match, then Bob can be sure that he is communicating with Alice and not Charlie. To understand why this works, we can look at Charlie's behavior in this scenario. Like before, Charlie has tapped the communication line and receives both Bob's challenge and Alice's response. The next day, when Charlie tries to pretend that he is Alice, he receives a challenge from Bob. This challenge however, is not the same as the one he saw the day before. This means that the correct response is different as well! Because the secret knowledge is a full function, the observation of a few challenge-response pairs is not sufficient to induce the full function or the correct response to additional challenges. If the secret functions are properly designed, then virtually no amount of observations of the challenge-response pairs will be sufficient for Charlie to induce the secret function. Upon realizing this information, the sullen Charlie decides to leave Alice and Bob alone to search for others with weaker verification algorithms to deceive.

## Utterance-response contingencies

How does this cryptographic mechanism relate to human communication and how does it help us avoid dead reckoning behavior? The problem in human communication is not in establishing the identity of the interlocutor, but rather in verifying the interlocutor's comprehension. If we replace the secret functions from challenge-response authentication with out latent conceptual understandings, we can use the same sort of strategy to verify the similarity or alignment between our communicative intentions and the interlocutor's interpretations. If Alice produces utterance $x$ for Bob, and Bob responds with utterance $y$, then Alice can check Bob's comprehension of $x$ by modeling the plausibility that Bob would have generated response $y$ given various interpretations of $x$. In the simple case, if Bob interprets $x$ exactly as Alice intends, then his response $y$ will be identical to Alice's prediction about his response given her intended interpretation. In the case where there are multiple plausible interpretations, Bob's response $y$ provides Alice with information about how likely Bob is to have made each of the possible interpretations of $x$. We will call this minimal pair of utterance and response an utteranceresponse contingency. Utterance-response contingencies are the basic building blocks of interactive communicative inference, a term I propose to denote the general process of inferring interlocutor beliefs through interaction. This also involves more complex cases where each interlocutor's beliefs about the others' understanding are updated through extended dialogical interaction, which can result in robust alignment processes that make effective discourse possible.

In real discourse, utterance-response contingencies look like this:

GEORGE (UTTERANCE): "Wasn't that a great speech yesterday?"
GEORGIA (RESPONSE): "I mean, it wasn't as horrible as I expected, but I definitely can't say it was good..."
GEORGE (REPAIR): "Oh, did you think I meant Donald's speech? I was talking about the address from the director of the ACLU."

These utterance-response contingencies can come in various forms. They can resolve referential misinterpretations like in the example above, or they can surface more subtle conceptual misalignments where the interlocutors' wordconcept mappings are misaligned, or even when the internal structures of their respective concepts are inconsistent with each other ${ }^{3}$.

The case of misaligned word-concept mappings is illustrated in the opening dialogue between Frieda and Fred.

FRIEDA: "I study cognitive science"
FRED: "Cool! The brain is so interesting!"
FRIEDA: "Uh, cognitive science $\neq$ neuroscience..."
Here we see that Frieda's concept of "cognitive science" is reflective of her being an insider to the field and therefore likely includes associations with each of the "six corners of the hexagon": psychology, computer science, philosophy, linguistics, anthropology, and neuroscience. Fred's concept, however, is closer to how many outsiders think of cognitive science ${ }^{4}-$ as alternative word for neuroscience. Using interactive communicative inference and utterance-response contingencies, Frieda is able to notice this conceptual misalignment and repair it, thus improving the alignment between interlocutors.

## A more systematic formulation

To make this idea a bit more concrete, we can situate it in the context of a more precise way of looking at human communication. Fundamentally, communication is comprised of two kinds of processes: inferences, and actions that facilitate inferences. The idea of an inference is mostly self explanatory. It refers to any kind of inference about the beliefs, communicative intentions, or mental state of your interlocutor. Such beliefs can be about things in the world or more abstract concepts, and so the contents of these inferences are almost unlimited in scope. Inference facilitation, on the other hand, refers to actions that are taken by one participant in the discourse (whom we call the speaker, even though their actions may not be vocally produced) and observed by another participant in the discourse. As these actions are caused (at least in part) by the speaker, they provide the observer of the actions (the listener) with information

[^419]about the speaker and consequently their beliefs, mental state, and communicative intentions. Since the roles of speaker and listener shift dynamically throughout a discourse, we do not associate these terms with particular conversational agents, but with the roles themselves. The listener-in responding to the speaker-therefore temporarily instantiates the role of the speaker, and even the most subtle facial expressions, when produced in a discourse, count as inference-facilitating actions. Besides these two components, there is also the idea of context, which is broadly defined to capture any effect of the discourse topic, the surroundings, or any other processes on the particular instance of communication ${ }^{5}$. The definitions of these communicative concepts are not constrained further than this because to do so would limit their generality as the basic constituents of human communication.

I choose this framework instead of other possibilities such as the pragmatic alternatives framework, classical communication theory, and informal schools of thought such as relevance theory and cognitive linguistics because it affords both precision and generality and it allows us to highlight the basic epistemics of human communication. In this formulation, all communicative actions have the same status. This is because, at the epistemic level, an utterance, a gesture, and an unintentional twist of the lips are all actions taken by a communicator that allow an interlocutor to make various inferences about her communicative intentions and her state of mind. While the contents and causal pathways associated with these actions may differ drastically, these details do not have bearing on the development of a basic framework for communicative analysis, only on specific theories subsequently derived from that framework.

To move towards a formal theory, we can choose a minimal Bayesian framework that captures only the epistemic relationships between the speaker's utterance, the listener's interpretation, the listener's response, and the context. Since all of these, except for the listener's interpretation, are observable to both parties ${ }^{6}$, we can capture their relationships in a causallyderived probabilistic graphical model where each of the nodes is observed except for the node representing the listener's interpretation, as seen in figure 2 (Pearl, 1988). This model captures the fundamental structure of the speaker's inference about the listener's interpretation via utterance-response contingencies, where the details of particular inferences depend on the particular distributions that comprise an instantiation of the model. While the broad epistemic structure of these inferences is simple, the corresponding real-world processes are anything but so. Filling in the details of this model will not be an easy process and will require a large amount of directed scientific experimentation and theoretical analysis. Therefore the goal here is not to develop a full theory of these communicative processes in real humans, but to provide a structured

[^420]

Figure 2: Bayesian network representation of interactive communicative inference. Bolded nodes are directly observable.
framework through which we can understand and investigate them. Bayesian probability is sufficiently abstract to allow us to represent these general inferential structures while allowing the rich human details to be added later.

## Application to known discourse phenomena

To further ground this framework and illustrate its relationship to empirical phenomena in human communication, we will look at three different concepts described in the literature and show how the idea of interactive communicative inference offers each of them a stronger theoretical foundation.

## Common ground

The idea of common ground, first proposed by H. H. Clark and Brennan (1991), suggests that people accumulate a shared repository of knowledge when they interact, and that subsequent interactions are facilitated by this common knowledge. This proposal has received a substantial amount of theoretical analysis, which has lead to a rich account of how humans establish common ground and make use of it in conversation (H. Clark, 1996). There is also a solid foundation of experimental evidence supporting the theory (Brennan \& Clark, 1996; Hanna, Tanenhaus, \& Trueswell, 2003). Perhaps the most notable experiment-known as the "tangrams experiment"-involved a pair of interlocutors who were given a set of cards depicting images of blocky figuresi.e. tangrams-and were tasked with getting the other person to arrange their cards in an order perceivable only to the designated speaker for the round. Complicating this significantly was the fact that the participants were separated by a visual wall and so could only communicate verbally. H. H. Clark and Wilkes-Gibbs (1986) found that the participants quickly established shared conventions for referring to the cards, which resulted in a decrease in the amount of communication required to complete the task as they continued to interact through multiple task rounds.

While this story is compelling both theoretically and empirically, it is missing a mechanistic account of the inference
processes that these interlocutors go through when building and making use of common ground. Dead reckoning models cannot capture this progressive coordination behavior, and so we turn to interactive communicative inference. The basic component of interactive communicative inference, the utterance-response contingency, accounts for how an exchange can allow the speaker to update their understanding of the listener's beliefs and therefore facilitate the listener's comprehension. When this occurs, the speaker can choose to use a referring term that they know the listener will understand, which allows the speaker to communicate more efficiently with the listener via this ad hoc convention. If both communication partners make use of such processes in their interaction, then they will come to a shared understanding of how to use language to communicate particular meanings. Over an extended interaction, such interlocutors can build a common communication system. This predicts the increasing communicative concision throughout an interaction that H. H. Clark and Wilkes-Gibbs (1986) observed. We can even imagine that, if this process involves additional people over multiple interactions, a complete conventionalized communication system should emerge from this process of building shared knowledge via interaction.

## Conversational alignment

Martin Pickering and Simon Garrod have developed a compelling theory of discourse as an interactive alignment process, which has a number of useful relations to the present theory of interactive communicative inference (Pickering \& Garrod, 2006, 2004; Garrod \& Pickering, 2004). Their theory claims that local lexico-syntactic priming in discourse produces a series of cascading effects that causes all participants in a conversation to produce similar surface structures and even to align on semantic content. Using this theory, they argue that the fundamental mechanisms operating in discourse are these alignment processes and construct an account of language processing that does not require a speaker to maintain an explicit and complex model of their interlocutor (Garrod \& Pickering, 2004). While this theory accounts for a wide range of phenomena, it does not offer any account of conceptual alignment phenomena. Conceptual alignment cannot arise from priming-based mechanisms because it is defined as the alignment between latent conceptual structures and surface communicative actions, and this relationship cannot be primed by observing surface structures from an interlocutor's communicative actions. In order to account for the facts that our conceptual structures tend to be relatively aligned within a conventionalized communication system and that we have evidence that they are aligned via interaction, an interactive communicative inference component needs to be added to Pickering and Garrod's theory of discourse.

Their theory also predicts that it should be easier for humans to efficiently communicate meaning through interactive dialog than unidirectional monologue because interaction facilitates the alignment of linguistic representations (Garrod \& Pickering, 2004). This prediction is both consistent with our
informal experience as well as predicted by the interactive communicative inference framework. For a monological description to yield effective communication, it must necessarily contain enough information such that, for all of the likely ways that a listener or reader might misinterpret the meaning, there is additional information that steers them away from these misinterpretations and towards the intended interpretation. In a discourse, however, these counterfactuals do not need to be handled via anticipation and mitigation. Instead, utterance-response contingencies make it so that only actual misinterpretations by the listener need to be ameliorated.

With the addition of the present account of conceptual alignment through interactive communicative inference, we can add a vital component to the conversational alignment story to yield a powerful framework for understanding human communication.

## Backchanneling and repair

Sociolinguistics and conversation analysis research has built an account of discourse expressed in terms of the constituent behaviors of conversations and the types of communications they enable (Sacks, Schegloff, \& Jefferson, 1974). Some of the core concepts in these accounts are the ideas of backchanneling and repair. Backchanneling is invoked in a multichannel model of communication in which interlocutors communicate the majority of their content via a main channel and provide meta-conversational signals in a backchannel (Yngve, 1970). For example, a listener may produce the affirmative "uh huh" in a backchannel to signal to the speaker that the she believes herself to be comprehending and that the speaker should proceed. While these behaviors have been convincingly shown to play a key role in natural conversation, this account leaves open the question of how the listener forms her beliefs about whether or not she is comprehending the speaker. As we have seen, belief of comprehension does not necessarily imply veridical comprehension, because there may be an undetected conceptual misalignment between the speaker and listener. Our account of interactive communicative inference suggests that listeners may be providing these cues to speakers in order to facilitate the speakers' interactive communicative inferences by completing the utteranceresponse contingency. It also suggests that speakers may be comprehending these backchannel signals, not truly as an unequivocal signal to proceed, but as a response that conveys the listener's beliefs about their comprehension. The following dialog illustrates a scenario with a distinction between the affirmative backchannel as anequivocal signal of comprehension and an account of backchanneling as concurrent response. (Tyra and Tyler are roboticists at different universities.)

TYRA (UTTERANCE): "STEVE can walk on two legs now!"
TYLER (BACKCHANNEL): "Oh"
TYRA (REPAIR): "Not Steven the child, STEVE (Self-
Taught-EVacuative-Entity) my robot. It's a ground-
breaking achievement!"

Here Tyra infers Tyler's miscomprehension through his affectless backchannel response to her achievement. She knows that he would be really excited to hear about this research achievement and therefore infers that he must believe her to be talking about a child instead. Tyler mistakenly believes himself to have comprehended Tyra's utterance and produces a backchannel response, but Tyra does not interpret it blindly. Instead, she uses the resultant utterance-response contingency to infer the miscommunication and repair the misunderstanding. As predicted in the classical account, the backchannel provides feedback to Tyra about Tyler's interpretation. However, the response does not reflect Tyler's veridical comprehension, but facilitates a more complex interactive communicative inference.

Miscommunications in conversations are corrected via repairs. These come in many forms, but are often divided into two classes: self-initiated and other-initiated. While the literature provides substantial experimental and ethnographic detail about the role of repairs in conversation, it does not offer an account of how interlocutors infer when a repair needs to be made (Schegloff et al., 1977). The present theory of interactive communicative inference offers a computational mechanism by which miscommunications can be detected in conversation, which allows speakers to repair the miscommunication by correcting their own production or by correcting the listener's interpretation.

## Conclusion

Contemporary models of communication are incomplete. While they offer a detailed understanding of the surface-level phenomena present in discourse, they do not provide a satisfactory explanation of the inferential mechanisms necessary for these phenomena. They are unable to account for the robustness of communication in spite of uncertainty, how people know when to update their beliefs about their interlocutors, and how people establish conventions. I have provided theoretical evidence tied to the empirical to show how all of these types of missing accounts can be derived from the idea of interactive communicative inference.

While researchers have long understood that discourse is not a unidirectional and isolated activity, we have demonstrated that treating it as such, even for the sake of delimiting the domain of a theory or a model, can have the effect of removing an important property of language. When the idea of interactive communicative inference is taken seriously, we can begin to construct a scientific study of communication that can account for how, despite the fact that we can never be in someone else's head to see first-hand what they believe and how they feel, they are able to show us these things simply by engaging us in a cooperative dance of action and interpretation.

## Acknowledgments

I would like to thank Sean Trott for helping motivate me to write this article as well as for his invaluable feedback. I would also like to thank Dorothy Howard for her time helping me polish the article. Finally, I am deeply indebted to the UCSD Department of Cognitive Science and all of its members for their continued support.

# Cognitive and Attentional Process in Insight Problem Solving of the puzzle game "Tangram" 

Yoshiki Nakano (nakano@ed.akita-u.ac.jp)<br>Faculty of Education and Human Studies, Akita University. Tegata Gakuen-machi 1-1. Akita City, 010-8502 JAPAN

#### Abstract

The purpose of this study is to demonstrate a constraint relaxation which is followed by the transition to an appropriate representation in insight problem solving. The puzzle game "Tangram" was used as a new insight problem, in which problem-solvers were presented a silhouette and asked to make the same configuration by arranging 7 pieces. At the beginning, problem-solvers had a constraint allocating the pieces into a geometric shape, but then relaxed this to reach the correct configuration at a later stage of problem solving. Participants' subjective assessments of their confidence to reach the solution predicted neither the constraint relaxation nor the successful problem solving. However, eye-tracking data suggested that the successful problem-solvers tended to search the problem space more widely than the unsuccessful-problem solvers.

Keywords: Tangram; insight problem solving; constraint relaxation; eye tracking.

## Introduction

The Insight problem solving, in general, exhibits a characteristic pattern as a following process (Kaplan \& Simon, 1990; Metcalfe, 1986). At first, an insight problem seems easy to solve, but problem-solvers are caught in an impasse soon after. They get stuck, think that all options have been explored and lose their way. When a sudden and useful idea comes to mind, it often leads problem-solvers rapidly to the solution.

There is an agreement that inappropriate constraints for a solution are the main source of the difficulty to solve an insight problem (Jones, 2003; Orrmerod, MacGregor, \& Chronicle, 2002). These studies suggested that insight requires the relaxation of such inappropriate constraints, and that an impasse can be broken by changing a representation of the problem. A constraint is a tendency of thinking and behavior that is taken in attempting to solve a certain problem. It usually facilitates the process to reach the solution. When a self-imposed constraint, however, is inappropriate to solve a problem, it prompts a critical difficulty to achieve insight, as it activates irrelevant knowledge and causes attempts that cannot contribute to correct solution. This leads problem-solvers into an impasse. In spite of the consensus about the source of difficulty of insight problems, a dynamic process to reach a solution has not been identified clearly. The purpose of this study is to specify an inappropriate constraint which inhibited the insight into the solution in a geometric problem solving, and to provide direct evidence about a critical factor for the

Figure 1: The 7 pieces of Tangram. Top: a configuration when the pieces are divided from a square. Bottom: Separated seven pieces. A problemsolver of Tangram move, rotate or combine them to complete a task silhouette.
successful problem solving. In addition, an eye-tracking technique is adopted to examine whether a proper searching of the problem space can lead successful problem solving or not (Thomas \& Lleras, 2009).

This study also aims to test whether the difficulty of the constraint relaxation can be reflected in an apparent task performance of a problem-solver while independent from subjective awareness. For these purposes, the puzzle game of "Tangram" was used as a new insight problem. Tangram consists of 7 triangular, square or parallelogram pieces (Figure 1). Problem-solvers are presented a task silhouette and required to make the same configuration by arranging these pieces. In Tangram, numerous task silhouettes can be composed by the 7 pieces; for example geometrical shapes, animals or objects. Because each silhouette has an individual configuration of the pieces, problem-solvers often cannot find a correct configuration immediately after the silhouette has been presented. They usually repeat trials with arranging the pieces until the solution is completed.

Tangram has the advantages of allowing researchers to monitor task performance of a problem solving requiring insight. Nakano (2009) recorded protocols of participants and movements of the pieces. His protocol data revealed that the participants who could complete the task silhouette had expressed an "Aha" experience before reaching the correct configuration. Nakano (2009) found that the participants tended to combine the pieces into a geometric shape such as a square or a triangle. This tendency was usually involved combinations of the 2 largest triangles among the 7 pieces. Such the constraints will facilitate the process to reach the solution, in the case that a correct configuration includes geometric combination of the pieces as a square or a triangle. For example, the task silhouette of an arrow has two patterns of the correct configuration, and the both include geometric combination of the 2 largest triangles (bottom in Figure 2). However, when these 2 pieces must be combined into an irregular configuration to complete a task silhouette, the tendency to construct a geometric shape will inhibits the insight into the correct configuration. For example, to complete the silhouette of a lion (top-left in Figure 2) the 2 triangle pieces must be attached by sliding their longer sides in an opposite direction to each other (top-right in Figure 2). Most problem-solvers who tried to complete this silhouette reported that it was difficult to discover this irregular configuration (Nakano, 2009). This finding indicated that the problem-solvers imposed apparent constraints on allocations and combinations of the pieces in the problem solving of Tangram.

The primary purpose of the present experiment is to investigate the correspondence between the constraint relaxation and explicit movements of the pieces. For this purpose, movements of the 7 pieces were recorded and combinations of the 2 largest triangle pieces were identified. These combinations will change as the initial constraint is relaxed and more appropriate representations are constructed. Participants who try to complete the task silhouette of an arrow will not have to relax the constraint to allocate the 2 largest triangle pieces in a geometric pattern. So they will reach the solution easier and faster comparing to the task silhouette of a lion. When they try to complete this task silhouette, they find it impossible to complete the solution only by arranging the pieces into familiar geometric combinations. Then, the participants arrange the pieces into other combinations. To investigate this hypothesis, arrangements of the 2 largest triangle pieces are categorized into three categories, geometric, transitional or irregular combinations. The geometric means the combination of the 2 pieces was a square or a triangle. The irregular combination is that the 2 pieces have a contact each other but no corners of the pieces meet or the edges of the pieces were placed adjacently without combining their corners. The rests of combinations, as that the pieces were arrange in the same direction or in a symmetric configuration, are categorized in the transitional combination.

The second purpose is to examine independence between

Figure 2: Top-left; the task silhouette of a lion. Topright; the correct configuration of the 7 pieces constructing the silhouette of a lion. The two largest triangle pieces (greyed part) are allocated in irregular combination. Bttom-left; the task silhouette of an arrow. Bottom-center and -right; the correct configuration constructing the silhouette of an arrow. There are two patterns of correct configuration. In both, the 2 pieces are allocated in a geometric combination.
the constraint relaxation and subjective awareness in the problem solving of Tangram. In Nakano (2009), participants were required to evaluate how confident they could complete the correct configuration before and during problem solving of Tangram. The subjective confidence decreased over time even in the successful problem-solvers. Thus, the subjective evaluation did not predict performance on the insight problem, as had been suggested by Metcalfe and Wiebe (1987). This finding supports the idea that the transition from one rule to a more appropriate representation for a solution proceeds without subjective awareness.

## Methods

## Participants

Twenty undergraduates ( mean age $=20.8$, age range $=20-$ 26) participated in the experiment. All were naive to Tangram.

## Apparatus

The Tangram was comprised of 7 pieces. A set of the pieces was made by dividing a square plate which was 11.8 cm in width and in height (Figure 1). The task silhouette was a lion or an arrow (Figure 2 left). The size of the both silhouettes were the same as one-fifth of the correct configuration which constructed by the 7 pieces. During the task, participants assessed how confident they were to complete the task at the Graphics Rating Scale (GRS). The GRS involved 6 verbal descriptors and 13 scale marks along a horizontal line. A description "Not at all" was written at the left end of the horizontal line, and "Nearly completed" was at the right end. An index arrow was attached on the GRS board so that the participants could indicate their
positions on the horizontal line taking the descriptions into account. At the beginning of the experiment, the index arrow was located on the center of the 13 scale marks. A digital video camera (Panasonic NV-GS100) recorded movements of the pieces and a location of the index arrow from 65 cm above.

## Procedure.

A participant sat down in front of a work desk on which the 7 pieces of Tangram and the GRS board were situated. The pieces were allocated on the desk as depicted in Figure 1 (below). After the instructions about what the experiment involved, the participant was presented the task silhouette which was printed in black and was required to complete the configuration of it by using all the pieces. The participant indicated how he or she would be able to complete the correct configuration of the silhouette by the index arrow on the GRS board. During the assessment, the participant was allowed to see the pieces and the silhouette but was not permitted to touch or move the pieces. After the assessment, the participant was allowed to move the pieces. Each session lasted for 240 sec , and was followed by the assessment on GRS. Then 1 minute of rest period was given to the participant until the next session was started.

When a participant completed the correct configuration, the problem solving was successfully ended. A sum of the manipulation time until the completion was accounted as a solution time of the "completer". A participant who could not complete the correct configuration until the end of session 5 was counted as a "non-completer". In this case, the total manipulation time was 20 min .

All the participants participated in the two-day experiment. Either the silhouette of the lion (lion task) or the arrow (arrow task) was given to the participant as a task in each day. The order of the task silhouettes was counterbalanced among the participants.

## Recording of eye movements

During process of the problem solving of Tangram, eye movements were captured using Talk Eye Lite (Takei Scientific Instruments Co. Ltd, Japan). Eye tracking was operated in monocular mode on the right eye and at a sampling rate of 33 Hz . The participants were seated on a chair and their head was fixed by using a chin and forehead rest to keep a distance from a surface of a work desk to eye in approximately 40 cm . The surface of the work desk was tilted to about 10 degree angle. The 7 pieces of Tangram were located on the desk surface and were moved within the range of 25 cm in length and 35 cm in width so as not to go outside the participant's eye-field.

## Results

Among the 20 participants, 9 completed the correct configuration of the task silhouette of a lion. The mean solution time was $594.7 \mathrm{sec}(S D=376.0 \mathrm{sec}$, Min $=106 \mathrm{sec}$, Max $=1080 \mathrm{sec}$ ). Three of the 9 completers had finished in session 1 , and 2 of the remaining 6 had finished in session 3. Three had finished in session 4 and 1 had finished in the last session. In the arrow task, 12 participants completed the
correct configuration within 5 sessions. The mean solution time was $483.6 \mathrm{sec}(S D=331.1 \mathrm{sec}$, Min $=58 \mathrm{sec}$, Max $=$ 1030 sec ). Among the 12 participants 4 had finished in session 1 . Two of the remaining 8 completers had finished in session 2. Three of the remaining 6 completers had finished in session 3. Two had finished in session 4 and 1 had finished in the last session. Eight of the 20 participants completed both the lion and the arrow task. The averaged solution time of these "high-achievers" was faster in the arrow task ( 532.8 sec ) than in the lion task ( 644.8 sec ), but statistical analysis revealed that the difference did not reach significant level ( $p>.1$ ). Therefore, contradicting to the expectation, both the ratios of the completer and their solution time did not indicate that there is a difference in difficulty between the two task silhouettes.

Ratings of subjective confidence to the completion were identified from a location of the index arrow on GRS from the video image. The value of 0 was assigned to the mark on left extreme side, and 12 was assigned to the right extreme mark. Six assigned to the central mark which located between the descriptions "possibly, I can complete" and "possibly, I cannot complete". A value of each rating was identified on the basis of relative distance of the index arrow from the marks. Mean ratings were calculated among the completers and the non-completers in each sessions. Figure 3 show the plots of the mean ratings as a function of the sessions for each task silhouette. Because the participants who had completed the task silhouette were not engaged in the assessment anymore, sample numbers included in the plots of the completer decreased as the session proceeded. All mean ratings of non-completers included 11 participants in Figure 3a and 8 in Figure 3b.

To investigate the relationship between participants' confidence and results of the problem solving, they were categorized into a high-achiever who completed the both task silhouettes or into a non-achiever who could not complete the both silhouettes. Thus, 5 participants who only completed the either task were eliminated from this analysis. Table 1 shows mean ratings of confidence in session 1 and in the last session for the high-achievers ( $n=8$ ), excepting one participant who completed the both tasks in session 1 , and for the non-achievers ( $n=7$ ), respectively. For the completers, the last session is when they completed the task, and for the non-completers it was always the fifth session. A $2 \times 2$ analysis of variance (ANOVA) with the variables achievement (high-achiever vs. non-achiever) and time (session vs. last session) showed that the effect of time was significant, $F(1,12)=52.2, p<.01$. In detail, the mean rating in session 1 was higher than that in the last session in the both groups. Supported with this result, the linear regression lines in Figure 3 indicated that participants' subjective assessments of their confidence decreased over time. The main effect of achievement and the interaction between the two variables did not reach statistical significance.

To investigate whether constraint relaxation was reflected on actual manipulation of the pieces, arrangements of the 2

Figure 3: Plots of mean ratings of subjective confidence and linear regression lines in the lion task (a) and the arrow task (b). The plots of Grey circle with a solid line indicate results of the completers and the plots of blank triangle with a dashed line indicate results of the noncompleters. The numbers beside the plots of the completer indicate a number of samples included in each mean value. Error bars indicate $S D$ s.

Table 1: Mean ratings and SDs of a participants' confidence

|  | High-achiever | Non-achiever |
| :--- | :---: | :---: |
| 1st session | $5.79(1.8)$ | $4.82(1.6)$ |
| Last session | $3.36(2.6)$ | $1.79(0.8)$ |

largest triangle pieces were categorized and their duration times were compared. When these 2 triangle pieces were in contact with each other at least on a corner or a side of them, this arrangement was counted as a combination of the pieces. All combinations of the 2 largest triangle pieces were identified on the video image and categorized into a geometric, a transitional or an irregular combination. In the case that the 2 pieces were combined into a triangle or a square, such the allocation was categorized into the geometric combination. In the arrow task, this category includes the correct combination of the 2 pieces. The participants often allocated the 2 pieces such that the short edge of one triangle is placed adjacent to the long edge of the second triangle so that no corners of the sides met, additionally the corner of the long edge of the second triangle did not make contact with the first triangle. As with these examples, an allocation of the 2 pieces in which the edges were placed adjacently without combining their corners was categorized into the irregular combination. In the lion task, this category includes the correct combination of the 2 pieces. All other combinations that were categorized neither into the geometric nor into the irregular combination were categorized into the transitional combination. A measure of the duration of the time in which each combination was made was taken from the video image. The measurement started from the moment at which the 2 pieces were allocated into a certain combination and ended when they were separated or changed into the other arrangement. To investigate a transition of a predominant combination of the pieces, overall manipulation time of each participant was divided into a first and a second half period. A cumulative duration time of each combination was calculated for each participant. Table 2 shows mean percentage of the cumulative duration time of each combination over the total manipulation time.

Three-way ANOVA with the variables completion (completer vs. non-completer), time ( $1^{\text {st }}$ vs. $2^{\text {nd }}$ half) and combination (geometric, transitional or irregular) was computed on percentage of the cumulative duration time. In the lion task, the results showed that there was a significant main effect of time variable, $F(1,18)=5.1, p<.05$, and two-way interaction between completion and time, $F(1,18)$ $=7.9, p<.05$. Post hoc analysis revealed that, in the completers, an averaged percentage of the cumulative duration time over the three combinations was significantly higher in the second half ( $14.9 \%$ ) than in the first half $(6.0 \%), F(1,18)=12.7, p<.01$, but the difference was not significant in the non-completer ( $11.3 \%$ in the $1^{\text {st }}$ half; $10.3 \%$ in the $2^{\text {nd }}$ half). Additionally, two-way interaction between time and combination was also significant, $F(2,36)$ $=7.5, p<.01$. Post hoc analysis revealed that the percentage significantly increased than the first half ( $5.7 \%$ in the $1^{\text {st }}$ half vs. $17.9 \%$ in the $2^{\text {nd }}$ half), $F(1,54)=12.8, p<.01$, while for the transitional combination the increase was marginally significant ( $8.2 \%$ vs. $14.8 \%$ ), $F(1,54)=3.7, p<.06$. In contrast, for the geometric combination, the percentage in the first half was significantly higher than the second half

Table 2: Percentage of the cumulative duration time of each combination over the total manipulation time

| Lion task <br> Geometric | Completer | Non-completer |
| :---: | :---: | :---: |
| $1^{\text {st }}$ half | $9.1 \%$ |  |
| $2^{\text {nd }}$ half | $2.3 \%$ | $15.2 \%$ |
| Transitional |  | $8.1 \%$ |
| $1^{\text {st }}$ half | $6.0 \%$ | $10.4 \%$ |
| $2^{\text {nd }}$ half | $13.1 \%$ | $16.5 \%$ |
| Irregular |  |  |
| $1^{\text {st }}$ half | $3.1 \%$ | $8.3 \%$ |
| $2^{\text {nd }}$ half | $29.3 \%$ | $6.3 \%$ |
| Arrow task | Completer | Non-completer |
| Geometric |  |  |
| $1^{\text {st }}$ half | $29.0 \%$ | $19.2 \%$ |
| $2^{\text {nd }}$ half | $26.8 \%$ | $27.1 \%$ |
| Transitional |  |  |
| $1^{\text {st }}$ half | $1.4 \%$ | $1.7 \%$ |
| $2^{\text {nd }}$ half | $6.1 \%$ | $1.5 \%$ |
| Irregular |  |  |
| $1^{\text {st }}$ half | $5.3 \%$ | $4.9 \%$ |
| $2^{\text {nd }}$ half | $5.3 \%$ | $3.7 \%$ |

$(12.1 \%$ vs. $5.2 \%), F(1,54)=4.1, p<.05$. The three-way interaction reached statistically significant, $F(2,36)=4.9, p$ $<.05$. Post hoc analysis revealed that in the second half the percentage of the irregular combination was higher in the completer than that in the non-completer ( $29.3 \%$ vs. $6.3 \%$ ), $F(1,54)=13.8, p<.01$, but in the first half the difference was not significant ( $3.1 \%$ vs. $8.3 \%$ ). Regarding the completers, the percentage of the irregular combination (29.3\%) was significantly higher than that of the geometric ( $2.3 \%$ ) and the transitional combination (13.1\%) in the second half, all $p s<.01$. This percentage of the completer in the second half was significantly increased than the first half $(3.1 \%), F(1,54)=29.8, p<.01$. In the arrow task, three-way ANOVA showed that the main effect of combination variable was significant, $F(2,36)=11.1, p<.01$. Multiple comparisons revealed that the percentage of the geometric combination averaged over time and completion variables ( $25.2 \%$ ) was significantly higher than that of the transitional ( $2.8 \%$ ) and the irregular combination ( $5.1 \%$ ), all $p \mathrm{~s}<.01$. The other main effect and the interactions did not reach statistical significance.

To investigate whether there is a characteristic attentional shift when problem-solvers reach the solution of Tangram, eye tracking data was recorded during the participants manipulated the 7 pieces. Areas of interests (AOIs) were surface of the each piece and the silhouette which was presented to the participants. When the participants looked
at the range of a single piece or at the silhouette for more than 33 while manipulating the pieces, this duration time was accumulated as a time spent looking at the AOI. The proportion of the time spent looking at the AOI per second during the total manipulation time was calculated for the each piece, and it summed over the 7 pieces for each participant. Table 3 shows the mean proportions of the time spent looking at the pieces and that looking at the silhouette, for the high-achievers who completed both the tasks and for the non-achievers who could not complete the both tasks. Statistical analysis revealed that the proportion of the time spent of the non-achievers looking at the pieces (283.1 $\mathrm{msc} / \mathrm{sec}$ ) was significantly longer than that of the highachievers $(137.4 \mathrm{msc} / \mathrm{sec}), F(1,13)=10.9, p<.01$. There was no difference between these two groups in the proportion of the time spent looking at the silhouette. The result that the time spent looking at the range of the pieces was relatively short might be reflected a wider or more active scanning over the problem space. In order to verify this inference more directly, eye movement distance during the participants manipulated the piece was calculated. The values in the bottom row of Table 3 indicate a mean eye movement distance per second in a visual angle for the high-achiever and for the non-achiever. Statistical test revealed that the eye movement distance of the highachiever was higher than that of the non-achiever but it was marginally significant, $F(1,13)=3.15, p<.10$.

Table 3: Mean proportion of the time spent ( $\mathrm{msc} / \mathrm{sec}$ ) and the eye movement distance (deg/sec)

|  | High-achiever | Non-achiever |
| :---: | :---: | :---: |
| Proportion of time |  |  |
| 7 pieces | $137.4(40.0)$ | $283.1(108.3)$ |
| Silhouette | $25.7(31.4)$ | $13.2(11.9)$ |
| Movement distance | $72.4(47.3)$ | $36.8(25.3)$ |

## Discussion

This research aimed to demonstrate a constraint relaxation which is followed by the transition to an appropriate representation in insight problem solving. For this purposes, Tangram was used as a new tool. To investigate the correspondence between the constraint relaxation and actual manipulation of the pieces of Tangram, combinations of the 2 largest triangle pieces which were the key to completing the two task silhouettes, a lion and an arrow, were analyzed. Nakano (2009) found that problem-solvers of Tangram tended to combine these 2 pieces into a geometric shape. This initial constraint would facilitate reaching an insight for the solution of the arrow task, because the correct configuration of this silhouette could be achieved by arranging the 2 pieces into either a square or a triangle. As expected, in this task both the completers and the non-
completers arranged the 2 pieces predominantly in a geometric combination through the problem solving. While in the lion task, this initial constraint to arrange the pieces into a geometric combination would inhibit the insight to occur, because the 2 pieces should be arranged in an irregular combination to complete the correct configuration of the lion task (top-right in Figure 2). Thus, the participants were expected to achieve better results in the arrow task than in the lion task. Contrary to this prediction, however, neither the percentage of the completers nor the time to completion of the high-achievers who were completed the both tasks were significantly different between the two tasks. This finding supported the view that the relaxation of the initial constraint was not the sole determinant of the insight for reaching the solution (Ormerod et al., 2002). As an evidence of this interpretation, in the lion task, the percentage of the cumulative duration time that the 2 pieces were arranged in the geometric combinations was decreased in the second half comparing with the first half. Importantly, such the decrease was found not only in the completers but also in the non-completers.

The critical difference between the completers and the non-completers was found in the lion task, in that, the completers arranged the 2 pieces in the irregular combination for a longer time in the second half than in the first half. This result for the completer should be a manifestation that the relaxation of the inappropriate initial constraint was followed by the construction of more appropriate representation. In contrast to this steady approach of the completers to reach the solution, the noncompleters could not distinguish which of the three types of combinations would lead them to the solution, even in the second half. Therefore, the critical determinant for reaching an insight to the solution was a clear cut differentiation between the appropriate representation and other alternatives.

The participants' eye movements were measured while they manipulated the pieces, in order to investigate specific feature of attention shift that facilitated the successful problem solving in Tangram. The analysis of the time spent looking at the surface of the pieces indicated the noteworthy difference between the high-achiever and the non-achiever that the latter had a longer time staying attention on the pieces. In contrast to this attentional feature of the nonachiever, the high-achiever had a slightly longer distance of eye movements during the manipulation of the pieces than the non-achiever. These findings suggested that the successful problem-solvers of Tangram tended to search the problem space of the pieces more widely or actively.

The second purpose of this research was to demonstrate the independence between the transition from the initial but inappropriate constraint to the more appropriate representation for the solution and the changing of the confidence to reach the solution. There was a remarkable difference between the results of the present experiment and the series of the researches by Metcalfe (Metcalfe, 1986; Metcalfe and Wiebe, 1987). In these previous researches,
most of the participants rated their confidence lowest level at the starting of the problem solving, and their selfevaluations stayed constant or slightly increased by the floor effect. While in the present experiment, the evaluation to the confidence was relatively high before starting the problem solving of Tangram, and it declined over time. Considering that the findings of Metcalfe was obtained by using insight problems including a spatial task and a linguistic task, Tangram is more likely to give the impression that it is easy to solve than those other insight problems, especially at the beginning of the problem solving. Another notable finding was that the participants who solved the insight problem had evaluated less confidence to reaching the solution (Metcalfe, 1986; Metcalfe and Wiebe, 1987). In other words, the actual achievement of each participant had opposite direction to their subjective confidence. Furthermore, the present experiment indicated that the completer manipulated the pieces so as to approach to the solution steadily but their confidence about it consistently declined. Therefore, this finding demonstrated that the process of deriving an insight and the subjective awareness to the problem solving did not progress independently but in the opposite direction over time.

#### Abstract

Biological systems are capable of acting in a shared environment to produce emergent, self-organized behavior that is the result of the constraints imposed by local interactionssuch as bird flocking or ant swarming behavior. These examples present minimal demands for a shared-intention between co-actors, whereas other instances necessitate the formation of a shared goal. In these goal-directed tasks, how much of the observed complexity can be explained by the constraints imposed by both the environment and adherence to the shared task goal? This paper begins to investigate this question by presenting results from a two-person cooperative "shepherding" task first developed in Nalepka et al. (2017) but with fewer constraints. Results provide further evidence that the emergent behavior is the result of the constraints imposed by the task. The included task-dynamic model suggests a general model that can be used to understand multiagent herding behavior in a variety of contexts.

Keywords: joint action, collective herding, task-dynamic modeling

## Introduction

Emergent collective behavior in animal systems can oftentimes be understood by agents whose behaviors are constrained by local information. In non-human systems, such as ant trails, the observed behavior to a food source can be attributable to local interactions between ants and the strength of a deposited pheromone trail (Deneubourg et al., 1989). For humans, the route chosen to go to class in the
winter can be attributable to the paths carved in the snow by previous students (Goldstone \& Roberts, 2006). These examples don't necessitate the formation of a sharedintention (Searle, 1990) as these agents are exploiting their environment to reach their own individual aims.

However, human actors can engage in complex goaldirected behavior such as playing in team sports where the actors are working towards a common shared goal - a jointaction. Work discerning the neurocognitive mechanisms that support the timing and prediction of actions have been proposed to explain how human systems successfully accomplish joint-action tasks (Vesper, et al., 2011). Indeed, suboptimal coordination not only leads to sub-optimal performance, but can have a negative impact on one's selfesteem and one's opinion of a co-actor (Lumsden, Miles, \& Macrae, 2014). Similarly, suboptimal coordination during human-robot interaction (HRI) also leads to poorer performance and a depreciated user experience, with users often attributing poorer performance to a lack of predictability and reciprocal compensation on the part of the robot (Medina, Lorenz, \& Hirche, 2015).

How much of the complexity observed in cooperative action can be attributed to the constraints imposed by the environment, as well as the task goal? An approach to understand the behavioral dynamics that shape and constrain natural human performance is to argue that humans organize themselves as "special-purpose devices" to satisfy the dynamics of a particular task (Saltzman \& Kelso, 1987). For
example, in a reaching task, the body self-organizes so the hand becomes a damped mass-spring that moves towards, say, a mug (a fixed-point attractor). These low-dimensional models, in the case of reaching, can produce straight-line trajectories and deal with perturbations that may occur during the action.

To date, such task-dynamic models, expressed as ordinary differential equations, have been used to understand human path navigation and obstacle avoidance (Fajen \& Warren, 2003; Warren, 2006) and tested in robotic systems, such as a skiing robot (Lahajnar, Koss \& Nemec, 2009). In the joint action literature, virtual agents have also been created to perform oscillatory movements with a human partner (Zhai, et al., 2014; Kostrubiec, et al., 2015) with the movement dynamics of the virtual agent defined by a coupled nonlinear oscillator that produces patterns of coordination consistent with the Haken-Kelso-Bunz (HKB) model of rhythmic coordination (Haken, Kelso, \& Bunz, 1985); namely, stable, or intermittent in-phase $\left(0^{\circ}\right)$ and anti-phase $\left(180^{\circ}\right)$ modes of behavior. Perhaps most noteworthy is recent work by Zhai et al. (2014) and Kostrubiec et al. (2015), who demonstrated the ability for artificial agents incorporating nonlinear oscillatory models to coordinate with humans to reproduce the dynamics observed in human-human pairs, with the added benefit of enabling these nonhuman agents to steer humans to new coordinative modes that are unstable and difficult to master (like a $90^{\circ}$ phase relationship).

Recently, Nalepka et al. (2017) created a virtual shepherding task (Figure 1) to explore and model goaldirected behavior in a multiagent task to understand how stable social behavior emerges in more complex tasks with changing environments. The task required pairs to coordinate their movements in such a way as to corral and contain reactive autonomous spheres (referred to as sheep) to the center of a game field by controlling their player cube (referred to as their sheepdog) with a handheld motiontracking sensor. In the beginning, participants engaged in a behavior termed search and recover (S\&R) which involved moving one's controller towards the farthest sheep so that the sheep would be repelled towards the containment region. Using this strategy, some pairs could meet the success criteria for the task (defined as keeping all sheep within the containment region for a certain proportion of time (see Figure 1). However, a subset of successful pairs transitioned to a new behavioral mode termed coupled oscillatory containment (COC) that was functionally superior to $\mathrm{S} \& \mathrm{R}$. COC was defined by both participants performing oscillatory movements around the containment region to wall-in the sheep.

Interestingly, the COC behavioral mode exhibited similar dynamic stabilities as prototypical interpersonal or visual rhythmic coordination (Schmidt, Carello, \& Turvey, 1990; see Schmidt \& Richardson, 2008 for a review) described by the HKB model above, with pairs naturally exhibiting inphase and anti-phase patterns of COC behavior. Therefore, the shepherding task supplies a functional consequence for coupled rhythmic behavior that can be used to study
interpersonal coordination more generally. Videos illustrating the shepherding task are found at http://www.emadynamics.org/bi-agent-sheep-herdinggame/.

Figure 1: Depiction of task from Nalepka et al. (2017)

## The Shepherding Model

Nalepka et al. (2017) formulated a task-dynamic model of the human behavior observed in the shepherding task (also Richardson et al., 2016); they also successfully validated that this model, embodied in a virtual avatar, can complete the task successfully alongside a human partner (Nalepka et al., 2016). The model defines the task space in terms of a polar coordinate system (see Figure 2). The radial component (whose origin is the center of the containment region) of the system is defined using the following damped mass-spring equation,

$$
\begin{gather*}
\ddot{r}_{i}+b_{r i} \dot{r}_{i}+\varepsilon_{i}\left(r_{i}-\xi_{i}\left(r_{p s(t), i}+\Delta r_{\min , i}\right)\right. \\
\left.-\left(1-\xi_{i}\right)\left(r_{\min , p s(t), i}+\Delta r_{\min , i}\right)\right)=0 \tag{1}
\end{gather*}
$$

where $r_{i}, \dot{r}_{i}$, and $\ddot{r}_{i}$ are the radial position, velocity and acceleration of player $i(i=1,2) ; b_{r i}$ is the radial damping term, $r_{p s(t), i}$ is the radial coordinate of the player $i$ 's radially farthest sheep on their side of the field, $\left(r_{p s(t), i}+\Delta r_{\text {min,i }}\right)$ is the preferred radial target position that the player approaches for this farthest sheep, and $\varepsilon_{i}$ scales the strength of the centrally-directed radial force attracting player $i$ to the targeted sheep. This force is gated by $\xi_{i}$, a Heaviside parameter:

$$
\xi_{i}=\left\{\begin{array}{l}
0, r_{p s(t), i}<r_{\min , p s(t), i}  \tag{2}\\
1, r_{p s(t), i} \geq r_{\min , p s(t), i}
\end{array}\right.
$$

If the radial coordinate of at least one sheep is greater than or equal to $r_{\min , p s(t), i}$, then the player will select the furthest sheep, $r_{p s(t), i}$, and move to ( $r_{p s(t), i}+\Delta r_{\text {min, } i}$ ); otherwise, when $\xi_{i}=0$, the player will move towards $\left(r_{\text {min,ps }(t), i}+\right.$ $\left.\Delta r_{\text {min, } i}\right)$, their preferred distance from the center.

To be consistent with the previous research modeling the dynamics of rhythmic human interlimb and interpersonal coordination captured by the HKB model (Haken et al., 1985), the angular component of the players' movements (centered on the player's sagittal plane on their side of the
field) was modeled using the following modified set of coupled Rayleigh/van der Pol hybrid nonlinear oscillator equations,

$$
\begin{gather*}
\ddot{\theta}_{i}+b_{\theta i} \dot{\theta}_{i}+\beta_{i} \dot{\theta}_{i}^{3}+\gamma_{i} \theta_{i}^{2} \dot{\theta}_{i}+\omega_{i}^{2}\left(\theta_{i}-\xi_{i} \theta_{p s(t), i}\right) \\
=\left(1-\xi_{i}\right)\left(\dot{\theta}_{i}-\dot{\theta}_{j}\right)\left(A_{i}-B_{i}\left(\theta_{i}-\theta_{j}\right)^{2}\right), \tag{3}
\end{gather*}
$$

where $\theta_{i}, \dot{\theta}_{i}$ and $\ddot{\theta}_{i}$ are the angular position, velocity, and acceleration of player $i, . \omega_{i}$ is a player's natural angular oscillation frequency; $b_{\theta i}$ is the angular linear damping term; $\beta_{i} \dot{\theta}_{i}^{3}$ and $\gamma_{i} \theta_{i}^{2} \dot{\theta}_{i}$ are Rayleigh and Van der Pol escapement terms, respectively; and $A_{i}$ and $B_{i}$ are the parameters used in the HKB model to define the relative strength of in-phase and anti-phase coordination patterns. The parameter $b_{\theta}$ is governed by the equation,
$\dot{b}_{\theta i}+\delta_{i}\left(b_{\theta i}-\alpha_{i}\left(r_{p s(t), i}-\left(r_{\min , p s(t), i}+\Delta r_{m i n, i}\right)\right)\right)=0$,
where negative values of $b_{\theta i}$ produce oscillatory behavior, while positive values produce fixed-point behavior. Parameters $\delta_{i}$ and $\alpha_{i}$ govern the dynamics of $b_{\theta i}$ across its range of allowable values.

Figure 2: Depiction of model task space. Player $i=1$ is exhibiting oscillatory behavior, while player $i=2$ exhibits S\&R behavior. The smaller circles illustrate the sheep that must be kept within the containment region (larger circle).

The interplayer system modeled by Eq. $1,3 \& 4$ dictates the behavioral mode player $i$ produces. If $\xi_{i}=1$, the player is uncoupled from their partner $j$ (via the right half of Eq. 3), and moves towards the angular component of the furthest sheep; otherwise, the player will center their angular component to $0^{\circ}$ (here $b_{\theta i}$ will move towards a negative value and begin to produce oscillatory behavior). Parameter $\omega_{i}$ is the rate at which these angular destinations are reached. However, when $\xi_{i}=0$, the player becomes coupled to the
angular component of their partner's movement. This coupling function reproduces both in-phase $\left(0^{\circ}\right)$ and antiphase $\left(180^{\circ}\right)$ stable relative phase relationships, with the relative strength of these two coordination patterns defined by the parameters $A_{i}$ and $B_{i}$.

## The Current Project

The behavioral modes observed in Nalepka et al. (2017) are very like the behavioral modes found in real sheepdog shepherding (Strömbom et al., 2014). However, it is unclear whether the oscillatory behavior seen in Nalepka et al. (2017) emerged from the local interactions of both players and the sheep, or if it was due to participants attuning to pre-defined environmental features of the task. Trajectories observed in Nalepka et al. (2017) tend to trace the outer white circle of the containment region (see Figure 1). In the original experiment, this white circle indicated a failure criteria that ended a trial if all sheep managed to escape. However, anecdotally, some participants asked if they could enter the containment region, opening the possibility that participants perceived certain visually-marked locations to be appropriate (like the white region) and others not (such as the red containment area). Thus, the oscillatory behavior observed may have been a consequence of this perceived task constraint and the circular goal region.

The present work removed these visual landmarks and edited the task to have fewer constraints to test the generality of the developed task-dynamic model. Criteria that would cause a trial to fail prematurely were removed, with participants simply instructed to corral the sheep together, without a target goal region in mind. To keep scoring criteria similar to the original work, a containment region (invisible to participants) moved in accordance with the center of the herd, consistent with Strömbom et al. (2014) who suggested that sheepdogs corral sheep that are furthest from the center of the rest of the herd.

We tested a new set of naive participants to determine whether S\&R and, more importantly, COC behavior would still emerge. We also compared the participant performance to the performance of a slightly modified version of the virtual shepherding model presented above. In short, the model was modified so that the center of the task dynamic space that defined the $(0,0)$ point of the radial distance and polar task axes was dynamically tied to the herd's center of mass (COM), as opposed to being fixed in the center of game field $(0,0)$. At any time $t$, the herd's COM was calculated as the average sheep position in Cartesian coordinates and was subtracted from each game object's $(\mathrm{x}, \mathrm{y})$ positions.

## Method

## Participants

Thirty-eight participants ( $M$ age $=18.82,17-22$ ), recruited as 19 pairs completed the experiment. All participants were undergraduates from the University of Cincinnati and received course credit for participation. For model simulations, 10 artificial pairs were created with the
following parameter values: $b_{r}=10.9987, \varepsilon=98.70672$, $r_{\text {min }, p s(t)}=.062 \mathrm{~m}, \Delta r_{\text {min }}=.061539, \delta=23.08993, \alpha=$ 80.59288, $\beta=.161641, \gamma=7.22282, \omega=7.85, A=-.2$, and $B=.2$. The model was designed to perform COC behavior if all sheep on the player's side of the field was within $r_{m i n, p s(t)}$, as described above. Up to $\pm 1 \frac{r a d}{s^{2}}$ and $\pm 1 \frac{\mathrm{~cm}}{\mathrm{~s}^{2}}$ noise was randomly added to both $\ddot{\theta}_{P i}$ and $\ddot{r}_{P i}$ at a rate of 50 Hz .

Figure 3: Virtual experimental room with example initial sheep arrangement.

## Apparatus and Task

The task was designed using the Unity 3D game engine (version 5.2.1; Unity Technologies, San Francisco, California) and was presented to participants via Oculus Rift DK2 (VR) headsets (Oculus VR, Irvine, California). The virtual environment (Figure 3) was modeled at $1: 1$ scale after the experimental room. The task was presented in the VR headset to appear on a virtual tabletop modeled at $1: 1$ scale to the glass tabletop in the real environment, which acted as the solid physical surface on which participants could move their motion sensors. Participants used wireless Latus motion tracking sensors operating at 96 Hz (Polhemus Ltd, Vermont, USA). Participants moved the sensor along the glass tabletop, and hand movements translated $1: 1$ to movements of the player's cube (sheepdog) in the virtual environment. Participants were given a body in the virtual world, modeled after a crash test dummy of height 1.8 m whose motion was controlled using an inverse kinematic calculator (model and calculator supplied by Root Motion, Tartu, Estonia) based on the real movements of the participant's right hand (via the Latus motion sensor) and head (via the Oculus Rift).

Participants could move their sheepdogs anywhere in twodimensional space within the 1.5 by 0.8 m fenced area of the grass task field. The goal of the task was to jointly find a solution to corral seven wool-covered stimulus spheres (sheep) towards one another so that they turned to a red color. The sheep were programmed to turn red when all sheep were within 10.8 cm of the herd's COM. Note, if the fence was 10.8 cm from the herd center, the sheep did not turn red. This was done intentionally to keep participants from adopting a strategy which involved keeping the sheep cornered. On each trial, sheep appeared randomly within a .50 by .80 m boxed
area, randomly centered either on the center of the game field, or $\pm .50 \mathrm{~m}$ to either side. Forces from a random direction were applied to each sheep at a sample rate of 50 Hz , resulting in Brownian motion dynamics. If a sheep collided with the fence, a repulsive force was applied to move the sheep back towards the center. The sheep also dynamically reacted to the participant-controlled sheepdogs as if threatened, being repelled away from a participant's sheepdog when the sheepdog was within 12 cm of the sheep's game location. When threatened, the sheep would move directly away from the player at a speed proportional to the inverse of the squared distance between the sheep and the player. If the sheep were red for at least $70 \%$ of the last 45 seconds of a two-minute trial, the pair received a point. The experiment ended when the participants scored eight points, or after 45 minutes, whichever came first.

## Procedure

Following informed consent, participants stood on either side of the experimental table where they put on their respective virtual headsets and were given a motion sensor to hold in their right hand. Following calibration, participants were informed about the task goal and the conditions for success and failure. Participants were not told how near the sheep needed to be to turn red. Instead, they were instructed that if the sheep were not red, then they either needed to be closer together, or that the herd was too close to the fence. Participants were told that once the experiment began, they were not allowed to speak with one another until after debriefing. The experimenter remained in the room to enforce the no-talking rule and to answer any questions.

## Results

A preliminary review of participant behavior revealed that all pairs exhibited S\&R behavior and, more importantly, that several pairs discovered and exhibited the same type of COC strategy observed by Nalepka, et al. (2017). Here we present the COC classification criterion utilized, and the performance differences observed between COC trials (from the COCclassified pairs) and S\&R trials (from S\&R-classified pairs). The focus of the analysis presented here was to confirm that (a) COC is a robust emergent mode of behavior and (b) that COC behavior was superior to S\&R behavior. The results from the model simulations followed the same analyses and were employed to determine whether the task-dynamic model could effectively capture the dynamics observed in this less constrained task context. Classification and analyses were conducted on the last 45 seconds of each two-minute trial. This was set because participants were told that performance was measured during this time and that the first 75 seconds was to be used as time to corral the sheep and initiate resultant containment strategy. Because success was defined as keeping the sheep within 10.8 cm of their COM, all data were converted to polar coordinates with the center located at the herd COM. For the purposes of this paper, only successful trials were analyzed.

As defined by Nalepka et al. (2017), a trial was classified as COC if the peak angular oscillatory component was between 0.5 Hz and 2 Hz . More specifically, the classification criterion was as follows,

$$
\begin{equation*}
\varphi_{i, k}=\frac{\omega_{\text {freq }, i, k}-.5}{\left|\omega_{\text {freq }, i, k}-.5\right|} \omega_{\text {power }, i, k}, \tag{5}
\end{equation*}
$$

where $\omega_{\text {freq,i,k }}$ is the peak angular oscillatory component for player $i$, of pair $k$ and $\omega_{\text {power }, i, k}$ is its associated power. The average for both players, $\bar{\varphi}_{k}$, is taken and if the resultant average is positive, the trial is classified as predominately COC. Conversely, negative values resulted in a trial being classified as an S\&R trial. For analyses, the angular component of each dog was detrended and $z$-score normalized and submitted to MATLAB's pwelch function using a $50 \%$ overlap window of 512 samples.

Thirteen of the 19 pairs met the success criteria for the task. One of the remaining six pairs had five of the eight successful trials completed and were included in the analysis, while the remaining five did not have a single successful trial. Successful S\&R trials had an average classification value $\bar{\varphi}_{k}$ $=-0.47$ and successful COC trials had a value $\bar{\varphi}_{k}=0.23$ for human pairs, while it was $\bar{\varphi}_{k}=.22$ for the artificial pairs, which only exhibited successful COC trials. In total, nine pairs exhibited predominately $S \& R$ behavior to complete the task (with two pairs exhibiting one and three trials classified as COC), while the remaining five pairs completed the task with at least four trials classified as $\operatorname{COC}\left(M_{\text {\#trials }}=5.8\right.$ classified as COC). The artificial pairs completed the experiment in less time ( $M=16.8 \mathrm{~min}, S D=1.03$ ) than both $\mathrm{S} \& \mathrm{R}(M=29.75 \mathrm{~min}, S D=8.03)$ and $\mathrm{COC}(M=26.00 \mathrm{~min}$, $S D=6.32$ ) human pairs, $F(2,20)=12.75, p=.001, \eta^{2}=.56$.

The following four variables were examined to characterize performance differences between behavior modes: (1) containment time-the number of seconds the sheep were within 10.8 cm of the herd center while also 10.8 cm away from the nearest fence; (2) average sheep radial distance-the average distance from the herd center; (2) herd travel-the total distance travelled by the herd center; (4) and herd area - the area of the convex hull formed by the set of sheep positions. Only S\&R trials were considered for S\&R pairs and COC trials for both COC pairs and artificial pairs.

Performance differences were found for all variables: containment time, $F(2,21)=68.18, p<.001, \eta^{2}=.87$, average sheep radial distance, $F(2,21)=142.74, p<.001, \eta^{2}=.93$, herd travel, $\left.F(2,21)=140.46, p<.001, \eta^{2}=.93\right)$, and herd area $F(2,21)=11.61, p<.001, \eta^{2}=.53$. Figure 4 provides a summary of the findings. Performance by COC pairs on COC trials were found to be superior to performance by $S \& R$ pairs in all cases: containment time (COC $M=44.1 \mathrm{~s}, S D=1.01$; S\&R $M=39.91 \mathrm{~s}, S D=1.42[p<.001]$ ), average sheep radial distance (COC $M=2.73 \mathrm{~cm}, S D=.41 ; \mathrm{S} \& \mathrm{R} M=3.99 \mathrm{~cm}$, $S D=.20[p<.001])$, herd travel $(\operatorname{COC} M=62.74 \mathrm{~cm}, S D=$ 10.91; S\&R $M=106.90 \mathrm{~cm}, S D=19.16[p<.001])$ and herd area $\left(\mathrm{COC} M=23.87 \mathrm{~cm}^{2}, S D=13.80 ; \mathrm{S} \& \mathrm{R} M=55.66 \mathrm{~cm}^{2}\right.$, $S D=29.32[p=.02])$. Compared to COC human pairs, the
artificial pairs contained the sheep closer to the herd COM ( $M=2.32 \mathrm{~cm}, S D=.04,[p<.01])$ and had less herd travel ( $M=8.92 \mathrm{~cm}, S D=.44,[p<.001])$.

Figure 4: Result Summary Plots.

## Conclusion

Consistent with findings by Nalepka et al. (2016; 2017), the results provide further support that COC behavior is not a consequence of players tracing a visually salient boundary to contain the sheep, but rather emerges naturally from interactions between players within the shepherding task environment. Further, the task-dynamic model developed by Nalepka et al. (2017) can be minimally modified to function in this less constrained herding task space, by tracking the center of the herd. It is important to note that seven pairs completed the experiment without exhibiting any COC behavior. This may be due to the relaxed scoring criteria that allowed for stable S\&R behavior. Increasing task difficulty, like increasing the time needed to contain the sheep, is predicted to cause more pairs to transition to COC behavior, as it was associated with better task performance.

An approach to understand multiagent coordination is to treat human systems as self-organized "special-purpose devices" whose dynamics adhere to the constraints dictated by the task and environment (Saltzman \& Kelso, 1987; Richardson et al., 2016). Task-dynamic models that embody these constraints can be embedded in robot systems to produce human-like behavior. Because the presented model embodies the constraints inherent to herding autonomous agents, the model can be extended to include systems that can
work alongside humans in other herding-like tasks such as fire evacuation and environmental hazard containment. Similarly, these systems can potentially be used to steer novices to discover more optimal modes of behavior - in the shepherding task, but possibly in rehabilitation or educational contexts in the future.

Finally, the shepherding model is symmetrical, but many examples exist where distinct but complementary actions are needed to reach a collective goal - for example a basketball player performing a "pick" while their teammate breaks free to take a shot. Work has been done to incorporate the recent shepherding model by Strömbom et al. (2014) to two virtual sheepdogs, who each are responsible for either collecting or driving the herd (Watanabe and Fujioka, 2017). However, the sheepdogs' roles were rigidly defined and led to greater sheep dispersion compared to single dog performance who could adaptively switch between both modes. Models that allow multiple agents to switch between multiple behavioral modes without interference are still needed to develop systems that can work fluidly alongside humans of various skillsets.

#### Abstract

People rely on various frames of reference (FORs), such as egocentric (EFOR) and intrinsic (IFOR), to represent spatial information. The present study examined electroencephalogram profiles on a two-cannon task, which could regulate the conflict of IFOR-IFOR (red cannon, blue cannon) and IFOR-EFOR (target cannon, observer), to elucidate the brain mechanisms of FOR conflict processing by using event-related potentials (ERPs). Results showed that both of the conflicts occurred in the reaction time (RT) and there was an interaction between them. ERP results showed more negative amplitudes on $\mathrm{N} 2(276-326 \mathrm{~ms}$ ) and P3 (396726 ms ) for IFOR-IFOR conflict of the $180^{\circ}$ cannon angle condition and EFOR-IFOR conflict of the target cannon point-down condition. What's more, there was also an interaction between these two conflicts on the P3 amplitudes ( $561-726 \mathrm{~ms}$ ). In summary, our findings shed new light on the domain-specific conflict monitoring and domain-general executive control for the IFOR-IFOR and EFOR-IFOR conflicts.

## Introduction

People adopt multiple frames of reference (FORs) to represent the spatial relationship of objects in a complex environment (Sun \& Wang, 2014). Based on the relationship with the observer, FORs can be classified into three types, egocentric FOR (EFOR), intrinsic FOR (IFOR) and allocentric FOR (AFOR) (Mou \& McNamara, 2002; Tamborello, Sun, \& Wang, 2012). An EFOR-based representation is anchored to the observer, which needs to be updated following the movement of the observer's eye, head, body coordinates (Wang, Johnson, \& Zhang, 2001). In an IFOR-based representation, an object or an object group in the viewing environment but exogenous to the observer is used as the reference point. For example, a car is used as an IFOR anchor in the description "the cat is in front of the car". IFORs remain stable with the observer's movement but have to be updated when the reference object moves. In an AFOR-based representation, the entire environment, such as a room or a city, is taken as the reference point. For a comprehensive review, see (Mou, Fan, McNamara, \& Owen, 2008; Mou \& McNamara, 2002; Sun \& Wang, 2010, 2014; Tamborello et al., 2012; Yamamoto \& Philbeck, 2013).
"Frame of Reference-based Map of Salience" theory (FORMS) states the human brain represents spatial information simultaneously using multiple FORs, all FORs consist of a FOR map of different salience, and human performance is determined by the interaction of all relevant FOR-based representations (Itti \& Koch, 2000; Sun \& Wang, 2010, 2014; Tamborello et al., 2012; Wang et al., 2001; Wang, Sun, Johnson, \& Yuan, 2005).

If different FORs generate different responses for one target, conflict may occur which requires cognitive control to solve it (Chen, Weidner, Weiss, Marshall, \& Fink, 2012; Nan, Li, Sun, Wang, \& Liu, in press; Sun \& Wang, 2014; Tamborello et al., 2012). According to the different kinds of FORs in the map (one EFOR, one AFOR, multiple IFORs), we could categorize the conflict of FORs as four types: EFOR-AFOR, EFOR-IFOR, AFOR-IFOR, and IFOR-IFOR. Plenty of studies has demonstrated that there exists the conflict of EFOR-AFOR (Chen et al., 2012; Conson, Mazzarella, Donnarumma, \& Trojano, 2012; Zhang et al., 2014), EFOR-IFOR (Wang et al., 2005). In addition, previous studies also showed the process of EFOR and AFOR were in parallel. EFOR has high salience and is almost processed automatically that needs little cognitive resource; EFOR is represented and processed in the dorsal visual stream subserving goal-directed actions. AFOR has low salience and needs more cognitive resource to process. AFOR is represented and processed in the ventral visual stream subserving the conscious perception of objects or spatial memory function (Goodale \& Milner, 1992; Zhang et al., 2014).

However, does it also exist a conflict of IFOR-IFOR and AFOR-IFOR? There were rare studies focusing on this question. If yes, how does our brain process and solve all these conflicts of different FORs (IFOR-IFOR, EFOR-IFOR, EFOR-AFOR, AFOR-IFOR)? What's more, in view of the limit cognitive resource, is the process of the multiple IFORs also in parallel as same as the process of EFOR and AFOR, or just in serial? If the process is in serial, only one IFOR could be represented and processed, so we could only observe the EFOR-IFOR conflict. Mou et al. $(2002,2008)$ found that people got higher accuracy for recalling spatial objects' locations represented by IFOR than that represented by EFOR, this means that people might prefer to use IFOR
to represent the environment, so IFOR might not need much cognitive resource. According to this, the process of multiple IFORs might be in parallel, different IFORs could be represented and processed, so we could observe the IFOR-IFOR conflict and the interaction among IFOR-IFOR conflict and the EFOR-IFOR conflict.

Following these questions and hypothesis, we developed a two-cannon task (see Figure 1) which could manipulate the EFOR-IFOR and IFOR-IFOR conflicts (Nan et al., in press; Tamborello et al., 2012). The EFOR-IFOR conflict was examined by the target cannon orientation (congruent condition: target cannon pointed-up, incongruent condition: target cannon pointed-down). The IFOR-IFOR conflict was examined by the cannon angle (congruent condition: $0^{\circ}$ cannon angle, incongruent condition: $180^{\circ}$ cannon angle). The behavioral studies' results showed that the IFOR-IFOR and EFOR-IFOR conflicts (RTs of the incongruent conditions were longer than that of the congruent conditions), and there was an interaction between these two conflicts. The cannon angle effect supported the hypothesis

Figure 1. A schematic illustration of the two-cannon task. At the beginning of each trial, a stimulus with two cannons (one blue and one red) and eight pellets (in either blue or red) was presented on the computer screen for 1000 ms , then the target would flash a yellow ring for 1000 ms , participants were asked to press two buttons in the keyboard to rotate the target cannon (with the same color of the target) to the target in the least distance, as quickly as possible. Cannon angle $\left(0^{\circ}, 180^{\circ}\right)$ was designed to test the conflict of IFOR-IFOR, target cannon orientation (target cannon point-up: the combination of target cannon points up-left, up, and up-right conditions; target cannon point-down: the combination of target cannon points down-left, down, and down-right conditions) was designed to test the conflict of EFOR-IFOR.
that there existed the IFOR-IFOR conflict. The target cannon orientation effect supported the hypothesis that there existed the EFOR-IFOR conflict. The interaction between two conflicts supported the hypothesis that the process of different IFORs was in parallel which the two conflicts would be interactive at the late response-selection stage. In summary, the behavioral results suggested that our brain might use a shared conflict processing mechanism for the IFOR-IFOR and EFOR-IFOR conflicts.

However, how does the conflict processing mechanism work at the neural level? Are they just process by the same conflict processing mechanism or by distinct conflict processing mechanisms? The event-related potential (ERP) has a high temporal resolution at the millisecond scale and could more directly reveal the brain activities of the cognitive process, so it is an excellent index to examine the neural mechanism of the FORs conflict processing (Luck, 2014). For the conflict processing, increasing electroencephalogram (EEG) evidence has demonstrated that the conflict-related N2 component which occurs approximately $250-350 \mathrm{~ms}$ after stimulus presentation is an effective indicator (Folstein \& Van Petten, 2008). The N2 amplitude is thought to index the degree of conflict, with its amplitude increasing as a function of conflict levels (Li et al., 2015). P3 was also typically reported to reflect ERP modulation of conflict process (Frühholz, Godde, Finke, \& Herrmann, 2011; Wang, Li, Zheng, Wang, \& Liu, 2014).

By applied the ERP to the two-cannon task, we expected to find the neural evidence of the conflict processing among different FORs (EFOR-IFOR, IFOR-IFOR), the parallel process of multiple IFORs and clarified the conflict processing among multiple FORs. Our expectation was that, for the behavioral results, we could replicate our previous behavioral studies' results (Nan et al., in press; Tamborello et al., 2012), which was that RT and error rates (ERR) were larger in the incongruent conditions of the EFOR-IFOR and IFOR-IFOR conflicts and there was also an interaction between them. For the ERP results, the N2 and P3 results could help to reveal the shared or distinct conflict processing mechanism of multiple FORs more clearly. We expected that the amplitude of N 2 and P3 would be more negative in the incongruent conditions of the two conflicts and there was also an interaction between them.

## Method

## Participants

Twenty undergraduate students (18-29 years old, average 22.8 years old, 6 women) participated in the present EEG experiment. All participants reported that they had no neurological or psychiatric history. All participants were right-handed and had normal or corrected-to-normal vision. Each participant voluntarily enrolled and signed an informed consent form prior to the experiments. This study was approved by the Institute of Psychology, Chinese Academy of Sciences.

## Procedures

Participants were seated comfortably in a dimly lit and sound-attenuating chamber approximately 80 cm away from a computer screen (resolution, $1024 \times 768$ pixels, vertical refresh rate, 75 Hz ). Stimulus presentation and manual response measurement were controlled by E-Prime 2.0 (Psychological Software Tools, Inc., Pittsburgh, PA, USA).

Each trial began with two cannons surrounding eight colored dots for 1000 ms . Then, the target pellet was marked by a yellow ring for 1000 ms . Participants were instructed to press a button on the keyboard (left-" $z$ " for counter-clockwise or right-"/" for clockwise), as quickly and accurately as possible, to rotate the target cannon (the one with the same color as the target pellet) to shoot the target in the least distance. After the target disappeared, a fixation cross was presented at the center of the screen for $1000-1300 \mathrm{~ms}$.

## EEG Recordings and Offline Processing

The EEG was recorded from 64 scalp sites using $\mathrm{Ag} / \mathrm{AgCl}$ electrodes arranged in an elastic cap according to an extension of the International 10-20 system (NeuroScan Inc., Herndon, VA). Vertical eye movements were recorded by two positioned above and below the left eye. The horizontal electrooculogram was recorded using lateral electrodes from both eyes. Impedances were below $5 \mathrm{k} \Omega$ for all recording sites. EEG signals were amplified using a NeuroScan SymAmps2 amplifier with a band-pass of 0.05 100 Hz and sampled with 500 Hz .

All scalp electrodes were referenced to the left mastoid online and were referenced to the average of the left and right mastoids offline. Each epoch started from 200 ms before the onset of the stimulus and lasted 800 ms , with the first 200 ms as the baseline. Trials with errors or trials that were contaminated with artifacts exceeding $\pm 100 \mu \mathrm{~V}$ were excluded from the analysis. The data were averaged for each condition and then digitally low-pass filtered at 30 Hz (24 dB/octave) with zero phase shift.

## Statistical Analysis

## Behavioral Data Analysis

Repeated-measures ANOVA and paired-sample t-test were performed on reaction times (RTs) of correct responses and error rates (ERs) and evaluated at $p<.05$. Trials with errors or with RT beyond three standard deviations were excluded from the RT analysis. A repeated-measures ANOVA was conducted for cannon angle effect and target cannon orientation effect (Figure. 2 B and Table 2), in which the $2 \times$ 2 factors tested were cannon angle ( $0^{\circ}, 180^{\circ}$ ) and target cannon orientation (up, down). Bonferroni correction was used for pair-wise comparisons.

## ERP Data Analysis

The ERPs of correct responses were averaged for each condition. The time window for N2 and P3 was identified
using the following protocol. First, we detected the peak latencies of all conditions at the midline electrodes ( $\mathrm{Fz}, \mathrm{FCz}$, $\mathrm{Cz}, \mathrm{CPz}$, and Pz ) and calculated the mean of these latencies for $\mathrm{N} 2(301 \mathrm{~ms})$ and P3 ( 561 ms ). For the N2 and P3 components, $50-\mathrm{ms}$ and $330-\mathrm{ms}$ time windows were centered on the mean peak latency, respectively. Therefore, the cannon angle effect and target cannon orientation effect were analyzed within $276-326 \mathrm{~ms}$ on N 2 mean amplitude and within 396-561 and 561-726 ms on P3 mean amplitude after stimulus onset.

Separated repeated-measures ANOVAs were performed on the mean N2 and the two time windows of mean P3, respectively. The factors cannon angle $\left(0^{\circ}\right.$ and $\left.180^{\circ}\right)$, target cannon orientation (up and down) and electrode ( $\mathrm{Fz}, \mathrm{FCz}$, $\mathrm{Cz}, \mathrm{CPz}$, and Pz ) were used to search for cannon angle effect and target cannon orientation effect. The significance level was set at $\alpha<.05$ for all ANOVAs. The mean number of trials retained for each condition are listed in the trial number of Table 1. A two-way analysis of variance (ANOVA) was calculated for the trial numbers of cannon angle and target cannon orientation, results showed there were no significant differences among them. The main effect of cannon angle: $F(1,19)=1.19, p>.05$, the main effect of target cannon orientation: $F(1,19)=1.17, p>.05$, the interaction between them: $F(1,19)=0.18, p>.05$. These analysis results eliminated the potential influence of different signal-noise ratios to statistical comparison.

## Results

## RTs and ERs

Regarding RTs (Figure 2 and Table 1), there was a significant main effect of target cannon orientation, $F(1,19)$ $=256.74, p<.001, \eta_{\mathrm{p}}^{2}=.93$, indicating that the RT in the target cannon point-down condition ( $697 \pm 24 \mathrm{~ms}$ ) was longer than that in the target cannon point-up condition (619 $\pm 22 \mathrm{~ms})$. There was a main effect of cannon angle, $F(1,19)$ $=50.43, p<.001, \eta_{\mathrm{p}}^{2}=.73$, indicating that the RT in the $0^{\circ}$ cannon angle condition ( $558 \pm 24 \mathrm{~ms}$ ) was shorter than that in the $180^{\circ}$ cannon angle condition ( $756 \pm 22 \mathrm{~ms}$ ). The interaction of the two factors was also significant, $F(1,19)=$ $6.48, p<.05, \eta_{\mathrm{p}}^{2}=.25$. Post-hoc analysis showed that target cannon orientation effect in the $180^{\circ}$ condition ( $89 \pm 13 \mathrm{~ms}$ ) was larger than target cannon orientation effect in the $0^{\circ}$ condition $(68 \pm 11 \mathrm{~ms}), t(1,19)=2.55, p<.05$.

ERs showed significant a main effect for target cannon orientation, $F(1,19)=22.54, p<.001, \eta_{\mathrm{p}}^{2}=.54$, indicating that the ER in the target cannon point-down condition (7.7 $\pm$ $1.1 \%$ ) was larger than that in the target cannon point-up condition ( $3.0 \pm 0.7 \%$ ). The main effect of cannon angle and the interaction of the two factors were not significant.

## N2 and P3

Regarding EFPs (see Figure 3), for N2, there was a significant main effect of target cannon orientation $F(1,19)$ $=4.88, p<.05, \eta_{p}^{2}=.20$, with more negative N 2 amplitudes

Table 1 RTs and ERs for target cannon orientation and cannon angle

| Target <br> cannon <br> orientation | Cannon angle |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\mathrm{RT}(\mathrm{ms})$ |  | $0^{\circ}$ | $180^{\circ}$ | $0^{\circ}$ | $180^{\circ}$ | $0^{\circ}$ |
| Down | $592 \pm 25$ | $802 \pm 24$ | $7.1 \pm 1.3$ | $8.2 \pm 1.1$ | $141 \pm 7$ | $147 \pm 5$ |  |
| Up | $524 \pm 23$ | $713 \pm 22$ | $2.5 \pm 0.8$ | $3.6 \pm 0.7$ | $144 \pm 7$ | $150 \pm 6$ |  |

Figure 2. RT of target cannon orientation effect and cannon angle effect. RT of the target cannon point-down condition was longer than that of the target cannon point-down condition; RT of the $180^{\circ}$ cannon angle condition was longer than that of $0^{\circ}$ cannon angle condition. The effect size of target cannon orientation effect in the $180^{\circ}$ cannon angle condition was larger than that in the $0^{\circ}$ cannon angle condition.
to the target cannon point-down condition $(0.27 \pm 0.76 \mu \mathrm{~V})$ than to the target cannon point-up condition $(0.83 \pm 0.76$ $\mu \mathrm{V})$. There was a marginally significant main effect of target cannon orientation, $F(1,19)=3.51, p=.076, \eta_{\mathrm{p}}{ }^{2}$ $=.16$, with more negative N 2 amplitudes to the $180^{\circ}$ cannon angle condition $(0.02 \pm 0.68 \mu \mathrm{~V})$ than to the $0^{\circ}$ cannon angle condition ( $1.07 \pm 0.791 \mu \mathrm{~V}$ ). There was a marginally significant interaction between cannon angle and electrode, $F(4,76)=3.27, p=.057, \eta_{\mathrm{p}}^{2}=.15$, post-hoc analysis showed that the cannon angle effect was significant at FCz and $\mathrm{Cz}, p \mathrm{~s}<.05$, revealed that the N 2 in the $180^{\circ}$ cannon angle condition (FCz: $-0.38 \pm 0.78 \mu \mathrm{~V}, \mathrm{Cz}:-0.18 \pm 0.81 \mu \mathrm{~V}$ ) was more negative than that in the $0^{\circ}$ cannon angle condition (FCz: $1.01 \pm 0.98 \mu \mathrm{~V}, \mathrm{Cz}: 1.21 \pm 1.07 \mu \mathrm{~V}$ ). There were no other significant effects obtained.

For the first time window of P3 (396-561 ms), there was a significant main effect of cannon angle, $F(1,19)=15.39, p$ $<.01, \eta_{\mathrm{p}}^{2}=.45$, with more positive P 3 amplitudes to the $0^{\circ}$ cannon angle condition $(2.07 \pm 0.81 \mu \mathrm{~V})$ than to the $180^{\circ}$ cannon angle condition $(-0.20 \pm 0.65 \mu \mathrm{~V})$. There was a significant main effect of target cannon orientation, $F(1,19)$ $=20.74, p<.001, \eta_{\mathrm{p}}^{2}=.52$, with more positive P3 amplitudes to the target cannon point-up condition (1.47 $\pm$ $0.69 \mu \mathrm{~V}$ ) than to the target cannon point-down condition $(0.40 \pm 0.69 \mu \mathrm{~V})$. There was a significant main effect of
electrode, $F(4,76)=24.01, p<.001, \eta_{\mathrm{p}}^{2}=.56$, with more positive P 3 amplitudes at $\mathrm{Cz}, \mathrm{CPz}$, and Pz compared with Fz and $\mathrm{FCz}(p s<.001)$. There was a significant interaction
between cannon angle and electrode, $F(4,76)=7.42, p<.01$, $\eta_{\mathrm{p}}^{2}=.28$, post-hoc analysis showed that the cannon angle effect was significant at five electrodes, $p \mathrm{~s}<.01$, and the largest difference was at $\mathrm{FCz}(3.04 \pm 0.74 \mu \mathrm{~V})$. There was a significant interaction between target cannon orientation and electrode, $F(4,76)=5.42, p<.01, \eta_{\mathrm{p}}^{2}=.22$, post-hoc analysis showed that the target cannon orientation effect was significant at five electrodes, $p \mathrm{~s}<.01$, and the largest difference was at $\mathrm{FCz}(1.36 \pm 0.30 \mu \mathrm{~V})$. No other significant effects were obtained.

For the second time window of P3 (561-726 ms), there was a significant main effect of cannon angle, $F(1,19)=$ 14.90, $p<.01, \eta_{\mathrm{p}}^{2}=.44$, with more positive P3 amplitudes to the $0^{\circ}$ cannon angle condition $(1.91 \pm 0.64 \mu \mathrm{~V})$ than to the $180^{\circ}$ cannon angle condition $(0.15 \pm 0.64 \mu \mathrm{~V})$. There was a significant main effect of target cannon orientation, $F(1,19)$ $=29.29, p<.001, \eta_{\mathrm{p}}^{2}=.61$, with more positive P3 amplitudes to the target cannon point-up condition (1.68 $\pm 0.59 \mu \mathrm{~V})$ than to the target cannon point-down condition $(0.38 \pm 0.62 \mu \mathrm{~V})$. There was a significant main effect of electrode, $F(4,76)=7.54, p<.01, \eta_{\mathrm{p}}^{2}=.28$, with more positive P 3 amplitudes at $\mathrm{Cz}, \mathrm{CPz}$ compared with Fz and $\mathrm{FCz}(p \mathrm{~s}<.05)$. There was a significant interaction between

Figure 3. Grand-average ERP results. A. N2 activity at FCz and P3 activity at CPz for cannon angle effect and target cannon orientation effect. B. the topography maps of the difference waveforms of cannon angle effect and target cannon orientation effect.

Figure 4. Three kinds of FOR conflict processing models. The three kinds of models are all parallel models. All of them showed the IFORs could be represented and processed in parallel that generates two conflicts of IFOR-IFOR and EFORIFOR. The difference is whether there are specific or shared conflict monitoring module and executive control module. The parallel model (1CM1EC) showed that there was only one conflict monitoring module (CM) and one executive control module (EC) for both conflicts. The parallel model (2CM1EC) showed that there were two conflict monitoring modules for each conflict and only one executive control module for both conflicts. The parallel model (2CM2EC) showed that there were two conflict monitoring modules and two executive control modules for each conflict.
cannon angle and electrode, $F(4,76)=5.96, p<.05, \eta_{\mathrm{p}}{ }^{2}$ $=.24$, post-hoc analysis showed that the cannon angle effect was significant at five electrodes, $p \mathrm{~s}<.01$, and the largest difference was at $\mathrm{FCz}(3.04 \pm 0.74 \mu \mathrm{~V})$. There was a significant interaction between target cannon orientation and electrode, $F(4,76)=16.52, p<.001, \eta_{p}^{2}=.47$, post-hoc analysis showed that the target cannon orientation effect was significant at five electrodes, $p \mathrm{~s}<.05$, and the largest difference was at $\mathrm{FCz}(2.53 \pm 0.60 \mu \mathrm{~V})$. Most interesting, there was a significant interaction between cannon angle and target cannon orientation, $F(1,19)=4.56, p<.05, \eta_{\mathrm{p}}{ }^{2}$ $=.19$, post-hoc analysis showed that target cannon orientation effect in the $180^{\circ}$ cannon angle condition (1.93 $\pm$ $0.40 \mu \mathrm{~V}$ ) increased and was significant compared to that in the $0^{\circ}$ cannon angle condition $(0.67 \pm 0.36 \mu \mathrm{~V})$. No other significant interactions were obtained.

## Discussion

Overall, the findings of the present study suggested that EFOR-IFOR and IFOR-IFOR conflicts had specific neural correlates and the process of IFORs was in parallel.

First, behavioral data showed the conflicts of EFORIFOR and IFOR-IFOR, the interaction between them. Second, the ERP results showed that the independent cannon angle effect and target cannon orientation effect on the N 2 amplitudes, from 276 to 326 ms , which indicated the independent conflict monitoring modules for the conflicts of EFOR-IFOR and IFOR-IFOR. What's more, the two effects interacted on the P3 amplitudes, from 561 to 726 ms , which indicated the shared executive control module for the two conflicts.

Yang, Nan, Li, and Liu (2015) used stimulus-response compatible tasks to collect behavioral and ERP data to support the 2CM1EC model (two domain-specific conflict monitoring modules and one domain-general executive control module for the conflicts of stimulus-stimulus and stimulus-response) of cognitive control for conflict processing, compared to the 1CM1EC model and 2CM2EC
model. For a comprehensive review, see (Li, Nan, Wang, \& Liu, 2014; Li et al., 2015; Liu, Nan, Wang, \& Li, 2013; Liu, Park, Gu, \& Fan, 2010; Wang et al., 2014; Yang et al., 2015).

On the spatial cognition area, we also could hypothesize three kinds of model for the conflict processing among different FORs (1CM1EC, 2CM1EC, and 2CM2EC, see Figure 4). 1CM1EC model shows there is only one general conflict monitoring module and one executive control for conflicts of EFOR-IFOR and IFOR-IFOR. The 2CM1EC model shows there are two specific conflict monitoring modules for conflicts of EFOR-IFOR and IFOR-IFOR, and one general executive control module for the two conflicts. The 2CM2EC model shows there are two specific conflict monitoring modules and two specific executive control modules for the two conflicts.

In our task, the behavioral results showed the cannon angle effect (conflict of IFOR-IFOR), target cannon orientation effect (conflict of EFOR-IFOR) and the interaction between them, which supported that the parallel process of the IFORs and the shared conflict process mechanism at the behavioral level. The ERP results showed the independent cannon angle effect and target cannon orientation effect on the N2 amplitudes, which further suggests there might be two specific conflict monitoring modules for the conflicts of EFOR-IFOR and IFOR-IFOR at the neural level. What's more, we also found the two effects, and the interaction between them on the P3 amplitudes. This suggests there might be only one shared executive control module for these conflicts at the neural level. In summary, our results supported the 2CM1EC model for the cognitive control of spatial conflict processing.

In the current two-cannon task, the AFOR is anchored on the computer screen which has the same direction (point-up) with the EFOR, so we could not separate the conflict of AFOR-IFOR and EFOR-IFOR. In the future, we could try to manipulate the AFOR and observe the interaction of all kinds of conflict which could be more comprehensive understand the spatial conflicts processing of FORs.

## Conclusion

Our task replicated the previous behavioral results well. What's more, the ERP results showed that common and distinct electrophysiological correlates for EFOR-IFOR and IFOR-IFOR conflict processing. On the one hand, EFORIFOR and IFOR-IFOR have domain-specific conflict monitoring modules, as revealed by the independent N 2 component. On the other hand, both of them share a domain-general executive control module, as revealed by the interaction of P3 component. The conflict of IFORIFOR and the interaction of EFOR-IFOR and IFOR-IFOR also suggest that the process of different IFORs is in parallel.'

Favela (luis.favela@ucf.edu)<br>Department of Philosophy, Cognitive Sciences Program, University of Central Florida 4000 Central Florida Blvd., Orlando, FL 32816 USA

#### Abstract

Studies of social cognition often assume a reductionist, computational-representational conceptual framework. Distributed cognition is one of the few extant conceptual frameworks for a nonreductive understanding of social cognition. This concept's prototypical cases are exclusively of technical-scientific human institutions, including ships, cockpits, and the Hubble Space Telescope. In the first part of the paper, we outline the properties of distributed cognitive systems. We look at the case of wolf (Canis lupus) packs as an instance of distributed cognition in nonhuman systems. Nevertheless, a broad range of social cognitive phenomena across human and animal populations may not fit into this conceptual framework. We present a case study of bird flocks as a counterexample to distributed cognition. We propose "swarm intelligence" as an alternative concept of nonreductive social cognition. This is not to replace distributed cognition as a concept, but to add to and diversify the taxonomy of nonreductive social cognitive systems.

Keywords: social cognition; distributed cognition; swarm intelligence; bird flocks; wolf packs; nonreductive explanations

## Introduction

As a field of research, social cognition grew out of a social psychology that was influenced by the cognitive revolution and its adherence to the computational-representational understanding of mind (CRUM; Gilbert, 1999; Thagard, 2005). CRUM holds that cognition consists of a series of computations performed upon representations. CRUM approaches to social cognition are reductionist in that social phenomena are explained by recourse to the mental or neural mechanisms of individuals. In other areas of the cognitive sciences, nonreductive and systems approaches have been developed as alternatives to CRUM, e.g., ecological psychology (e.g., Gibson, 1979/2015), extended cognition (e.g., Clark \& Chalmers, 1998), embodied cognition (e.g., Rowlands, 2010), radical embodied cognitive science (e.g., Chemero, 2009), and radical embodied cognitive neuroscience (e.g., Favela, 2014).

The primary example of a nonreductive understanding of social cognition is Edwin Hutchins' distributed cognition. Hutchins (1995a) analyzed the cognitive structure of a navy ship's navigation across a network of agents (sailors) and navigational instruments. This study introduced an early
social cognitive concept that did not reduce explanations to events in the brain. In his "cognitive ethnography," the entire system of sailors and nautical instruments constitute a cognitive system. Navigation of the ship is achieved only through the combined efforts of these actors and tools.

While distributed cognition has provided a nonreductive lens by which to understand social cognition, it is rooted in a highly specific prototypical case of social and instrumental organization. We outline the properties of distributed cognitive systems and give an example of a nonhuman social system (wolf packs) in which distributed cognition is operating. We then argue that not all social cognitive systems are cases of distributed cognition. We argue that other forms of social cognition exist, such as swarm intelligence, via a case study of bird flocks.

## Distributed Cognition

Distributed cognition is a nonreductive account of social cognition that includes both agents and tools. Social cognition is not limited to mental events or brain activity in the individual agents who happen to constitute a social network. That is not to say that individual mental or neural events are irrelevant. However, the unit of analysis is the entire organization of agents and tools oriented around specific group tasks, such as a navy ship being navigated (Hutchins, 1995a) or an airplane cockpit being piloted (Hutchins, 1995b).

In Hutchins' studies of distributed cognition, the paradigm cases are of vehicles operated by two or more human agents. An airplane cockpit's cognitive organization consists of two agents (pilot and copilot) and an array of navigational instruments. An orthodox CRUM account of the social cognition of the cockpit would analyze the mental and neural events occurring in the brains of the two pilots. For Hutchins, however, the cognitive phenomena of perception and locomotion of the airplane as a whole occur as a coupled system of the pilots and their instruments.

Giere (2006) offers the Hubble Space Telescope (HST) as another prototypical case of distributed cognition. The HST is not merely a vehicle to be navigated or piloted, but a complicated instrument measuring ultraviolet, visible, and infrared spectra in deep space (Shayler \& Harland, 2016). Its operators are human, but it is orientated and programmed with commands and algorithms rather than piloted or
navigated. The HST itself consists of a vast array of complex, specialized instruments. Significantly, not only does it produce images of deep space objects, but it also provides higher-level scientific outputs such as "authenticated claims about the age of the universe" (Giere, 2006, pp. 712-713). In this respect, the HST is more cognitively complex than a ship or cockpit. The HST collectively produces these scientific outputs as a system of instruments, engineers, and scientists. No one instrument or operator is sufficient to produce any one of these outputs. For example, claims about the age of the universe cannot be substantiated without the HST's spectral analyses of galactic redshifts. Likewise, galactic redshifts cannot be measured without human programmers or the scientists who requested such measurements to, for example, confirm the Hubble constant.

Giere treats the HST as more than a deep space telescope. It is a scientific institution producing empirical claims about the universe. Nevertheless, like Hutchins' navy ship and airplane cockpit, it remains constituted by a network of agents and nonagentic instruments and tools. Kirsh (2006) provides a similar framework for distributed cognition, altering the methodological focus from a systems analysis to one of both individuals and systems, i.e., a "bottom-up topdown model" (p. 250). We provide a formalized list of the components of distributed cognitive systems consistent with Hutchins (1995a, 1995b), Giere (2006), and Kirsh (2006).

## Properties of Distributed Cognitive Systems

Distributed cognitive systems are not explained reductively. They are emergent in the sense that they are not merely the sum of the individual cognition of its components. Crucially, the actors are agentic (Giere, 2006). The sailors of the navy ship, pilots of the cockpit, and engineers and scientists of the HST exhibit significant degrees of agency.

These agents maintain their agency even as members of the system actively participate in its system-wide goals and joint tasks (cf. Amon \& Favela, 2017). Significantly, the cognitive behavior of a distributed cognitive system is not limited to perception and locomotion. Giere's HST system is not merely orientated towards celestial objects to capture images. The HST (the physical HST and its operators) produces falsifiable scientific claims. The following is modified from Amon and Favela (2017).
$S$ is a distributed cognitive system if:
D1. $S$ is emergent.
D2. There is continuous coordination of agents and nonagentic tools as members of $S$.
D3. Each agent maintains a degree of individual agency within $S$.
D4. Each agent actively participates in the overall goal or joint task in which $S$ is engaged.
D5. There is specialization of functions among members of $S$.
D6. The cognitive behavior of $S$ is complex and not limited to perception and locomotion.

In the following, we discuss wolf packs as an example of distributed cognition in the nonhuman animal world. We then present the case of bird flocks as a counterexample of social cognitive systems that are not distributed cognitive systems. We propose a new concept for nonreductive social systems for cases not in lieu of, but along with, distributed cognition.

## Wolf Packs as Distributed Cognitive Systems

Many paradigm cases of distributed cognition are anthropocentric and limited to human technical-scientific institutions (e.g., navy ship, airplane cockpit, and HST). However, social cognition is not limited to humans or such institutions. In some cases, collective animal systems may indeed be described by this anthropocentric concept. Wolf (Canis lupus) packs on the hunt ${ }^{1}$ are one such case of distributed cognitive systems in the animal world.

Wolves hunting in pack formation consist of four to 30 individual members, with hunting efficiency negatively correlated to increasing pack size (Mech, Smith, \& MacNulty, 2015). They are loosely organized around a breeder ("alpha" in older literature) but do not operate by a command structure. Individuals converge upon the prey and, assuming a successful hunt, a single wolf ultimately makes the kill (Tang, Fong, Yang, \& Deb, 2012).

Pack hunting patterns, organization, and coordination are emergent (D1). Several apparent hunting strategies have been noted, including encircling, ambushing, and relay hunting (Mech et al., 2015). Mech (2007) notes that wolves express a degree of mutual comprehension. He concludes from this that wolves communicate hunting strategies. This hypothesis assumes the existence of communication mechanisms that have yet to be discovered. Current evidence provides a more parsimonious account: The observed hunting patterns are wholly explicable in terms of a set of basic perceptual and locomotive procedures operating on the individual level and giving rise to a global structure. This simple process constrains the position of individual wolves so as to be neither too far away from nor too close to other wolves of the pack. Furthermore, individual wolves coordinate their own positions relative to both their prey and relative to the breeder (Muro, Escobedo, Spector, \& Coppinger, 2011). Global hunting patterns, such as encirclement, are not premeditated, directed, or otherwise centrally controlled. They emerge from these basic processes of local interaction (see Figure 1).

Within the pack, there is a continuous coordination of wolves (D2). Simulations by Muro and colleagues (2011) found that emergent hunting patterns can arise from the coordination of spatial positions in real time. Individual wolves coordinate their positions relative to those of both the breeder and the prey (see Figure 1). No advanced

[^421]communication of ideas or intentions is necessary to produce these patterns.

Figure 1: D1. Individual wolves continuously coordinate their movements based on the spatial positions of the breeder (top right) and prey (center). D2. This can result in emergent hunting patterns, such as encirclement (after Tang et al., 2012). Credit: Ahmed Labban.

Each wolf maintains a degree of individual agency within the pack (D3). As noted, the association of the pack is very loose. During the hunt, individual wolves often take individual initiatives, such as cutting off the prey (Mech et al., 2015). Each wolf actively participates in the overall goal or joint task in which the pack is engaged (D4). In this case, the focus is on hunting. The collective task of hunting may be the only activity around which the pack becomes cohesive enough to be considered a distributed cognitive system. Otherwise, a reductive account as is standard in accounts of social cognition may be appropriate.

There is a specialization of functions among the members of the pack (D5). The pack is hierarchical with the breeders at the top of the hierarchy (Mech et al., 2015). During the chase, the breeder serves as one of the two reference points for other wolves. Therefore, there are at least two functional differentiations among the wolves of the pack.

The cognitive behavior of the pack is complex and not limited to perception and locomotion (D6). Hunting is a goal-oriented process of gathering food. The wolf pack does not merely perceive and move towards the prey. It actively seeks to slay it in order to consume it. The hunt itself is a complex and demanding task and each individual actively engages in the task. Certainly this is far less complex of behavior than making falsifiable scientific claims about the age of the universe. Nevertheless, it is beyond the mere perception and locomotion that may characterize the simplest of cognitive systems (cf. Maturana \& Varela, 1980; Thompson, 2007).

## Non-Distributed Social Cognition in Flocks

The prototypical cases of distributed cognition are of very specific types of human institutions. Social cognition is not necessarily circumscribed to such specialized technicalscientific institutions or setups. The social cognition exhibited by wolf packs is appropriately treated as
distributed cognition. ${ }^{2}$ However, not all social systems, human or nonhuman animal, may be compatible with this concept. We present bird flocks as an example of nonreductive, but non-distributed, social cognition.

Flocks of birds vary in size across species and environments. They can range from less than a hundred to many hundreds of thousands of individuals. Quelea quelea flocks, for example, typically range from several to 500 birds but occasionally coalesce to form swarms of biblical proportions with comparable plague-like effects on agriculture (Crook, 1960). They migrate, evade predators, locate food and water, and navigate to roosts.

Flocks do exhibit some of the features of distributed cognition, but not all. Flocks are emergent (D1). Selfpropelled particle (SPP) models, as well as empirical vector analyses captured by computerized cameras, have for the first time made possible the study of cognition as a property of collective systems (Baglietto, Albano, \& Candia, 2013). SPP models show that global flock patterns and behavior can arise from a simple set of procedures governing the local interactions of individual birds (Bialek et al., 2012). In this respect, they are similar to wolf packs.

Bialek and colleagues (2012) model starling (Sturnus vulgaris) flocks by a set of procedures of alignment synchronization. Individual birds each align themselves with several proximal birds, henceforth coordinators (see Figure 2). The number of birds used for alignment synchronization is small, especially relative to the potentially enormous size of the flock itself. An increase in this parameter to a larger set of coordinators increases the entropy of the system, destabilizing the flock and breaking it apart into several smaller flocks (Castellana, Bialek, Cavagna, \& Giardina, 2016).

There is a continuous coordination of birds within the flock (D2). The procedures of alignment synchronization are simple and consist of successive zones of attraction, repulsion, and orientation (Couzin, 2008). If the coordinator is too far away, the bird moves towards it (or is "attracted" to it). If the coordinator is too close, the bird moves away from it (or is "repulsed" by it). If it is neither too close nor too far, it maintains its orientation (cf. Couzin, Krause, James, Ruxton, \& Franks, 2002). Kattas and colleagues (2012) find similar results in homing pigeons (Columba livia domestica) using a different method than Bialek and colleagues (2012), creating a model directly from recorded flight data. These local processes produce an emergent global order of flock movement (Cavagna, Giardina, \& Ginelli, 2013). The apparently wispy and erratic movements characteristic of flocks are effects of the inherent noise arising from imperfect alignments (Cavagna, Duarte Queirós, Giardina, Stefanini, \& Viale, 2013). This global

[^422]order in turn affects individual flight trajectories in local regions of birds.

Individual agency, to the degree to which it may exist to begin with, is not preserved in the flock. This violates D3. Individual birds within the flock, insofar as they constitute the flock, are not agentic in the same sense that a captain is free to abandon their ship. Nor do they express anything akin to the minimal agency of wolves in a pack. Individual wolves operate as a pack by a loose association and often act upon individual initiative (Mech et al., 2015). Birds in a flock, on the other hand, act predictably according to the basic processes of attraction, repulsion, and orientation. While flocks are noisy, the system's noise is constituted by the imperfect coordinating efforts of the birds.

Figure 2: Individual birds within a flock coordinate their movements relative to the positions of a small number of proximal birds. Credit: Ahmed Labban.

In violation of D 4 , each bird does not actively participate in the overall goal or joint task in which the flock is engaged. When a flock evades a hawk, for example, the entire flock does not necessarily perceive the predator. This is especially true of larger flocks of tens of thousands of members or more. To evade the raptor, it is sufficient that a local group within the larger flock perceive and react to it. This local reaction, manifest as a sudden shift in flight paths, creates a ripple effect in the flock as the other birds attempt to realign themselves. In this case, the massive flock is not engaged in the joint task of predator evasion. Rather, a local group is engaged in predator evasion while the majority of the remaining birds are merely continuing to implement the processes of attraction-repulsion-orientation. ${ }^{3}$ This situation contrasts markedly from that of wolves on the hunt, wherein each of the individual wolves perceives the prey and is actively engaged in hunting.

There is no significant specialization of functions among the members of the flock. Within the flock, each bird is more or less functionally isomorphic to the other birds. Hierarchies within flocks exist, but are fluid. "Leader" roles, such as directing migration routes (Mouritsen, 2003), are interchangeable and constantly shifting (Nagy, Ákos, Biro,

[^423]\& Vicsek, 2010). This contrasts with, for example, the captain of a ship or a pack breeder.

The behavior of the flock is limited to perception and locomotion, violating D6. Birds are individually complex and can perform a variety of functions besides moving and perceiving, such as fighting, mating, or raising offspring. Insofar as they constitute a flock, however, they are limited to basic procedures of attraction-repulsion-orientation. ${ }^{4}$ These require only that 1) the bird perceives the coordinators, and 2) the bird adjusts its flight accordingly. The flock as a system likewise only perceives and moves. In the example of predator evasion, the flock (but not necessarily each member thereof) perceives the hawk and changes its flight patterns to evade it. Flocks do not fight, mate, or raise offspring. They are defined only as a perceptual-locomotive social system.

Crook (1960) notes curious synchronized, wave-like movements during feeding and drinking in Quelea quelea. While drinking, the birds collectively alternate their positions, moving forward birds who have not yet drank and moving back birds who have. These "wave-like progression $[\mathrm{s}]$ " (p. 5) are broadly consistent with a system of basic attraction-repulsion-orientation processes. Nevertheless, SPP studies of avian populations have yet to go beyond an analysis of flight patterns and this is a particular research desideratum.

Of the six criteria of distributed cognition, flocks satisfy only two. The concept of "distributed cognition" is too limited to capture the manifold manifestations of social cognitive systems. New concepts are needed to understand complex systems such as bird flocks. We introduce "swarm intelligence" as a concept capable of describing social cognitive systems with characteristics like flocks.

## Swarm Intelligence as a Concept of Social Cognition

We appropriate the term 'swarm intelligence' from computing. In computing, swarm intelligence describes a set of optimization methods with emergent and self-organizing algorithms (Yang \& Karamanoglu, 2013) inspired by bees, ants, wolves, and other collectivist organisms (Beekman, Sword, \& Simpson, 2008). In our usage, "swarm intelligence" refers to a class of rudimentary and nonspecialized social cognitive systems. The prototypical case we offer is the bird flock, although it may also cover cases such as schools of fish, mosquito swarms, and human crowds.
$S$ is a swarm-intelligent system if:
S1. $S$ is emergent.
S2. There is a continuous coordination of individuals as members of $S$.
S3. Individual agency is minimal insofar as the individual constitutes $S$.

[^424]S4. The cognitive behavior of $S$ is limited to perception and locomotion.
S5. Communication or interaction between members of $S$ as they constitute $S$ is minimal.
S6. The organization of $S$ is relatively isomorphic, with no significant specialization of functions.
Flocks are emergent (S1). Overall flock movement in flight arises from the local processes of attraction-repulsionorientation. This global order in turn affects the local movements of individual birds. Comprehending why one bird happens to be caught up in a swirling arm of a murmuration requires a dynamical systems analysis of the entire flock. There is a continuous coordination of individuals as members of the flock (S2). Individual birds orientate themselves continuously in reference to several neighboring birds (see Figure 2).

Individual agency is minimal insofar as the individual constitutes the flock (S3). We noted this earlier as a violation of D3. Regardless of how agentic individual birds may be, they do not exhibit any significant agency within the collective. The cognitive behavior of the flock is limited to perception and locomotion (S4). Flocks are restricted to evasion, migration, and food-locating behaviors. For example, while ants construct elaborate nests as a form of collective shelter, most birds are only capable of creating roosts individually.

Communication or interaction between members of the flock insofar as they constitute the flock is minimal and there is no communication of intentions (S5). While birds have complex modes of communication (e.g. birdsong), they do not directly communicate qua members of a flock. The only information indirectly communicated is relative distance and position. The organization of the flock is relatively isomorphic. There are no significant specializations of functions among members of the flock (S6). Some transient local leaders might guide flight away from predators or towards food sources, but these positions are not enduring.

Overall, swarm intelligence is far simpler than distributed cognition. It does not necessitate any shared goals or joint tasks and its cognitive functions are limited to perception and locomotion. Nevertheless, it may describe systems as varied as bird flocks, mosquito swarms, schools of fish, and human crowds. Indeed, schools of fish and human crowds appear to operate by the same basic processes of attraction, alignment, and repulsion as do flocks of birds (Couzin, 2008; Moussaid et al., 2009).

## Conclusion: Towards a Taxonomy of Nonreductive Social Cognition

The field of social cognition remains dominated by reductionist and CRUM approaches. Since the mid-1990s, studies in distributed cognition have challenged this orthodoxy and demonstrated that social cognition can be understood from a nonreductive and systems perspective. Nevertheless, distributed cognition remains circumscribed in its applicability to different social cognitive systems. Its
paradigm cases are of human technical-scientific institutions. We provide formal criteria for the identification of distributed cognition consistent with Hutchins (1995a, 1995b), Giere (2006), and Kirsh (2006).

Distributed cognition remains useful for describing some systems that are nonhuman or non-technical-scientific, such as wolf packs. We demonstrate point-by-point how wolf packs are cases of distributed cognition. However, this concept is inappropriately applicable to many other social cognitive systems. We offer bird flocks as a counterexample to distributed cognition and propose "swarm intelligence" as an alternative concept of nonreductive social cognition. These two forms of social cognition are not proposed as absolute categories, but rather as relative points of difference between which gradations may exist.

The implications of this are significant. Beyond flocks, swarm intelligence is potentially found among schools of fish, mosquito and other flying insect swarms, and human crowds (cf. Moussaid et al., 2009). Swarm intelligence does not operate in lieu of distributed cognition. Nor is it the only alternative type of nonreductive social cognition. New concepts are needed to establish a more accurate taxonomy of nonreductive social cognition as diverse as the phenomena under investigation. Such a taxonomy allows the many and varied phenomena of social cognition to be recognized as such and studied through an appropriate theoretical lens (cf. O'Donnell et al. 2015 for a misattribution of distributed cognition in part due to such a lack of diversity).

As we have demonstrated, wolf packs or the HST do not operate by the same organizational principles as do bird flocks. This is not surprising given their radically different structures, functions, and components. What is far more surprising is that wolf packs operate, on an abstract level, analogously to certain technical-scientific institutions. Still other types of social cognitive systems await discovery. Ant colonies may not be well described by either distributed cognition or swarm intelligence. For example, unlike birds in a flock, ants have up to 12 modalities of communication (Hölldobler \& Wilson, 1990). Furthermore, they are able to engage in intricate collective projects such as nest building without a central planner. Ultimately, the project of creating a taxonomy of different social cognitive systems will serve to delineate and extend the outer bounds of the concept of "cognition."

# Modeling categorical perception with auditory neurons 

Chris Neufeld<br>University of Maryland

#### Abstract

It is well-known that the auditory perception of speech sounds is strongly influenced by the phonetic categories which divide up acoustic space. This paper approaches the problem of modeling categorical perception from the ground up, using a linear model of the tuning properties of auditory neurons - the spectro-temporal receptive field (STRF). An STRF which discriminates voiced from voiceless stops was derived from the TIMIT corpus, and two computer simulations were conducted to investigate its properties. In one simulation, this model neuron was found to exhibit a categorical response to a linear voice-onset-time continuum, closely tracking human behavior. In the second simulation, the STRF was found to exhibit a less categorical, more linear response to a stop-voicing continuum, also in line with human behavior. These two simulations show that perceptual responses to speech, whether non-linear or veridical, can be modeled by the action of auditory neurons.

# Brief Mindfulness Meditation Improves Attention in Novices 

Catherine J. Norris, Ph.D. (cnorris2@swarthmore.edu)<br>Department of Psychology, Swarthmore College, 500 College Avenue Swarthmore, PA 19081 USA<br>Dan Creem (dancreem@gmail.com)<br>Department of Psychology, Swarthmore College, 500 College Avenue Swarthmore, PA 19081 USA

#### Abstract

Past research has found that mindfulness meditation training improves executive attention and that this effect could be driven by more efficient allocation of resources on demanding attentional tasks, such as the Flanker Task. However, it is not clear whether these changes depend on long-term practice. We sought to investigate the effects of a brief, 10 -minute meditation session on attention in novice meditators, compared to a control activity. We also tested moderation by individual differences in Neuroticism. We found that participants randomly assigned to meditate for 10 minutes showed improved performance on incongruent trials on a Flanker task, with no detriment in reaction times, indicating better allocation of resources. Neuroticism moderated this effect, as only those low in Neuroticism showed improved allocation of attentional resources following meditation.

Keywords: mindfulness meditation; attentional network test; executive attention; neuroticism

## Introduction

Mindfulness is often defined as a two component process: (1) attention to present moment experience, coupled with (2) an attitude that is open, non-reactive, and accepting of things as they are (Bishop et al, 2004; Ludwig \& Kabat-Zinn, 2008). Over the past few decades a wealth of research has emerged in both popular science and academic journals on the benefits of mindfulness meditation for cognitive performance (e.g., creativity; Ding, Tang, Tang \& Posner, 2014; attention; Sedlmeier et al., 2012), mental health (Hofmann, Sawyer, Witt, \& Oh, 2010), negative mood (Goyal et al., 2014), treatment for addiction (Brewer et al 2011a; Bowen 2014), prejudice and discrimination (Lueke \& Gibson, 2016), and many other psychological processes. One premise in this area of research is that becoming mindful of an internal state or physiological function, such as one's breath or heartbeat, can hone abilities such as focused attention, working memory, and acceptance. In turn, this is thought to have long-term positive consequences when mindfulness is trained and practiced over an extended period of time.

Much of the past research has focused on the effects of mindfulness meditation training on attentional processes, including alerting, orienting, and executive attention. For example, Maclean and colleagues (2010) found that 3 months of intense meditative training can improve performance on tasks of perceptual discrimination and sustained visual attention. Elliott, Wallace and Giesbrecht
(2014) showed that a weeklong intensive meditation retreat can improve both executive attention and alerting (but not orienting). Jha, Krompinger and Baime (2007), however, found that both an 8 -week MBSR (i.e., mindfulness based stress reduction) course and a 1-month intensive MBSR retreat improved orienting but not executive attention. To the contrary, Tang and colleagues (2007) used a slightly less time-intensive approach and reported that 5 days of 20minute training sessions can improve executive attention and a more recent empirical article also found that mindfulness meditation increased executive attention (Ainsworth et al., 2013). In a review article comparing multiple forms of meditation, Lippelt, Hommel, \& Colzato (2014) conclude that there is good evidence to suggest that focused attention meditation (such as mindfulness) increases sustained attention (Carter et al., 2005; Brefczynski-Lewis et al., 2007). Notably, all of these studies have utilized extensive meditation training, including multiple hour-long sessions administered over an extended period of time.

Clearly, the literature on the effects of meditation on attention is both diverse and in some disarray, with different approaches to meditation (e.g., MBSR retreats vs. daily selfguided sessions) having divergent effects on different forms of attention. In addition, most of these studies have examined the effects of intensive, longitudinal meditative training composed of multiple sessions over weeks and/or years, and often recruit meditation-motivated or experienced individuals as participants.

Mindfulness meditation training takes many forms in the literature, but most often involves either an extended immersive experience (e.g., a 3-month retreat) or repeated daily practice, either in the form of a multi-week course or weeks (or months) of self-guided meditation. Indeed, the vast majority of published work has been on the effects of 8 weeks of training or longer (e.g., Hofmann, Sawyer, Witt, \& Oh, 2010, Brewer et al 2011b). And, although these studies have often documented beneficial outcomes of mindfulness meditation practice, the relevance of such time-consuming, extensive training is debatable for the average individual who might be either unmotivated or unable to dedicate the time and resources necessary to reap such benefits. This relates to the questions of "dose" - once someone begins to practice mindfulness, how soon can they expect to see beneficial effects (e.g., Tang et al., 2015; Zeidan, 2015)? A few recent studies have shown that 3-4 days of training are associated with some beneficial effects (e.g., Zeidan et al.,

2010a, 2010b). The current study focuses on meditationnaïve college students, to examine whether 10 minutes of meditation may have an immediate impact on attention. This approach represents an extreme test of the impact of mindfulness meditation on attention, but also may greatly expand our knowledge of the power of meditation, its boundary conditions, as well as its potential for practice in daily life. In the current studies we focus on whether a single brief audio-guided meditation can have similar benefits for attention in novice meditators.

In an initial attempt to examine the effects of a brief guided meditation on attention in novice meditators, we asked participants to listen to an audio tape (mindfulness meditation vs. control) and then subsequently complete a version of the Flanker task (Eriksen \& Eriksen, 1974; Eriksen, 1995), a measure of executive attentional control. Participants also completed the Big 5 Personality Dimension Inventory to allow for the investigation of moderation by individual differences in Neuroticism.

## Method

Participants. 40 (14 female) undergraduate students between the ages of 17 and $22(\mathrm{M}=19.48, \mathrm{SD}=1.18)$ were recruited from Swarthmore College. Three participants were omitted from final analyses because of scores greater than 3 SDs from the mean (i.e., outliers), leaving a final sample size of 37 ( 12 female; Mage $=19.51, \mathrm{SD}=1.19$ ). Participants were entered into a raffle for one of two \$25 prizes as compensation for completion of the study. All participants gave informed consent, and the study was conducted under the guidance of the Swarthmore College Institutional Review Board.

Procedure. Upon arriving at the laboratory, participants were told that the purpose of the study was to investigate the effects of audio attention on visual acuity. Each participant was seated in front of a desktop computer and was asked to wear headphones and a blindfold, to allow a focus on the audio recording. After the recording, the experimenter returned, removed the blindfold, and provided verbal instructions for the Flanker task. Participants completed twelve practice trials and were given the opportunity to ask questions before beginning the experimental trials. Following the Flanker task participants completed the Big 5 Personality Inventory (John, Donahue, \& Kentle, 1991) and a demographic survey. Finally, the experimenter and participant engaged in a face-to-face funneled debriefing interview.

Experimental Conditions. Participants were randomly assigned to either listen to a 10 -minute guided audio meditation tape (meditation) or a 10 -minute audio control tape (control). The mindfulness meditation tape was developed based on classic mindfulness instructions used in MBSR, and in consultation with several meditation teachers. This tape led participants through a breath-focused mindfulness exercise oriented towards beginners. It included
instructions such as "please set the intention to observe your experience with an accepting attitude," "please notice and begin to follow the natural and spontaneous movement of the breath, not trying to change it in any way," and "stay open and curious about your experience." The control tape was a reading of a National Geographic article about giant sequoias. Importantly, both recordings used the same speaker, speed of speech, number of words, and had similar word frequencies. In addition, both tapes began with instructions on posture within the first few seconds, and included pauses at approximately the same times and for similar durations, throughout.

Flanker Task. The flanker task was delivered using EPrime 2.0 software on a Dell computer with a 22 " LCD monitor (refresh rate $=60 \mathrm{~Hz}$ ). The flanker array consisted of white arrowheads on a black background and was 4.5 cm wide by 1.3 cm high. On average participants sat approximately 70 cm from the screen, producing a visual angle of the array width of 0.026 degrees and of the array height of 0.091 degrees. Each trial consisted of a 500 ms white fixation cross in the center of the black screen, followed by an array of five arrows, which remained on the center of the screen until a response was made. Participants pressed the " f " key with their left hand if the center arrow was facing left, and the " j " key with their right hand the center arrow was facing right. Flanking arrows were either facing in the same direction (i.e., congruent trials) or in the opposite direction (incongruent trials; Figure 1). There were 20 trials in each cell of the 2(direction: left, right) x 2(trial type: congruent, incongruent) design, resulting in a total of 80 trials, presented randomly. Participants were told to respond as quickly and accurately as possible. As soon as a response was made, the next trial began (i.e., there was no intertrial interval).

Big 5 Personality Inventory. After the flanker task, participants completed the Big 5 Personality Inventory (John, Donahue, \& Kentle, 1991), a self-report survey consisting of 44 items designed to measure five personality factors: Openness, Conscientiousness, Extraversion, Agreeableness, and Neuroticism. Participants indicated the degree to which they agreed or disagreed with each item on a 5-point Likert scale, with endpoints labeled disagree strongly (1) and agree strongly (5). Each item began with the phrase "I see myself as someone who..."; sample items for the Neuroticism subscale items include: "worries a lot" and "is emotionally stable, not easily upset," with the latter reverse-coded.

Demographic Survey. Participants also completed a standard demographic survey in which they reported their age, gender (male, female), and self-reported their race and ethnicity.

Debriefing. Finally, participants completed a funneled debriefing interview in which they were given the
opportunity to report any suspicion about the true purpose of the study, as well as reporting any previous experience with meditation, including duration and frequency of practice.

## Results

We conducted independent samples $t$-tests to examine any differences between groups of participants randomly assigned to listen to the meditation tape versus those randomly assigned to listen to the control tape on variables including: age, gender, race, Big 5 Personality traits, and meditation experience. There were no significant group differences on any of these measures.

Response times. RTs for correct trials only were subjected to a 2(condition: meditation, control) $x$ 2(trial type: congruent, incongruent) general linear model (GLM), with the first factor manipulated between-participants and the second factor manipulated within-participants (collapsing across arrow direction). The main effect of trial type, $F(1,35)=129.32, p<0.001$, indicated that participants were faster to respond on congruent trials $(M=427.05 \mathrm{~ms}, S E=$ 6.84) than on incongruent trials ( $M=466.26, S E=7.53$ ), a replication of past research. No other effects reached traditional levels of significance.

Accuracy. Rates of accurate responding were subjected to a similar 2(condition: meditation, control) x 2(trial type: congruent, incongruent) GLM. The main effect of trial type, $F(1,35)=35.123, p<0.001$, indicated that participants were more accurate on congruent ( $M=0.99, S E=0.003$ ) than on incongruent $(M=0.93, S E=0.01)$ trials, another replication of past research. The main effect of condition was marginally significant, $F(1,35)=3.10, p=.087$, and indicated that participants in the mediation condition were more accurate ( $M=0.97, S E=0.007$ ) than were participants in the control condition $(M=0.95, S E=0.007)$. Importantly, there was a significant interaction between trial type and condition, $F(1,35)=5.24, p=0.028$. Pairwise tests showed that whereas both groups of participants were more accurate on congruent than on incongruent trials ( $p \mathrm{~s}<.05$ ), participants in the meditation condition performed better on incongruent trials $(M=0.95, S E=0.01)$ than did those in the control condition $(M=0.91, S E=0.01), p=.044$ (Figure 2). Participants in the meditation condition $(M=$ $0.99, S E=0.004)$ and the control condition $(M=0.99, S E=$ 0.004 ) performed equally well on congruent trials, $p=.39$.

To further probe the effects of meditation on attention on the Flanker task, we calculated difference scores to capture the overall "Flanker effect" in correct RTs (incongruent - congruent) and accuracy (congruent incongruent), separately. Two independent samples $t$-test conducted on these difference scores showed no difference between meditation and control conditions in correct RTs, $p$ $=.48$, and a significant difference in accuracy, $t(35)=2.29$, $p=0.028$, such that participants in the meditation condition ( $M=0.04, S E=0.06$ ) exhibited a smaller Flanker effect
than those in the control condition $(M=0.08, S E=0.06)$. Thus, participants in the meditation condition showed a decreased Flanker effect in accuracy - reflecting better executive attentional control - as compared to those in the control condition, due to their improved performance on incongruent trials.

Moderation by Neuroticism. First, we conducted an independent samples $t$-test to examine whether random assignment to condition (i.e., meditation versus control tape) affected self-reported Neuroticism. As expected, Neuroticism did not differ between participants assigned to the meditation tape $(M=0.03, S D=0.97)$ and those assigned to the control tape $(M=-0.02, S D=1.06), t(35)=$ $0.14, p=.89$. Thus, Neuroticism scores can be assumed to represent true, stable individual differences rather than an unintended effect of random assignment to condition.

To examine moderation of the effects of meditation on attention by individual differences in Neuroticism, RTs were subjected to a 2(condition: meditation, control) $x$ 2(trial type: congruent, incongruent) x $z$-scored Neuroticism GLM, with the first factor manipulated betweenparticipants, the second factor manipulated withinparticipants, and Neuroticism entered as a continuous between-participants covariate. This analysis allows for the examination of main effects and the interaction between condition and trial time holding Neuroticism constant, as well as investigating the main effect of Neuroticism and its interactions with all other variables. As expected, this analysis merely revealed a main effect of trial type, $F(1,33)$ $=126.30, p<.001$, such that participants were faster on congruent than on incongruent trials even when controlling for neuroticism.

A similar GLM was conducted on accuracy scores. As expected, the main and interaction effects reported above held when controlling for neuroticism, including the condition x trial type interaction, indicating that individuals in the meditation condition were more accurate on incongruent trials than were those in the control condition. However, we also found a condition x trial type x Neuroticism interaction, $F(1,33)=3.72, p=.06$. To better understand this interaction, we examined accuracy estimates at 1 SD above and below the mean Neuroticism score. Those individuals lower in Neuroticism ( -1 SD ) generally exhibited the overall pattern: individuals in the control condition were more accurate to congruent than to incongruent trials ( $p<.001$ ), the two groups did not differ in their accuracies to congruent trials $(p=.30)$, but individuals in the meditation condition performed better on incongruent trials $(M=0.98, S E=.02)$ than did those in the control condition ( $M=0.91, S E=.02$; Figure 3 ). Indeed, meditation improved performance to such a degree that participants in this condition performed as well on incongruent trials ( $M=$ $0.98, S E=.02$ ) as they did on congruent trials $(M=0.99, S E$ $=.01$ ), $p=.78$. Individuals higher in Neuroticism ( +1 SD ), however, showed no effect of meditation: both groups were more accurate on congruent than on incongruent trials ( $p \mathrm{~s}<$
.005) and did not differ in accuracy on either trial type ( $p \mathrm{~s}>$ .75 ; Figure 3).

## Discussion

Results indicate that a brief 10 -minute guided meditation can improve executive attentional control even in naïve, inexperienced meditators. Perhaps more interesting is the fact that this meditation-induced improved performance was only observed for individuals relatively low in Neuroticism; individuals higher in Neuroticism did not exhibit any performance boost following meditation. Neuroticism, which is characterized by anxiety, high negative affect, and worry, may prevent individuals from reaping the benefits of meditation, as it may be difficult for individuals higher in Neuroticism to disregard their negative emotionality and focus on the early stages of mindfulness practice.

Previous research has focused on the reduction of neuroticism, anxiety, and stress due to meditation and less on personality predictors (e.g., Neuroticism) of response to meditation. For example, Williams, Francis, and Durham (1976) found that males who practiced transcendental meditation (i.e., a self-selected group) were more neurotic than the general population, but that they also became less neurotic over the course of a 6 -month period of study and that decreases in Neuroticism were directly associated with frequency of meditation. Similarly, Lane and colleagues (2007) found that Neuroticism moderated treatment effects in a group of individuals who completed training in meditation, such that individuals higher in Neuroticism at baseline showed greater decreases in negative mood, perceived stress, and anxiety over the course of training. Thus, Neuroticism appears to have a positive impact on more long-term consequences of meditation. Less is known about its ability to predict who will benefit from the practice of meditation.

In an early review of the literature, Delmonte (1985) argued that prospective meditators often report higher than average anxiety levels, and that anxiety predicts lower frequency of practice. Ironically, Delmonte (1985) also reported that meditation reliably decreases levels of anxiety over the course of practice. Furthermore, many studies have shown that regular meditators tend to be lower in trait Neuroticism (Leung \& Singhal, 2004). Thus, greater stress and anxiety may drive individuals to engage in meditation, while also negatively impacting the frequency of practice. If they, however, do persist in meditation, these individuals often show decreases in their anxiety and negative affect.

The current study is unique in that we recruited healthy undergraduate students who had not expressed any desire to practice meditation and simply measured Neuroticism; in this way, we did not bias our sample toward particular personality traits. Indeed, we did not tell participants that they were engaging in a guided meditation in order to minimize expectancy effects. And we controlled for frequency of practice by requiring that all participants simply complete one 10 -minute guided meditation in the
laboratory. Thus, our results suggest that trait Neuroticism may negatively impact the efficacy of short, guided meditation; individuals high in anxiety and self-awareness may not be able to relax and follow the instructions presented in guided audio meditation, thus preventing them from reaping the benefits of a meditation intervention. This finding has strong implications for the field, as it suggests that the very population thought to benefit most from meditation (i.e., individuals high in anxiety and Neuroticism) may have difficulty initially engaging in the practice. As meditation becomes more frequently prescribed as part of a holistic treatment for mental health disorders often associated with high Neuroticism, including depression, phobia, and other anxiety disorders, practitioners would benefit from an understanding of the difficulties individuals high in Neuroticism face in both learning and persisting in the practice of mindfulness meditation.

In sum, our results suggest that even in novices, one brief 10-minute audio-guided meditation improves attention. Specifically, on an attentional task performed under time pressure, participants in the meditation condition exhibited a boost in accuracy reflecting increased attentional control. Importantly, this effect was strongest for individuals lower in Neuroticism, indicating that personality may impact the ability to reap the benefits of brief meditation. Although much remains to be studied, the current paper suggests that brief meditation impacts attention even in novice practitioners and therefore has widespread implications.

Figures

Figure 1: Trial schema for the Flanker Task.

Figure 2: The condition $x$ trial type interaction in accuracies. Both groups were more accurate on congruent than on incongruent trials, but individuals in the meditation condition performed better on incongruent trials than did those in the control condition.

Figure 3: The interaction between condition, trial type, and Neuroticism. Meditation was effective in improving performance on incongruent trials for individuals lower in Neuroticism (-1 SD) but not for those higher in Neuroticism (+1 SD).

## Acknowledgments

We would like to thank all of the members of the Norris Social Neuroscience Laboratory at Swarthmore College for their help with data collection, analysis, and feedback. Nikhil Paladugu was instrumental in study design and data collection. Most importantly, we are extremely grateful to Hedy Kober, Ph.D., of Yale University for developing and sharing the meditation and control audio tapes used in both studies.

# Who makes use of prior knowledge in a curriculum on proportional reasoning? 

Daniela Nussbaumer (daniela.nussbaumer@hfh.ch)<br>University of Applied Sciences of Special Needs Education, Schaffhauserstrasse 239, 8050 Zurich, Switzerland<br>Christian Thurn (christian.thurn@uni-konstanz.de)<br>Institute for Behavioral Sciences, ETH Zurich, Universitätsstrasse 41, 8092 Zurich, Switzerland<br>Ralph Schumacher (schumacher @ifv.gess.ethz.ch)<br>Institute for Behavioral Sciences, ETH Zurich, Universitätsstrasse 41, 8092 Zurich, Switzerland<br>Elsbeth Stern (stern@ifv.gess.ethz.ch)<br>Institute for Behavioral Sciences, ETH Zurich, Universitätsstrasse 41, 8092 Zurich, Switzerland

#### Abstract

Understanding proportions is a time-intensive process that does not come cheap during late childhood and early adolescence. It is fostered by learning experiences in which students have opportunities to explore, discuss and experiment with situations involving proportions. Children must undergo many informal learning opportunities before they can gain from direct instruction on proportional reasoning. In this study, we aimed to determine whether physics curricula focusing on the concept of density prepares students for learning from a curriculum on proportional reasoning. A $2 \times 2$ design with the factors "physics curricula" (with, without) and "concept used to introduce proportional reasoning" (speed, density) was applied to 253 children from 12 classrooms at the beginning of grade 5 . We expected the "density, with physics curriculum" group to outperform the other three groups. However, only the students who scored in the highest quartile on an intelligence measure gained from the prior knowledge they had acquired through the physics curricula. The results show that curricula on proportional reasoning are worthwhile for all students in early adolescence. However, more capable students can boost their proportional reasoning if they have the chance to acquire prior knowledge through a physics curriculum.

Keywords: proportional reasoning, prior knowledge, STEM

## Theoretical Background

Proportional reasoning involves comparing ratios within or between quantities, and it is based on the formula $\mathrm{a} / \mathrm{b}=\mathrm{c} / \mathrm{d}$. The crucial step is understanding the multiplicative relationship between the quantities, which means knowing that increasing "a" by a certain factor requires either multiplying "c" or "b" with the same factor or dividing "d" by this factor. Most elementary school children erroneously compute differences rather than ratios. Multiplicative proportional reasoning strategies are considered a cornerstone in the cognitive development of adolescents because they are prerequisites for learning more advanced mathematics and for understanding scientific concepts in various formal domains. Moreover, proportional reasoning supports decision making in everyday life, such as when cooking or when evaluating sales.

As stated before, understanding proportions is a timeintensive process during late childhood and early
adolescence. It emerges through repeated and varied experiences and enables mathematical terms and the associated ideas to become connected. The understanding of proportions is fostered by learning experiences in which students have opportunities to explore, discuss and experiment with situations involving proportions. Children must undergo many informal learning opportunities before they can gain from direct instruction on proportional reasoning.

The period from late childhood to adolescence is one of great change, not only in executive control and emotional regulation but also in cognitive competencies. Mastering science and mathematics competencies requires these cognitive tools and skills, which are expected to emerge during elementary school. For example, topics such as fractions, decimals, or ratios, which are at the focus of secondary school mathematics education, presuppose proportional reasoning abilities. These abilities emerge from extending the number concept beyond simple counting (Siegler \& Lortie-Forgues, 2014). Elementary school children's competencies in solving mathematical problems addressing relations and proportions of numbers are highly predictive for secondary school performance, even more so than general cognitive abilities (Stern, 2009; Siegler et al., 2012).

Broadly applicable formal reasoning skills and learning strategies (e.g., proportional, logical and scientific reasoning and metacognitive knowledge) result from an interaction between brain maturation and education. Additionally, proportional reasoning, which is considered a domaingeneral competence, emerges from an interaction of cognitive development (stimulated by brain maturation) and exposure to learning opportunities (Ben-Chaim, Fey, Fitzgerald, Benedetto, \& Miller, 1998). These broadly applicable competencies can be fostered through direct instruction, but most children also acquire them incidentally by abstracting knowledge acquired during elementary school. However, children vary significantly in the ease with which they acquire these skills; these differences are attributed to person characteristics such as intelligence and learning opportunities. Earlier theories of cognitive development focused on universal maturation processes and
assumed that all children reach a formal reasoning stage around puberty (Case, 1993). However, the considerable individual differences found within age groups with regard to formal reasoning tasks demonstrate the importance of domain-specific knowledge. Several studies have detected remarkable individual differences in proportional reasoning: While some eight-year-olds already master multiplicative strategies, some 15 -year-olds still struggle, and adults with little or no standard schooling may never master these skills (Lawson, 1985). Thus, proportional understanding would not suddenly appear if there were no formally or informally acquired knowledge available upon which to build. For example, playing board games in preschool facilitates number-line understanding in elementary school (Siegler, \& Ramani, 2008), and the number-line competencies of elementary school children predict later proportional reasoning and understanding of fractions (Siegler, Thompson, \& Schneider, 2011). These and other longitudinal intervention studies with preschool and elementary school children have identified which learning opportunities support children in developing proportional reasoning competencies.

Research has rarely examined how knowledge about proportional reasoning is represented in a broader network. Represented as a domain-general principle, it should be transferable to isomorphic problems in various contexts. This kind of transferable knowledge is difficult to acquire and requires intensive instruction (Bransford \& Schwartz, 1999). In particular, guided inquiry stands out as an effective means to train the transfer of domain-general principles across situations and time (Chen \& Klahr, 1999, 2008). Similarly, inquiry-based science and math learning has been shown to be a successful means for developing domain-specific content knowledge throughout preschool (Leuchter, Saalbach, \& Hardy, 2014), elementary school (Hardy, Jonen, Möller, \& Stern, 2006), and secondary school.

A longitudinal focus in researching such a complex concept as proportional reasoning would be optimal. However, studies often concentrate on short-term interventions to identify the learner characteristics and instructional factors that affect learning outcomes. These findings do not necessarily capture a generic understanding of proportional reasoning that can be transferred to superficially different but structurally isomorphic problems. Thus, unless learners have acquired expertise, they rarely develop representations of abstract formal structures such as domain-general proportional reasoning (Chi \& VanLehn, 2012).

Embedding a general principle such as proportional reasoning in various contexts can support learners in developing an abstract understanding of general principles that can flexibly be used in novel contexts and situations (Alfieri, Nokes-Malach, \& Schunn, 2013; Gentner, 2010).

## The Current Study

The current study builds on the Swiss MINT Study. (MINT is the acronym for Mathematics, Informatics, Natural Science, and Technology.) In this longitudinal study, elementary school teachers were trained in implementing physics curricula developed by a team of science education experts (https://verlage.westermanngruppe.de/spectra/reihe/ KINTBOX). The inquiry-based curricula included four different basic physics topics: floating \& sinking, air \& atmospheric pressure, sound \& spreading of sound, and stability of bridges. Classes started in third and fourth grade. The curricula were tailored to develop children's domainspecific conceptual content knowledge on these four topics (Möller, \& Jonen, 2005).

In every curriculum, children engaged frequently in experimentation to explore the different basic physics concepts. This inquiry-based approach was accompanied by a strong emphasis on instructional guidance and teacher-led classroom discussion. Teachers who agreed to participate in the study underwent four half-day trainings conducted in small groups. In total, the four curricula encompassed 60 classroom lessons. The floating \& sinking curriculum, for instance, introduced the concepts of water displacement and object density over 15 lessons.

The children were engaged in extensive guided experimentation activities within and across the four curricula, and they encountered many examples of proportional reasoning. In the swimming and floating curriculum, for example, they immersed pieces of different materials with a similar size or similar materials with different sizes into water to examine how these two characteristics influence floating ability. Through this inquiry-based process, children learned about the concept of density. Therefore, through this curriculum, elementary school children gained not only content knowledge but also experience with regard to the domain-general concept of proportions. None of the four curricula involved general, direct remarks about proportional reasoning.

In this study, we want to find out whether children who studied physics curricula that implicitly included proportional concepts better comprehend proportional reasoning in a subsequent teaching unit than those who studied the traditional way. We expected that the manifold guided experimentation activities not only fostered children's domain-specific content knowledge but also helped them understand abstract mathematical concepts such as (the domain-general principle of) proportional reasoning. Thus, we expected a significant main effect of "physics curricula".

We wanted to distinguish between a more general and a more specific effect of prior physics curricula. Therefore, two curricula on proportional reasoning were developed:
one based on the concept of speed, which was not part of the physics curriculum, and one based on the concept of density, which was central in the unit on floating and sinking. The curricula on proportional reasoning were applied either to classes that were part of the previously described Swiss MINT study (and therefore had undergone the physics curricula) or classes that underwent regular science education (which usually does not include physics at all). Thus, we expected a significant interaction between "physics curricula" and "concept used to introduce proportional reasoning".

This led us to the following research questions and hypotheses:

1. Does early science learning affect later mathematical learning (for proportional reasoning)?
We assumed that later math learning is affected positively (but that this effect depends on the problem context chosen for the intervention; see next point). In other words, we assumed that students with early science learning understand proportions better after receiving instruction on proportional reasoning.
2. In what way does early science learning prepare students for future learning? Does it work more generally or more specifically?
For the familiar problem context of density, we expected a greater advantage; for the non-familiar problem context of speed, we expect only marginal group differences. We predicted that students who underwent the physics curricula were able to link the new information to their knowledge about physics.
In short, we predicted that children who underwent the physics curricula and were taught proportional reasoning with density scored highest on a transfer test on proportional reasoning.

## Method

## Participants

Participants included 253 children from 12 classrooms at the beginning of grade 5 (age: $M=10.73$ years, $S D=0.55$ ). Participants per cell of the $2 \times 2$-design are as follows (see below): density/without physics curricula: $n=66$, density/with physics curricula: $n=62$, speed/without physics curricula: $n=66$, speed/with physics curricula: $n=$ 59).

The children in our sample came from different regions of Switzerland. All of them were part of the Swiss MINT Study and either had completed all four physics themes with the aforementioned curricula prior to the curriculum on proportional reasoning or were part of a waiting group that had not yet started with the physics curricula. Whole schools rather than individual teachers volunteered to be a part of the Swiss MINT Study (and it was not the students
who chose a particular school, educational track or curriculum). Nevertheless, it can be assumed that teachers (and school teams) taking part in the current study were STEM oriented and that there were no differences between the "waiting group" stage and the "applying the curricula" stage. Attempts were made to minimize the differences between the student populations by parallelizing the catchment areas of schools at the "waiting group" stage and the "applying the curricula" stage (rural, agglomeration, city and average socioeconomic status of a particular area), as in Switzerland, students are assigned to schools according to their place of residence. Teachers were recruited through a mailing list, and the teachers and classes participated voluntarily during their class time. They received no monetary compensation.

We chose fifth-grade classes for the study as this is a time in which the development of the understanding of proportional reasoning increases, and only towards the end of fifth grade (that is, at the end of our intervention) is proportional reasoning an explicit part of the official study curriculum. Thus, we were able to test whether and to what extent proportional reasoning can develop without formal instruction and to what extent physics experimentation experience additionally boosts this development.

## Procedure

A $2 \times 2$ design with the factors "physics curricula" (with, without) and "concept used to introduce proportional reasoning" (speed, density) was applied. The curriculum on proportional reasoning (both speed and density) consisted of 3 lessons ( 45 minutes each) that were based on the idea of concreteness fading (Goldstone \& Son, 2005). In the speed group, children were faced with two cars that traveled the same distance in different times, while in the density group, children were shown cubes of the same size but different weights. Afterwards, the children were faced with different combinations of time/distance and weight/volume. The dependent variable was a test on proportional reasoning that was applied at the end of the curriculum (subsequently called the transfer test, as this test consisted of untrained word problems). To control for differential effects, a measure of general intelligence was applied.

## Material

Intervention: The intervention was designed in a way that is scientifically proven to be most effective. With the intervention, we followed some basic principles: We tried to make students focus on the underlying mathematical structure of a problem and on multiple solution and representation strategies. We promoted the use of external representations in learning and calculating proportions. We explicitly compared and contrasted the different solutions and representations (see Ziegler and Stern, 2014). Furthermore, we tried to implement self-explanations (Jitendra et al., 2008 on schema-based instruction). To accomplish this, we combined direct instruction with phases
of working alone (vs. in pairs). Furthermore, the lessons were based on the idea of concreteness fading (Goldstone \& Son, 2005).
Problem presentation influences task difficulty and often determines whether a student can solve a problem (see Boyer et al., 2008). Our participants therefore solved and received feedback on two different problem types: comparison problems and missing values problems (see Van Dooren, De Bock, Hessels, Janssens, \& Verschaffel, 2005). The two problem contexts were tightly parallelized, and the same values were used in both of them.
Pre-test, post-test and transfer test (see table 1): In a pretest, prior knowledge about the two problem contexts was assessed, i.e., students' knowledge on density and speed. Additionally, the N 2 subscale of a cognitive ability test (kognitiver Fähigkeitstest, KFT; Heller \& Perleth, 2000) was administered at pre-testing. After the above-described intervention (proportional reasoning introduced in the context of density vs. speed), a post-test on the understanding of proportions (very similar to the pre-testthe same in structure as the tasks solved during the intervention) was administered. Additionally, a transfer test (proportion problems embedded into word problems) had to be solved (see table 1). All participants of the $2 \times 2$ design solved the same test versions. Both tests (post and transfer) took place one to two days after the intervention.
Table 1: Schematic view of the experimental design

| Pre-test | $\begin{aligned} & \text { g } \\ & \frac{0}{0} \\ & 0 \end{aligned}$ | Post-test and transfer test (one to two days after the intervention) |
| :---: | :---: | :---: |

## Results

## Pre-Test

Keeping in mind our research question, "Who makes use of prior knowledge in a curriculum on proportional reasoning?" it was important to check whether prior knowledge was actually still available. Indeed, this was the case: The physics knowledge test consisting of the themes floating \& sinking revealed significantly higher knowledge in the group with prior experience with the physics curricula (and no significant difference between the speed vs. density conditions). For the group with prior knowledge, the test can be considered a long-term follow-up from the physics curricula; the students completed the physics curricula up to
two years prior to the actual proportional reasoning curriculum. For the group without prior experience with the physics curricula, the test and the themes were new. For the group with prior physics knowledge, the solution rate was $40 \%$, whereas the solution rate of the group without prior experience was slightly over $20 \%$. Therefore, for the problem context of density, we can build on the differences in knowledge between the groups with and without physics curriculum experience.
For further analyses, we formed subgroups; i.e., we grouped participants into quartiles according to the results on the N2 subscale of the cognitive ability test. The four groups of the 2x2-design did not significantly differ in their level of cognitive abilities, $\mathrm{F}(3,242)=0.33, \mathrm{p}=0.8$. Additionally, when looking at each quartile separately, we find no significant difference between the four groups of the $2 \times 2$ design. Therefore, the distribution of cognitive abilities and quartile groups is comparable between the four groups of the $2 \times 2$ design.
When they had no prior experience with the physics curricula, participants of all quartiles scored similarly low, and their scores closely overlapped. Cognitive abilities were not reflected in the results regarding physics understanding when physics had not yet been formally taught. However, when the physics curricula had been applied, intelligence differences unfolded, with the highest quartile scoring significantly higher ( $47 \%$, right) than the other quartiles (see figure 1 and note that error bars indicate standard errors of the mean). Thus, the cognitive ability test did its share only in the group with prior physics instruction.

Figure 1: Results of the physics test on floating and sinking. Left: group with prior experience with the physics curricula (for this group, the test can be considered a long-term, i.e., up to one year, follow-up test). Right: group without experience with the physics curricula. Depicted are solution rates; error bars indicate standard errors of the mean. Q1-4 refers to grouping participants into quartiles according to their results on the cognitive ability test, with Q4 indicating the quartile with the highest cognitive ability.
The test on prior knowledge about speed revealed no difference between the groups (with/without physics curricula) as a whole and when split into quartiles. "Speed" was not part of the physics curricula. Prior knowledge about speed, however, was positively correlated with participants' results on the cognitive ability test ( $r=.32$ ). Cognitively
abler participants scored higher on the test of prior knowledge about speed. See figure 2 for the differences between the quartiles. The average solution rates were around $50 \%$.

Figure 2: Test of prior knowledge about speed. Left: group with prior experience with the physics curriculum. Right: group without experience with the physics curriculum. Depicted are solution rates; error bars indicate standard errors of the mean. Q1-4 refers to grouping participants according to their results on the cognitive ability test, with Q4 indicating the quartile with the highest cognitive ability. No difference between the groups (with/without physics curriculum) is found. "Speed" was not part of the physics curriculum.

## Post-Test

The post-test was very similar to the pre-test and had the same structure as the tasks solved during the intervention. Therefore, the post-test can be viewed as a manipulation check of the implemented proportional reasoning curriculum. This manipulation check was positive in that participants were able to redo tasks that were administered during the curriculum ( $80 \%$ of participants solved all tasks correctly with no mistakes, and there were no differences between the four groups of the $2 \times 2$ design).

## Transfer-Test

Coming to the core results of this study, overall, no significant interaction was observed between groups (with and without prior physics curricula experience) and context of the intervention (values of the ANOVA comparing the four cells of the $2 \times 2$ design: $F(3,236)=0.94, p=0.42)$ ). Therefore, the main effect of "physics curricula" turned out not to be significant. Additionally, the interaction between "physics curricula" and "concept used to introduce proportional reasoning" turned out not to be significant.

Therefore, the findings corroborate neither the more general nor the more specific hypothesis of a positive influence of prior physics curricula on the learning of proportional reasoning. This encouraged us to more closely examine whether the subgroups possibly gained from the physics curricula with regard to learning proportional reasoning. Indeed, we did find effects: When grouping participants by quartiles according to their cognitive ability measure, we
found the expected positive effect of prior physics learning for students in the highest quartile. Those in the highest quartile who underwent the physics curricula scored higher on the proportional reasoning transfer test than students in the lower three quartiles $(p<.05)$. No such effects were found for students in the highest quartile who did not undergo the physics curricula. In the transfer test, the solution rates were relatively low (mean solution rate just slightly over $20 \%$ ); see figure 3 . Similar distributions were found when we only looked at the density groups without evaluating the speed groups: The highest quartile with prior knowledge scored significantly higher than the three lower quartiles, and for those without prior knowledge, the quartiles did not differ. Taken together, for the most intelligent students, the findings corroborate the more general hypothesis. Therefore, physics curricula can serve as preparation for future learning of proportional reasoning.

Figure 3: Results of the proportional reasoning transfer test by physics curriculum (with/without). Left: group with prior experience with the physics curriculum. Right: group without prior experience with the physics curriculum. The transfer test consisted of entirely novel proportional word problems. Depicted are solution rates; error bars indicate standard errors of the mean. Q1-4 refers to grouping participants according to their results on the cognitive ability test, with Q4 indicating the quartile with the highest cognitive ability.

## Discussion

Our results confirm what has been demonstrated many times: Transfer does not come cheap. The study focused on learning opportunities that foster the emergence of consecutive competencies in related fields. Contrary to our expectation, we did not find a general advantage of physics learning (more precisely, density learning) for learning proportional reasoning taught by referring to density.

However, students scoring in the highest quartile of the intelligence measure were able to make use of the prior knowledge they had acquired during the physics curriculum. We therefore conclude that intelligence differences can unfold students' individual potential in combination with sufficient prior knowledge. If a child has high cognitive ability and encounters many examples of proportional
reasoning situations, he or she will be prepared for a subsequent formal learning situation on proportional reasoning. It is the combination of high intelligence and prior experience or specific prior knowledge that leads to the ability to exploit a learning situation better.

The results show that curricula on proportional reasoning are worthwhile for all students in early adolescence. However, more capable students can boost their proportional reasoning if they have the chance to acquire prior knowledge in a physics curriculum.

Future work could focus on the question of how physics curricula can better support students in understanding proportions. It is possible that introducing the abstract structure of the mathematical concept prior to inquiry-based instruction would have an even greater effect.

#### Abstract

We infer the thoughts and feelings of other people by taking their perspectives, the accuracy of which depends on abilities to control egocentric bias. Similar processes could arguably be used to understand how we would be affected by future events, such as delayed rewards in intertemporal decisions, by allowing us to accurately take the perspective of future selves. In this paper, we test this idea in two studies. In Study 1, we attempted to lower preferences for delayed rewards to examine if this redced abilities to control egocentric bias in a visual perspective-taking task. In Study 2, we examined the neural overlap in intertemporal decision-making and the control of egocentric bias in a false-belief theory-of-mind task. In both studies, a positive relationship was identified between behavioural and neural markers of egocentric bias control and preferences for delayed rewards. The overall pattern of results suggest the overlap in processes of egocentric bias control and those that determine preferences in intertemporal choices, and demonstrate for the first time the effect of sexual arousal on social cognition in reducing abilities to separate one's own perspective from others'.

Keywords: intertemporal choice, temporal discounting, egocentric bias, perspective-taking, temporoparietal junction

## Introduction

The ability to see the world from different perspectives, imagining the thoughts or feelings that might occur in us and others in a variety of situations, is highly useful. It helps to take the perspectives of others to understand and interact effectively with them. This ability is also useful in an intertemporal context, for instance, when faced with decisions or events with delayed consequences, we typically shift our own perspective into the future to assess how these might impact us later. The relationship between these
capacities for taking the perspectives of others and future selves has previously been speculated (see Jamison \& Wegener, 2010; Mitchell et al., 2011; Buckner \& Carroll, 2007), but it is still unclear if and how they overlap. To investigate this, we previously laid out an empiricallygrounded framework to make plausible hypotheses of how these capacities relate to each other (O'Connell et al., 2015), called the Simulation-based Model of Intertemporal Preferences (SMIP).

The SMIP uses the phenomenon of temporal discounting to illustrate how perspective-taking abilities might underlie the perception of future events. Temporal discounting describes how when making choices between rewards to be received now or larger rewards later, the delayed larger reward decreases in subjective value when its receipt is delayed further in the future, leading to smaller but immediate rewards being preferred, and the rate of which is indexed by the steepness of the "discounting curve".

One way the accuracy of perspective-taking can become compromised is through the false presumption that other people think or feel the same way as we do, an error called egocentric bias, as measured using false-belief theory-ofmind (ToM) tasks. Neuroimaging studies of psychiatric patients and children have found that better control of egocentric bias during ToM judgments corresponds to stronger coinciding neural activity in the right temporoparietal junction (rTPJ) (Gweon et al, 2012; Kana et al., 2009; Dodell-Feder et al, 2013). Further reports indicate the rTPJ is preferentially activated for false beliefs that require egocentric bias control, and not true beliefs (Hartwright et al., 2012; Sommer et al., 2007), specifying
the role of this region in egocentric bias control, and not general capacities of perspective-taking.

The SMIP hypothesizes that intertemporal choices situations are analogous to social situations in which perspective-taking occurs, in how there is a target perspective to be inferred, and an egocentric perspective which needs to be controlled for. The SMIP argues that from one's current egocentric perspective, delayed rewards have to be waited for to be received, and therefore incur costs-of-waiting that diminishes their subjective value. In contrast, from the perspective of one's future self, there is no cost of waiting because they are at the right point in time to receive the reward instantly. Controlling this egocentric bias when taking the perspective of the future self should therefore lead to delayed rewards being preferred more, leading to less steep temporal discounting. The SMIP further explicitly predicts the rTPJ as one of the key nodes for control of egocentric bias during both perspective-taking and intertemporal choices. Note these are only a few of the mechanisms and predictions outlined in the SMIP which are relevant to the current study (for further information see O'Connell et al., 2015).

A recent paper from Soutschek et al. (2016) provides direct support for this neural overlap hypothesized by the SMIP. In two studies, repetitive transcranial magnetic stimulation (TMS) was administered to participants' rTPJ regions to disrupt its function. It was found that both the degree of egocentric bias exhibited by participants in a visual perspective-taking task, and preferences for immediate over delayed reward choices in a temporal discounting task, were both subsequently increased. Furthermore, a positive relationship between egocentric bias and immediate reward preferences was observed across individuals. By demonstrating a relationship between egocentric bias and increased temporal discounting, these two findings can be explained by the SMIP framework.

In this paper, we tested the hypotheses of the SMIP by examining the relationship between egocentric bias control and temporal discounting in two studies: 1) examining the effect on one process when the other is experimentally manipulated, 2) examining their neural overlap using fMRI.

## Study 1: Sexual Arousal Manipulation

In Study 1, instead of brain stimulation as per Soutschek et al. (2016), we attempted to increase the steepness of temporal discounting psychologically by inducing sexual arousal with erotic images, which multiple reports indicate is reliable means of increasing the steepness of temporal discounting (Kim \& Zauberman, 2013; Van den Bergh, Dewitte, \& Warlop, 2008; Wilson \& Daly, 2004). Sexual arousal is thought to lead to steeper temporal discounting by causing a generalized state of desire, in which the immediacy of a reward overshadows its objective value. For a comparison control, equally arousing sports images were used, as per Kim \& Sauberman (2013). The Director task was used to index control of egocentric bias.

## Methods

## Participants and procedure

Heterosexual German speaking males were recruited ( $\mathrm{n}=$ 90, range $19-59$ years, mean 29.3) performed tasks in the following order: 1) temporal discounting (baseline), 2) visual perspective-taking Director task, 3) temporal discounting (manipulation-check), 4) Continuous performance task (CPT). After task 1) the impulsivity manipulation was initiated, where in separate groups participants viewed either erotic or arousal-matched sports images for 8 s , which occurred every trial of the Director task, 6 trials of the temporal discounting task, 13 trials of the CPT, for an average of one image every 14 s .

## Temporal discounting (baseline)

Participants made intertemporal choices between a variable amount of money now $(<100 €)$ or $100 €$ at one of four randomly selected delays (months: 1, 3, 6, 12). The amount of immediate options and indifferences-points were calculated using the double-limits algorithm, and temporal discounting rates ( $k$ ) were estimated by fitting a hyperbolic non-linear model to each participant's indifference-points

## Director task

In the Director task, participants move objects around a set of shelves as instructed by a "director" standing on the opposite side, but to take into account that some objects cannot be seen by the director because they are occluded from their side of the shelf. This requires the participant to control for egocentric information from their own viewpoint when inferring the director's. The Director task was computerized with a real person in the role of director, and the impression of actual shelves was created by positioning the participant's screen back-to-back with the director's. A previously used eye-gaze metric of egocentric bias was used - the average dwell time (sum of 100 ms fixations) to distractor objects, a basic index of how much the distractor object (the correct object from the participant's egocentric viewpoint) was considered as the correct option.

Participants' heads were placed in a chin-rest positioned in front of an Eye-tribe 30 Hz eye-tracker. Trials began with a fixation cross when the experimenter read aloud a scripted instruction, then pressed a key to present the shelves on screen. Instructions in experimental trials referred to distractor objects on dimensions of spatial (e.g. "move the top ball" could refer to a higher hidden ball), size (e.g. "move the large ball" could refer to a larger hidden ball), or semantic (e.g. "move the mouse" could refer to a computer mouse or a hidden toy mouse). In control trials instructions referred to objects without competing referent. 30 trials were performed ( 24 experimental, 6 control), featuring 9 sets of 6 objects, presented in a fixed randomized order.

## Temporal discounting task (manipulation-check)

Participants performed intertemporal choices a second time to check the sexual arousal manipulation. Immediate
reward options were present from ranges $( \pm 10 €)$ around participants' baseline indifference points in 32 trials. Changes in temporal discounting were estimated as valueweighted changes from baseline temporal discounting.

## Continuous Performance Task (CPT)

The CPT measures general attention to test possibility that erotic images affected egocentric bias by merely distracting attention from task goals. Single digit numbers were presented for $100 \mathrm{~ms}(1 \mathrm{~s}$ ISI), and participants had to press one key following a sequence of 3-7 (average every 10 of 130 trials), and another key otherwise.

## Results

## Effects of sexual arousal manipulation

Note tests of the hypothesis were directional and conducted at the 1-tailed level. In the Director task, dwell time to the distractor object was significantly higher following erotic $(\mathrm{M}=317 \mathrm{~ms}, \mathrm{SE}=.18)$ images versus sports images $(\mathrm{M}=270 \mathrm{~ms}, \mathrm{SE}=.17), t(88)=1.9, p=.032$, $\mathrm{d}=.4$ (Figure 1B), an effect not observed in control trials, $t(88)=.043, p=.97$. Although changes from baseline temporal discounting were ordinally higher following erotic $(\mathrm{M}=1.5, \mathrm{SE}=3.3)$ compared to sports $(\mathrm{M}=-.6, \mathrm{SE}=3.6)$ images, this difference was not significant, $t(88)=.44, p=$ .33. There was no significant difference in error rates in the CPT task between the erotic ( $\mathrm{M}=5 \%, \mathrm{SE}=.02$ ) or sports $(\mathrm{M}=2 \%, \mathrm{SE}=.01)$ image groups, $t(88)=1.3, p=.18$.

## Relationship between egocentric bias and temporal discounting

A linear regression was used to model the relationship between baseline temporal discounting rates and egocentric bias, controlling for the influence of group. The model found that after controlling for the group factor $(B=-.524, t$ $=-2.11, p=.038$ ), temporal discounting was a significant positive predictor of egocentric bias $(B=.316, t=2, p=$ .048). Note, data from the second temporal discounting task could not be used for this form of analysis because in this task, choice options were pre-determined from baseline, and not the double-limits algorithm which is required to reliably estimate new temporal discounting rates (Figure 1A).

Figure 1. A: Scatterplot of temporal discounting and egocentric bias (residuals partialling out group effects). B: Group differences in egocentric bias (error-bars: SE).

## Discussion

In support of the hypothesis, it was found that people who exhibited steeper temporal discounting were also more susceptible to egocentric bias. Also in line with this view, egocentric bias was higher following erotic stimuli, which although previously reported to lead to steeper temporal discounting, was not specifically observed here.

Contrary to previous findings, sexual arousal from did not significantly alter temporal discounting here, limiting the extent to which changes in egocentric bias can be attributed to changes in self-control. One explanation for this null finding is that the arousing effects of erotic images had habituated by the second time the temporal discounting task, after already 15 mins of repeated exposure to images. It's worth noting that in pilot data, where temporal discounting was the first task performed, steeper temporal discounting was found following erotic images compared to sports images ( $\mathrm{n}=32, p=.05$ ), giving some confidence that full counterbalancing of tasks in this study would have increased chances of observing effects of sexual arousal on temporal discounting. However, this null effect still warrants caution in interpreting the results.

## Study 2: fMRI

In Study 2, we tested the relationship between egocentric bias and temporal discounting using fMRI. If rTPJ activity during perspective-taking is a correlate of egocentric bias control, as hypothesized by the SMIP and suggested by empirical evidence, then people higher in this marker should prefer delayed rewards more during intertemporal choices. To test this hypothesis, we used a false-belief functional localizer task to extract activity in the rTPJ related to egocentric bias control from each participant. We further tested if activity in this rTPJ cluster was higher when delayed rewards are chosen, as would be expected if egocentric bias control reduces temporal discounting.

## Methods

## Participants and procedure

36 English speaking adults ( 21 female, aged 18-34 years, mean 22.6) performed the following tasks in order: outside scanner, 1) temporal discounting task; inside scanner, 2) temporal discounting task, 3) ToM localizer task.

## Temporal discounting (outside scanner)

Same as temporal discounting task (baseline) in Study 1, except with pounds in place of euros, and using the following delays (months: $1,3,6,9,12,18$ ).

## Temporal discounting (in scanner)

In the scanner, participants were presented with intertemporal choices featuring three delays (months: 6, 9 , 12). As in the temporal discounting task (manipulationcheck) in Study 1, immediate options were estimated from participants' temporal discounting data collected outside
scanner in order to predict how participants would decide and efficiently balance the number of trials in conditions of immediate (IMM) and delayed (DEL) choices, this time from value ranges $\pm £ 5-15$ indifference-points. Trials continued until 32 (balanced across delays) were collected in which each immediate and delayed rewards were chosen (the IMM and DEL conditions). Options were presented together for 5 s , followed by a jittered ITI of 7-15 s.

## fMRI temporal discounting acquisition and analysis

25 out of the 36 participants performed the scanner version of the temporal discounting task. Scanning was conducted using a Siemens 3T Trio MRI scanner with an EPI sequence of TR 3 s , TE $30 \mathrm{~ms}, 2 \mathrm{~mm}^{3}$ voxel size, and 35 interleaved 3 mm slices. Data were preprocessed using a GLM in SPM8, with slice-timing correction, realignment for motion correction, field map unwarping, and sequential co-registration. We contrasted rTPJ activity in DEL > IMM separately for each individual in their specific rTPJ ROIs from the ToM task, by first registering individual rTPJ ROIs to MNI space using FEAT, and the mean contrast values of DEL and IMM conditions were then extracted.

## False-belief ToM localizer task

The false-belief localizer task consisted of 10 stories about other people's beliefs (False Belief) or historical facts (FACT). Each trial started with a blank screen for 12 s , followed by the story for 10 s , and then a question screen for 4 s , which required a "True" or "False" response.

## fMRI ToM localizer data acquisition and analysis

Scanning was conducted with an EPI sequence of TR 2 s , TE $30 \mathrm{~ms}, 2 \mathrm{~mm}^{3}$ voxels, and 37 interleaved 3 mm slices. Using FSL, data were field map unwarped, pre-whitened, motion corrected, slice-time corrected, and high-pass filtered at 128 Hz and smoothed at 8 mm FWHM in native space. False Belief and FACT trials were defined as the 14 s of the story and question screens. Using FEAT, clusters from the False Belief $>$ FACT contrast were identified at height threshold $\mathrm{z}=2.3$, cluster threshold $\mathrm{p}<.05$, minimum size 200 voxels, Gaussian Random Field FWER corrected.

## rTPJ ToM localization procedure

An iterative threshold-adjusting procedure was adapted from Mitchell (2008) to identify individual rTPJ clusters related to false-belief processing. This procedure involved increasing the height activation threshold of the False Belief $>$ FACT contrast in native space in steps of $10-1$, starting from $\mathrm{p}<0.01$ until a cluster in the rTPJ region was identified $25-50$ voxels in size. Percentage signal change in participants' individual clusters, hereafter referred to as $\mathrm{rTP}_{\mathrm{FB}}$. For thoroughness of reporting, this procedure was applied to other regions associated with ToM in the left temporoparietal junction (lTPJ) and precuneus.

## Results <br> Data cleaning and sample selection

rTPJ clusters could not be localized for two participants, and 2 participants were extreme outliers in the DEL vs. IMM in the rTPJ ROI (Tukey's interquartile range), This threshold identified two cases for exclusion.

## Correlation between egocentric bias control rTPJ response and temporal discounting

A significant negative correlation was found between temporal discounting rates $k$ and $\mathrm{rTPJ}_{\mathrm{FB}}, \mathrm{r}=-.32, p=.03$ (Figure 2) ( $\mathrm{lTPJ}_{\mathrm{FB}}, \mathrm{r}=-.36, p=.02$; precuneus ${ }_{\mathrm{FB}}, \mathrm{r}=-.37, p$ $=.01$ ), an effect still significant in the temporal discounting scanning session subsample, $\mathrm{r}=-.36, p=.04$.

Figure 2. Scatterplot of temporal discounting and magnitude of $\mathrm{rTPJ}_{\mathrm{FB}}$ activity.

## fMRI temporal discounting results

A significant difference was found in individual rTPJ ROIs in DEL $>$ IMM, $t=2.06, p=0.025$ (Figure 3B).

Figure 3. A: Overlaid individual rTPJ ROI clusters (crosshairs at peak). B: Differences between choice conditions in individual rTPJ ROIs (error bars: SE).

## Discussion

In Study 2, we found two pieces of evidence in support of the hypothesis that better control of egocentric bias reduces steepness of temporal discounting. First, people exhibiting a higher rTPJ response during false-belief judgments, a putative neural marker of egocentric bias control, had less steep temporal discounting. Second, responding in the same rTPJ cluster involved in egocentric bias control was higher
when delayed rewards were preferred over immediate rewards when making intertemporal choices in the scanner.

Evidently, this interpretation of the results relies on a reverse-inference about the rTPJ's function of egocentric bias control. Neural markers of egocentric bias control have the advantage of being continuous, and more resistant to ceiling effects that standard measures (e.g. false-belief tasks) are often prone to, making them better suited for measuring variability in healthy adults. Increased rTPJ activity has been repeatedly shown to be associated with higher ToM accuracy (Gweon et al., 2012; Kana et al., 2009). Similarly here, despite ceiling effects in accuracy in the current ToM data, a trending positive correlation was noted between this accuracy and magnitude of rTPJ activity ( $\mathrm{r}=.23, p=.09$ ), providing some behavioural support for the function of rTPJ activity claimed here. Some studies with children, who do not show the ceiling effects typically seen in ToM tasks in adults, have shown positive links between accuracy and preferences for delayed rewards (Launay et al., 2015; Marchetti et al., 2014).

The exact function of the rTPJ in perspective-taking remains an open question. Based on reports of the rTPJ's importance in focusing attention on distinctions between self and others (e.g. in terms of preferences; Nicolle et al., 2012), it has been proposed that this region helps avoid the perceptual blurring of self and other perspectives that drives egocentric bias (Brass et al., 2009). More generally, the rTPJ has been claimed to be involved in orienting attention towards task goals (Corbetta \& Shulman, 2002). In any form of choice, it could be argued that a goal to maximize reward outcomes, irrespective of the time of receipt, becomes activated. In intertemporal choices, delayed rewards are larger, and hence, most relevant to this goal. In contrast, immediate rewards could be considered distractions that draw attention away from this goal, shifting focus instead to the immediacy of enjoyment. This view of rTPJ function would account for its observed increased activation when choosing delayed rewards.

## General Discussion

The effects in this paper are modest and mixed, but support the view that temporal discounting is related to abilities of perspective-taking, as hypothesized by the SMIP. To sum up, in both Study 1 and Study 2, individual differences in perspective-taking corresponded to steepness of temporal discounting. In Study 1, an experimental manipulation previously shown to led to steeper temporal discounting was found to increase egocentric bias. However, because of the null effect on temporal discounting itself, the extent to which this egocentric bias can be attributed to processes overlapping with temporal discounting is limited. In Study 2, evidence for the SMIP was found in how individually-localized neural markers of egocentric bias control were higher when delayed rewards were preferred over immediate ones. In all, these findings, provide exploratory first steps in examining potential connections between intrapersonal and interpersonal forms of cognition.

Such a connections has numerous theoretical and practical upshots. Linking the fields of social cognition and intertemproal decision-making would allow the benefits of one (e.g. conceptual frameworks in social cognition, mathematical models in decision-making) be transferred to the other. Practically, it would suggest the potential of temporal discounting as a continuous and fast index of perspective-taking abilities in adults, which are currently required in social cognition research.

To-date, the overwhelming amount of research in intertemporal decision-making has restricted focus to the concept of value, and inputs and outputs to its computation. Increasingly, more concepts about how this value is psychologically represented have come under study, including future prospection (Kwan et al., 2015), and feelings of connectedness with one's future (Urminsky, 2017). The SMIP aims to extend this line of inquiry by attempting to provide a mechanism for how these representations are built, and why they degrade to cause temporal discounting, parsimoniously based on mechanisms that already underlie social abilities.

Sexuality is an integral social setting, but its impact on perspective-taking abilities has not been tested before now. The present finding thus furthers understanding of how an everyday social context modulates mentalizing capacities, which vital information for theories to build sufficiently detailed descriptions of these processes (for similar work, (Galinsky, Magee, Ena Inesi, \& Gruenfeld, 2006; Kanske, Böckler, Trautwein, Parianen Lesemann, \& Singer, 2016; Todd, Forstmann, Burgmer, Brooks, \& Galinsky, 2015).

The current findings, along with those of Soutschek et al. (2016), encourage further investigations of the overlap in intertemporal choice and perspective-taking, but the noted inconsistencies warn that conclusive evidence could be challenging to find. One clear example of this is the difficulty in detecting overlap in capacities that are measured by tasks with vastly different structures and demands. The results also flag sexual contexts as influential to the ability to look past our own perspective to better understand those of others, calling for further investigations into this important but little understood topic. Future work can test the generalizability of these effects in larger samples, using different measures, especially ones that can measure these capacities in more closely matched structures.

#### Abstract

Humans are highly social creatures. Evidence from the dot perspective task suggests that humans automatically track the perspective of other individuals - a disposition that, if true, may help to facilitate social interaction. However, variants of the original dot perspective task suggest the alternative interpretation that the effect in the task is not due to perspective taking. Here, we present a new variant, using improved stimuli to address these issues. Our results replicate previous findings, across both animate and inanimate stimuli, and suggest that the effect is due to directional cueing rather than automatic perspective taking.

Keywords: perspective taking; dot perspective task; automaticity; theory of mind; mindreading

## Introduction

The ability to reason about other individuals' mental states ("mindreading") is thought to be a central component of social cognition in humans (Corballis, 2011; Graziano, 2013; Tomasello, 2008, 2014). In order to explain the social abilities that are best accounted for by mindreading, it seems necessary that certain forms of mindreading are highly efficient (Apperly, 2011; Apperly \& Butterfill, 2009; Butterfill \& Apperly, 2013). Evidence for efficient mindreading comes from various experimental paradigms (Freundlieb, Kovács, \& Sebanz, 2016; Schneider, Slaughter, \& Dux, 2017; Scott \& Baillargeon, 2017), including the dot perspective task (DPT) (Samson, Apperly, Braithwaite, Andrews, \& Bodley Scott, 2010), which suggests that participants rapidly and automatically calculate the perspective of other agents.

However, the interpretation of these results is disputed. Different variants of the DPT (e.g. Cole, Atkinson, Le, \& Smith, 2016; Santiesteban, Catmur, Hopkins, Bird, \& Heyes, 2014) have produced results that may be explained by a simple directional effect, in which attention is directed not exclusively by the gaze of an agent, but rather by any directional stimuli. If the task results are indeed attributable to directional cueing, it would undermine the use of this task as evidence for fast and automatic mindreading. We describe the different variants in the next section, before describing a new variant, using Lego figures, that may be used to address these issues, and the experimental results obtained using it.

## Variants of the Dot Perspective Task

In the dot perspective task, participants observe scenes and answer a simple yes/no question based on the number of dots in the scene. The scenes that participants view feature an on-screen human avatar standing in a room. Arranged on walls around the room are various dots. In some scenes, the dots all appear in front of the avatar, making the avatar's perspective of the dots consistent with the participant's: e.g. if there are two dots on the front wall, the avatar and the participant both see two dots. In other scenes, some of the dots are behind the avatar, making the avatar's perspective inconsistent with the participant's: the avatar might see only one dot, while the participant can see two.

Participants are shown a digit (e.g. " 2 "), followed by one of these scenes, and asked to confirm whether the number of dots matches the pre-scene digit by answering "Yes" or "No." In three different experiments, Samson et al. (2010) found longer reaction times for inconsistent scenes compared to consistent scenes, which they interpreted as evidence for "altercentric interference": the participant had to suppress the avatar's perspective in order to answer the question of whether the digit matched their own perspective, resulting in a delayed response. This suggests that perspective taking, even for an on-screen avatar, is rapid and automatic.

In the first two of these three experiments, participants were asked to judge their own perspective on certain scenes (cued by the word "YOU" appearing before the digit), and the avatar's perspective on others (cued by the word "HE" or "SHE"). Because this may have caused participants to take the avatar's perspective in all scenes, Experiment 3 instructed participants to ignore the stimuli in the middle of the room and judge only their own perspective; the consistency effect persisted.

Santiesteban et al. (2014) argue that the effect of the avatar on reaction times was driven not by perspective taking of the avatar but rather by a directional effect: because the avatar faced one or the other side of the room, the participant's attention might be directed towards stimuli on that side. They repeated the experiment using avatarsized arrows (rather than columns) as controls, finding a consistency effect for both avatars and arrows, both when perspective switched between trials (Experiment 1), and

Figure 1: Example scenes.
A: The main components of each scene. B: Example scene with Sally. C: Example scene with Andrew. D: Example scene with arrow.
when participants were instructed to ignore the stimuli in the centre of the room and judge only their own perspective (Experiment 2). However, because both kinds of stimulus were presented to all participants (i.e. the avatar vs arrow manipulation was within-subjects), it is possible that participants were transferring the "perspective taking" of the avatar over to the arrow.

Cole et al. (2016) note a further problem with this experiment: although arrows and avatars produce a similar effect on reaction times, these effects may in fact be driven by different processes-perspective taking in the case of the avatar, and directional cueing in the case of the arrows. Indeed, Marotta, Lupiáñez, Martella, \& Casagrande (2012) find that, while eye gaze cues participants to a specific location, an arrow provides a more general cue. This suggests that different processes are involved in following the directional cue of an arrow and an avatar.

As an alternative control, Cole et al. (2016) use a set of stimuli that includes a barrier in front of the avatar, as is used in mentalising experiments in non-human animals (Hare, Call, \& Tomasello, 2001). When the barrier "window" is open, allowing the avatar to "see" the dots, they find the expected consistency effect; but they also find the effect when the barrier window is closed, suggesting that the effect is driven simply by the directional effect of the avatar, rather than by mental state attribution.

However, the stimuli used in this experiment do not make it perfectly clear whether or not the barrier is transparent, and the depth and angle of the barrier placement within the room could be ambiguous. Further, the temporary nature of the barriers may create a problem: given that the participant likely assumes that the avatar is a single agent, it is possible that participants infer the agent's knowledge of what is on the other side of the barrier on the basis that they can
sometimes see what is there, and may have done so before the barrier window closed.

Cole et al. (2016) do attempt to deal with these problems. The open or closed barriers were shown in different blocks of trials, and at the beginning of each block, participants were explicitly told whether or not the avatar could see the wall that was blocked by the barrier. However, given the visual ambiguity of the stimuli, it is possible that this kind of explicit knowledge is not taken into account in fast processing, when at a glance the image might be interpretable in different ways.

Using different stimuli and a modified experiment design, we conducted a conceptual replication of Experiment 3 in Samson et al. (2010) and Experiment 2 in Santiesteban et al. (2014). Although our experiment was designed to address details of Yes vs. No responses and arrow vs. avatar stimuli, the design also allowed us to explore the effect of barriers as in Cole et al. (2016), while addressing the problems of ambiguity. Unlike Samson et al. (2010) but following Santiesteban et al. (2014) we used arrows as a directional control for avatars; unlike Santiesteban et al. (2014), we manipulated avatars vs arrows in a between-participants design, rather than within-participants. Our stimuli did not have the same temporal and physical ambiguity as the images used by Cole et al. (2016) (see Figure 1). We used photographs of Lego figures in scenes with unambiguous depth in the third dimension, and solid black barriers were used, preventing any ambiguity in whether or not Lego figures were able to see through them.

A variety of hiding places allowed balls (our equivalent of dots/discs) to be hidden from view of the Lego figures, even when placed in front of them. This allowed us to test the claim that the altercentric effect could be explained by the general directionality of the avatars, rather than perspective taking.

In addition, the use of arrows as control stimuli should indicate whether, as in Marotta et al. (2012), the arrows have a more general directional effect than the avatars. If this were the case, one would expect arrows to cause a reaction time delay only when there are balls placed in the opposite direction to that indicated by the arrow; and the more specific perspective attributed to avatars to cause a reaction time delay in all cases where there are balls not in its field of view (regardless of whether they are hidden behind a barrier in front of, or behind, the avatar).

## Method

## Participants

Sixty participants were recruited through the University of Edinburgh Student and Graduate Employment Service. They were compensated $£ 4$ for their participation, which lasted approximately 20 minutes. Thirty participants viewed stimuli with the Lego figures, and thirty viewed control stimuli showing columns with arrows on them. One further participant was excluded from analysis because a postexperiment questionnaire indicated that they had successfully guessed the purpose of the experiment.

## Materials

Participants observed scenes consisting of photographs (Figure 1) of Lego figures (dubbed "Sally" and "Andrew" for ease of reference), a series of barriers created by Lego bricks, and red beads that, at Lego scale, had the appearance of red balls. Control stimuli consisted of Lego columns with the same colours and proportions as Sally and Andrew, with a black arrow on the yellow block, pointing in the same direction as a figure's direction of facing. Each scene featured either Sally or Andrew (each figure could appear on either side of the screen), and between 0 and 4 balls (with a maximum of two balls in any given location).

## Procedure

On each trial, participants were presented with a fixation cross for 750 ms , followed by a digit between 0 and 4 (displayed for 750 ms ), followed by a Lego scene, with the words "Yes" and "No" in the bottom corners of the screen (Yes-side was counterbalanced across participants but remained consistent across trials for a given participant). Participants were instructed to judge whether the picture had the same number of balls as the digit they had been shown with no other comment given about the other elements of the scene - using a two-button button box, pressing the Yesside button for yes and the No-side button for no. Scenes timed out within 2000 ms if no response was given, and moved on to the following trial.

After completing 12 practice trials with correct/incorrect feedback on responses, participants completed 324 trials (36 filler trials with zero balls, and 288 test trials), in random order, divided into four blocks, with a self-paced break between blocks. These 288 trials balanced three different variables: the number of balls in a scene, the consistency
between the Lego avatar's and participant's perspective, and the match between the digit shown and the number of balls in the scene.

There were 72 trials for each number of balls; that is, 72 scenes with one ball, 72 with two balls, and so on. Half of the trials were consistent in perspective: that is, the figure/arrow could "see" (i.e. had unobstructed line of sight to) the same number of balls that the participant could see. The other half were inconsistent, with balls hidden from the figure or arrow by either the central, table-like barrier or the external wall-like barriers, introducing an inconsistency between the participant's perspective and that of the avatar/arrow. The match between the digit shown and the on-screen perspective was balanced (Table 1); the results of analysis of this variable will be reported in a future paper.

Table 1: Match between digit and perspective

|  | Inconsistent |  |  | Consistent |  |
| :---: | :---: | :---: | :---: | :---: | :---: |

Post-experiment questionnaires were used to assess whether participants' intuitions about the figures' lines of sight matched those of the experimenters. Pictures showing a variety of scenes with balls in different positions were displayed, and participants were asked to note how many balls the Lego figure could see (regardless of whether they had just completed the avatar or arrow condition of the experiment). All responses to these questionnaires indicated that participants did not expect the Lego figures to be able to see balls hidden by either the central or external barriers, but did expect them to see balls either on the table or at their feet.
The experiment was implemented using PsychoPy (Peirce, 2010).

## Results

We used lme4 (Bates, Maechler, Bolker, \& Walker, 2015) and lmerTest (Kuznetsova, Brockhoff, \& Christensen, 2016) to perform a series of linear mixed effects analyses on reaction time (RT); RT was our only dependent variable given the lack of effect on error rate found in our own data and in previous studies. We removed training trials, trials with zero balls on screen, timed-out trials $(0.69 \%, \mathrm{n}=119)$, and trials where participants made an incorrect response ( $3.12 \%, \mathrm{n}=533$ ). As per Whelan (2008), trials in which the response RT was lower than 100 ms were also removed, on the assumption that these trials could not be genuine responses to the stimuli $(0.01 \%, \mathrm{n}=2)$. No trimming was conducted on higher reaction times, given the imposed cutoff of 2000 ms on all trials. Visual inspection of the reaction time data revealed an obvious deviation from the normal distribution, necessitating a log transform of the data (Baayen \& Milin, 2010).

Figure 2: Mean RTs showing a significant effect of Consistency (error bars show 95\% CI) and no Stimulus x Consistency interaction. The effect of Stimulus is not significant (note that Stimulus, unlike Consistency, is manipulated between-subjects). Y-axis limited for easier comparison with earlier experiments.

## Replication

We first conducted an analysis of the relationship between RT, Consistency and Stimulus. As fixed effects, we entered Consistency and Stimulus (with interaction term) into the model. As random effects, we included random intercepts for participants and images, as well as by-participant and by-image random slopes for the effects of Consistency and Stimulus (without interaction term, to facilitate model convergence).

Following Samson et al. (2010), the model showed a significant effect of Consistency (Figure 2), with consistent trials faster than inconsistent trials $\left(\beta=0.047^{1}, \mathrm{SE}=0.008\right.$, $p<.001$ ). Contra Samson et al. (2010) but consistent with Santiesteban et al. (2014), there was no effect of Stimulus ( $\beta=-0.065, \mathrm{SE}=0.049, p=.187$ ) and no Stimulus x Consistency interaction ( $\beta=0.012$, $\mathrm{SE}=0.01, p=.220$ ). This suggests that an inconsistency in perspective resulted in slower responses, but that this was true for both avatars and arrows. Our between-subjects manipulation of avatars vs arrows ensures that, unlike for Santiesteban et al. (2014), this cannot be explained as a consequence of transfer from avatars to arrows: our participants seeing the arrow stimuli had not seen Lego figures in those positions.

Figure 3: Mean RTs showing a significant effect of Directional Consistency.

## Directional Consistency

Our experimental setup also allowed us to test the hypothesis that the delay is caused not by processing of the altercentric perspective, but rather by preferential attention to objects in the direction of facing/arrow pointing. We predicted, based on Marotta et al. (2012), that the delay would appear only on those trials where balls in front of the avatar are within the avatar's actual field of view, and not on trials where there are balls in front of the avatar, but hidden by obstacles, consistent with the explanation of altercentric interference. We similarly predicted that when the stimulus was an arrow instead of an avatar, the delay would occur on all trials where there are balls within the arrow's field of reference, regardless of barriers between the balls and the arrow.

[^425]To test these predictions, we re-coded the data to classify all trials with balls in front of the avatar/arrow as directionconsistent, and only those trials where a ball appeared behind the avatar/arrow as direction-inconsistent. We then modelled the relationship between this Directional Consistency, Stimulus, and RT (Figure 3). Contrary to our predictions, the results showed that directional-inconsistent trials were slower than directional-consistent trials ( $\beta=0.047, \mathrm{SE}=0.01, p<.001$ ), with no significant effect of Stimulus ( $\beta=-0.058, \mathrm{SE}=0.049, p=.24$ ) and no significant interaction ( $\beta=0.004$, $\mathrm{SE}=0.011, p=.73$ ). This suggests that the consistency effect may be driven by preferential attention to objects within a directional figure's direction of facing/pointing, regardless of the animacy of that figure.

Table 2: Congruence

## 

| Line of Sight | Line of Sight | Line of Sight |
| :---: | :---: | :---: |
| consistent | inconsistent | inconsistent |
| Directional | Directional | Directional |
| consistent | consistent | inconsistent |

However, a further model with both Consistency and Directional Consistency as fixed effects found a significant effect for both variables $(\beta=0.032, \mathrm{SE}=0.011, p=.005$ and $\beta=0.04, \mathrm{SE}=0.008, p<.001$ respectively). In order to explore this, the data was recoded to classify each scene as consistent and/or inconsistent for both definitions of consistency (Table 2). That is, each scene could be (a) line of sight consistent + directional consistent (balls within the avatar's direction of facing and actual field of view); (b) line of sight inconsistent + directional consistent (balls within the avatar's direction of facing, but hidden from the avatar's field of view); or (c) line of sight inconsistent + directional inconsistent (inconsistent based on both direction of facing and field of view).

A model with this variable (Congruence) and Stimulus as fixed effects (with interaction term) found that line of sight consistent + directional consistent trials were faster than both line of sight inconsistent + directional consistent ( $\beta=0.036, \mathrm{SE}=0.012, p=.003$ ) and line of sight inconsistent + directional inconsistent $(\beta=0.077$, $\mathrm{SE}=0.012, p<.001$ ) trials (Figure 4); a re-levelled model showed that line of sight inconsistent + directional consistent was significantly faster than line of sight inconsistent + directional inconsistent $(\beta=0.041$, $\mathrm{SE}=0.01, p<.001$ ). There was no effect of Stimulus or Stimulus x Congruence interaction.

Figure 4: Mean RTs showing a significant effect of Congruence: scenes with consistent perspectives and unobstructed balls are faster than scenes with inconsistent perspectives created by barriers in front of the stimuli; which in turn are faster than scenes with balls hidden both in front of, and behind, the stimuli.

Figure 5: Without the confound of peripheral balls, there is no effect of Line of Sight consistency on RT.

These results would suggest a role for both Consistency and Directional Consistency in affecting reaction times, but there is an important confound: within directionally consistent scenes, line of sight consistent scenes can only have balls in the centre of the screen, while line of sight inconsistent scenes may have balls on the periphery of the screen (the same confound does not apply across directional
consistent vs. directional inconsistent scenes, which may both have peripheral balls). Once data is restricted to only those scenes with balls in the centre of the scene (all of which are directionally consistent), there is no longer an effect of line of sight consistency ( $\beta=-0.008, \mathrm{SE}=0.013$, $p=.525$, Figure 5). This suggests that the consistency effect may be accounted for by the directional hypothesis.

## Conclusion

These results replicate the headline result of Samson et al. (2010) by finding a robust effect of Consistency on reaction times. However, they also replicate the results of Santiesteban et al. (2014) by finding that the Consistency effect appears with inanimate but directional stimuli, even when those stimuli appear in a between-participants design. Additionally, the analysis of Directional Consistency suggests that the effect is driven by a directional cueing effect. These findings cast uncertainty on interpretation of DPT data as evidence for automatic mindreading.

Heyes (2014) argues that evidence for a directional explanation, such as the data we have presented here, is evidence against a mentalising explanation. This dichotomy may be too sharp: directionality and perspective taking are not unrelated. Taking another individual's perspective must entail first following the direction of their gaze; or, in other words, directional effects may be a necessary pre-condition of perspective taking. Our results (and other results too) suggest that directional effects - which are a relevant input into any possible fast and efficient perspective taking - are indeed automatic and efficient. They just do not seem to necessarily lead to perspective taking.

If this speculation is correct, it may be important to distinguish automatic cognitive processes (i.e. those that are mandatory upon the perception of relevant inputs) and spontaneous ones (i.e. those that occur quickly and efficiently as and when needs arise). Our results - and results from other experimental paradigms (e.g. Freundlieb et al., 2016; Schneider et al., 2017) - are consistent with the interpretation that perspective taking is spontaneous but not automatic. Future experimental research could test this possibility directly.

## Acknowledgements

We would like to thank our colleagues Simon Kirby and Jennifer Culbertson, who provided insight and expertise that greatly assisted this research.

# Creation of Spatial Mental Models with Figural Stimuli: Validation of the Emoji-based Spatial Integration Task 

Polly O’Rourke (porourke@casl.umd.edu)<br>Nick B. Pandža (npandza@umd.edu)<br>Susan Campbell (susanc@umd.edu)<br>Center for Advanced Study of Language<br>University of Maryland, $700552^{\text {nd }}$ Avenue<br>College Park, MD 20742 USA

#### Abstract

The current study examined a new spatial integration (SI) task, based on figural rather than linguistic stimuli, to measure the construct of mental modeling ability. Previous tasks conflated linguistic ability with mental modeling ability by requiring sentence processing, which may have contributed to mixed findings with respect to the relationship between mental model ability and working memory capacity (WMC). The figural spatial integration task produced the canonical continuity effect, such that discontinuous items had lower accuracy than continuous items. Furthermore, WMC and visuospatial ability predicted SI task performance, and both were stronger predictors for the continuous condition. The interactions between predictors and task conditions suggest reliance on heuristics and/or rehearsal during performance of the more difficult discontinuous items.

Keywords: Spatial integration, mental modeling, working memory capacity, spatial manipulation.

## Introduction

Mental models are abstract representations of a situation, derived from a narrative or some other form of input (Ehrlich \& Johnson-Laird, 1982). Successful creation of mental models contributes to logical thinking (e.g., Bell \& Johnson-Laird, 1998; Evans, Handley, Harper, \& JohnsonLaird, 1999) and spatial and temporal reasoning (e.g., Baguley \& Payne, 1999; Carreiras \& Santamaria, 1997; Roberts, 2000). It is also strongly connected to the ability to comprehend written or spoken narratives (Bower \& Morrow, 1990; de Vega, 1995; Radvansky \& Copeland, 2004).

The experimental task most commonly used to assess spatial mental model ability is the Spatial Integration (SI) task (Copeland \& Radvansky, 2007; Radvansky \& Copeland, 2004). In this task, participants are presented with a sequence of three sentences (one at a time), each describing the spatial relation of two of four objects. Immediately following this presentation, participants select from an array the picture which represents the correct spatial arrangement of the four items. There are two conditions referring to how the spatial information is presented in the learning phase: continuous and discontinuous. In the continuous condition, the second screen includes one item from the first screen and the third
screen includes one item from the second, enabling the participant to incrementally construct a mental model. In the discontinuous condition, the second screen and third screen are switched such that the second screen does not contain either of the items in the first screen but the third contains one item from each of the previous screens.

The use of sentence stimuli in this task is, however, problematic. First, task performance may reflect verbal rather than mental model abilities. Second, the processing demand associated with language comprehension may obfuscate the relationship between mental model ability and key underlying cognitive factors, like working memory capacity (WMC; Conway, Kane, Bunting, Hambrick, Wilhelm, \& Engle, 2005). Extant findings support the problematic nature of using sentence stimuli in this task. While several studies have found no relationship between identification accuracy in the SI task and WMC (Radvansky \& Copeland, 2001; 2004; Radvansky, Gibson \& McNerney, 2014), O’Rourke and Bunting (in press) found that when controlling for reading comprehension ability, WMC predicted accuracy in the discontinuous condition. They also found that when participants performed the SI task in their second language, second language proficiency alone predicted performance. As operating in L2 is widely known to absorb available WM resources, this finding and the finding for L1 indicate that variability related to language processing may obfuscate the relationship between WM and mental model creation.

Copeland and Radvansky (2007), in their study of mental model ability in aging adults, a population which generally has reduced WMC (Myerson, Emery, White, \& Hale, 2003), examined both verbal and figural versions of the task. They implemented the SI task with sentence stimuli describing the spatial configurations (Experiment 1), word stimuli appearing in the relevant spatial configurations (Experiment 2), and picture stimuli appearing in the configurations (Experiment 3). Aging adults did very poorly on both continuous and discontinuous conditions in Experiment 1, with performance on the discontinuous condition not differing significantly from chance. WMC (indexed by Operation Span; Turner \& Engle, 1989) predicted identification accuracy in the older participants, but not the young adult group. Performance on the continuous condition was improved in Experiments 2 and 3. Only in Experiment 3, the figural version, did aging adults perform above chance in the discontinuous
condition. WMC predicted performance in both age groups in Experiments 2 and 3. Furthermore, this finding suggests that the cognitive burden of language processing absorbs working memory resources required for successful performance of the SI task.
The goal of the current study was to validate a new figural version of the SI task and to examine the relationship between task performance and working memory capacity. Another potential source of variance in this task is spatial visualization ability, which reflects the ability to represent and manipulate parts of an image (Carroll, 1993). This ability may underpin performance of the figural version in particular as stimuli can be represented visually immediately, without the step of converting word/sentence stimuli into images. Spatial visualization ability will, therefore, also be included as a predictor in the analysis.

## Method

## Participants

A total of 161 ( 96 female) participants between the ages of 18 and $39(\mathrm{M}=20.32, \mathrm{SD}=1.67)$ with normal or corrected-to-normal vision were tested and retained for analysis in the current experiment. They were paid for their participation. Two additional participants were excluded for exhibiting a pattern of not following study directions across multiple tasks.

## Tasks

## Spatial Integration Task

The SI task (adapted from Copeland \& Radvansky, 2007) tests the ability to construct a mental model of the spatial arrangement of four items. In the learning phase, participants are presented with three screens, each containing two of four objects in particular spatial arrangements (see Figures 1 and 2). Items are presented in the continuous (see Figure 1) or discontinuous condition (in which the second and third screens in Figure 1 would be switched; see Figure 2). After the learning phase, participants must select from eight diagrams the one that correctly represents the spatial arrangement of all four objects in relation to one another (see Figures 1 and 2 for correct arrangement for the example item). The three screens in the learning phase are presented for 2 seconds per screen, while the test screen remains available until the participant responds. The task stimuli consisted of 80 emoji downloaded from the Emojione database (emojione.com), representing 20 sets of four semantically related emoji (e.g., fruits, vegetables, vehicles). Each task item was composed of one of the sets of four. Each item appeared once per stimulus list. Two forms of the test were created such that items were matched across conditions; a particular set of emoji appeared in one stimulus list in the continuous condition and in the other stimulus list in the discontinuous condition. As participants must choose the correct answer from eight options, chance performance is about $12 \%$.

Figure 1. Example of continuous item from the SI task with the full spatial arrangement of the four items. Participants can build a partial model immediately.

Figure 2. Example of corresponding discontinuous item from the SI task with the full spatial arrangement of the four items. Participants must wait to integrate the model based on information that comes on the third screen.

## Shapebuilder task

The Shapebuilder (SB) task is a complex visuospatial working memory measure (Atkins et al., 2014). In this task, participants are shown a series of shapes in a $4 \times 4$ grid, and they must recall the shape, color, and location of the series of the shapes in the correct presentation order. There are 26 items and the number of shapes in each item's sequence increases over the course of the task from two shapes (six items), to three shapes (nine items), and finally to four shapes (11 items). Points were earned for each shape in the sequence for which the location, shape, and color were correctly recalled. Partial credit was awarded if the location was correctly recalled. More points were awarded for longer sequences. See Atkins et al. (2014) for full scoring parameters and for WMC factor loadings alongside other working memory measures.

## Paper Folding task

The Paper Folding (PF) task used in the current study to measure spatial visualization ability was a computerized
test adapted from the ETS Kit of Factor-Referenced Tests (Ekstrom et al., 1976). Two forms were created with 20 items each. Items were ordered by increasing difficulty. As participants must choose the correct answer from five options, chance performance is $20 \%$.

## Procedure

The tasks pertinent to this study were administered as part of a larger battery of 18 behavioral tasks and surveys. The 18-task battery was administered in two sessions of three hours each with the opportunity for breaks between each task. Testing took place in a classroom-style computer lab. Written consent was obtained at the beginning of the first testing session. SI and PF were administered in session one and SB was administered in session two.

## Results

Data from six participants in the SB task is missing due to study attrition as they did not return for the second session. As a result, the sample size for analyses including SB is 155. We ran Wilcoxon Signed Rank tests comparing forms, and found no significant differences; therefore forms for SI and PF were collapsed in the correlational analysis. See Table 1 and 2 for descriptive statistics and correlations among measures, respectively.

Table 1. Task performance - Descriptive statistics

| Task | Mean | SD | Min | Max |
| :--- | ---: | ---: | ---: | ---: |
| SI_Con | .67 | .26 | .00 | 1.00 |
| SI_Discon | .52 | .22 | .00 | 1.00 |
| SB | 1711.52 | 466.53 | 755.00 | 2325.00 |
| PF | .74 | .18 | .15 | 1.00 |

Table 2. Correlations among measures. Numbers on the diagonal reflect average internal consistency.

| Task | SI_Con | SI_Discon | SB | PF |
| :--- | :---: | :---: | :---: | :---: |
| SI_Con | $(.75)$ |  |  |  |
| SI_Discon | $.50^{*}$ | $(.56)$ |  |  |
| SB | $.44^{*}$ | $.33^{*}$ | $(.73)$ |  |
| PF | $.60^{*}$ | $.37^{*}$ | $.43^{*}$ | $(.86)$ |
| $* p<001$ |  |  |  |  |

* $p<.001$

We conducted a logistic multilevel model (MLM, or mixed-effects model) on the binary individual trial-level accuracy data in order to generalize across participants and items and account for the fact that particular items were present in both conditions (Baayen et al., 2008; Linck \& Cunnings, 2015). Condition (continuous vs. discontinuous) was included as a fixed effect, nested within-item, as each item appeared in both conditions across the two forms.

The model predicts estimated log-odds (b) of a correct response on the SI task, from which we can derive the
change in odds and probability of accurate performance on the task. The independent variables included to explain variance in subject and item performance were Condition (Continuous, discontinuous), z-scored SB and PF , and the two-way interactions of Condition with SB and PF. Results of this modeling procedure are shown in Table 3, with the model baseline being the discontinuous condition.

Table 3. Logistic MLM results for SI item accuracy

| Fixed Effects | Estimate <br> $(\boldsymbol{b})$ | Odds <br> $(\exp (\boldsymbol{b}))$ | SE | $\boldsymbol{p}$ - <br> value |
| :--- | :---: | :---: | :---: | :---: |
| Intercept | 0.10 | 1.11 | 0.13 | .43 |
| Continuous | 0.18 | 2.17 | 0.08 | $<.001^{*}$ |
| SB | 0.22 | 1.25 | 0.09 | $.01^{*}$ |
| PF | 0.30 | 1.35 | 0.09 | $<.001^{*}$ |
| Con $\times$ SB | 0.16 | 1.18 | 0.10 | $.09^{\wedge}$ |
| Con $\times$ PF | 0.42 | 1.53 | 0.09 | $<.001^{*}$ |
| Random Effects |  | Variance | $\boldsymbol{S D}$ |  |
| Intercepts $\mid$ Subject | 0.47 | 0.69 |  |  |
| Intercepts \| Item | 0.22 | 0.47 |  |  |
| $* p<.05, \wedge p<.10$ |  |  |  |  |

The results show a main effect of Condition, confirming the effect of continuity for the SI task while controlling for the effects of SB and PF.

The results further show visuospatial WMC and spatial visualization (as measured by the SB and PF tasks, respectively) contribute independent variance to SI accuracy on both discontinuous and continuous items. Since SB and PF are z-scored and on the same scale, the sizes of the estimates can be directly compared. The effect for PF is slightly stronger than for SB on discontinuous items ( $b_{\mathrm{PF}}=0.30>b_{\mathrm{SB}}=0.22$ ) and the effect for PF is almost twice the size of the effect for SB on continuous items ( $b_{\text {PF }}$ $+b_{\mathrm{Con} \times \mathrm{PF}}=0.72>b_{\mathrm{SB}}+b_{\mathrm{Con} \times \mathrm{SB}}=0.38$ ).

The effect for SB is positive: as SB scores increase, so do the odds of a correct response on discontinuous items on SI. There is a marginal interaction of continuous $\times \mathrm{SB}$, suggesting that the effect of SB may be even stronger for continuous items than discontinuous (see Figure 3).

Figure 3. Depiction of SI accuracy regressed on Shapebuilder z-scores split by Condition. Shaded area around line represents 1 SE .

The effect for PF is also positive: as PF scores increase, so do the odds of a correct response on discontinuous SI items. Finally, there is a significant interaction of continuous $\times \mathrm{PF}$, indicating that, for each standard deviation increase on PF performance in our sample, the odds of a correct response are higher on continuous items than discontinuous items on the SI task (see Figure 4).

Figure 4. Depiction of SI accuracy regressed on Paper Folding z-scores split by Condition. Shaded area around line represents 1 SE .

## Discussion

The results show that young adults perform similarly on this figural, emoji-based version of the SI task to previously tested text-based versions of the task. Our mean accuracies of $67 \%$ for continuous items and $52 \%$ for discontinuous (both of which are far above chance performance of $12 \%$ ) are consistent with Copeland \& Radvansky (2007)'s findings using the standard, sentence based task ( $68 \%$ for continuous condition and $47 \%$ for discontinuous), and their figure task ( $73 \%$ for continuous and $53 \%$ for discontinuous). The fact that accuracy levels and continuity effects for our figural version of SI mirror extant findings provides evidence that this new version of the task performs similarly to the standard task. One limitation of this study is that we did not compare performance on our figure version to a standard text based version of the SI task.

Our emoji-based SI task extends the findings of Copeland and Radvansky (2007) in regards to the utility of a non-linguistic SI task and has several advantages over their instantiation. In our version of the SI task, the learning phase for each item was experimenter-paced such that participants saw each of the three screens for two seconds. When examined by Copeland, Radvansky and colleagues (Copeland \& Radvansky, 2007; Radvansky \& Copeland, 2001; 2004; Radvansky et al., 2014) the learning phase was self-paced such that participants had as long as they wanted for each training screen and reading times for each screen were dependent variables. The two-second time limit for the present task was ased on pilot data such that it represented a window within which most participants advanced to the next screen. While accuracy was similar to previous results with a self-paced learning phase (Copeland \& Radvansky, 2007), our experimenter-paced version of the task is easier to administer remotely, without a proctor, due to a more consistent task duration.

Another key methodological difference is that our SI task included pictures of real-world objects (e.g., coffee, glass) across different semantic sets (e.g., vegetables, vehicles), allowing greater generalizability of the items than simple geometric shapes (e.g., red square, green star). The more complex nature of the images could also have led to a lower probability of verbal rehearsal strategies, especially since the same four colors were used in every trial in the Copeland and Radvansky (2007) task; however, future research will be needed to test this claim.

Finally, the current study had greater power than Copeland and Radvansky (2007), in that there were more trials ( 20 versus 8 total, 10 versus 4 by condition), more participants ( 161 versus 60 , the latter split between two groups), and all trials were used for more powerful statistical analyses thanks to a multilevel model design.

The examination of the cognitive underpinnings of mental model ability showed that both WMC and spatial visualization ability predict performance on the SI task. Spatial visualization ability emerged as a slightly stronger effect than WMC. Interestingly, both predictors accounted
for more variance in the Continuous condition than the discontinuous condition.

In contrast to other studies using text based versions of the task (Copeland \& Radvansky, 2007, Exp. 1; Radvansky \& Copeland, 2001; 2004; Radvansky et al., 2014), the current study found evidence for WMC as a predictor of performance on the SI task in young adults. As previously noted, lack of effects using the sentence-based SI task could be due in part to the processing demands associated with converting linguistic representations into spatial representations. Furthermore, the interim spatial representations must be maintained while the next sentence is parsed into spatial information. While in figural form, the SI task is demanding on WM resources, eliminating the sentence as a conveyor of spatial information may have resulted in an increase in resources available for mental model creation.

Another possible reason for lack of effect in previous studies, particularly for the discontinuous condition, is that WMC may be a weaker predictor in the discontinuous condition, as shown by the marginal two-way interaction in the current study. This may be due to the "choke" factor whereby high WMC individuals start performing like low WMC individuals when they are under pressure (Sattizahn, Moser, \& Beilock, 2016; Wang \& Shah, 2014), such that WMC no longer predicts performance.
Strategy use may be another factor reducing the effect of individual WMC on performance. Wang and Shah (2014) note that when heuristics are available, people with high and low WM spans may perform similarly. It may be that all participants develop strategies in order to reduce the cognitive effort (Shah \& Oppenheimer, 2008) involved in determining the correct response in the discontinuous condition and, therefore, WMC would no longer predict performance. For example, in the discontinuous condition, after seeing the third screen in the learning phase, a participant may only partially incorporate the spatial arrangement such that he/she knows the positioning of two of the four images (e.g., top two images in the square). This information, though incomplete, may be enough to select the correct answer in the test phase. It may be possible in future iterations of the task to reduce the utility of heuristics via changes to the design. Specifically, the options in the test phase could be modified such that strategy use would be less likely to lead to a correct response.
Another possibility is that participants were more likely to engage in rehearsal in the discontinuous task. Rehearsal is a means of maintaining information in a short-term memory store, without any WM or executive involvement (Conway, Cowan, Bunting, Therriault, \& Minkoff, 2002). As such, if participants were more likely to use rehearsal in order to remember the spatial configurations in the discontinuous condition, then WMC would be a less effective predictor of performance. There are many strategies for preventing rehearsal during cognitive task performance (Cowan, 2008). One example is adding a secondary processing task (e.g., counting backwards) for participants to perform during the period in which information needs to be retained. Given that the retention
interval is fairly brief in this task, it is not clear that a secondary processing task would be effective. Another option might be further reducing the time for which the screens in the learning phase are presented to a less comfortable pace. This adjustment would likely have consequences, however, for the WMC demand. Additional testing is necessary to determine how researchers can prevent rehearsal in this task.

While WMC accounted for a significant amount of variability in SI performance, spatial visualization ability emerged as a stronger predictor. It is, perhaps, unsurprising that spatial visualization ability would predict performance on a spatial reasoning task like SI, particularly our figural version. Spatial visualization ability interacted with task condition such that its utility as a predictor was better in the continuous condition. This pattern is, of course, similar to the pattern observed for WMC, but with spatial visualization ability the effect was significant.

This finding supports the account that in the discontinuous condition, participants were more likely to not create true spatial mental models but rather to use heuristics or rehearsal in order to determine the correct answer at test. The case for rehearsal is particularly strong in that reduced role of spatial visualization ability in the discontinuous condition suggests that participants may not be creating visual representations. If that is the case, then verbal rehearsal is one way to perform the task. While the example of a strategy described above requires some level of visuospatial representation, there may be strategies, other than rehearsal, that do not.

Hitherto unexamined effects of individual variability in spatial visualization ability may have been another factor contributing to the mixed findings in the literature with respect to the contribution of WMC. In the previous textbased versions of the SI task, perhaps individuals with poorer spatial visualization ability had more difficulty transitioning from text-based representations to full visual representations, regardless of WMC, and therefore were unable to create a spatial mental model of the four items.

In conclusion, the current study validated a figure version of the SI task such that results from this task show performance levels and continuity effects consistent with previous studies. Given that this task is not sensitive to individual variability in language processing, or even native language, it can be used as a more pure measure of spatial mental model ability. This conclusion is supported by the finding that WMC predicted task performance in the figure version of the task, and language-related variability may have obscured this relationship in previous studies. Furthermore, we present evidence that spatial visualization ability is a significant predictor of task performance, and that while both WMC and spatial visualization ability predicted performance in both conditions, there was evidence suggesting the effect was stronger in the continuous condition. Future research will determine the source of this interaction.

#### Abstract

According to cognitive appraisal theory, emotion in an individual is the result of how a situation/event is evaluated by the individual. This evaluation has different outcomes among people and it is often suggested to be operationalised by a set of rules or beliefs acquired by the subject throughout development. Unfortunately, this view is particularly detrimental for computational applications of emotion appraisal. In fact, it requires providing a knowledge base that is particularly difficult to establish and manage, especially in systems designed for highly complex scenarios, such as social robots. In addition, according to appraisal theory, an individual might elicit more than one emotion at a time in reaction to an event. Hence, determining which emotional state should be attributed in relationship to a specific event is another critical issue not yet fully addressed by the available literature. In this work, we show that: (i) the cognitive appraisal process can be realised without a complex set of rules; instead, we propose that this process can be operationalised by knowing only the positive or negative perceived effect the event has on the subject, thus facilitating extensibility and integrability of the emotional system; (ii) the final emotional state to attribute in relation to a specific situation is better explained by ethical reasoning mechanisms. These hypotheses are supported by our experimental results. Therefore, this contribution is particularly significant to provide a more simple and generalisable explanation of cognitive appraisal theory and to promote the integration between theories of emotion and ethics studies, currently often neglected by the available literature.

Keywords: Cognitive appraisal theory; computational emotion model; emotion combination; ethics

## Introduction

The attribution of an emotional state to self or others can occur when a complex state of the organism is accompanied by variable degrees of awareness, often referred to as appraisal (Scherer, 2001). Two levels of appraisal can be distinguished (Lambie \& Marcel, 2002): a first-order phenomenological state and a conscious second-order awareness. Both states can be either self-directed (first-person perspective) or worlddirected (third person perspective) (Vitale, Williams, Johnston, \& Boccignone, 2014). The present work will be concerned in discussing the nature of the conscious second-order appraisal process, known as cognitive appraisal process of emotion.

Traditional literature in emotional processing studies suggests that this cognitive appraisal process may underlie the evaluation of a set of variables called appraisal variables (Ortony, Clore, \& Collins, 1990; Lazarus, 1991; Roseman, Spindel, \& Jose, 1990; Scherer, 2001). Appraisal variables can be understood as the criteria used to assess a situation in relation to emotion elicitation process. For example, in
appraisal theory of Ortony et al. (1990), core appraisal variables ${ }^{1}$ considered are desirability - which assesses how desirable an event is, praiseworthiness - which measures how praiseworthy the action of an agent is and appealingness which measures how appealing is the agent to the appraising individual. Appraisal theories suggest that individuals converge to an emotional state depending on the evaluation of these variables. This position is further supported by the majority of existing computational explanations of cognitive appraisal (Dias \& Paiva, 2005; El-Nasr, Yen, \& Ioerger, 2000; Velasquez, 1997). However, the proposed accounts offer limited perspectives addressing only domain specific situations and making use of knowledge shaped as a set of pre-defined rules (Dias \& Paiva, 2005; El-Nasr et al., 2000). Thus, (i) the available literature in cognitive appraisal theory currently does not provide a clear computational explanation for domain-independent cognitive appraisal mechanisms. This is a significant research problem for both cognitive science and computer science research communities; in fact, on one hand, having a computational theory of domain-independent cognitive appraisal mechanisms can assist cognitive science researchers in addressing open research gaps in emotional processing studies, and, on the other hand, this computational account can be more easily integrated in disparate intelligent systems without the need of defining a complex set of domain-dependent rules.

However, this is not the only limitation presented by currently available explanations of cognitive appraisal theory. According to cognitive appraisal theory of emotion, an event can elicit more than one emotions simultaneously with varying intensities (Ortony et al., 1990). Nevertheless, (ii) it is not clear yet what is the best strategy to select an emotional state for attribution following this appraisal process. This is again a significant research problem. In particular, having a mechanism able to determine the final optimal emotional state is a highly desirable feature for intelligent systems interacting with humans, such as social robots (Williams, 2012), since this is a necessary skill for being proficient in emotional intelligence (Mayer \& Salovey, 1993). For example, it has been widely documented that the appraised emotional state of an individual has direct impact on decision making and action selection (Isen \& Means, 1983; Loewenstein \& Lerner,

[^426]2003). Thus, without an appropriate mechanism able to determine the final optimal emotional state, the intelligent system cannot take socially acceptable and ethical actions (Vitale, Williams, \& Johnston, 2014).

This paper aims to present a computational model of emotion processing that adds a higher layer of cognition to appraisal mechanism. The significance of this paper is further increased by this novel approach going beyond the domain of emotion theories and embracing the strengths of ethical theories. Although, the literature includes previous studies suggesting interactions between theories of emotions and ethics (Callahan, 1988; Gaudine \& Thorne, 2001), to our knowledge, there are no computational explanations addressing the interactions between ethics and emotion processing mechanisms (Ojha \& Williams, 2016). Therefore, in this paper we aim to:
(i) Provide a computational model of cognitive appraisal of emotion able to elicit appropriate emotional states without the need of defining pre-determined rules, but rather by using a general domain-independent approach facilitating easy extensibility of the emotionally intelligent systems;
(ii) Provide a novel computational process inspired by ethical theories for the selection of the optimal emotional state among the elicited ones.

The offered outcomes will provide valuable insights to gather a better understanding on how integrating ethical theories in emotion processing mechanisms can improve existing computational models of emotions. This in turn will advance the understanding of the role of cognition in emotion.

## Computational Models of Cognitive Appraisal

Theories from cognitive science and psychology have been implemented in various computational models of cognition. In this section, we will present some of the computational models of emotions implementing cognitive appraisal theory of emotion that are related to our discussion and identify their current limitations.

The models available in literature use evaluation criteria called appraisal variables (Ortony et al., 1990; Lazarus, 1991; Roseman et al., 1990; Scherer, 2001) to assess or evaluate the events for the generation of emotion. The choice of appraisal variables depends on the appraisal theory used and also on the application of the model. One common limitation of the existing accounts is their heavy specificity to the considered application domain and the determination of the elicited emotional states by means of pre-defined rules (Dias \& Paiva, 2005; El-Nasr et al., 2000). This approach likely leads to low extensibility of the system.

One available account is Fuzzy Logic Adaptive Model of Emotions (FLAME), a fuzzy logic based computational model of emotion (El-Nasr et al., 2000) inspired by appraisal theories suggested by Ortony et al. (1990) and Roseman et al. (1990). The main strategy used by FLAME is the evaluation of $i f$-then rules in order to assess the considered appraisal
variables. As we already discussed, this approach leads to a particularly poor extensibility of the system, since adding a new rule would require to consequently revise and adapt the entire knowledge base.

EMotion and Adaptation (EMA) (Gratch \& Marsella, 2004; S. C. Marsella \& Gratch, 2009) borrows the ideas from the cognitive motivational appraisal theory of Lazarus (1991). It stands out from other existing computational models of emotion in that it is able to compute emotions irrespective of the experiment domain. However, this model is not able to achieve this only by using the perceived positivity or negativity of an event like our model, which will be discussed later.

Another related account is Fearnot AffecTIve Mind Architecture (FAtiMA), a computational model of emotion proposed by Dias and Paiva (2005). It is significantly inspired by appraisal theory of Ortony et al. (1990). FAtiMA considerably uses domain specific scenarios built on top of predefined appraisal rules in order to appraise the desired situation without clearly suggesting how to easily generalise the proposed appraisal mechanisms for different domains.

Beside not providing a valid and easy strategy to integrate the suggested computational model in disparate application domains, the available accounts do not offer an effective way to determine the final emotional state in response to an event in a specific situation. This is still an open research problem since most appraisal theories do not explain how this can be achieved (see, for example, Ortony et al. (1990); Scherer (2001)). Some strategies propose to select the emotional state exhibiting (i) highest intensity (Gratch \& Marsella, 2004) or driven by the higher motivational state (i.e. hunger, thirst, pain, and fatigue) (El-Nasr et al., 2000), whereas other strategies propose to (ii) blend the elicited intensities of multiple emotions in order to determine the final emotional state (see Reilly (2006) for more details on the strategy used). In the Evaluation section, we shall discuss why these approaches might not be desirable methods to reach to a final emotional state.

As previously discussed, an emotion processing model developed by using a rule-based approach is unlikely to offer easy extensibility and high integrability in disparate emotionally intelligent systems among different application domains. Thus, in this paper we provide computational mechanisms general enough to be used in different domains without the need of re-implementing or adapting the proposed model, but at the same time able to appraise the appropriate emotional states for the considered situation. In addition, we suggest to use ethical theories to determine the final emotional state among the ones elicited by the cognitive appraisal process. Determining this state is particularly important to drive socially acceptable behaviours.

## Hypotheses

Consider a social interaction between two subjects. In this work we will call sender the subject producing a behavioural
response directed to the other subject, which we will call receiver. Denote with $S_{\text {receiver }}^{(\mathbf{B}, \mathbf{C})}$ a value determining how negative or positive the behaviour $\mathbf{B}$ of the sender is perceived by the receiver in a given context $\mathbf{C}$. $S_{\text {receiver }}^{(\mathbf{B}, \mathbf{C})}$ is a plausible computational representation summarising within a single valanced value the somatovisceral reactions of the body to the given situation $(\mathbf{B}, \mathbf{C})$ following the first-order phenomenological stage of emotional processing (Bechara, Damasio, \& Damasio, 2000). As previously mentioned in the introduction of this paper, this work is not concerned with discussing the implementation of first-order phenomenological processes.

Denote with $\mathcal{C}\left(S_{\text {receiver }}^{(\mathbf{B}, \mathbf{C})}\right)$ a cognitive appraisal process able to appraise the intensities $\mathbf{I}=\left\{i_{e_{1}}, \ldots, i_{e_{n}}\right\}$ of a set of $n$ considered emotional states $\left\{e_{1}, \ldots, e_{n}\right\}$ given the first-order phenomenological reaction of the receiver $S_{\text {receiver }}^{(\mathbf{B}, \mathbf{C})}$. Thus, our first hypothesis is that:
Hypothesis 1 The value $S_{\text {receiver }}^{(\mathbf{B}, \mathbf{C})}$ is a sufficient information to perform a cognitive appraisal process $C$ able to elicit the intensities of the considered emotional states and consequently promoting the selection of a final emotional state resembling human cognitive appraisal.

Importantly, the value $S_{\text {receiver }}^{(\mathbf{B}, \mathbf{C})}$ is completely independent from other pre-existing values $\mathcal{S}$ already available by the system and concerning different behaviours and contexts. In other words, adding a new value $\mathcal{S}$ to our model, thus extending the knowledge of the system, will not require to adapt the pre-existing knowledge and it will not necessitate to modify the parameters of the computational model.

Denote with $\mathcal{E}\left(\mathbf{I}, \theta^{\text {ethics }}\right)$ and with $\mathcal{E}(\mathbf{I})$ two processes able to provide a final emotional state given the set of the elicited emotion intensities I realised by the cognitive appraisal process $\mathcal{C}$. $\mathcal{E}\left(\mathbf{I}, \theta^{\text {ethics }}\right)$ includes parameters operationalising ethical theories, whereas $\mathcal{E}(\mathbf{I})$ uses a generic strategy without considering the ethical dimension of the given situation. Therefore, our second hypothesis is that:
Hypothesis 2 The cognitive appraisal process augmented by ethical reasoning mechanisms $\mathcal{E}\left(\mathbf{I}, \theta^{\text {ethics }}\right)$ converge to more accurate emotional states compared to cognitive appraisal processes augmented by generic reasoning mechanisms $\mathcal{E}(\mathbf{I})$.

In the remainder of this paper we will offer the functional level description of our computational account and experimental results validating our hypotheses.

## Model Implementation

Cognitive Appraisal Process. The process of emotion generation in our computational model ${ }^{2}$ is shown in Figure 1. As mentioned earlier, when an event occurs, its appraisal (evaluation) is done by using a set of variables called appraisal variables. Ortony et al. (1990) state that these appraisal variables are computed based on the goals, standards and attitudes of

[^427]the individual. In the context of our computational model of emotion, if we denote these goals, standards and attitudes as an internal parameter $\theta^{\text {int }}$ and the perceived knowledge of the environment that the system receives when an event occurs as $K^{e n v}$, then a function for computing appraisal variable can be represented as:
\[

$$
\begin{equation*}
v_{i}=\mathcal{V}_{i}\left(K^{e n v}, \theta^{i n t}\right) \tag{1}
\end{equation*}
$$

\]

Which means that the quantitative value of an appraisal variable is the function of the event knowledge gathered from the environment ( $K^{e n v}$ ) and the internal goals, standards and attitudes $\left(\theta^{\text {int }}\right)$. This computation is done by an Appraisal Mechanism component, as shown in Figure 1. Each computed appraisal variable contributes in the generation of one or more emotions (Ortony et al., 1990) and helps in estimating the intensities of the considered emotions ${ }^{3}$.

The majority of available computational models of emotion compute $v_{i}$ by using domain-specific rule-based functions (Dias \& Paiva, 2005; El-Nasr et al., 2000; Velasquez, 1997). Because of this, when the application domain or input parameters ( $K^{e n v}$ ) change in those models, the internal representation of goals, standards and attitudes $\left(\theta^{\text {int }}\right)$ also needs to be changed. In our model, $K^{e n v}$ is modelled as a set of valanced scores $S$ providing an interpretation of the negative or positive connotation of the experienced events. Importantly, the scores $\mathcal{S}$ are completely independent from $\theta^{i n t}$. Thus, extending our model with new knowledge or adapting previous one will not necessitate to modify the model's parameters $\theta^{\text {int }}$. In this paper we will not provide implementation details and we consequently limit our contribution to this functional description, since this is sufficient for the validation of the proposed hypotheses. The detailed mechanism of computation of appraisal variables in our computational model can be found in another paper (Ojha \& Williams, 2017).

Figure 1: General Appraisal Mechanism.

Emotional State Selection. Next crucial step is determining the final emotional state of the system. Our proposition is that when more than one active emotions are generated, then a final emotional state is best determined by a higher cognitive layer of ethical reasoning.

Figure 2 shows more details of the Emotion Combination Mechanism included in Figure 1 and suggests the mechanism to determine the final emotional state for attribution. The emotions $e_{1}, e_{2}, e_{3}, \ldots$. and $e_{n}$ with respective intensities $i_{e_{1}}$,

[^428]

Figure 2: Ethical Emotion Combination Mechanism.
$i_{e_{2}}, i_{e_{3}}, \ldots$. and $i_{e_{n}}$ output from the Affect Generation component are processed by applying the concepts of deontological and consequentialist ethics (Hooker, 1996) in order to determine the final emotional state. Deontological ethics says that one should satisfy owns duties before making a choice of action/decision and consequentialist ethics says that one should consider the consequences to all the relevant parties before making a decision (Hooker, 1996). Functionally, our ethical emotion combination mechanism is shown in 2.

$$
\begin{equation*}
e_{\text {ethical }}=\mathcal{E}\left(\mathbf{I}, \theta^{\text {ethics }}\right) \tag{2}
\end{equation*}
$$

Where, $e_{\text {ethical }} \in\left\{e_{1}, e_{2}, e_{3}, \ldots, e_{n}\right\}$ is the final emotional state. $I$ is the set of emotion intensities and $\theta^{e t h i c s}$ represents ethical standards.

$$
\begin{gather*}
e_{\text {high }}=\mathcal{E}_{\text {high }}(\mathbf{I})  \tag{3}\\
e_{\text {blended }}=\mathcal{E}_{\text {blended }}(\mathbf{I}) \tag{4}
\end{gather*}
$$

Equations 3 and 4 represent the functions computing respectively the final emotional states for highest intensity approach and blended intensity approach, which were introduced earlier. Clearly, these functions only take the intensities of various emotions for the determination of the final emotional state. However, our model reaches to a final emotional state with the help of higher cognitive mechanism of ethical reasoning (as shown in 2).

The emotional responses of our computational model based on: (1) Highest Intensity Approach, (2) Intensity Blending Approach and (3) Ethical Reasoning Approach will be compared with emotion data obtained from human participants in the Evaluation section.

## Evaluation

In order to operationalise our model and to consequently validate our hypotheses, we designed two sets of web-based surveys requiring two tasks: an action scoring task and a mindreading task. In both the experimental conditions we provided a set of stories concerning social exchanges between two individuals, a sender and a receiver, as previously denoted.

Participants covering a broad set of countries were invited on Facebook or through mailing lists to take our surveys. The surveys were completely anonymous. We received a total of

153 responses (male $=82$, female $=71$ ). Importantly, the subjects were randomly attributed to either the action scoring task or the mind-reading task.

## Scenario Design

In order to avoid ad-hoc scenarios facilitating our model, we did not design the scenarios ourselves. Rather, we requested 4 naïve adults, without any knowledge about the objectives of the present research, to cooperate in designing six scenarios under the following conditions:

- The scenario shall include the interactions of two subjects, one of them denoted as sender and the other as receiver;
- A minimum of 5 and a maximum of 10 actions of the sender directed to the receiver describing a plausible social interaction between two persons shall be provided;
- At the beginning, each scenario shall provide the contextual information about the designed situation and the two considered subjects. Moreover, additional contextual information could be provided during the development of the described social exchanges, whenever this information is necessary to contextualise the remaining interactions;
- No contextual information suggesting the potential emotional state of the receiver shall be provided for individual interactions, with the exception of the contextual information provided at the beginning of the scenario.

The result of this process was a set of scenarios used during both the action scoring and the mind-reading tasks mentioned earlier. The scenarios included interactions between (1) two strangers (a male and a female) interacting on a bench of a park, (2) two close friends (both males) meeting at a beach, (3) a husband and a wife having an argument about forgetting the birthday, (4) an elderly woman affected by dementia and her nurse (both females) experiencing a distressful moment, (5) a guy having argument with his brother, and (6) an interaction between a customer of a café and a waiter (both males). In total, the scenarios included 48 social exchanges of the senders directed to the receivers.

## Action Scoring Task

The experimental subjects participating in the action scoring task were asked to guess, for each scenario, how positive or negative each social exchange performed by the sender would be perceived by the receiver in that specific context. The rating was based on 7-point Likert scale: Extremely Negative, Very Negative, Negative, Neither Negative Nor Positive, Positive, Very Positive, Extremely Positive. We numerically evaluated the responses by attributing a weight to each point of the scale (i.e. $-1,-0.66,-0.33,0,0.33,0.66$ and 1 respectively). We averaged the responses obtaining a value $S$ for each of the considered social exchanges $\mathbf{B}$ in the specific context $\mathbf{C}$. In this way we were able to provide the

Figure 3: Results of the experiments. (a) The cumulative rank-distances of the models' predictions from human assessment. (b) The rank-distances of the models' predictions from human assessment.
necessary input knowledge to our system (i.e. a set of numeric scores $S \in[-1,+1]$ ) and to consequently perform cognitive appraisal processes estimating the emotional state of the receivers in each considered scenario. Recall that this process did not require any changes to our computational model, which provides a valid domain-independent approach of cognitive appraisal process.

## Mind-Reading Task

In order to compare the emotional response of our computational model, we asked to the subjects participating in the mind-reading task to guess, for each interaction of the sender, what would have been the chances that the receiver would happen to be in a particular emotional state, based on the just happened interaction and the previously occurred social exchanges and contextual information. Therefore, for each of the eight considered emotional states the rating was based on 6-point Likert scale: Not at all, Very Low, Low, Medium, High and Very High. The additional rating "Not at all" was necessary to allow the participants to express no chances to attribute such emotional state to the receiver. We numerically evaluated the responses by attributing a weight to each point of the scale (i.e. $0.0,0.2,0.4,0.6,0.8$ and 1.0 respectively). Average score given by the participants to various emotions was calculated by performing the weighted average of the ratings.

## Results

Based on the results of the mind-reading task, the emotions for each interaction of each scenario were ranked from 1 to 8 , with the emotion having the highest average score ranked as 1 and the one with lowest score ranked as 8 .

We considered three strategies to computationally predict the final emotional state of each interaction: choosing the emotional state with highest intensity, blending the emotional intensities to determine the final emotional state as described
by Reilly (2006), and our suggested approach based on ethical reasoning. Each of these three strategies followed a common domain-independent cognitive appraisal process, as discussed in the model implementation section. We compared these computational predictions against the gathered human assessments (i.e. emotions ranked 1) by computing their rank-distances, suggesting how close the computational model was compared to human assessment. The results are summarised in Table 1.

Table 1: Descriptive statistics of the gathered results.

|  | Mean | Median | Std |
| :--- | :---: | :---: | :---: |
| High intensity | 2.4167 | 2 | 2.3232 |
| Blended emotion | 2.3125 | 2 | 2.0228 |
| Ethical reasoning | 2.0833 | 1 | 2.3140 |

In order to demonstrate that the proposed common stage of domain-independent cognitive appraisal was able to elicit emotional intensities similarly to human cognitive appraisal process (Hypothesis 1), we analysed the human responses of the mind-reading task. We noticed that for most of the considered interactions some of the emotions resulted in very close averaged scores. Therefore, given $\varepsilon=0.1$, for each interaction we counted the number of emotions having an average score of greater than or equal to the score of highest scored emotion minus $\varepsilon$ for that interaction. $\varepsilon$ was chosen to be equal to half of the score attributed to each point of the Likert scale (i.e. 0.2 ), thus being able to group emotions plausibly ranked with similar likelihood by most of the human assessors. The average number of similarly rated emotional states among all the 48 interactions was 3.2 , thus suggesting that on average human cognitive appraisal promoted 3 comparable emotional states to attribute to the receiver. From Figure 3a it is clear to see that for distances less than 2 ranks to the human assessment (i.e. predictions among the first 3 higher scored emo-
tions) our cognitive appraisal model was able to promote the selection (using all the three considered strategies) of approximately $70 \%$ of the emotional states plausibly attributed by humans participants to the receivers described in the mindreading task scenarios.

In addition, we can also observe that the cognitive process augmented by the proposed ethical reasoning mechanism converges to more accurate emotional states compared to the other investigated strategies (Hypothesis 2). Figure 3b further suggests that the proposed ethical reasoning mechanism reduces average rank-distances from human appraisal. Therefore, the present results support both the proposed hypotheses.

## Conclusion and Future Work

In this paper, we presented our computational model of emotion based on appraisal theory that is able to generate emotions using the expected degree of positivity or negativity associated with an action/event. This allowed our model to be completely independent of the application domain and efficiently appraise a situation for the elicitation of various emotions. In addition, our model adds a higher layer of cognition in the emotion mechanism by integrating an ethical reasoning capability for the determination of the final emotional state when more than one emotions are generated by the model. Experimental results support our first hypothesis proposing that cognitive appraisal is possible without prior domain knowledge and second hypothesis suggesting that ethical reasoning is a better strategy to explain human emotional state attribution process.

Yet, our computational model still has some room for improvement. For example, it is important to consider that people with different personality generate emotions in different ways. Thus, in the future, we aim to use the concept of personality and examine how the difference in personality makes difference in ethical standards and hence in emotion generation.

#### Abstract

This paper explores the dual meaning of counterfactual conditionals, such as 'if there had been gloves, then there would have been scarves', by tracking the temporal course to envisage the possibility corresponding to the conjecture 'there were gloves and there were scarves' and the presupposed facts, 'there were no gloves and there were no scarves'. To test this, we used the visual world paradigm, in which counterfactual and indicative conditionals were heard while four images corresponding to the conjecture, such as an image of gloves and scarves, and the presupposed facts, such as an image of no gloves and no scarves, and two distractors were shown on the screen and eye movements were monitored. We found that people looked at the affirmative image in the indicative conditional, and both types of images (affirmative and negative) in the counterfactual conditional. Results support the dual meaning of counterfactuals.

# Investigating Sensitivity to Shared Information and Personal Experience in Children's Use of Majority Information

#### Abstract

When learning from others, rather than simply following the majority's opinion, we need to accurately evaluate the quality of the information both the majority and the minority provide, and integrate that information with our own personal experience. This is especially true when the majority's opinion is based on lower quality information, because they shared the same evidence rather than collecting evidence independently. Previous work demonstrated that adults are sensitive to the quality of the majority's information, consistent with the predictions of a Bayesian rational model (Whalen, Griffiths, \& Buchsbaum, in press). In two behavioural experiments, we investigated how preschoolers combine testimony from a majority that conflicts with a minority or with the child's own personal evidence. Unlike adults, children over-relied on the majority when given only testimony. However, when also given their own conflicting evidence, children relied significantly less on the majority and over-relied on their own evidence. These findings help explain why children may follow the majority at times, but in others trust their own judgements.

Keywords: Selective Trust; Conformity Bias; Children; Statistical Dependency; Bayesian Modeling; Social Learning

## Introduction

Learning from others is a valuable strategy to use when encountering uncertainty. Human's use of social information is thought to underlie our ability to live in almost every known environment, and to underpin the evolution of human culture (Boyd \& Richerson, 1985). The information we receive from others is also integrated with the information we gather ourselves through personal experience. Rather than blindly following what others say, it is important we evaluate the information we receive by understanding how others may have formed their opinions, especially when there is disagreement amongst individuals or when their testimony conflicts with our own personal observations.

Evaluating informant testimony is particularly important when the testimony is based on shared information. For example, imagine you are reading four restaurant reviews. In the first two reviews, the reviewers independently visited the restaurant and ordered different dishes, and they both
recommended the restaurant. In the third and fourth reviews, the reviewers went to the restaurant together and shared a single dish, and then both did not recommend the restaurant. Which set of reviews should you trust?

From a pure numbers standpoint, the number of positive and negative reviews is equal. However, the first and second reviews may provide additional information about what an average experience (your experience) at the restaurant would be like. The third and fourth reviews provide less information because the reviewers' shared experience makes their responses statistically dependent on each other. For instance, if the two reviewers shared an unusually salty dish they are both likely to write negative reviews and as such, given the third review, the fourth review provides no new information. Thus, being aware of this statistical dependence will help social learners avoid the mistake of placing trust in a group based on just their number of opinions.

This ability to assess the quality of information being provided is especially important for young children, who are learning much about the world from the testimony of others (e.g., Mills, 2013). Whether young children can use statistical dependency to evaluate testimony quality is an interesting question because much of our social learning occurs during early childhood, when the ability to understand mental states is still developing (Wellman, Cross, \& Watson, 2001). The ability to assess quality of information may require a complex form of "theory of mind" that goes beyond simply copying the majority. To accurately assess the quality of information, children must consider not only the testimony each person gave, but also the unseen information leading to that testimony, and how that information was gathered.

In addition, one's own personal experience can also conflict with what others say, and must be integrated with the testimony received. Imagine that you have a negative experience at that restaurant, and are debating whether to go there again. If there are enough other positive reviews, you may be willing to disregard your own judgement, and give the restaurant another chance. Can children evaluate the quality of their own information relative to a conflicting majority in a similar manner?

In two experiments, we examined how 4- and 5-year-old children evaluated their own private information and the information they received from informants who either shared a piece of evidence or collected evidence independently. Specifically, we investigated whether children can distinguish the quality of information provided by multiple informants and exhibit a sensitivity to shared data (as suggested by Hu et al., 2015) or if they merely conform to the majority (Corriveau, Fusaro, \& Harris, 2009). We then compared children's performance to that of adults' on a similar task (Whalen et al., in press), and the predictions of a Bayesian rational model to understand the extent to which children may conform to the majority despite the amount of information the majority provided.

In Experiment 1, we investigated whether children were sensitive to evidence being shared by a majority group when a single dissenter with independent evidence was present. We found that children were biased towards following a majority opinion and were not sensitive to statistical dependencies between informants. In Experiment 2, we highlighted the source of informants' knowledge by providing children with their own private evidence that conflicted with the majority. We found that given conflicting personal evidence, children no longer followed the majority and instead sided with their own evidence regardless of the quality of the majority's information. Compared to both adults and to the rational model, children were not sensitive to dependency, trusting statistically dependent informants more in Experiment 1, and placing more weight on their own evidence in Experiment 2.

## Background

Previous work by Whalen et al. (in press) demonstrated that adults are sensitive to statistical dependency between informants. Participants correctly rated that an option was more likely when it was endorsed by a majority group with independent evidence than a group with shared evidence (see Figure 1(b) for results). Adults also integrated their own evidence with testimony, appropriately demonstrating no bias towards their own evidence when it conflicted with the majority endorsement. In particular, they endorsed the majority opinion when the group had a higher quality of information than provided by their own personal evidence.

These findings were consistent with a Bayesian model of social learning which captures how an idealized learner might learn from multiple informants with shared information. The model illustrates that conforming to the majority is rational when the majority has a greater quality of information because (like our independent restaurant reviewers) each member contributed additional independent information. Thus, although in some cases adults disregard their own evidence and favour the majority, this may be a product of rationally integrating the two sources of information and assessing their quality, and not a bias towards the majority.

In this paper, we investigated whether 4- and 5-year-old children could assess the information quality provided by a majority when it conflicted with the information of a minority or with the child's own personal evidence. At the age of 4,
children already start to implement strategies in choosing who to listen to by selectively trusting informants, for instance by preferring those who are knowledgeable or accurate (Koenig \& Harris, 2005), or experts in the field (e.g., Kushnir, Vredenburgh, \& Schneider, 2013). However, the current literature is unclear on whether children value conformity or information quality during social learning.

Previous studies argued that children value a consensus even when it conflicts with the child's own perception. For instance, children sometimes followed the majority even when they understood and identified the endorsement of the majority to be incorrect (Corriveau \& Harris, 2010; Haun \& Tomasello, 2011). Using the Asch (1956) paradigm, children were observed to conform especially when answering in public in front of their peers (Haun \& Tomasello, 2011). At the age of four, children are already capable of recognizing a consensus and conforming to them even in ambiguous tasks such as labelling a novel object (Corriveau et al., 2009). These findings then suggest that children may have a bias to conform to a majority, even when the conflicting information comes from their own perception.

On the other hand, some studies have argued that children do exhibit the ability to evaluate the quality of information they receive from multiple informants (Hu et al., 2015). Hu and colleagues (2015) found that, when given testimony from two groups, children preferred the group with the highest quality of knowledge - favouring the group that received direct knowledge via visual perception over those who received indirect knowledge via hearsay. However, when group sizes were not equal, children preferred the group with the most members, even if the members of the larger group had only received hearsay.

Additional work has shown that children avoid a conformity bias if the majority group is proven to be unsuccessful in reaching an apparent goal (Wilks et al., 2014), provide implausible functions for a novel object (Schillaci \& Kelemen, 2014), or have lower expertise than the minority (Burdett et al., 2016). These findings then suggest that, at least in some cases, children have a preference for informants with a greater quality of knowledge, rather than having a preference for the majority per se.

Preschoolers also demonstrate the ability to integrate a single informant's testimony with their own observations. When the two sources conflict, preschoolers acknowledge the confidence and statistical data provided by an informant to assess causal relationships of novel toys (Bridgers et al., 2015), and acknowledge an informant's awareness for appearance-reality when considering their own perception as misleading (Lane et al., 2014). These findings suggest that children can integrate both sources of information, which contrasts with previous theoretic models that emphasized reliance on only social learning (e.g., Rendell, Fogarty, \& Laland, 2010; but see Perreault, Moya, \& Boyd, 2012).

Therefore, whether children can appropriately integrate the quality of informants' knowledge given a majority and conflicting information from either a minority or from personal observation is an open question. However, it is not
always obvious how these different sources of information should normatively be integrated.

## Bayesian Model of Learning from Independent and Dependent Informants

To further understand how an individual can combine the information they receive from testimony and personal evidence, we followed the Bayesian model developed by Whalen et al. (in press) which captures how an idealized learner would integrate information provided by groups with different sources of data - shared or independent - with personal evidence. In this model, a learner collects personal evidence about the state of the world, $e$, and receives testimony from $n$ informants, $t_{1}, \ldots, t_{n}$ who collect their own evidence about the state of the world, $d$. Learners evaluate a potential hypothesis, $h$, using Bayes' rule,

$$
\begin{equation*}
p\left(h \mid e, t_{1}, \ldots, t_{n}\right) \propto p\left(t_{1}, \ldots, t_{n} \mid h\right) p(e \mid h) p(h) \tag{1}
\end{equation*}
$$

where $p\left(h \mid e, t_{1}, \ldots, t_{n}\right)$ is the posterior probability of $h$, the probability that a hypothesis about the state of the world is true given the personal evidence and testimony, while $p(h)$ is the prior probability of $h$, the probability the hypothesis is true before any evidence is given. Finally, $p(e \mid h)$ is the probability of getting that evidence given the hypothesis, and $p\left(t_{1}, \ldots, t_{n} \mid h\right)$ is the probability of getting that testimony.

When multiple informants provide independent testimony, the probability of a series of testimony is equivalent to the product of the probability of each individual testimony:

$$
\begin{equation*}
p\left(t_{1}, \ldots, t_{n} \mid h\right)=\prod_{i=1}^{n} p\left(t_{i} \mid h\right) \tag{2}
\end{equation*}
$$

The testimony of each informant is based on their private data $d_{i}$, so $p\left(t_{i} \mid h\right)$ is obtained by marginalizing over $d_{i}$ :

$$
\begin{equation*}
p\left(t_{i} \mid h\right)=\sum_{d_{i}} p\left(d_{i} \mid h\right) p\left(t_{i} \mid d_{i}\right) \tag{3}
\end{equation*}
$$

where $p\left(t_{i} \mid d_{i}\right)$ is the probability that the informant produces testimony $t_{i}$ after observing $d_{i}$. On the other hand, when multiple informants base their testimony on shared private data, denoted as $d^{\prime}$, the probability of a series of testimony is obtained by marginalizing over the shared private data:

$$
\begin{equation*}
p\left(t_{1}, \ldots, t_{n} \mid h\right)=\sum_{d^{\prime}} p\left(d^{\prime} \mid h\right) \prod_{i} p\left(t_{i} \mid d^{\prime}\right) . \tag{4}
\end{equation*}
$$

In both cases, we assume that informants give testimony in support of a hypothesis proportional to the product of the informant's evidence given the hypothesis and the prior probability, $\quad p\left(t_{i}=h_{i} \mid d_{i}\right) \propto p\left(d_{i} \mid h_{i}\right) p\left(h_{i}\right) \quad$ (for more information, see Whalen et al., in press). This Bayesian model illustrates that, in many cases, conforming to the majority is rational when the majority collects independent
evidence, increasing their quality of information (see Figure 1(a) for example predictions based on our experiment task). In addition, this model accurately predicted the performance of adults in our experimental task suggesting that adults integrate both sources of information rationally (see Figure 1(b) for adult performance).

Following the approach of Whalen et al. (in press), we ran two behavioural experiments that examined how children evaluated the information they were provided by a majority group with shared or independent evidence, along with either a dissenting informant or conflicting private evidence.

## Experiment 1: Dissenting Informant

In Experiment 1, children were shown a video about two jars with differing proportions of red and yellow balls and were asked to guess which jar was being sampled from, given the testimony of three friends who received a ball from the chosen jar. The first two informants endorsed the same jar and made up the majority group while the third informant dissented and endorsed the opposing jar. Children were randomly assigned to either the Shared condition, where the majority shared one ball, or the Independent condition, where majority members each received their own ball.

Our model predicts that a rational learner would choose the jar endorsed by the majority only when each member collected independent evidence, but be at chance when the majority shared one piece of evidence, Figure 1(a). On the other hand, if children have a conformity bias, we should expect them to pick the majority's jar in both conditions.

## Methods

Participants A total of 29 preschoolers (female $=17$, male $=$ 12; mean age $=4$ years 11 months; range $=49-71$ months) were recruited either through local museums or in lab. They were randomly assigned to one of two conditions: The Independent condition $(n=14)$ or the Shared condition ( $n=$ 15). An additional 6 children were excluded due to atypical development (1), provided ambiguous answers (1), did not provide an answer (2), or experimenter error (2).

Procedure In this experiment, children were shown a video on a laptop, where an experimenter introduced two jars comprised of coloured balls - one with mostly yellow balls, a few red balls, and one green ball and one with mostly red balls, a few yellow balls, and one white ball, and introduced her three adult friends. The experimenter explained that she would pour just one of the two jars into her bag and give each of her friends a ball from the bag. Each of her friends would then tell her which of the two jars they thought she picked.

Once the experimenter filled the bag with one of the two jars, she used a cup to randomly scoop a ball from the bag to hand to each of her friends. After looking inside the cup, the informants provided testimony as to which jar they thought the bag was filled from, either the jar with mostly red or mostly yellow balls in it. The first two informants always endorsed the same jar and made up the majority group, while the last informant always chose the opposite jar. The jar

## $\square$ Shared $\square$ Independent

Figure 1: Probability of endorsing the majority opinion in both experiments as predicted by the Bayesian model (a), the average rating of endorsing the majority in both experiments as performed by adults (b) from Whalen et al. (in press), and the percentage endorsing the majority in both experiments as performed by children (c) in the current study.
endorsed by the majority and the actor playing the minority informant were counterbalanced.

In the Independent condition, informants were in the room one at a time and were each given their own randomly sampled ball to view. Each informant stated, for instance, "I looked at the ball and I think that the bag has mostly red balls in it." In the Shared condition, all three informants were present in the room and the first two informants shared a single randomly sampled ball. After providing a testimony, the first informant was asked to pass the same cup to the second informant who then agreed with the first, e.g. "I looked at the ball and thought about what my friend said. I agree with Jessie. I think that the bag has mostly red balls in it." While the third informant received a different random ball and disagreed with the rest, e.g. "I looked at the ball and thought about what my friends said. I disagree with Jessie and Sarah. I think that the bag has mostly yellow balls in it."

Once the video was completed, the on-site experimenter, a different person than the one in the video, reminded the child which jar each informant endorsed and if they saw the same or a different ball as the previous informant, and that all the balls came from just one jar. Finally, she asked a forcedchoice question of which jar the child thought the bag was filled from, either the jar with mostly red or yellow balls in it. The order in which the jars were stated was randomized.

## Results

Each child was given a score of 0 or 1 , with 1 as agreeing with the majority and 0 as disagreeing. Results are shown in Figure 1(c). Overall, children chose the jar endorsed by the majority significantly more often than chance, regardless of how the members of the majority collected their information (binomial test, 21 out of 29 endorsed the majority, $p=0.024$ ).

We analyzed the differences between the conditions using a Fisher's exact test. The difference between the Independent and Shared condition was not significant (10 out of 14 endorsed the majority in the Independent condition, 11 out of 15 in the Shared condition, $p=1$ ). Children chose the majority's jar equally often when the majority had higher quality independent information and lower quality shared information. Finally, compared to adults and to our model,
children appeared to place more weight on the statistically dependent testimony in the Shared condition.

## Discussion

Unlike our model predictions and adults' performance, children were not able to appropriately evaluate the quality of information in an informant's testimony. When two informants received the same ball and gave the same testimony, children over-weighed the majority's shared information relative to the dissenter's independent information. These results support previous findings by Corriveau et al. (2009) who found that children conform to a majority when faced with an ambiguous decision.

Based on the results of Experiment 1, we wanted to identify ways to help children avoid relying on the majority and instead, evaluate which group has the greater quality of information. To do this, we highlighted the independent nature of the minority information by having the child receive private evidence that conflicted with the majority testimony which mimicked many real-world scenarios where our own private experience conflicts with testimony. If the child then has to integrate social learning with personal observation, this may help identify the source of knowledge each individual has and overcome a conformity bias.

## Experiment 2: Own Ball

In Experiment 1, children were making a decision based on testimony alone. However, in most real-world cases, we take in the information that others provide us and evaluate it with our own information. Therefore, in Experiment 2, children no longer saw a minority group, and instead were given their own ball from the bag that conflicted with the testimony. For example, if the informants all endorsed the jar with mostly red balls, the child received a yellow ball from the bag.

As predicted by the Bayesian model, children should choose the jar endorsed by the majority when the members independently collected data and have more information than provided by the child's own single piece of evidence. If, however, the members of the majority shared a single piece of evidence, children should endorse the majority at chance, as the child's own evidence would be as reliable as the
majority's. Similar to Experiment 1, if children present a conformity bias, they will follow the majority regardless of the quality of information provided by the group.

## Methods

Participants A total of 52 preschoolers (female $=24$, male $=$ 28; mean age $=4$ years 11 months; range $=48-71$ months) were recruited through local museums and daycares, or in lab. They were randomly assigned to one of two conditions: The Independent condition ( $n=26$ ) or the Shared condition ( $n=$ 26). An additional 14 children were excluded due to experimenter error (10), previous participation in Experiment 1 (1), inattentiveness (1) and ambiguous answers (2).

Procedure Experiment 2 had the same jars and actors, and similar sampling procedures. However, all three informants endorsed the same jar and made up the majority group for both conditions. As in Experiment 1, children were randomly assigned to either the Independent or Shared condition.

In the Independent condition, each informant received their own distinct randomly sampled ball and provided their testimony in the room one at a time. In the Shared condition, all three informants were present in the room and shared a single randomly sampled ball and provided testimony agreeing with the previous informants.

After the video ended, the on-site experimenter reminded the child which informant endorsed which jar, if they looked at the same or different ball as the previous informants, and that all the balls came from just one jar. In this experiment, all the informants endorsed only one jar. Next, the on-site experimenter brought out an identical bag and stated that it was the same bag from the video containing the same balls. Similar to the experimenter in the video, she used a plastic cup to give the child their own ball from the bag. The on-site experimenter pretended to scoop up a ball at random, but in fact the child always received a ball that was a different colour from the majority testimony. After the child looked inside the cup, the on-site experimenter asked which jar they thought all the balls came from, as in Experiment 1.

## Results

Results are shown in Figure 1(c). Overall, children chose the jar endorsed by the informants below chance regardless of how the informants collected their information (binomial test, 11 out of 52 endorsed the majority, $p<0.001$ ). Similar to Experiment 1, we found that children did not choose the informant's jar more in the Independent condition compared to the Shared condition (5 out of 26 endorsed the majority in the Independent condition, 6 out of 26 in the Shared condition, $p=1$, Fisher's exact test). In both conditions, children weighed their own evidence more, compared to both adults and the predictions of the Bayesian model.

## Discussion

We found that in Experiment 2, children relied heavily on their own evidence and chose the jar consistent with their own ball regardless of whether the majority collected
independent or shared evidence. As in Experiment 1, we found no significant difference between the Independent and Shared conditions, suggesting that children were not sensitive to the statistical dependency. These results support previous findings suggesting that children may rely on their own evidence that they personally collected over the evidence collected by others (Kushnir \& Gopnik, 2005; Kushnir, Wellman, \& Gelman, 2009).

## General Discussion

We investigated how children weighed the value of information they received from multiple individuals and their own personal evidence. We compared the performance of 4and 5-year-old children to the performance of adults on a similar task (Whalen et al. in press) and to the predictions of a Bayesian rational model. Experiment 1 showed that children were not sensitive to the shared information of a group and were instead following the majority. Experiment 2 demonstrated that children would no longer use the strategy of conforming to the majority if they themselves collected conflicting evidence and instead, relied on their own evidence, regardless of the quality of the majority's information. Therefore, compared to adults, children applied a different strategy in the integration of information.

Children's apparent conformity bias is consistent with previous findings that argued that children prefer to rely on the majority (e.g., Corriveau et al., 2009; Haun, Rekers, \& Tomasello, 2012; Haun \& Tomasello, 2011). Children may exhibit this reliance on the majority because it is often a useful and reliable social learning strategy (Haun et al., 2014). After all, the majority made their choices for a reason.

However, in the presence of children's own conflicting evidence, a conformity bias was no longer present. Although previous work has suggested that children may present a conformity bias even in the face of conflicting direct perception (Corriveau \& Harris, 2010; Haun \& Tomasello, 2011), it is important to note that in those studies, a majority of children still favoured their own evidence over the testimony of the majority.

This bias to rely on personal evidence over the evidence collected by others has previously been observed in the causal domain as a self-agency bias, especially when the evidence seemed to be ambiguous or probabilistic (Kushnir et al., 2009). Kushnir and Gopnik (2005) discovered that children would weigh their own causal interventions more heavily than the causal interventions of others. They suggested that children had this bias because they viewed their own actions to be more controlled and reliable and less likely to be confounded than those of other individuals. However, this bias to one's own evidence has not yet been observed in a non-causal domain like that of our current study. Similarly, children in our study might have considered their direct perception of their own ball to be more reliable than the information they received from the informants' testimony.

One possible explanation for the presence of both a bias towards conformity and towards personal evidence in this task is that preschoolers learning how to integrate
information have yet to develop more complex aspects of theory of mind (e.g., Gweon et al., 2012). At this age, children might have had difficulty reasoning about how the informants generated their testimony based on the evidence that they likely received. In other words, 4- and 5-year-old children know that people can have beliefs, but may have difficulty in knowing how these people came to believe something. As a consequence, children might rely on the number of endorsements given rather than on their quality, leading to the appearance of a conformity bias. On the other hand, children were likely confident in what they themselves saw which appeared as a bias towards their own evidence.

Future work should investigate whether children have difficulty inferring the evidence informants likely received based on their testimony, by testing how children respond when they can observe this evidence directly, for instance by presenting it in clear cups. We expect that children would then compare the amount of evidence between the majority and minority group rather than the number of endorsements. If children can identify the statistical dependency when the evidence is visible, they should no longer demonstrate a conformity or a personal evidence bias.

In addition, in ongoing follow-up studies, the child's evidence is presented on-screen within the video rather than performed live to equate saliency. If children still present a bias towards their own evidence, the salience from a live performance as a reason for this bias can be ruled out.

Taken together, our findings suggest that children implement a different social learning mechanism than adults and our Bayesian model. When integrating testimony alone, children over-weighed the quality of information provided by the majority. On the other hand, when the child was given their own conflicting evidence, children under-weighed the quality of information provided by the majority and relied on their own perception. Thus, unlike adults, children require further development in their social learning and perhaps their reasoning of mental states to avoid biases and become sensitive to statistical dependency.

## Acknowledgments

We are grateful for all the families for their participation, and to the Computational Cognitive Development lab for their help with data collection, especially Nafisa Bhuiyan and Elina Kadriu, and Tom Griffiths for helpful discussions. This work was supported by the Natural Science and Engineering Research Council of Canada and the Canada Foundation of Innovation.

# Do Speaker's Emotions influence their Language Production? Studying the Influence of Disgust and Amusement on Alignment in Interactive Reference 

Charlotte Out (c.out@uvt.nl)<br>Tilburg center for Cognition and Communication, Tilburg University, PO Box 90153, 5000 LE, The Netherlands<br>Martijn Goudbeek (m.b.goudbeek@uvt.nl)<br>Tilburg center for Cognition and Communication, Tilburg University, PO Box 90153, 5000 LE, The Netherlands<br>Emiel Krahmer (e.j.krahmer@uvt.nl)<br>Tilburg center for Cognition and Communication, Tilburg University, PO Box 90153, 5000 LE, The Netherlands

#### Abstract

The influence of emotion on (the early stages of) speech production processes, notably content selection has received little scholarly attention. Goudbeek \& Krahmer (2012) found evidence for alignment at the conceptual level: speakers may start using a dispreferred attribute over a preferred attribute in their referring expressions when they are primed by a prerecorded female voice in a preceding interaction. The current study aimed to assess the role of emotion (using amusement and disgust) in alignment, while simultaneously replicating this finding in a more naturalistic setting involving two human participants in naturalistic dialogue. Our results replicate the findings by Goudbeek \& Krahmer (2012), generalizing their findings to a much more naturalistic setting. In addition, we found that amused, but not disgusted speakers tend to use the preferred attribute more to describe objects to their conversational partner.

Keywords: alignment; egocentricity bias, attentional bias, emotion; amusement; disgust; speech production; referential expressions, psycholinguistics.

## Introduction

Several effects of emotion on various processes in speech have been studied extensively, including effects on articulation and pronoun use. For instance, speakers often signal their emotional state in their prosody, by sobbing, crying or shouting (Bachorowski, 1999; Goudbeek \& Scherer, 2010) and depressed writers have been shown to use more first person singular pronouns (Pajak \& Trzebiński, 2014; Stirman \& Pennebaker, 2001). However, the impact of emotion on other aspects of the speech production processes has received little attention. In this study, we aim to investigate the role of emotion in the earlier processes in speech production, in particular on content selection stage ("deciding what to say") of language production, focusing on referential expressions.

## Emotion and speech production

As far as we know, only a few studies have looked at the relationship between emotional state and content selection. For example, Kempe, Rookes and Swarbrigg (2012) looked at the effect of speaker emotion (positive or negative emotion) on ambiguity avoidance in the production of referring expressions. In their experiment, emotion was
induced by a positive or negative video, accompanied by emotion congruent classical music. After the emotion manipulation, participants were asked to uniquely describe four pictures on the sheet. In the critical trials, two of the four pictures could be described in a linguistically ambiguous way, e.g. as a "bat" which could either be a flying bat or a baseball bat. They found that speakers in a positive state were less likely to disambiguate the second linguistically ambiguous picture, that is, they were more likely to use the word 'bat' for both the flying bat and the baseball bat. These findings suggest that positive emotions might increase ambiguity in referring expressions, which could be the result of an attentional shift in the speaker (Beukeboom and Semin, 2006).
Attentional bias It has been generally accepted that positive emotions (e.g., amusement) broaden attention, whereas negative emotions (e.g., sadness) narrows attention (see Frederickson, 2001). However, Harmon-Jones, Gable, and Price (2013) state that not valence, but the motivational intensity of emotions influence attention: emotions of low motivational intensity (e.g., sadness) broaden cognitive scope and emotions of high motivational intensity (e.g., disgust) narrow cognitive scope. They found that individuals exposed to disgusting pictures (compared to neutral pictures) who did a global-local letter task (Navon, 1977) responded slower to global than to local targets (Gable and Harmon-Jones, 2010), supporting the hypothesis that emotions of high motivational intensity narrow attention and make people focus more on details.
Egocentricity bias Egocentricity of speakers has been known to influence content selection. The egocentricity bias is the tendency of individuals to use their own perspective as reference point to the world (Ross \& Sicoly, 1979). Many authors claim that although individuals are often able to adjust to the perspective of the listener, they initially act egoistically (Epley, Morewedge, and Keysar, 2004; Horton and Keysar, 1996), although some beg to differ (see for example Bezuidenhout, 2013). According to Converse, Lin, Keysar and Epley (2008) and Clore and Hutsinger (2007), individuals in a positive state are less likely to adopt to the perspective of another person than individuals in a negative state, the shift of perspective to the listener might be impaired because positive emotions promote automatic responses.

Although these studies suggest an interesting link between emotion and (the early stages of) speech production, many questions remain. For example, what is the effect of emotion on the language production of speakers and listeners in an interaction?

## Alignment in interaction

In the current study, we focus on the effect of emotion on the amount of alignment between conversational partners in referential expressions. As argued by Garrod and Pickering (2004), one of the ways conversational partners can align to each other is by using the same attributes to refer to an object as their conversational partner. For example, if the other person just referred to an object in terms of its size (the large table), the speaker would be more likely to use size as well in a subsequent reference, because the previous use of size would prime this attribute. However, this is at odds with another tendency that has been reported in the literature, namely that speakers prefer to use certain attributes that are more "absolute" in their meaning over attributes that are less so (e.g. color over size, Martin, 1969; Pechmann, 1989). Inspired by observations such as these, Dale and Reiter (1995) developed the Incremental Algorithm which assumes a fixed preference order of attributes to determine in what order certain attributes are used in the generation of referential expressions. This Incremental Algorithm states that when individuals describe an object, they will first use the most preferred attribute and matching value, e.g., color and then "red", leading to the red chair. When this is not sufficient to single out the target object (e.g., there are multiple red chairs), the speaker will proceed by adding a less preferred attribute, e.g., size, leading to the large red chair. The speaker will continue adding attributes until the listener is able to identify which chair she is talking about. Dale and Reiter's (1995) Incremental Algorithm thus predicts that speakers will never use a dispreferred attribute when a preferred attribute is sufficient for identification. However, Goudbeek and Krahmer (2012) primed speakers with dispreferred attributes (attributes that were used earlier in an interaction) - and investigated whether they would stick to their preferences or align by incorporating the dispreferred attribute that was used by their conversational partner. In their study, participants listened to a pre-recorded female voice referring to one of three furniture objects, using either a preferred (color; "the red chair") or dispreferred (orientation, "the chair seen from the side") attribute. They subsequently indicated which image (the target) matched this description. When they were asked to describe a new target object, they tended to use the same type of attribute that they were primed with before, even when they could also use the preferred attribute to distinguish the target. These results show that speakers may thus use dispreferred attributes over preferred ones when they are primed to do so. In this paper, we study whether the emotions amusement and disgust might inhibit or promote this tendency. In addition, we aim to replicate the findings by Goudbeek and

Krahmer (2012) using a more naturalistic elicitation paradigm.

## The present study

Based on the results from Goudbeek and Krahmer (2012) we predict that speakers will indeed align with their dialogue partners and start using the dispreferred attribute in their referring expressions when primed to do so. With respect to the effect of emotion, previous research (e.g., Kempe et al., 2013, Beukeboom \& Semin, 2006) indicates that the emotional state of a speaker influences the content selection process of language production, and thus potentially the degree to which speakers align with respect to the attributes they use in interaction.

However, mainly the influence of emotions differing in valence (positive vs. negative) on speech production has been studied (see Kempe et al., 2012; Converse et al., 2008) which severely limits our understanding into the role of emotion in speech production. After all, emotions can be differentiated in other ways, which might influence speech production as well.

We induced amusement and disgust, two emotions that differ on multiple appraisals, among which is valence, but also approach/avoidance, potency/control and, possibly, intensity (see Scherer, 2013). Amusement is a positive emotion that occurs when a person experiences something entertaining (e.g., a joke) and feels pleasant (Tong, 2015). Disgust is an emotion that is elicited when a person is confronted with something they deem repulsive, for instance bodily fluids (vomit, pus, urine). We will study the effect of disgust and amusement on alignment in an interactive referential task. Will amused speakers or disgusted speakers align more with their conversational partners, even when they use a dispreferred way to refer to a target?

## Methods

## Participants

A total of 140 Dutch-speaking university students (36 male), participated in the experiment in pairs ( $\mathrm{n}=70$ ).

## Materials

Stimuli Following Goudbeek and Krahmer (2012), we used pictures taken from the TUNA corpus (van Deemter, Gatt, van der Sluis, \& Power, 2012), depicting front-facing furniture items (a fan, a chair, a couch, and a desk) in four different colors (blue, green, red, and grey) and two different sizes (large or small). Participants were asked to uniquely identify the target picture (accompanied by two distractors) to their conversational partner. Previous studies (Gatt et al., 2007; Goudbeek \& Krahmer, 2012) indicate the well-known preference of participants for color in their description of the target picture.

There were three types of trails: color trials, size trials and filler trials. Each participant pair was presented with 60 trials, divided into two blocks, consisting of 20 color trials
and 20 size trials. Additionally, each block included 10 filler trials, all containing large pictures of furniture in greyscale. Four versions were created, containing different orders of trials.

Mood questions To control for participants' mood before the experiment, we asked the participants to rate their mood before they watched the video. They indicated on a 1 to 7 scale how much they experienced each of the following moods: happy/sad, pleasant/unpleasant, satisfied/unsatisfied, content/discontent, cheerful/sullen, in high spirits/lowspirited (Krahmer, van Dorst, \& Ummelen, 2014, based on Mackie and Worth, 1991 and Bohner et al. 1992; English translations of Dutch originals).

Manipulation check To check whether emotion induction was successful, we asked participants after viewing the video to report how much amusement and disgust (and pride, anger, sadness, disgust, surprise and fear) they experienced on a 1 ("not at all") to 7 ("extremely") point Likert scale.

Other-participant questions After the director-matcher task, participants rated on a 7-point Likert scale (ranging from 1: "not at all" till 7: "very") how much they liked the other participant, how empathic they felt towards them, and how much they thought they got along. Finally, they indicated if they knew the participant, choosing either "no", "yes, a little", or "yes, very well".

Videos To counter the possibility of film specific effects, two different disgust-inducing and two different amusement videos were shown. Based on existing literature, we used four videos that were moderate to highly successful in inducing the corresponding emotions amusement and disgust, respectively. The amusement videos were "When Harry met Sally" (1989) and "There's Something About Mary" (1998). The disgust videos were "Trainspotting" (1996) and "Pink Flamingos" (1972). We selected these videos because they have been used effectively in recent work (e.g., Hewig, Hagemann, Seifert, Gollwitzer, Naumann, and Bartussek, 2005; Fajula, Bonin-Guilaume, Jouve, and Blin, 2013; Harlé and Sanfey, 2010; Schaeffer, Nils, Sanchez, and Philippot, 2010; and Rottenberg, Ray, and Gross, 2007).

## Procedure

After the participants had read and signed the consent form, they were sent to separate cubicles and filled in the demographics and answer the mood questions. The participants were informed that they were going to view an (emotional) video and were instructed to pay attention to the video and keep their eyes on the screen, because they would need this information in the video later in the experiment. After viewing the video (the emotion induction), they answered the questions of the manipulation check with respect to their current emotional state. Subsequently, they
went into a new room together with the other participant. To enhance the emotion manipulation, participants discussed the video they viewed with each other for approximately 2 minutes. They were instructed to focus on describing what they saw in the video, and telling the other participant what they thought and felt while viewing the video. They then filled in the mood questionnaire again and go on to perform the director-matcher task together.

Each trial consisted of four turns. First, participant A, the director, described the target picture (framed by a red border on the screen) to participant B , the matcher. Depending on the trial, participant A used (was forced to use) either a preferred or dispreferred attribute to describe the target picture to participant $B$. In the color trials, participant $A$ could only use the preferred attribute color to distinguish the target picture from the distractors. For example, the target picture was a large blue fan, and the distractors were a large red couch and a large red fan. Therefore, participant A had to use color to describe the target picture. In the size trials, participant A could only use the dispreferred attribute size to distinguish the target picture from the distractors. For example, the target picture was a large green desk, and the distractors were a small green desk and a small green fan. Therefore, participant $A$ had to use size to describe the target picture (see Figure 1, square 1).
Second, participant B, the matcher, saw the same pictures on their screen in a different order than participant A. After listening to the description of participant A, they indicated the matching picture by pressing the key of the corresponding number on their keyboard, e.g., " 2 " (see Figure 1, square 2). When participant A knew that participant B had selected an answer, she pressed "Enter" and the participants viewed a new screen.

Figure 1. Example of a size trial in the director-matcher task. Square 1 and 2 depict green pictures. Square 3 and 4 depict a red couch (the target), a blue desk and a grey chair.

Third, the participants switched roles: now participant B was the director and participant A the matcher. In contrast to the previous turn, the combination of pictures on this screen gave participant B the choice to use either the preferred or dispreferred attribute to distinguish the target picture from the distractors. For example, the target picture was a large red couch and the distractors were a small grey chair and a small blue desk. Participant B could either use the preferred attribute ("the red couch") or use the dispreferred attribute ("the large couch") to distinguish the target picture from the distractors (see Figure 1, square 3). In case participant B aligned with participant A , they used color when participant A (i.e., in color trials) used the preferred attribute, and size when participant A used the dispreferred attribute (i.e., in size trials).

Fourth, participant $A$, now the matcher, selected the picture that matched participant B's description by pressing the key of the corresponding number on the keyboard, e.g., "2" (see Figure 1, square 4). When participant B knew that participant A had selected an answer, participant B pressed "Enter", marking the end of the trial. After participant B had pressed "Enter", a new trial appeared and the procedure was repeated. Following the director-matcher task, both participants filled in the questions about the other participant. They got debriefed and received compensation (credits or money).

Figure 2a. Proportion of preferred and dispreferred attributes per Prime (Color or Size) for Amusement

Figure 2b. Proportion of use of preferred and dispreferred attributes per Prime (color or size) for Disgust

## Results

## Manipulation check

First, we tested whether the emotion manipulation was effective. We performed a one-way analysis of variance with Emotion Video (Amusement vs. Disgust) as independent variable and Emotion Scale (amusement vs. disgust) as dependent variable. As expected, we found a significant effect of Emotion on amusement, $F(1,138)=$ $88.89, p<.0001$, and disgust, $F(1,138)=255.47, p<.0001$. The mean scores of the combined videos per emotion indicate that participants who viewed an amusing video reported higher levels of amusement ( $M=4.89, S D=1.38$ ) than disgust ( $M=2.60, S D=1.49$ ). Participants who viewed a disgusting video reported a higher level of disgust ( $M=$ $6.26, S D=1.38)$ than amusement $(M=2.51, S D=1.39)$. This indicates that the emotion manipulation had the desired effect.

## Analyses

To statistically evaluate the effects of emotion, prime, and attribute, we conducted an analysis of variance with the proportion of attribute use as dependent variable and Emotion (Amusement vs. Disgust) as between subject factor, and Prime (Color vs. Size) and Attribute (preferred vs. dispreferred) as within-subject factors. The results of this analysis can be found in Table 1.

A significant main effect was found for Prime, $F(1,68)=$ 47.36, $p<.0001, \eta^{2}=.41$, indicating that the prime indeed influences the selection of attribute. Mean scores (with standard deviations) of the proportion of attribute use as influenced by prime can be found in Table 2.

A significant main effect was found for Attribute, $F(1$, $68)=33.67, p<.001, \eta^{2}=.33$, confirming that the preferred property color $(M=.80, S E=.03)$ is indeed preferred over size $(M=.52, S E=.03)$.
The effect of emotion The interaction between Emotion and Attribute is significant, $F(1,68)=5.01, p=.028, \eta^{2}=$ .07. A one-way analysis of variance with Emotion and Attribute shows a significant effect of Emotion for the use of preferred attribute, $F(1,68)=5.54, p=.022$, regardless of prime. Amused individuals showed a preference for the preferred attribute color ( $M=.86, S D=.19$ ) over the dispreferred attribute size ( $M=.48, S D=.22$ ). Disgusted participants did not show a preference for color ( $M=.73$, $S D=.28)$ or size $(M=.56, S D=.25), F(1,68)=1.91$, $p=.172$. The three-way interaction between Emotion, Prime and Attribute was not significant $(F(1,68)=3.34, p=$ .072), but there was a significant interaction between Emotion and Attribute $(F(1,68)=5.01, p=.022)$. The proportions of preferred and dispreferred attributes as a function of Prime and Emotion are shown in Figure 2a (for Amusement) and Figure 2b (for Disgust).

Table 1. Summary of statistical analysis

|  | $F$ | $p \leq$ | $\eta^{2}$ |
| :--- | :--- | :---: | :---: |
| Emotion | 0.05 | .376 | .01 |
| Prime | 47.36 | .001 | .41 |
| Attribute | 33.67 | .001 | .33 |
| Emotion x Prime | 3.34 | .072 | .05 |
| Emotion x Attribute | 5.01 | .028 | .07 |
| Prime x Attribute | 119.89 | .001 | .64 |
| Emotion x Prime x Attribute | 0.31 | .580 | .01 |

Table 2. Proportions of preferred and dispreferred attributes per Prime (color vs. size)

| Prime | Attribute | $M$ | $S D$ |
| :--- | :--- | :--- | :--- |
| Color | Preferred | 0.85 | 0.21 |
|  | Dispreferred | 0.31 | 0.28 |
| Size | Preferred | 0.75 | 0.31 |
|  | Dispreferred | 0.72 | 0.29 |

## Discussion

The aim of this study was twofold. One, investigating the effect of emotion on alignment in interactive reference production. Two, providing a more naturalistic replication of the results by Goudbeek and Krahmer (2012) by investigating alignment on dispreferred properties in a truly naturalistic version of the interactive alignment paradigm.

Regarding the effect of emotion on attribute use, we found that amused speakers have a stronger preference for the preferred attribute (color) over the dispreferred attribute (size) than disgusted speakers. This finding can be explained by the theory that individuals in a positive state tend to process information more shallow and global than individuals in a negative state (e.g., Beukeboom \& Semin, 2006) therefore using the preferred attribute because it is the default.

Regarding the effect of emotion on alignment, we did not find a statistically significant interaction between emotion, prime and attribute. However, upon inspecting our data, we did observe some interesting trends. We found that amused speakers aligned with their conversational partner regardless of prime. In other words, amused speakers aligned when they were primed with color and when they were primed with size (Figure 2a). This is in line with Harmon-Jones et al. (2013): amusement, an emotion of low emotional intensity, broadens the cognitive scope and therefore, speakers align with their conversational partners, regardless of prime. However, our amused speakers still used the preferred attribute color more (Figure 2a), supporting Clore and Hutsinger (2007), who state that speakers in a positive state find it harder to shift to the perspective of their conversational partner.

Disgusted speakers aligned when they were primed with color and when they were primed with size as well (Figure 2b). However, disgusted speakers primed with size
(opposed to the amused speakers primed with size) use the dispreferred attribute more than the preferred attribute, indicating that disgusted speakers have an even stronger tendency to align than amused individuals. This might be explained by the theory that individuals in a negative state have a narrower scope of attention (Beukeboom \& Semin, 2006). A narrow scope of attention might cause disgusted speakers to focus more on the words of their conversational partner than amused speakers who have a broad focus. The increased attention for the conversational partner in turn results in more alignment, regardless of prime (color or size). However, the result that disgusted speakers align more when they are primed with size than their amused peers can also be explained by the egocentricity bias (see Kempe et al., 2012). If amused speakers are more egocentric than disgusted speakers, they will rely more on their own perspective, using the preferred attribute color more, regardless of prime. This might not be the case for disgusted speakers, who are less self-focused and therefore align with their conversational partner, even when the prime was a dispreferred attribute.

The results of this study are perfectly in line with those of Goudbeek and Krahmer (2012). First, we found that participants generally used the preferred attribute color over the dispreferred attribute size. Second, participants primed with size used the dispreferred attribute size more than when they were primed with color. This is an interesting result, because the paradigm used in the study by Goudbeek \& Krahmer (2012) was much more artificial than the one in our current study. In their experiment, speakers interacted with a computer and were primed by a pre-recorded computerized female voice. In our study, two human participants interacted in pairs in a relatively natural setting: they were asked to interact normally, without restrictions. The participants who primed did this naturally and unconsciously, by being only able to use the preferred or dispreferred attribute to describe the target picture.

The preliminary evidence for the differential effects of amusement and disgust on attribute choice in referential expressions should lead to further explorations of the effect of (various) emotions on language production in human interactions. Future studies could, for example, focus on finding the (inter- and intrapersonal) mechanisms that might underlie the preference of emotional speakers to use either preferred over dispreferred attributes. In our study, amused speakers preferred color much more than disgusted speakers did, which implies that the emotional state of a speaker influences her attribute preferences. These and similar studies should result in a more detailed picture of the underlying mechanisms of the language production of emotional speakers.

# Nudging Problematic Smartphone Use to a Lower Level 

Lauri Palokangas (Lauri.Palokangas@gmail.com)<br>Jyrki Suomala (Jyrki.Suomala@Laurea.fi)<br>Laurea University of Applied Sciences, NeuroLab, Vanha maantie 9<br>02650 Espoo, FINLAND

#### Abstract

Smartphone usage has evolved in people's lives from necessity to habit and in some cases leading to compulsive use and addiction. However, only a little research has been performed on the prevention of Problematic Smartphone Usage (PSU). Behavioral economics has been applied to investigate how smartphone users respond to nudges that try to lower their smartphone usage. Findings revealed that the Total Screen On Time (SOT) decreased when nudging smartphone users with information on their usage behaviors. Intermittent glancing, as well as the median session time increased, and the reduction in SOT was no longer statistically significant in the observation period after the nudges were no longer applied, suggesting relapse in smartphone usage behavior.

Keywords: addiction; behavioral insights; nudge; smartphone

## Introduction

Behavioral economics researchers (Kahneman, 2003) have identified a large number of systematic biases in people's decision-making and judgements. These biases have been regarded as evidence that people do not follow principles of the rationality suggested in neoclassical theory (Samuelson, 1937). Instead, people use a series of heuristics that often lead to systematic errors (Tversky and Kahneman, 1973). Thus, the results of the mainstream views in behavioral economics have a generally low opinion about human rationality.

A new positive approach - nudge - for peoples' decisionmaking have emerged (Thaler and Sunstein, 2008). According to this approach, people could be helped by a nudge to make optimal decisions (Thaler and Sunstein, 2008). By planning the environment based on so-called "choice architects" in order to make people change behavior to make decision makers better off as judged by themselves (Thaler \& Sunstein 2008). One example of the benefit of the nudge and choice architecture is to prompt vaccination receivers to write down the date and time of the appointment to increase vaccination rate (Milkman et al., 2011).

According to the dualistic model people engage two systems of thinking. System 1 is an automatic, effortless and often influenced by habits that cannot be influenced easily, whereas System 2 is effortful, deliberately controlled and associated with conscious thinking operations (Kahneman, 2003). The limited capacity of mental effort results to people preferring the System 1 thinking by applying heuristics. As an outcome, many decisions are based on beliefs of probabilities of possible outcomes (Tversky \& Kahneman, 1973). Nudges build on the proposition of dualistic system. By preferring the effortless processing, "choice architects" can for instance design routinization of medication, thus
creating a habit that is easier to maintain than a medication that is not based on a routine (Ryan \& Wagner, 2003).

## Problematic Smartphone Use

The heuristics suggested from the dualistic system can be theorized to be present in a person's smartphone usage habits. The high daily usage of a smartphone in people's lives have become significant (Montag et al., 2015b; Kim, 2013; Oulasvirta et al., 2012; Lin et al., 2015). Even if $82 \%$ of the respondents say that using their phone during the conversation hurts the setting, $89 \%$ of the people have used a phone themselves during their most recent social gathering (Rainie \& Zickuhr, 2015). People have been shown to frequently return to their uncompelled behavior even if they were willing to change their behavior for better (O'Connell, 1996). Smartphone usage can be seen to have evolved into a habit which can lead to compulsive use and addiction (Lee, Chang, Lin \& Cheng 2014, 373).
Frequent phone use has been connected to the indicators of certain types of addiction. Some studies (Lin et al., 2015; Hong et al., 2012; Lin et al., 2014; Leung, 2008) indicate that the compulsive use of smartphones share the characteristics of drug and alcohol addiction, and internet dependency. Moreover, pathological gambling analyses has been used to classify this type of smartphone addiction (Leung \& Liang, 2016).

Using a mobile device frequently and at excess durations has been shown to lead to various types of symptoms. Using phones in excessive quantities in personal business situations has been shown to lower quality outcomes in negotiations and to give a less trustworthy and less professional impression (Krishnan et al., 2014). In addition, the increased use of smartphones has been shown to lead to reduced concentration levels during school classes and unsafe driving habits (Hong, Chiu \& Huang, 2012). Furthermore, by taking a wireless device even for a short time can increase anxiety (Cheever, Rosen, Carrier \& Chavez, 2014).

Whereas most of studies have focused frequent phone use from addiction point of view, it is hard to find studies that have focused on the prevention of Problematic Smartphone Use (PSU) on healthy test subjects. In order to help lower the smartphone use without coercion or policies, it is important to investigate how PSU can be influenced by using behavior change interventions.

Behavioral economics can be applied to investigate how smartphone users respond to nudges (Thaler and Sunstein, 2008) that try to lower their smartphone usage. A concept of 'nudge' has been introduced in contrast to policies enforcing a desired behavior or to introducing significant economic
incentives. Nudges can be used to design an environment that "alters people's behavior in a predictable way without forbidding any options or significantly changing their economic incentives" (Thaler et al., 2008). Although the nudge has been applied in many studies and projects (Johnson \& Goldstein, 2003; Shu et al., 2012), it is hard to find research reports that have focused on applying behavior change interventions to influence smartphone usage.

The nudges used in this research to influence smartphone use were designed based on Michie, van Stralen and West's (2011) Capability, Opportunity-Motivation-Behaviour (COM-B) framework. According to this framework, behavior change involves changing one or more of the capability, opportunity and motivations that relate to the behavior (Michie, Atkins \& West, 2014). Capability refers to knowledge and skills that influence engaging in the activity, opportunity refers to everything outside the test subject that prompts for behavior or makes it possible, and motivation refers to processes that energize and direct behavior (Michie et al., 2014). The first nudge used in this study was designed to influence to the capability component, whereas Motivational and Goal-Attainment nudges were designed to influence to the motivational component in the COM-B framework.

Goal setting combined with a commitment, and feedback concerning the behavior has been shown to lead to behavior change. Where providing information has improved knowledge about the issue, the behavior change has resulted from tailored information, goal setting and feedback. Whether the goal has been set by an external party or the subject themselves, it has not been shown to have influence. (Abrahamse, Steg, Vlek \& Rothengatter, 2007).

The Capability-nudge provided information regarding the phone use. The nudge was designed to be compatible with Hansen \& Jespersen's (2013) definition of Transparent type 1 nudge. In this category, the reflective thinking of a subject is a by-product of the nudge.

Both Motivational-nudge and the Goal-attainment-nudges added influence to the motivational component by providing an optional valentic emoticon based on the progress of the smartphone use. The appearance of the valentic emoticon in a Goal-attainment nudge was shown if the test subject attained a self-defined personal goal in reducing smartphone usage. The valentic emoticon was designed to influence behavior through reflective thinking and to indicate an attainment of a desired behavior. These nudges built on Hansen \& Jespersen's (2013) definition of Transparent type 2 nudge: the emoticon provided feedback to reinforce the commitment mechanism while the test subject maintained a complete freedom of choice, both before engaging with the phone, or after opening the phone and thus becoming subject to the nudge.

Even though excessive smartphone usage can lead to compulsive use and addiction (Lee, Chang, Lin \& Cheng, 2014), little is known how people can voluntarily lower smartphone use. Here we use the COM-B behavioral change
framework to study how smartphone usage can be influenced by nudges.

## Method

## Participants

Total of 201 users were recruited from social media (Twitter, Facebook and LinkedIn) to participate in the research using the following recruitment message: "Are you hooked to your phone? Do you use it way too much? Find it out. Participate in a research. Install Deglancer." The participants were not assessed or selected based on their attitudes towards smartphone usage. The participants were incognito to the researchers throughout the study. The study was initiated by a test subject when installing the application onto their Android smartphone from Google Play store. The users were presented information about the research both before installing the research application, and when the research information sheet was made available to them in the application.

Following the research practices of an earlier research project (Montag et al., 2015b) the data was filtered to include only the participants that completed the full five weeks of research without stopping their phone usage for more than three consecutive days during the research. After discarding corrupted research data and ineligible users, 78 users were included to the data analysis.

Earlier research results (Mueller, van der Heijden, Klein \& Potters, 2011; Altmann \& Traxler, 2014) had shown that the effect of nudges do not significantly correlate with economic or socio-demographic variables. Therefore, sociodemographic background variables are not reported. The ethics committee of the Federation of Universities of Applied Sciences approved the study.

## Procedure

A smartphone application was developed to conduct an intervention study using three different type of nudges. The study was constructed for consecutive five stages, each lasting for 7 days. As soon as the users started the application for the first time, the study initiated. The application registered itself to the service hosted in Google cloud computing infrastructure. In the beginning of the research, the test subjects responded to the Smartphone Addiction Inventory (SPAI) questionnaire in the research application, measuring their attitudes and effects towards smartphone usage (Lin et al., 2014), however, the SPAI data has not been analyzed for this paper. The participants used their personal smartphone for the duration of five weeks during which the interventions were performed and the research data was collected.

The first Baseline stage created a personal baseline of smartphone usage of a participant. During the second, Capability stage, at every unlock of the smartphone, the user was presented a nudge including the following information: the number of minutes that the phone was locked before the unlock event, the number of unlock events so far during the
ongoing day and the total duration that the screen has been turned on during the ongoing day. The purpose of this stage was to test the effect of information to the smartphone use. During the third, Motivational stage, a user was presented with a similar nudge to the second stage. Information in the nudge was preceded with a positively valenced injunctive emoticon if the smartphone user had lowered the smartphone usage and therefore the indicator value had improved: if smartphone was locked for longer than the average sleep time one week earlier, if the number of unlocks up to the current hour of the day was less than the number of unlocks up to the current hour of the day one week earlier, or if the total screen time up to the current hour of the day was less than up to the same hour of the day one week earlier. The purpose of this stage was to test the effect of positively valenced injunctive emoticon judged by an external authority.

In the beginning of the Goal-attainment stage, the user was prompted to select a goal for how much he or she wished to decrease the phone usage this week. If the user did not select a goal, the application used the default goal of $5 \%$ improvement to the previous week. Every time the user unlocked the smartphone, the application calculated if one or more of the indicators had improved more than the target percentage compared to the previous week's information. If the sleep time was at least $5 \%$ longer than the average sleep time in the previous week, if the number of unlocks was at least $5 \%$ less than the number of unlocks up to the same hour of the day in the previous week, or if the total duration of the screen time was at least $5 \%$ less than up to the current hour of the day in the previous week, the indicator was preceded with the same injunctive emoticon that was used in the Motivational stage.

As in the Motivational stage, the nudge in the Goalattainment stage built on the motivation component of the COM-B. However, as the stage included a task to define the percentage of the desired reduction in smartphone use, the goal-setting intended to direct attention and effort to reach the goal defined by the test subject. In order for the test subjects to easily maintain their state of goal attainment, the test subjects would have to reflect their phone usage before engaging with the phone, thus reducing phone usage. The purpose of this stage was to test the effect of goal-attainment, and the effect of injunctive emoticon based on a personally set goal. By prompting the test subject with active decisionmaking regarding the amount to reduce their smartphone use, it was expected that the test subjects would make effort to attain the goal that they had specified themselves.

As the study progressed to the fifth week, all notifications stopped, and application only recorded the user behavior for one week. In the same way with the first stage of the study, the fifth stage did not involve a nudge. The purpose of this stage was to investigate if users relapse to their prior behavior after the nudges are no longer present.

After full five weeks, the application notified the user that the study had been completed. However, the user could continue to use the application, and choose the type of nudge to present at every unlock. The test subjects had a choice to
continue to use the application, or uninstall the application from their smartphone.

## Data Analysis

A total of 606062 events were collected over the 5 -week study period were tested. These events were converted to 2304 observations, each of them representing one day of one test subject, equivalent to the definition of per day per user (pdpu) used in an earlier similar research (Oulasvirta et al. 2012). Five key indicators of smartphone usage were calculated from the research data: Total Screen On Time per day (SOT), Median Screen On Time of each session (Session Time), Total number of phone usage sessions per day (Unlocks), Number of phone usage sessions equal or shorter than 30 seconds in duration, over 10 minutes apart from the previous session (Glances) and Median Screen Off Time between two sessions (Median SFT). Of the 78 participants who completed the research, 58 chose to set their own goal in the goal-setting phase, whereas 20 participants got the default as a goal.

Time series of each key indicator was processed with Hilbert-Huang Transform (HHT). In this so-called sifting process, the time series of each key indicators were broken into intrinsic mode functions (i.e. IMFs) and by sequentially de-composing these intrinsic modes from the original signal, the remaining data represented the trend of the data over the study period. This analysis was compatible with the method used by Lin et al. (2015). Inferential statistics were performed to measure the effect of nudges in Capability, Motivational and Goal-attainment stages compared to the Baseline and to the Observation stages. The differences in key indicators were tested between the stages of the study for each test subject. The inferential statistic tests were done by performing independent-samples t-test using different stages of the study as a grouping variable, and each key indicator as test variable. Finally, a regression equation was calculated to predict a key indicator from another key indicator. The processing of the data was performed with the MatLab software package and the inferential analysis was performed with an SPSS statistical software.

## Results

There was a significant effect of intervention for SOT between Baseline and Capability stages. Between these stages, mean SOT lowered from 3 hours and 40 minutes pdpu to 3 hours and 14 minutes pdpu. The effect of intervention for SOT was also significant between the Baseline stage and the Motivational stage, as well as and between the Baseline and Goal-attainment stages. In the Motivational stage, SOT lowered to approximately 3 hours and 10 minutes, and to 3 hours and 13 minutes in the Goal-attainment stage. The decrease in SOT was not statistically significant when comparing the first stage to the last week, Observation stage, of the study. Table 1 below illustrates differences and statistical significance of SOT by stage.

Table 1: SOT by stage ( $\mathrm{N}=78$ ).

| Stages | Difference | Significance and effect size |
| :--- | :--- | :--- |
| 1 vs. 2 | -26 minutes | $\mathrm{t}(922)=2,888, \mathrm{p}<.01, \mathrm{~d}=0,19$ |
| 1 vs. 3 | -30 minutes | $\mathrm{t}(925)=3,356, \mathrm{p}<.01, \mathrm{~d}=0,22$ |
| 1 vs. 4 | -27 minutes | $\mathrm{t}(916)=2,871, \mathrm{p}<.01, \mathrm{~d}=0,19$ |

The difference in Session Time was significant between the Baseline stage and Observation stage. The mean duration of individual session increased from 51 seconds pdpu to 92 seconds pdpu. The difference was also significant between Capability and Goal-attainment stages, as well as between Capability and Observation stages. This difference was also significant between Motivational and Observation stages. The mean duration increased from 44 seconds in the Capability stage to 49 seconds in Motivational, to 63 seconds in Goal-attainment and finally to 92 seconds in Observation stage. The changes were not significant between adjacent stages. Table 2 below illustrates the changes in Session Time by stage.

Table 2: Session Time by stage ( $\mathrm{N}=78$ ).

| Stages | Difference | Significance and effect size |
| :--- | :--- | :--- |
| 1 vs. 5 | 41 seconds | $\mathrm{t}(913)=-2,466, \mathrm{p}<.05, \mathrm{~d}=-0,16$ |
| 2 vs. 4 | 5 seconds | $\mathrm{t}(920)=-2,298, \mathrm{p}<.05, \mathrm{~d}=-0,15$ |
| 2 vs. 5 | 19 seconds | $\mathrm{t}(917)=-2,945, \mathrm{p}<.01, \mathrm{~d}=-0,19$ |
| 3 vs. 5 | 33 seconds | $\mathrm{t}(920)=-2,674, \mathrm{p}<.01, \mathrm{~d}=-0,18$ |

The difference in Glances was only significant between Capability and Observation stages, $\mathrm{t}(917)=-2,006, \mathrm{p}<.05$. Mean Glances pdpu increased from 41,24 times in Capability to 45,55 times in Observation stage.

Simple linear regression was calculated to predict SOT based on Glances. Poor regression equation was found $(\mathrm{F}(1,2274)=142,124, \mathrm{p}<.000)$ with an R2 of .059 . Also, simple linear regression was calculated to predict Unlocks based on Glances. A significant regression equation was found $(\mathrm{F}(1,2274)=10188,592, \mathrm{p}<.000)$ with an R 2 of .818 .

Median SFT was significantly different between the last two stages when compared to the first three stages. However, due to the HHT being used in the pre-processing stage to address the non-linearity and non-stationarity of the research data, the comparison of the key indicator values using original units of measure might not be accurately depicted. Median SFT values after HHT pre-processing smoothed the data to a negative range without equivalent real world phenomenon. The changes in Median SFT can be characterized so that the difference in Median SFT is not significantly different between stages 1,2 and 3 , but Median SFT is markedly higher in stages 1,2 and 3 compared to stages 4 and 5 . The below Table 3 illustrates the trend of change in Median SFT by stage.

Table 3: Median SFT by stage ( $\mathrm{N}=78$ ).

| Stages | Significance and effect size |
| :--- | :--- |
| 1 vs. 4 | $\mathrm{t}(916)=3,194, \mathrm{p}<.01, \mathrm{~d}=0,21$ |
| 1 vs. 5 | $\mathrm{t}(913)=2,815, \mathrm{p}<.01, \mathrm{~d}=0,19$ |
| 2 vs. 4 | $\mathrm{t}(920)=3,194, \mathrm{p}<.01, \mathrm{~d}=0,21$ |
| 2 vs. 5 | $\mathrm{t}(917)=2,801, \mathrm{p}<.01, \mathrm{~d}=0,18$ |
| 3 vs. 4 | $\mathrm{t}(923)=2,299, \mathrm{p}<.05, \mathrm{~d}=0,15$ |
| 3 vs. 5 | $\mathrm{t}(920)=2,491, \mathrm{p}<.05, \mathrm{~d}=0,16$ |

## Discussion

There was a significant main effect for SOT between the Baseline stage and all of the three stages with the nudges. Consistent with COM-B framework (Michie et al., 2011) this change in SOT could be associated to an individual's aptitude to change their phone usage. Especially in the Capability stage the information pertaining to the user's phone usage was planned to be consistent with the definition of the type 1 transparent nudge (Hansen \& Jespersen, 2013). It can therefore be suggested that the effect of the nudge was significant enough to trigger an automatic reflection of smartphone use.

It is not possible to conclude that one type of nudge has higher significance to smartphone behavior than the other. Statistically significant decrease of SOT between the Baseline stage and both the Capability stage and the Motivational stage suggests that by using nudges that increase capability or motivational components can result to behavior change. However, there was no significant change in any of the key indicators between the different types of interventions.

Locke and Latham (2002) have earlier suggested that "the effects of goal setting are very reliable". Michie, Atkins and West (2014) have also reported that the interventions with "explicit targets and actions plans to feedback" had a higher impact compared to interventions without targets. According to Locke and Latham (2002), failures to replicate the effects of goal settings can be due to many reasons, including for example the lack of feedback, lack of commitment or failure to match the goal to the performance measure. It is possible that the key indicators used in this research do not mediate smartphone usage behavior. Also, by only providing positively valenced feedback about the goal attainment but inhibiting negatively valenced feedback about the failure to attain a goal could explain why this research could not successfully replicate the effects of goal setting.

The level of SOT per day ( 162 minutes) is in line with what Oulasvirta et al. (2012) reports, but it is only 62,3 percent of what Lin et al. (2015) reports as a median daily use time. Lin et al. (2015) report that the recruitment strategy in their study was "based on the potential higher penetration rate of smartphone use". Montag et al. (2015a) have written that substantial part of the sample in Lin et al.'s (2014) study was characterized as being smartphone addicted. The difference in the level of usage compared to Lin et al.'s research results
may suggest that the sample in this research did not include substantial amount of problematic smartphone users or smartphone addicts.

There was a significant difference in Session Time between number of stages as indicated in Table 2. In these comparisons with Observation stage, the Session Time increased from the stage under comparison.

The difference in Glances was only significant between the Capability stage and the Observation stage. Oulasvirta et al. (2012) define intermittent smartphone use as SIRB, short duration isolated, reward-based usage sessions. This definition includes a notion about the type of application: "at least $50 \%$ of the usage session duration is spent interacting with applications that provide the reward values". The definition of Glances is not therefore fully compatible with the definition of SIRBS.

There was no evidence that nudges can reduce the number of Glances. Oulasvirta et al. (2012) have suggested earlier that "checking habits may lead to more use overall". Poor regression equation to predict SOT based on Glances did not support Oulasvirta et al.'s previous findings, however, significant regression equation to predict Unlocks based on Glances would suggest that even though changes in Unlocks were not statistically significant during the research, Unlocks can be expected to increase after the nudges are no longer in effect. Oulasvirta et al. (2012) have earlier concluded that the increased "checking habit" is associated with higher phone usage overall. Oulasvirta et al. (2012) suggest that short sessions act as a "gateway" for other content on the device, and that they can be seen as a proxy for habitual usage.

Median SFT was significantly lower from Motivational stage onwards compared to the baseline. It was not possible to find a report that would have included at least descriptive statistics about the Session Time or Median SFT. In this research, Session Time was 23 seconds, and Median SFT was 198,50 seconds. Due to the lack of prior reported research evidence, these numbers provide little basis for inferential or comparative analysis. Davis (2001) has suggested that procrastination has a role in both the development and maintenance of generalized PIU. However, based on the data from this research it is not evident if a more frequent engagement with the phone is due to the test subjects putting off their responsibilities - as Davis suggests - or due to other reasons.

It can be theorized that the changes in SOT and Median SFT is due to the test subjects reducing their screen time overall even if they engaged with their phone more frequently. In the Goal-attainment stage the nudge was built on Motivational component in COM-B framework, proposing that the explicit goal is associated with lower phone usage. Evidence referred by Klasnja (2009) have proposed that the automatic goal activation can be triggered with presentation of salient information. It is possible that the nudge in the Capability stage had already triggered automatic goal activation, and the differences in nudges between the stages were not significant enough to trigger additional ways of behavior change beyond what was already active from the

Capability stage onwards. This could support an unchanged amount of glances throughout the experiment, although it remains unclear what triggered an increase in the mean Glances in the Observation stage.

Neither Session Time nor the number of unlocks lowered significantly between the Baseline and Capability stage. One possibility is that there was a mere-measurement effect from the beginning of the study and the users made an effort to generally lower the amount of engagement with the phone throughout the study by spending less time with the phone at each unlock. Another possibility is that the users generally reflected their phone usage and did not unlock the phone as often as before. In this case, as soon as they would engage with their phones, they would approximately spend the same amount of time with their phone, but that would happen less often. The changes can, however, be so small that it is not statistically significant for Unlocks or Median SFT. If the latter assumption was true, it would suggest that automatic goal may have triggered users to reflect their phone usage before they engage with their phone. As SOT was significantly or highly significantly lower in all stages of the study compared to the Baseline stage, the observation could be a sign of learning the phone usage behavior resulted by the interventions.

According to these results, a systematic relapse in behavior was seen after the interventions were no longer in effect. Block (2008) has earlier reported that the individuals with internet addiction are resistant to treatment and tend to relapse at a high rate. The findings from this research are compliant with Block's suggestion, although it is not possible to associate the findings from this research to a relapse based on psychiatric reasons.

Even though this research supports both Klasnja et al.'s (2009) as well as Oulasvirta et al.'s (2012) conclusion that interventions can help trigger behavior change, this research does not support the proposition that interventions can help maintain a behavior change.

This research does not provide evidence that the type of nudge explains differences in the number of unlocks or glances per day. It is possible that this is due to the path dependence between the stages of the research and the lack of a control group. Even though there was statistically significant different in the mean Glances between the Capability and the Observation stage, this finding is not supported by current literature. More evidence would be required to prove relapse in smartphone use resulting from the absence of a nudge, by randomizing the order of stages in the research and by introducing a control group.

It can be concluded that nudges can help lower key indicators of smartphone use, however, this might increase intermittent glancing and result to overall increased usage of the phone when the interventions are no longer present.

# Auditory and Visual Contributions to Multisensory Integration 

Jessica L. Parker (parker.1026@osu.edu)<br>Department of Psychology, The Ohio State University at Newark<br>1179 University Dr., Newark, OH 43056, USA<br>Christopher W. #### Abstract

Multisensory integration, or the merging of information from multiple sensory modalities, is important for many everyday tasks. One methodology used for examining this process is the Sound Induced Flash Illusion (SIFI), which presents participants with a number of flashes and either the same number of beeps (congruent) or a different number of beeps (incongruent), and requires the participant to respond by entering how many flashes they saw. The study expands on this research by examining the relative contributions of auditory and visual information on multisensory integration. While congruent and incongruent auditory stimuli affected visual perception (Experiment 1), there was little evidence that visual input affected auditory processing (Experiment 2). These findings support auditory dominance and modality appropriate hypothesis in adult populations and have implications on tasks that require integration across auditory and visual modalities.

Keywords: Crossmodal Processing; Multisensory Integration; Modality Dominance; Sound Induced Flash Illusion

## Introduction

A majority of our daily experiences require people to process multisensory information. As a person walks down the street, for example, they may see a car driving by, hear the engine as it approaches, smell the exhaust and feel the breeze as the car passes. How information from the different sensory modalities is integrated and combined into a unitary percept is considered multisensory integration (Shams, 2000). Using the example above, these multisensory experiences are perceived as one percept (car) instead of having independent experiences. Given the evident impact of multisensory integration in our everyday experiences, it is important to understand the contributions of auditory and visual contribution to multisensory integration and factors that facilitate and inhibit multisensory integration.

Shams, Kamitani, and Shimojo (2000) developed a test of multisensory integration called the Sound Induced Flash Illusion (SIFI), where the number of beeps influences how many flashes people see. In their study, they presented one, two, or three flashes, and in the cross-modal condition, these flashes were paired with one, two or three beeps. Participants were then asked to report how many flashes they saw, regardless of how many beeps they heard. If the number of beeps exceeded the number of flashes, participants tended to overestimate the number of flashes (fission). If the number of
beeps was less than the number of flashes, participants tended to underestimate flashes (fusion). Fission and fusion responses are implications of multisensory integration. This shows that the auditory information is being integrated with the visual information. Another study, using a different procedure and stimuli, tested perception of beeps to see if they could create a flash-induced sound illusion (Andersen, 2004). Under normal intensity levels, the visual flashes had no effect on auditory perception; however, they did find some evidence that flashes influenced beep perception when intensity levels of beeps were weakened to near threshold levels. This finding, in conjunction with Shams et al., may suggest that auditory information has a stronger effect on visual processing than vice versa; however, there were also numerous differences across studies; thus, making it difficult to make strong conclusions.

Why do auditory beeps affect participants' perception of the number of visual flashes? One possible explanation underlying this illusion is auditory dominance (Robinson \& Sloutsky, 2010a). According to this account, auditory and visual stimuli compete for attentional resources; thus, increased attention to one modality might come with a cost delayed or attenuated processing in the other modality. Moreover, because auditory stimuli are dynamic and transient, it may be adaptive to first allocate attention to the auditory modality before the information disappears. Most of the supporting research for auditory dominance comes from the developmental literature, where multisensory presentation attenuates visual processing more than auditory processing (Lewkowicz, 1988a; 1988b; Robinson \& Sloutsky, 2004; 2010b; Sloutsky \& Napolitano, 2003; Sloutsky \& Robinson, 2008). According to this account, the beeps in SIFI may interfere with processing of the visual flashes; whereas, the visual input may have little effect on processing of the beeps. Another possible reason why beeps may affect flash perception is modality appropriateness hypothesis, which states that the modality that is more appropriate for the task is the one that dominates (Welch \& Warren, 1980). Welch and Warren (1980) describe that with information processing, vision is dominant in spatial situations and audition is dominant for temporal judgements. When these two modalities are simultaneously presented and the task has a temporal aspect, studies have shown that audition becomes the dominant modality and can influence vision (Wada, Kitagawa, \& Noguchi, 2003). Thus, both
auditory dominance and modality appropriateness predict that auditory input should have a greater effect on visual perception than vice versa, especially when the task is temporal in nature (but see Tsay, 2013, where visual information affected judgements about musical performance).

Predicting that auditory information will have a greater effect on visual processing conflicts with much of the past research with adults that showed visual dominance, where the simultaneous presentation of auditory and visual information seems to inhibit auditory processing (see Sinnett, Spence, \& Soto-Faraco, 2007, and Spence, Parise, \& Chen, 2012). For example, when adults were required to press one button when they detected a visual stimulus, a different button when they detected an auditory stimulus, and a third button (or both buttons) when both stimuli were presented at the same time, participants often made errors on cross-modal trials by only pressing the visual button (Colavita, 1974). Thus, visual dominance tends to occur when adults are required to make speeded, modality-specific responses to auditory, visual, and crossmodal stimuli (Colavita, 1974; see Sinnett, Spence, \& Soto-Faraco, 2007 for review). One possible explanation for visual dominance is that adults may have a visual response bias to compensate for the fact that visual input is less alerting than auditory (Posner et al., 1974). It is important to note that the current study testing the SIFI is different from some of the modality dominance studies because it requires quantity judgements (how many beeps or flashes), rather than requiring speeded, modality-specific responses to auditory or visual input.

The current study used a modified SIFI task to test both auditory and visual processing and expands previous research in three ways. First, the study expands SIFI research by examining the relative contributions of the auditory and visual modalities in multisensory integration, as opposed to only examining the effects of auditory input on multisensory integration or visual input on multisensory integration. Second, the current study expands SIFI research by using facilitation effects (greater accuracy on cross-modal congruent trials than unimodal trials) as a measure of multisensory integration. Do congruent auditory or visual stimuli increase the accuracy of beep/flash perception? Finally, the current study will contribute to the modality dominance literature by using quantity judgements and accuracy (how many beeps or flashes) rather than speeded, modality-specific responses to auditory and visual information. Experiment 1 examined the effect of beeps on perception of flashes (replicating most SIFI studies), and Experiment 2 tested the effect of flashes on perception of beeps. Based on auditory dominance and modality appropriate hypothesis (Robinson \& Sloutsky, 2010a; Welch \& Warren, 1980), it is expected that congruent and incongruent auditory information will have a stronger effect on visual perception, whereas, it is expected that visual input will have a weak or no effect on auditory perception.

## Experiment 1

## Method

Participants Participants for Experiment 1 included 24 young adults ( 18 to 35 years). Young adults were recruited from the Ohio State University, and received class credit for the Introductory Psychology course in return for their participation. Three participants with uncorrected hearing or vision, as self-reported, were excluded from the data analyses.

Apparatus The experiment was conducted on a 22 " Dell PXL 2230 MW monitor with $1920 \times 1080$ resolution and Dell Optiplex 7040 systems with Intel Core i5 processors. Bose QuietComfort 25 Noise Cancelling headphones were used for auditory stimulus presentation. Stimulus timing and presentation and reaction time/accuracy data was collected using Direct RT software.

Materials The visual stimulus was a white circle $2^{\circ}$ in visual angle in the center of the screen with a black background. Each flash has a 20 ms duration with a 50 ms Inter-Stimulus Interval (ISI) between consecutive flashes. The auditory stimulus was a sine wave presented at 3.5 kHz (no rise or decay ramps). Each beep lasted for 20 ms , and there was a 50 ms ISI in between consecutive beeps. Auditory stimuli were presented via headphones at approximately 50 dB . In the crossmodal condition, the first beep occurred 35 ms before the first flash, or vice versa. The beep first and visual first conditions were randomized among the participants. Figure 1 shows the timing of the stimuli. The stimuli and timing was modeled after the original SIFI study (Shams, Kamitani \& Shimojo, 2000). Based on previous research and on preliminary analyses, the asynchronous timing had no significant effect on the SIFI.

Figure 1. Timeline of a 2 flash $/ 2$ beep stimuli. The dark blocks represent presentation of the stimuli and the grey represent ISI. The numbers above represent the time in ms from the beginning of the stimulus.

Design The experiment consisted of three blocks: visual unimodal, auditory unimodal, and crossmodal. There were five trials for each stimulus in the unimodal visual condition ( 2 flashes, 3 flashes, 4 flashes), and there were five trials for each possible stimulus in the unimodal auditory condition (2 beeps, 3 beeps, 4 beeps). There were also five trials of each possible stimulus in the crossmodal conditions (1 flash/1 beep, 1 flash $/ 2$ beeps, 1 flash $/ 3$ beeps, etc.). See Table 1 for all stimulus frequencies. Of the crossmodal trials, 15 were congruent and 30 were incongruent. Congruent trials had the same number of flashes and beeps, and incongruent had different numbers of flashes and beeps), which provided conflicting information.

Procedure In the unimodal auditory condition, participants heard 2, 3, or 4 beeps, and were asked to report how many beeps they heard. In the unimodal visual condition, they saw 2,3 , or 4 flashes and were asked to report how many they saw. In the crossmodal condition, participants were presented with 2,3 , or 4 beeps and/or 2,3 , or 4 flashes, and they were asked to report only how many flashes they saw. Each condition had a set of instructions before the trials and a conclusion to let the participant know when the condition was over. The order of condition was randomized among the participants, and each trial started within a condition started approximately 1000 ms after responding to the previous trial.

| Unimodal |  |
| :---: | :---: |
| Auditory | Visual |
| 2 Beeps (5) | 2 Flashes (5) |
| 3 Beeps (5) | 3 Flashes (5) |
| 4 Beeps (5) | 4 Flashes (5) |
| Crossmodal |  |
| *2 Flashes/2 Beeps (5) |  |
| *3 Flashes/3 Beeps (5) |  |
| * Flashes/4 Beeps (5) |  |
| 2 Flashes/3 Beeps (5) |  |
| 2 Flashes/4 Beeps (5) |  |
| 3 Flashes/2 Beeps (5) |  |

| 4 Flashes/3 Beeps (5) |  |

Table 1: Experiment 1 trial types and frequencies. Note, "*" denotes congruent trials.

## Results and Discussion

On each trial, participants reported how many flashes they perceived. Below we first report overall accuracies and then we report more traditional analyses focusing on actual responses ( 2,3 , or 4 ) and making a distinction between fission trials (more beeps than flashes) and fusion trials (fewer beeps than flashes).
Accuracy Each trial was classified as correct or incorrect. See left side of Figure 2 for means and standard errors of visual responses and the right side of Figure 2 for unimodal auditory accuracy. Analyses in Experiment 1 focus exclusively on visual responses. Using a 3 (number: 2, 3, 4) x 3 (trial type: congruent, incongruent, unimodal baseline) repeated measures ANOVA, a significant effect of condition was found, $F(2,46)=68.31, p<.001, \eta_{p}{ }^{2}=.75$. Accuracies were lower on unimodal trials $(M=.53, S E=.03)$ than congruent trials $(M=.66, S E=.03), t(23)=-3.613, p=.001$, which is consistent with facilitation effects. Interference effects were also found with higher accuracy on unimodal trials than incongruent trials $(M=.21, S E=.09), t(23)=8.42$, $p<.001$. Also, accuracy was also higher on congruent trials than incongruent trials, $t(23)=9.91 p<.001$.

The ANOVA also revealed a significant effect of number, $F(2,46)=17.05, p<.001, \eta_{p}{ }^{2}=.43$, with accuracy decreasing as the number of flashes increased. There was significantly higher accuracy on the 2-flash trials ( $M=.56$, $S E=.03)$ than on the 4 -flash trials $(M=.31, S E=.04), t(23)$ $=4.47, p<.001$. The 3-flash trials $(M=.53, S E=.03)$ also had a higher accuracy than the 4-flash trials, $t(23)=5.02, p$ $<.001$. Finally, the analyses also revealed a trial type x number interaction, $F(4,92)=5.32, p=.001, \eta_{p}{ }^{2}=.188$. As can be seen in Figure 2, cross-modal facilitation effects (congruent > unimodal) was most pronounced when presented with four flashes, and interference effects (unimodal > incongruent) decreased, with the strongest interference on 2-flash trials.

Figure 2. Accuracies across number and trial type. Error Bars denote Standard Errors.

The remaining analyses focus on actual responses ( 2,3 , or 4 ), not accuracies. On fission trials, there were more beeps than flashes, and on fusion trials, there were fewer beeps. Moreover, for fission and fusion cross-modal trials, we could only test two of the three numbers. For example, as can be seen in Table 1, there were no fission trials for 4 flashes and no fusion trials for 2 flashes because there were no trials where we presented five or one auditory stimulus, respectively. Thus, we used two $2 \times 2$ repeated measures ANOVA's to test for fission and fusion effects.

Fission Actual responses were collected on each trial and only fission trials and unimodal trials were submitted to a 2 (trial type: unimodal, fission) x 2 (number: 2, 3) repeated measures ANOVA. See left side of Figure 3 for means and standard errors. A significant effect of trial type was found, $F$ $(1,23)=71.41, p<.001, \eta_{p}^{2}=.76$, suggesting that auditory input affected perception of flashes. In particular, participants reported more flashes on fission trials $(M=3.23, S E=.08)$ than unimodal trials $(M=2.54, S E=.06)$, which was expected since there were more beeps than flashes. There was also a significant effect of number, $F(1,23)=60.15, p<.001$, $\eta_{p}{ }^{2}=.72$. Not surprisingly, participants on 2-flash trials ( $M=$
2.68, $S E=.05$ ) reported fewer flashes than on 3-flash trials ( $M=3.09, S E=.07$ ).

Fusion Actual responses were collected on each trial and only fusion trials and unimodal trials were submitted to a 2 (trial type: unimodal, fusion) x 2 (number: 3, 4) repeated measures ANOVA. See right side of Figure 3 for means and standard errors. A significant effect of trial type was found, $F$ $(1,23)=15.87, p=.001, \eta_{p}^{2}=.41$, which suggests that the number of beeps affected perception of flashes. Participants reported fewer flashes on fusion trials $(M=2.56, S E=.03)$ than on unimodal trials $(M=2.95, S E=.09)$, which was expected since there were fewer beeps than flashes. There was also a significant effect of number of stimuli on response, $F(1,23)=62.16, p<.001, \eta_{p}{ }^{2}=.73$, with participants reporting fewer flashes on 3-flash trials $(M=2.57, S E=.045)$ than 4-flash trials $(M=2.94, S E=.06)$.

Figure 3. Actual responses across number and trial type. The left side of the figure denotes fission trials and the right side denotes fusion trials. Error Bars denote Standard Errors.

## Experiment 2

The purpose of Experiment 2 was to test if the relative contribution of auditory and visual information on multisensory integration was symmetrical or asymmetrical. In cross-modal trials of Experiment 2, participants were asked to report how many beeps they heard. It was hypothesized that the effects would be asymmetrical, with visual input in Experiment 2 having little to no effect on auditory processing.

## Method

Participants, Materials, and Procedure Experiment 2 was identical to Experiment 1, with the exception that we tested effects of flashes on beep perception; thus, the same participants from Experiment 1 were told to respond to report out how many beeps they heard, regardless of how many
flashes they saw. To ensure that they were paying attention to the visual stimuli and did not shut their eyes in the crossmodal condition, a green visual stimulus (small green square) was presented for each possible trial type, and participants were asked to hit the space bar instead of 2,3 , or 4 when they saw the green stimulus. Five participants were removed because they did not detect the green catcher stimulus on at least $75 \%$ of the trials.

## Results and Discussion

Accuracy See left side of Figure 4 for mean accuracies and standard errors on auditory response trials and right side of Figure 4 for unimodal visual responses. Experiment 2 focused exclusively on auditory responses. Using a 3 (number: 2, 3, 4) x 3 (trial type: baseline, congruent, incongruent) repeated measures ANOVA, a significant effect of number of beeps presented was found, $F(2,46)=19.15, p$ $<.001, \eta_{p}{ }^{2}=.45$. Based on the data, there was significantly higher accuracy on the 2-flash trials $(M=.80, S E=.03)$ than on 3-flash trials $(M=.67, S E=.04), t(23)=2.75, p=.011$, and 4-flash trials $(M=.48, S E=.05), t(23)=5.22, p<.001$. The 3-flash trials also had a higher accuracy than 4-flash trials, $t(23)=4.09, p<.001$. In addition, a condition x number interaction was observed, $F(4,92)=3.36, p=.013$, $\eta_{p}{ }^{2}=.13$. No differences were found across trial types for 2and 4-flash trials; however, congruent and incongruent trials both exceeded the baseline on 3-flash trials, $t \mathrm{~s}(23)>-1.94$, ps < . 033 (one-tailed).

Figure 4. Accuracies across number and trial type. Error Bars denote Standard Errors.

Fission Actual responses were collected on each trial and only fission trials and unimodal trials were submitted to a 2 (trial type: unimodal, fission) x 2 (number: 2, 3) repeated measures ANOVA. See left side of Figure 5 for means and standard errors. Using a 2 (condition: unimodal, fission) x 2 (number: 2, 3) repeated measures ANOVA, a significant effect of number of stimuli presented on response was found, $F(1,23)=160.07, p<.001, \eta_{p}{ }^{2}=.87$. The 2-flash trials $(M=$ $2.24, S E=.04$ ) had a significantly lower response than the 3flash trials $(M=2.96, S E=.06), t(23)=-12.65, p<.001$.

There was no effect of trial type, suggesting that flashes did not affect beep perception.

Fusion Actual responses were collected on each trial and only fusion trials and unimodal trials were submitted to a 2 (trial type: unimodal, fusion) x 2 (number: 3, 4) repeated measures ANOVA. See right side of Figure 5 for means and standard errors. A significant effect of number of stimuli presented on response was found, $F(1,23)=60.30, p<.001$, $\eta^{2}=.72$. The 3-flash trials $(M=2.95, S E=.06)$ had a significantly lower response than the 4-flash trials ( $M=3.40$, $S E=.08), t(23)=-7.77, \mathrm{p}<.001$. Again, there was no effect of trial type, suggesting that the flashes did not affect beep perception.

Figure 5. Actual responses across number and trial type. The left side of the figure denotes fission trials and the right side denotes fusion trials. Error Bars denote Standard Errors.

## General Discussion

Many tasks require processing and integration of multisensory information. The primary goal of the current study was to examine relative contributions of auditory and visual information on multisensory integration. In Experiment 1, we hypothesized that auditory information would have a strong effect on visual processing, as seen in Shams et al. (2000). The results of Experiment 1 supported this hypothesis. In particular, when auditory and visual information provided the same information (congruent trials in Figure 2), adults were more accurate at reporting the number of flashes. Moreover, incongruent trials also affected visual perception. Participants overestimated the number of flashes when the flashes were paired with more beeps (fission trials in Figure 3) and underestimated the flashes when paired with fewer beeps (fusion trials in Figure 3). In Experiment 2, it was hypothesized that the visual information would not have as strong of an effect on the auditory processing, based on auditory dominance (Robinson \& Sloutsky, 2010a) and the modality appropriateness hypothesis (Welch \& Warren, 1980). The results of Experiment 2 supported this hypothesis,
as most of the analyses showed that the visual information had no effect on auditory processing.

This expands the SIFI research by observing the effects of both auditory and visual information on multisensory integration. According to our knowledge, previous research has only focused on effects of auditory input on visual processing or vice versa; thus, these studies cannot determine if effects are symmetrical. The current study also used facilitation effects as a measure of multisensory integration. Facilitation effects were observed, and performance on the congruent trials was better than performance on the unimodal trials (baseline). These effects are seen in the visual responding condition with auditory input facilitating visual processing, but were not seen in the auditory responding condition. This asymmetry is consistent with both auditory dominance (Robinson \& Sloutsky, 2010a) and the modality appropriateness hypothesis (Welch \& Warren, 1980).

This study also expands modality dominance literature by measuring quantitative responses, rather than just response times, as seen in visual dominance research. Visual dominance has been observed for the past forty years in adults, showing that visual input often dominates auditory processing when making speeded, modality specific responses (e.g., Colavita, 1974). The findings of the current study were not tied to speeded modality specific responses, but were associated with accuracy of quantitative judgments. The findings support auditory dominance and modality appropriateness hypothesis and show that auditory input has a larger effect on visual processing than vice versa. Future research could take further measures to separate these two findings, as it cannot be distinctly determined whether the results are an effect of auditory dominance or modality appropriateness. Finally, it will be important to examine the role of stimulus intensity on multisensory integration, as changes in unimodal sensitivity may underlie developmental changes in multisensory integration. In particular, increased multisensory integration with age might stem from older adults compensating for weakened unimodal processing (DeLoss, Pierce, \& Anderson, 2013). While Anderson (2004) found that weakening the auditory stimulus to near threshold increased visual effects on multisensory integration, weakening both modalities tends to decrease the SIFI (Parker \& Robinson, in prep), and it is unclear how weakened auditory stimuli affect multisensory integration.

In summary, most of our experiences are multisensory in nature and it is important to understand how auditory and visual information contributes to multisensory integration. Future research needs to examine how this ability changes across the lifespan.

# The effect of acute physical activity on children's memory for language 

Carla Pastorino Campos (cap72@cam.ac.uk)<br>Department of Theoretical and Applied Linguistics, 9 West Road Cambridge, CB3 9DP UK

John N. Williams (jnw12@cam.ac.uk)<br>Department of Theoretical and Applied Linguistics, 9 West Road Cambridge, CB3 9DP UK

#### Abstract

Research on the relationship between acute physical activity and cognition in children has often found beneficial effects of exercise on a variety of cognitive abilities. One domain that remains underexplored, however, is the relationship between exercise and long-term memory in children, and in particular whether the general-domain effects observed in previous studies could translate to a school-based learning activity, such as vocabulary learning. To address this issue, this study focused on the possible effects that a bout of moderate, aerobic physical activity could have on the immediate and delayed recall of newly acquired word forms and formmeaning connections of children in a school setting. In line with previous research, the results show a positive effect of exercise, but only for word form recall. This study expands our understanding of the differential effects of exercise on memory, while raising questions regarding the possible moderating influence of gender and memory consolidation.

Keywords: language acquisition, acute physical activity, memory, vocabulary learning, child cognition.

## Introduction

Research on the effects of physical activity has consistently shown that children who lead an active lifestyle also have healthier bodies, and that exercise plays a significant role in the prevention and control of certain diseases, including, but not limited to, obesity and cardiovascular disease (Kesaniemi et al., 2001). The effects of exercising, however, are not purely physiological. Over the last couple of decades, a growing body of research has concentrated on the effects of physical activity on the developing mind, mainly focusing on whether acute or chronic physical activity can influence cognition.

Interest in the effects of exercise on cognition was sparked by the observation that exercising provokes a series of transient cardiorespiratory, hormonal and metabolic changes that affect the brain's function and organization. These changes ultimately influence the way in which humans, and other animals, perform cognitive activities, including those involving executive function, attention, and memory (Coles \& Tomporowski, 2008; Hötting \& Röder, 2013; McMorris, Turner, Hale, \& Sproule, 2016). In recent work, memory consolidation has emerged as a process that could be particularly affected by physical activity (Robertson \& Takacs, 2017). The possible pathways by which exercise-induced arousal may affect long-term memory are still not entirely understood. However, it has
been suggested that exercise-induced upregulation of catecholamines, cortisol or brain-derived neurotrophic factor (BDNF), a protein shown to be involved in neurogenesis and neuroplasticity, could underlie the effects of acute physical activity on memory processes (McMorris et al., 2016; Roig et al., 2016).

Regarding child cognition, few studies have focused on the possible effects of physical activity on children's longterm memory. An exception would be the work of Pesce and colleagues (Pesce, Crova, Cereatti, Casella, \& Bellucci, 2009) who studied the performance of a group of 11 and 12-year-old students in an immediate and delayed ( 12 minutes later) free-recall test. The participants attended several learning sessions, two of which were preceded by a physical education class, one involving high cognitive and social demands (team games) and one with low demands (circuit training). Delayed recall improved for both exercise conditions when compared with the rest condition, whereas immediate recall improved only after the team games. More recently, Etnier, Labban, Piepmeier, David, \& Henning, (2014) observed children's performance on the Rey Auditory Verbal Learning Test - intended to evaluate verbal learning and memory, administered after a period of physical activity or rest. The participants were tested immediately and 24 hours later. Results showed that participants who exercised had better memory retention immediately, but not 24 hours later.

These studies provide interesting insights regarding the effect of exercise on children's memory, yet they focus on general-domain cognitive abilities, tested through tools that do not closely resemble ordinary classroom activities. In both experiments, the participants were tested on their recall of already known words, a task that, though related to different aspects of memory, does not involve learning new linguistic information, such as word forms or form-meaning connections. Learning such linguistic information is at the core of one standard part of school curricula around the world: second/additional language learning. Therefore, it would be of interest to extend the findings of these studies by assessing whether the advantages noticed in these general memory tasks could translate to a particular language learning activity, such as vocabulary learning.

There is some precedent for this type of studies in research done with adults. For example, despite some differences in the experimental designs, benefits of a moderate to intense bout of exercise were found for
vocabulary learning, achieved through the association of translation equivalents (Schmidt-Kassow et al., 2013; Schmidt-Kassow, Kulka, Gunter, Rothermich, \& Kotz, 2010) or through a statistical, associative learning paradigm (Winter et al., 2007). These encouraging results, however, have not yet been observed in children.

Based on the brief review of the literature presented above, the primary purpose of this study was to assess the possible effects of a bout of aerobic, moderate physical activity on children's memory for language learning. In particular, we were interested in observing whether exercising before encoding could lead to a higher rate of recall immediately after learning and after a delay. Acquiring new vocabulary items is a complicated process that involves many different learning activities, from item segmentation to the integration of novel items to existing networks. In this instance, however, we have chosen to focus on only two of these activities: the acquisition of the word's phonological/orthographical form and the linking of the newly acquired form to a meaning. From the results of previous studies and the theorized mechanisms underlying the exercise-cognition effect, we hypothesize that children in the exercise group would exhibit increased recall of both forms and meanings in the delayed tests, after a period of consolidation including sleep.

## Method

## Participants

51 school-aged children (mean age $=9.3,25$ females) were recruited at their school to participate in this experiment. All children were monolingual Spanish speakers, with no knowledge of other languages besides school-level English. None of the children had visual or hearing impairments, nor cardiac or respiratory conditions that would prevent them from exercising at a moderate pace. As reported by their parents or tutors, the children had normal sleeping patterns, with an average sleeping time of 8.5 hours per night.

## Materials

Pseudowords Twenty-four bisyllabic, pronounceable pseudowords were created using legal Spanish consonant/vowel combinations. All pseudowords were four letters long and followed a CVCV pattern. Care was taken to ensure that an equal amount of pseudowords were 'masculine' (ended with 'o') and 'feminine' (ended with ' $a$ ').

Pictures Twenty-four pictures of everyday objects extracted from a subset of Rossion \& Pourtois' (2001) pictorial set, which was based on Snodgrass \& Vanderwart's (1980) original standardized set of visual stimuli but with added detail and colour. For this experiment, we transformed the pictures to greyscale to preserve the enhanced details while avoiding the distraction of colour. Pertinent country-specific normative data was used to assess the concreteness and imagery ratings of the objects depicted (Manoiloff, Artstein,

Canavoso, Fernández, \& Segui, 2010). Following Pesce et al's (2009) procedure, the objects were evaluated by classroom teachers to ensure that they would be recognizable and familiar to the children.

Learning lists Each pseudoword was randomly paired with one of the pictures selected. We divided the pseudoword/picture pairings into two lists of 12 items, that would be presented in different experimental sessions. The order of presentation of both the learning and testing stimuli was randomized for each group.

## Procedure

The experiment used a within-subjects design, counterbalancing the order in which the children participated in each of the experimental conditions, exercise, and no-exercise (control).

The experiment was carried out at the participants' school, during school hours, with the assistance of classroom and physical education teachers. Participants attended six sessions spread over three weeks. The first and fourth sessions started with an intervention stage, where participants either performed a 30 -minute bout of aerobic physical activity (exercise condition) or remained in the classroom doing a passive activity (drawing and colouring) for the same amount of time (control condition). After the intervention, and after a 5 -minute recovery time for the exercise group, the children performed the vocabulary learning activity. In the final stage of the first session, the children were asked first to write down all the words they remembered, regardless of the order of presentation (free recall) and later to write down the words corresponding to the pictures shown in posters by the teachers (cued recall). The free and cued recall tasks constituted the first testing session (immediate test).

This testing phase was repeated on sessions two and three for the pairings learnt in session one, and on sessions five and six for the pairings learnt in session four.

All participants were exposed to both learning lists and took part in both intervention conditions (exercise or control); the order of the interventions was counterbalanced and randomized so that some participants exercised on session one while others exercised on session four.

The experimental procedure is schematized in Figure 1.
Vocabulary learning activity The children were exposed to the lists of 12 pseudoword/picture pairings, presented in printed posters, and shown at a regular interval. The classroom teachers led the presentation, reading the pseudoword aloud and asking the children to repeat it back. This exposure was repeated three times.

Testing tasks Two testing tasks were intended to separately measure children's ability to recall the phonological form as well as the form-meaning connections of the pseudowords learnt in the exposure phase.

Figure 1: Experimental procedure. L1 = word list 1, L2 = word list $2,24 \mathrm{~h}=24$ hours later, $6 \mathrm{~d}=6$ days later, $1 \mathrm{wk}=1$ week later.

The first task, free recall, was designed to assess whether the participants could remember the phonological forms of the newly acquired pseudowords, without prompting from their associated meanings. To perform this task, the teachers instructed the students to write down all the pseudowords they could remember, irrespective of the order of presentation or their ability to associate the words with the drawings.

For the second task, cued recall, the teachers showed the students only the pictures, and the children had to write down which pseudoword corresponded to each picture shown. The pictures were shown at a steady pace, and the children were instructed to leave blank spaces for the pictures they did not remember. This test intended to observe if children could recall the form-meaning connections they had previously learnt.

Physical activity intervention The physical activity intervention consisted of 30 minutes of child-adapted circuit training, focalised on activities that would engage the aerobic system. We chose this type of exercise task since it maintains a major focus on aerobic exercise - as opposed to group games, for example, that may be more cognitively and socially demanding - while still being part of what students normally do in their physical education classes, and thus ecologically valid. The task took place in the school's playground under the supervision of the children's physical education teachers (student-to-teacher ratio $=15: 1$ ).

We used a modified Borg Scale of Perceived Exertion (Borg, 1998) to assess exercise intensity. It was administered to the children in the exercise condition while
they were performing the activities. This scale has been widely used for children in similar contexts and has proved to be reliable not only in assessing intensity but also in determining the nature of the exercise being conducted (aerobic versus anaerobic). By maintaining the general perceived exertion of the group in the second tier (considered "moderate" in our scale), it was assured that the children were performing aerobic exercise at a moderate intensity.

## Results

## Data pre-processing

Ten participants were removed from the final sample, two for reporting learning or psychological conditions that might interfere with the experiment's outcome and eight for not having participated in either of the two experimental conditions (exercise or control). Given that a significant number of children were absent on the day of the very delayed test, for reasons not related to the experiment, we excluded the very delayed test (sessions three and six) in the reported analyses. To keep the design balanced, we additionally removed two participants for not having completed the delayed testing session. All analyses were carried out on the remaining 39 participants (mean age $=$ 9.32, 21 females).

We computed an accuracy score for each testing activity (free or cued recall) by summing all the correct responses given at each testing time. Participant responses were given one point when they matched exactly one of the taught pseudowords (e.g. lofa/lofa), and half a point if the answer had one substitution (e.g. lofa/lifa). For the cued recall task, the responses had to match one of the pseudowords in the taught set in addition to matching the corresponding picture. Partial matches that were placed with the correct picture were awarded half a point.

All statistical analyses were performed using R (R Core Team, 2016) and the ez package (Lawrence, 2016).

## Free recall

A two-way analysis of variance was conducted to evaluate the effects of the experimental condition and testing time on the number of items recalled in the free recall task. Experimental condition (exercise vs. control) and testing time (immediate vs. 24 hours later) were included as factors. No significant effect of experimental condition, $\mathrm{F}(1,38)=$ $1.092, \mathrm{p}=.302$, or testing time, $\mathrm{F}(1,38)=.032, \mathrm{p}=.574$ was found. However, the interaction between exercise intervention and testing time was significant, $\mathrm{F}(1,38)=$ 5.932, $\mathrm{p}=.019, \eta_{\mathrm{g}}{ }^{2}=.006$ ). As shown in Figure 2, it would seem that, whereas there is no difference in the immediate test for the experimental conditions (exercise: $\mathrm{M}=5.97$ [49.7\%], $\mathrm{SD} \pm 2.73$; control: $\mathrm{M}=6.07$ [50\%], $\mathrm{SD} \pm 2.59$ ), participants recalled more items in the delayed test if they had exercised prior to encoding (exercise: $\mathrm{M}=6.26$ [52\%], $\mathrm{SD} \pm 2.71$; control: $\mathrm{M}=5.5$ [45.8\%], $\mathrm{SD} \pm 2.94$ ).

Figure 2. Free recall correct responses per condition and testing time.

Gender differences were also taken into account in the analysis. Figure 3 displays the number of correct responses in each experimental condition, grouped by gender and testing time. From this graph, it is possible to see that, overall, girls seem to remember the same or a larger number of items when compared to boys. Furthermore, the profiles of performance per experimental condition appear to be similar for both genders: when in the exercise condition, the number of accurate responses is either maintained or increases from the immediate to the delayed test, whereas when in the control condition performance decreases. However, while the girls' performance does not seem to be particularly affected by the exercise intervention in either of the tests (exercise immediate: $\mathrm{M}=5.28$ [44\%], $\mathrm{SD} \pm 2.72$; exercise delayed: $\mathrm{M}=5.85$ [48.8\%], $\mathrm{SD} \pm 2.86$; control immediate: $\mathrm{M}=6.04$ [50\%], $\mathrm{SD} \pm 1.8$; control delayed: $\mathrm{M}=$ 5.71 [47.6\%], $\mathrm{SD} \pm 2.93$ ), the boys recalled more items immediately (exercise: $M=5.22$ [43.5\%], $\mathrm{SD} \pm 2.79$; control: $\mathrm{M}=4.33$ [ $36 \%$ ], $\mathrm{SD} \pm 2.95$ ) and 24 hours (exercise: $\mathrm{M}=5.33$ [44.4\%], $\mathrm{SD} \pm 2.63$; control: $\mathrm{M}=4$ [33.3\%], $\mathrm{SD} \pm$ 2.76) when they exercised before encoding.

Given the unequal number of boys and girls in the sample (female $=21$, male $=18$ ), which limits the possibility of comparing the groups, a two-way repeated measures ANOVA, including experimental condition and testing time as factors, was conducted on a reduced dataset comprising only the boys' data. The effect of experimental condition was significant, $\mathrm{F}(1,17)=5.101, \mathrm{p}=.037, \eta_{\mathrm{g}}{ }^{2}=.035$, indicating that the difference between experimental conditions (exercise vs. control) observed in Figure 3, albeit numerically small, may be worth further exploration.

## Cued recall

To assess the effects of experimental condition and testing time, a two-way, repeated-measures ANOVA was performed. As shown in Figure 4, no significant main effects of experimental condition, $\mathrm{F}(1,38)=.026, \mathrm{p}=.872$, or testing time, $\mathrm{F}(1,38)=.638, \mathrm{p}=.429$, were found. The interaction between both independent variables was also
non-significant, $\mathrm{F}(1,38)=.014, \mathrm{p}=.9, \eta_{\mathrm{g}}{ }^{2} \leq .001$. These results indicate that exercise did not influence the cued recall of form-meaning connections in this sample, either immediately (exercise: $\mathrm{M}=5.43$ [45.2\%], $\mathrm{SD} \pm 2.93$; control: $\mathrm{M}=5.51$ [45\%], $\mathrm{SD} \pm 2.52$ ) or 24 hours after encoding (exercise: $\mathrm{M}=5.64$ [47\%], $\mathrm{SD} \pm 2.48$ ); control: M $=5.66[47.2 \%], \mathrm{SD} \pm 3.05)$.

Figure 3. Free recall correct responses by gender, experimental condition and testing time.

A visual inspection of the plotted cued recall data divided by gender showed no indication of a differential effect of exercise. Hence no additional analyses were conducted.

Figure 4. Cued recall correct responses per condition and testing time.

## Discussion

The purpose of this study was to assess whether a bout of aerobic, moderate physical activity performed before encoding could affect children's retention of newly acquired pseudowords and their meanings, immediately after learning and with a delay. In particular, we were interested in observing the possible effects of physical activity in the recall of novel word-forms (pseudowords) and meanings
(pseudoword/picture association). These questions were motivated by the scarcity of studies focusing on exercise and language learning, particularly with child participants.

The free recall test focused on the children's retention of word forms. Data from this task showed that exercising before encoding facilitated recall, but only on the delayed test (24 hours after learning). This outcome may indicate that exercising before learning could help reduce timedependent forgetting on a moderate scale. This finding concurs with previous research outlining the beneficial, rather than detrimental, effects of acute exercise on children's recall (Etnier et al., 2014; Pesce et al., 2009). However, in contrast to these studies, in which increased memory performance was noticed in the immediate test (or after a very short delay), in this experiment the influence of exercise appears to affect the delayed test, performed 24 hours later and after a period of sleep. This may indicate a possible link between acute physical activity and memory consolidation. A relationship between exercise and consolidation has already been postulated for healthy adults (e.g. Coles \& Tomporowski, 2008; Labban \& Etnier, 2011; Robertson \& Takacs, 2017), but would require further exploration to extend it to child memory consolidation. The discrepancy between the results of the present study and previous work could also suggest that, consistent with several meta-analyses (Chang, Labban, Gapin, \& Etnier, 2012; Lambourne \& Tomporowski, 2010; Tomporowski, 2003), the effects of physical activity on cognition could be selective. Since the learning activities used in Etnier and colleagues and Pesce and colleagues' work were focused on the recall of already known linguistic information, and not on the acquisition of entirely novel forms as was the case in this experiment, the tasks rely on different memory processes that may be differentially affected by exercise.
A bout of physical activity before encoding did not affect recall of form-meaning connections. This finding is somewhat unexpected, given that previous research had found an influence of bouts of aerobic physical activity on associative memory in adults (Schmidt-Kassow et al., 2013; Schmidt-Kassow, Kulka, Gunter, Rothermich, \& Kotz, 2010; Winter et al., 2007). Since this experiment required children to learn forms and form-meaning connections simultaneously, it may be that the acquisition of the form was privileged to the detriment of the formation of formmeaning connections. This could have been reinforced by the order of the testing activities - always free recall followed by cued recall - that could have made the recall of forms more prominent. To our knowledge, this is the first study that addresses the effect of a bout of physical activity on the formation of form-meaning connections in children; as such, it only begins to describe the effects observed. Further research could help elucidate whether the effects of exercise seen on standardized associative memory tests could transfer to memory-supported activities that more closely resemble the tasks performed by children in a learning environment.

Another surprising effect was the difference observed in boys and girls. A tentative explanation of this difference, based on the assumption that exercise works as a stressor, would fall in line with research highlighting gender-based differences in brain reaction to stressors, both of an emotional and physical nature (for a review, see Cahill, 2006). Furthermore, because this gender difference appears on the second day, the possibility of the existence of gender differences in offline consolidation, that could be enhanced by exercise, should also be considered. Some evidence points towards greater motor skill memory gains obtained by males after a period of offline consolidation (Dorfberger, Adi-Japha, \& Karni, 2009), an advantage that may be related to differential responses to cortisol levels (Andreano \& Cahill, 2006). Cortisol is a stress hormone shown to be affected by acute exercise interventions, and that plays a role in memory consolidation. It should nonetheless be noted that since not all previous studies on the effects of exercise on cognition have addressed gender differences, and as it was not the primary purpose of this study, it is hard to draw conclusions from this result.
There are some limitations that should be considered in relation to the current study. First, the sample size is relatively small when considering the number of variables addressed. Furthermore, the effects found, although significant, were subtle and can therefore only be considered with caution. Future experiments should also include more information about the sample, including a measure of fitness level and baseline memory performance, as well as some indication of school achievement (e.g. grades). The inclusion of these data could help disentangle variation that might be motivated by external factors not related to the experimental manipulation.
Overall, this study expands our knowledge of the effects of acute, aerobic physical activity on children's cognition, in that it includes a 'learning element' that had been thus far overlooked. The fact that participants had to learn novel word forms, as well as their connection to meaning, after exercising makes this experimental activity more closely related to regular classroom language learning activities, thus providing an initial glimpse into the effects of physical activity in a school environment. The finding that the experimental condition affected free- but not cued-recall in this experiment could suggest a selective effect of exercise on children's memory, but it could also underline the need to utilize more nuanced tests to assess associative memory in this context. Future research on this topic could build upon these findings, by adding more and more sophisticated tests of relational memory, as well as addressing some of the questions that this study has raised, such as the possible moderating effect of gender and the influence of acute physical activity on memory consolidation in children.

# Replacing Language: Children Use Non-Linguistic Cues and Comparison in Category Formation 

Margarita Pavlova (margarita.velinova@gmail.com)<br>Department of Cognitive Science and Psychology, New Bulgarian University, 21 Montevideo Street<br>Sofia, Bulgaria

#### Abstract

Language is a powerful instrument for extracting relational information from stimuli. In a label extension task common labels invite comparison processes that help children focus on the more subtle relational similarity and away from the readily available perceptual similarity of the stimuli. The current experiment aims to explore whether non-linguistic representations of category membership are sufficient to invite such abstractions of relational information. Preschool children were asked to extend a category to either a relational or an object match. When given the opportunity to compare two instances of the category, and provided with a nonlinguistic cue children extended the category to the relational match. These results further extend the benefit of comparison in learning, and suggest that language labels are not the only cue children can use in category formation.

Keywords: categorization; cognitive development; relational processing; non-linguistic representations of relations.

## Introduction

Analogical reasoning - the ability to see and use relational similarity between situations and events lies in the core of human cognition (Hofstadter, 2001). It is what makes humans so smart and it is potentially what distinguishes us from other species (Gentner, 2003; 2010). Analogy is central to many cognitive processes including learning, reasoning, decision-making, and categorization (Gentner, 1983; Gentner \& Markman, 1997; Kokinov, 1998) and it promotes conceptual development in children (Christie \& Gentner, 2010; Gentner \& Namy, 1999; Graham, Namy, Gentner, \& Meagher, 2010; Rattermann \& Gentner, 1998). Thus, analogy is a key process of higher-order cognition that benefits learning (Gentner, 2010; Kokinov, 1998).

There is evidence that young children show analogical abilities, if they have knowledge of the relations involved (Gentner, 1983; 1988; Holyoak, Junn, \& Billman, 1984). However, children tend to focus first on object similarities, before they start to notice common relational structure, independent of the objects involved. Gentner defines this phenomenon as the relational shift hypothesis (Gentner, 1988). She asked children to interpret different kinds of metaphors and say how they are alike. When children were asked to interpret the metaphor "A tire is a shoe", 5-6-yearolds replied based on perceptual similarity (e.g. both are black), and $9-10$-year-olds based their answer on the specific roles and functions of the two, thus giving a relational answer [e.g. you can go places with both (Gentner, 1988)]. When asked to perform a mapping task,
children first base their reasoning on the salience of object features (e.g. color, shape, etc.) thus failing to map the relations involved. To have a true relational ability, children must resist the temptation of the object features, and base their reasoning on the more subtle common relations involved (Gentner \& Toupin, 1986).

Rattermann \& Gentner (1998) provided further support for the relational shift hypothesis. They gave children a relational mapping task in which the experimenter and the child each had a set of three objects. The experimenter hid a sticker under one of her objects (e.g., the middle one). The child had to find his sticker in the same place (the middle of his objects). In some of the conditions, objects were crossmapped, i.e. the middle object in the experimenter's set was the same size as the leftmost object in the child's set. In this condition, 3 -year-old children had a difficulty resisting the perceptual similarity and instead of searching under the corresponding relational location, they searched under the identical object in their set. In contrast, 5-year-olds were better able to resist the object matches and give relational matches.

When searching for an interpretation of a given similarity, people (especially young children and novices) first focus on the object commonalities (Christie \& Gentner, 2010; Kotovsky \& Gentner, 1996). However, interpretations based on object attributes are not useful in deriving causal principles. Potential analogs are more difficult to notice because relations are more subtle and require a deeper analysis of the information. However, once found, the analogy is very useful in deriving key principles, since the structure holds true for both the base and the target (or the two situations), regardless of the objects involved in it. There are two factors that contribute to relational reasoning - relational comparison and relational language.

## Relational Language and Learning

The first question is whether providing children with a noun label would help them learn a novel category. Evidence suggests that providing children with a count noun may bias them toward an object-centered interpretation of what kind of members are to be included into the category, since labels invite children to group things of like kinds together (Markman, 1989). Young children often base their reasoning on the more compelling perceptual similarity, and thus their intuition of likeness relies on object similarity. On the other hand, providing a common term could also serve
as an invitation to search for and find a common relation, thus promoting relational abstraction (Gentner, 2010).

When exploring children's understanding of categories, researchers use the word-extension task in which children are taught a new word and are given an example for it and then asked to extend the word to another example, thus showing an understanding of the category membership of the new item. Common labels invite deep reasoning and help children focus on like kinds. For example, in a series of experiments Gentner and Namy (1999) explored children's categorization abilities. The results show that children group items based on shape when they examine them in isolation (i.e. when they see only one standard). However, providing a label enhances the likelihood of children engaging in comparison, prompting children to compare the items bearing the same label.

Christie and Gentner (2010) extended these findings and showed that 3 - and 4 -year-old children successfully learned a novel label and extended category membership to the relational match. They explored how children base their hypotheses for category membership and showed the mutual benefit of comparison and relational label. When children had the opportunity to compare two examples of a given (novel) category, and heard a novel label, they extended the category to a relational match. This research shows the mutual bootstrapping between relational language and analogical abilities in preschool children (Christie \& Gentner, 2010; Gentner, 2010).

Language and analogical comparison interact in the process of learning. This claim is supported by the language as a toolkit view, proposed by Gentner (2003; 2010). According to this view, acquiring a language provides new resources that support cognitive skills, while not replacing prelinguistic abilities. Specifically, this view assumes that structural alignment supports language learning, and that relational language supports structural alignment and reasoning. In addition, Gentner discusses four ways in which language interacts with analogical abilities to foster learning (Gentner, 2003; 2010). First, common labels invite comparison and abstractions, thus prompting children to compare two items that share the same label. Second, a linguistic label helps to preserve the abstraction derived from the comparison and makes it more accessible for future use, thus promoting reification. Next, naming promotes uniform relational encoding, which ensures the encoding of the relations in the same manner on different occasions. Last, the systematic structure of language can invite conceptual structure. Thus, language and analogical comparison interact with analogical abilities to foster learning and development (Gentner, 2010).

## Relational Comparison and Learning

Analogical comparison promotes learning via a structural alignment process that is akin to relational mapping, thus highlighting the common relational structure and rendering it more salient (Gentner, 2010; Gentner \& Markman, 1994; 1997). Similarity comparison process is one of alignment
and mapping of common relational structure, like the structure-mapping process of analogy. A result from carrying out a similarity comparison is that it highlights the relational structure and makes it more salient, thus enabling further abstractions and use. The alignment hypothesis assumes that the process of making a similarity comparison may lead to change in the representation. This change in turn will increase the uniformity of the two representations (Gentner, 1983; Gentner \& Markman, 1997). Thus, alignment makes the relational commonalities more salient and the representations uniform. This typically increases the perceived similarity between the paired items. For example, Gentner and colleagues conducted a series of experiments that investigated the effects of comparison and common labels in children's categorization. The results show that when preschool children saw only one instance of a particular category, they extended the category to the perceptually similar match. In contrast, when children saw two examples simultaneously and were prompted to compare them, they were more likely to extend the category to a new, structurally similar item, than to a perceptually similar one (Christie \& Gentner, 2010; Gentner \& Namy, 1999; Graham, et al., 2010).

Gentner and Namy (1999) sought out to investigate how children form categories. They gave 4 -year-olds a novel label (e.g. a blicket) for a pictured object (e.g. a bicycle) and asked children to find another blicket between two alternatives: a perceptually similar, but taxonomically different object (e.g. eyeglasses) or a perceptually different object from the same category (e.g. a skateboard). When children were presented with only one example of the category (e.g. a bicycle or a tricycle), they tended to choose the perceptual match. However, when they observed two examples (a bicycle and a tricycle), they were more likely to choose the relational match. Interestingly, the obtained results cannot be accounted to a traditional view in which comparison is considered a simple feature overlap. Rather, it seems that comparison selectively highlighted the relational commonalities (Gentner \& Namy, 1999; Gentner, 2010).

Christie and Gentner (2010) followed this procedure and further extended the findings, showing the benefits of comparison in learning new relations. They presented 3- and 4-year-olds with animals in a novel spatial orientation and attached a novel label to it (e.g. a dax). When presented with only one example, or when two examples were provided but children were not prompted to compare them, they extended the category to the object match. However, children who compared the two examples of the category extended it to a relational match.

These results show that analogical comparison is useful in learning new principles, forming new categories, and retaining material better for transfer. One cannot help but see a tendency in all experiments discussed above - the mutual presentation of two (versus one) examples and providing a common label. It would be interesting to see if these two factors work mutually or if they could contribute
to category formation separately. This question is of particular interest in the present study.

## Can language be replaced?

The main question we are asking here is whether language is unique in promoting analogical abstraction. Mutafchieva \& Kokinov (2007) explored the hypothesis that a nonlinguistic representation of specific relations would be beneficial in a relational mapping task. Following the procedure of Rattermann \& Gentner (1998), they used labels (e.g. Daddy, Mummy, and Baby), a train analogy, or a physical representation of the relation pulling in the analogy (e.g. drawbars). The hypothesis was that the drawbars should be sufficient for the child to abstract the relation, and thus solve the mapping task. The results showed no difference between the various types of presentation (i.e. language labels, drawbars, or analogy). Interestingly, there was no evidence that providing labels further benefit performance on a mapping task. The drawbar condition seemed to be successful in promoting relational matches, similar to the labels, and the analogy condition.

Similarly, Gentner and colleagues conducted a series of experiments on the acquisition of relational categories that show that for 4 -year-olds comparison alone without relational language is sufficient to invite relational responding (Gentner, Anggoro, \& Klibanoff, 2011). In addition, Gentner, Namy and colleagues examined the role of comparison and shared names in categorization of novel objects. For example, Graham et al. (2010) gave 4-year-olds novel object sets that consisted of one, or two standards and two test objects to choose from, a texture match and a shape match. The results of the study are quite interesting. When children were presented with one standard, they extended the category based on shared shape, regardless of whether the objects were named. When children were presented with two standards that shared the same texture and the objects were named with the same noun, they extend category based on shared texture. Interestingly, the opportunity to compare in the absence of a shared label, led to an attenuation of the effect of shape, although not to a significant preference of texture. Interestingly, the authors found that adding a common label by itself did not change children's responding, however, it seems to augment the effect of comparison in shifting children toward the texture response (Graham et al., 2010).

One possible explanation of the obtained results is that in the No-word condition the authors provided children with a broad term (e.g. pointing to the standard(s): "This is one!"), thus limiting the possibility that the child could abstract a specific category cue. The term used is too general for children to elicit specific category representations and abstract common relational features between the two standards. On the other hand, the interesting fact that even without labels but with the opportunity to compare, children still could start to resist the perceptual match (e.g. shape), leaves a possibility that another type of non-linguistic representation of the category membership in addition to
comparison could benefit categorization among preschool children.

Continuing this line of research, the present experiment aims to explore the possibility that comparison is sufficient not only to promote abstraction of relational information, but also to aid category formation. The present study suggests that a non-linguistic cue in addition to comparison would successfully promote relational matches in a categorization task, thus showing that language labels are not unique in promoting relational categorization.

## Experiment

The goal of this study is to explore the possibility that children can use non-linguistic cues when categorizing items. If language (a common label) is unique in promoting relational categorization, then it should be sufficient. Moreover, when deprived from the opportunity to benefit from a common label, children should fail to extend category membership based on relational similarity. However, if another mechanism (comparison) is present, and children rely on it during categorization, then it is possible that a non-linguistic cue will provide sufficient ground for children to extend the category based on relational similarity. Specifically, a non-linguistic cue that represents the category membership of two standards (e.g. a sticker) could provide enough ground for children to extend the category membership based on relational similarity. Bearing in mind that young children typically are tempted by the perceptual similarity and often fail to notice the relational similarity between two instances, it is important to investigate the various strategies children use to group the things they encounter into categories.

Following the idea that providing a means for category inclusion (whether the cue is linguistic or not) will further benefit children in their performance, here we test the roles of comparison and various types of cues. Comparison enables children to abstract the interconnected relational structure and focus on the commonalities between the two examples, especially shared relations. This helps children to disambiguate between two working hypothesis: object match vs. relational match. The specific cue provides further support and acts to focus their attention to the underlying common relations. Thus, the highlighted structure will become more salient and more available to new examples of the category.

The specific hypothesis of the study was that children in the Label and Sticker Condition would choose the relational match more often compared to the children in the NoWord Condition. In addition, children in the Label and Sticker Condition will do equally well. This logic follows from the language as a toolkit view discussed earlier (Gentner, 2003; 2010). Building upon this view, I posit that a non-linguistic cue will act in the same way as novel language labels do, prompting children to go beyond the readily available perceptual commonalities, and focus on the deeper relational commonalities.

## Methods

Participants Forty-three 4 -year-olds were recruited from kindergartens in Sofia area ( 28 females, $M_{\text {age }}=52$ months; 15 in Label Condition, 14 in Sticker Condition, and 14 in NoWord Condition). Permission to participate was obtained from their parents prior to the study. Children received a small gift for their participation.

Materials The study uses the materials from the original study ${ }^{1}$. The instructions were translated into Bulgarian. Children were given a word extension task on a triad of pictures that depicted animals. The two standards were labelled with a novel noun, and children were asked to extend the label to one of two alternatives: a relational match (new animals in the same configuration) or an object match (same animal[ $[\mathrm{s}]$ in different configuration).

The stimuli consisted of eight sets of animal pictures, with two standards, an object match and a relational match. Each picture depicted two or three animals configured in a novel spatial relation (e.g., two identical pigs facing each other). The second standard within a given set showed different animals in the same spatial configuration (e.g., two identical fish facing each other). The object match contained an exact animal match from each standard but in a different relational pattern (e.g., a pig and a fish turned back on each other). The relational match was composed of new animals in the same relational configuration as the two standards (e.g., two identical turtles facing each other; Figure 1).

In addition, two training sets depicting shapes were included that aimed to help children become more familiar with the procedure. Children did not receive feedback during the training session and the results from it were not counted in the analyses.

Procedure Children were randomly assigned to one of three between-subjects conditions: Label, Sticker, or NoWord. Materials were presented on laminated paper cards. Children were seated across from an experimenter.

In the Label condition, the experimenter laid the two standards and labeled them with a novel count noun (e.g. pointing to the first card, "This is a blicket." Then, pointing to the second card, "And this is a blicket, too."). Next, the child had to compare the two standards: "Do you see why these two are both blickets?" The experimenter then placed the two alternatives side by side below the standards and asked the child, "Which one of these is also a blicket?" After the child made a choice, the experimenter continued with new standards from a new set. Eight unique novel labels were used, one for each relational pattern.

The NoWord condition began the same way. The experimenter laid the two standards, but instead of labelling them with a novel word, she used the same generic term for all sets: (e.g. "This is one. And this is one, too."). Then, the child was prompted to compare the standards, "Do you see why these two are the same kind of thing?" Last, the two

[^429]alternatives were presented, and the child was asked: "Which one of these is the same kind of thing?" This procedure continued for all eight sets of pictures.
In the Sticker condition, the experimenter laid the two standards and placed a sticker (a small circle) in the top middle of each standard. Then, the child had to compare the standards: "Do you see why these two have stickers?" Then, the two alternatives were presented and the child was asked: "On which one of these should we also put a sticker?" After the child made a choice, the experimenter continued with the next set. Eight different stickers were used for each of the sets.

Figure 1: A sample of the sets in the categorization task

## Results and Discussion

Mean proportion of relational matches in the category task were measured. Two different analyses were used to measure performance. First, a one-way ANOVA was used to calculate differences between the conditions. The analysis revealed a significant effect of condition, $F(2,40)=4,867, p$ $=.013$. Bonferroni post-hoc tests showed that children in the Sticker condition ( $M_{\text {relational }}=0.6, S D=0.35$ ) made significantly more relational matches compared to the Label $\left(M_{\text {relational }}=0.23, S D=0.36\right)$ and the NoWord $\left(M_{\text {relational }}=\right.$ $0.28, S D=0.34$ ) conditions. The Label Condition was not different from the NoWord condition, $p=1.00$.

In the second analysis, the means of each group was compared to chance (50\%). The comparisons revealed that children in the Label and NoWord condition chose object matches significantly more than chance, $t(14)=-2.981, p=$ .01 and $t(13)=-2.48, p=0.028$, respectively. However, the Sticker Condition was not significantly different from chance, $t(13)=1.076, p=.301$.

As predicted, children who received a generic label performed worse than children who received a nonlinguistic cue during category formation. Further, they showed a strong preference toward the object match, selecting it significantly more than chance. However, contrary to prediction, children who heard a novel label also performed worse than the children who received a nonlinguistic cue, choosing the object match more often and significantly above chance level. Importantly, children in
the Sticker condition chose the relational match more often, though not significantly above chance level. The obtained results provide further insights into the strategies that are available for children to use during category formation tasks.

## General Discussion

Children improve dramatically in their analogical abilities over the preschool and early school years. Various factors contribute to the development of analogical abilities in young children. General experience (Rattermann \& Gentner, 1998), maturation of executive functions (Richland, Morrison, \& Holyoak, 2006; Thibaut, French, \& Vezneva, 2010), and processing capacity (Halford, Wilson, \& Phillips, 1998) all contribute to the development of analogical abilities. However, other mechanisms are also crucial to relational ability and learning in general relational language and comparison (Gentner, 2003; 2010; Alfieri, Nokes-Malach, \& Schunn, 2013).

Comparison is a general learning mechanism that provides efficient means for learning. In particular, in relational learning, comparisons provide children with the opportunity to engage in a process that is akin to relational mapping. This means that children are able to notice and abstract the underlying relational structure between the two standards and thus it becomes more salient and more available for new examples. Children acquire relational terms that support relational representation and reasoning (Christie \& Gentner, 2010; Gentner, 2003; 2010; Gentner et al, 2011). Previous research shows that providing two examples with a common label prompts children to focus their attention to the more subtle structural commonalities (Christie \& Gentner, 2010; Gentner \& Namy, 1999; Namy \& Gentner, 2002).

In this experiment, we sought to replicate data from the Christie and Gentner study (2010) and to further the findings with new conditions. We asked 4 -year-olds to compare two examples of a given category and to extend the category to either an object match or a relational match. The results obtained in this study show that when children received a non-linguistic cue (e.g. a sticker) that represented category membership, they extended the category to a relational match. However, when they received either a specific novel label (e.g. a blicket) or a generic word (e.g. one), they extended the category to an object match.

Concerning the linguistic cues, there are two possible explanations for the obtained results. First, it is possible that providing children with a count noun as a category label focused them to pay more attention to the objects involved (Markman, 1989). As mentioned above, children understand that labels refer to like kinds, but their naïve intuition is to assume that the likeness refers to the objects and not to other commonalities. Children often encounter relational nouns (nouns whose meaning is defined by their relation to other entities) in everyday speech when interacting with adults. However, there is some ambiguity between object construal and relational construal. For example, when children hear a
relational noun (e.g. X is an uncle), they typically focus on perceptual features (e.g. old man) than relational features [(e.g. brother of mother); Gentner, 2003; Christie \& Gentner, 2010].

A second possibility is that children in the Label condition had a difficulty to encode the specific labels used. It is possible that the labels we used are phonologically very different from the majority of words in Bulgarian. If children focused on trying to understand the meaning of an awkward word, their capacity to process the relational information for the two standards was limited. In addition, children in both the Label condition and the NoWord condition heard a word representing the category membership, whereas children in the Sticker condition were able to see the sticker at all times during the categorization task. It is possible that when children hear a word it is more difficult to encode and update the cue, but when a cue is always present and readily available there is no need to store it in working memory and thus encoding it is easier. Although such an assumption seems rather unsupported, having in mind the data from previous research on language labels and comparison among preschool children, it is worth investigating further why our experiment failed to replicate the Label condition in the original study.

Following the main idea of the present study - to explore the various strategies children use during relational categorization, further work is needed to see how comparison supports relational abstraction in preschool children independent from language. It is worth mentioning that the experiment presented here is part of a larger ongoing study. We are currently collecting more data that will provide further insights into the specific roles of different types of presentation and cues in category formation in preschool children.

## Acknowledgements

I am grateful to Stella Christie for providing the stimuli used in this experiment and to Dedre Gentner for the stimulating discussions and insightful suggestions. I thank the children who participated in the study, their families, and teachers. I thank Areta Zumerova for her help with data collection.

#### Abstract

An important part of explaining how people communicate is to understand how people relate language to entities in the world. In describing measurements, people prefer to use qualitative words like 'tall' without precise applicability conditions, also known as vague words. The use of vague language varies widely across contexts, individuals, and tasks (single reference vs. comparisons between targets), but despite this variability, is used quite successfully. A potential strategy for using vague language is to leverage the set of alternative descriptors to settle on the best option. To determine whether people use this strategy, we conducted an experiment where participants picked vague words from sets of alternatives to describe either probability or color values. We varied the set of alternatives from which participants could choose. Empirical evidence supports the hypothesis that people use the set of available options to pick vague descriptors. The theoretical implications of this work are discussed.

Keywords: Vagueness, Alternative sets, Probability, Color

## Introduction

An important aspect of human communication is understanding how people use language to describe the world (Quine, 1969). In the simplest case, people use language to refer to concrete real world objects and categories, such as trees or humans. More interestingly, people use words such as blue, tall, and likely to flexibly refer to indefinite ranges of continuous values across different contexts-a phenomenon known as vagueness. Vague words vary in evoking degrees along different kinds of dimensions (Kennedy, 2007; Kennedy \& McNally, 2010). This paper explores people's expectations for different classes of vague words and how they leverage these expectations to communicate effectively.

## The constrained variability of vague language

Although the use of vague language is ubiquitous in everyday talk, it varies dramatically across communicative situations (Budescu \& Wallsten, 1987). To start, different people relate vague words differently to the values they want to describe (Budescu \& Wallsten, 1987; Wallsten, Budescu, Rapoport, Zwick, \& Forsyth, 1986). For example, in comparable contexts, different people may use the same word to describe different values, or different words to describe the same values.

Nevertheless, meanings in context are not random: vague words seem to always denote bounded, convex regions in the appropriate property space (Gärdenfors, 2004). For example, we can appeal to the convexity of color categories to explain patterns of color naming within and across language communities (Jäger, 2010; Regier, Kay, \& Khetarpal, 2007).

At the same time, individuals' use of vague language varies as a function of the context. People use vague words differently depending on the specific objects they need to distinguish in a situation (Van Deemter, 2006). They also use vague words differently depending on the possible alternative descriptions that would be appropriate (Degen, 2015). For instance, the presence of numbers in the set of available options (e.g.['some', 'all', 'not all', '4']), influences the use of the option 'some' (Degen \& Tanenhaus, 2015). Again, there are limits on such effects. For example, absolute terms, such as 'empty', 'flat' and 'straight', are more constrained in how they vary in context than terms that signal open-ended comparisons, such as 'tall' (e.g. Leffel, Xiang, \& Kennedy, 2016).

Finally, vague language varies as a function of speakers' semantic memory, as revealed by the implicit class to which comparisons are drawn (Lassiter, 2009; Wallsten et al., 1986; Kennedy, 2007). In the quintessential example, the word tall is understood very differently when used to describe a basketball player versus a toddler, and differently again when used to describe a skyscraper versus a glass of water (Schmidt, Goodman, Barner, \& Tenenbaum, 2009). Similar semantic effects are seen in the relationships between different cultures, environments, and their color categories (Regier, Carstensen, \& Kemp, 2016; Stickles, 2014).

Despite this constrained variability, people generally communicate successfully with vague words and prefer to use vague language in many tasks (Van Deemter, 2012).

## Characterizing the variability of vagueness

Bayesian cognitive modeling suggests accounting for these effects in terms of expectations derived from semantic memory, the communicative context and patterns of individual variation (Potts, Lassiter, Levy, \& Frank, 2016). Conversely,
it suggests we can also characterize people's semantic and pragmatic representations through analysis of their interpretation of vague language.

In particular, it's natural to suppose that language users coordinate on specific interpretations in context by assuming that speakers have chosen the most informative description from the available alternatives in light of their expectations. Although several models predict that interpretations of vague language will vary in this way (Potts et al., 2016; Wallsten et al., 1986), empirical evidence supporting this hypothesis is thin.

To investigate this hypothesis, we conducted a forced choice experiment where subjects selected one of a small number of linguistic alternatives to describe a value. Critically, as we varied the number of alternative descriptions, we provided a reject option (i.e. 'none of the above') to measure limits in flexibility of vague terms. Despite a large range of related work, no previous studies have addressed this issue explicitly. We compared performance in the forced choice experiment to a free generate task where participants provided their own words to describe values.

We hypothesize that two possible behaviors may arise. When presented with different sets of alternative descriptions, people may flexibly use the same vague word to refer to different ranges of values. In contrast, people may consistently use vague words to describe the same values regardless of the alternative set of words, instead choosing rejection when preferred options are unavailable.

To foreshadow, we find evidence for both patterns, depending on semantic domain. Probability descriptions vary widely depending on the alternative terms presented to subjects, but color terms vary much less. These results suggest that, although individuals representations of the meaning of some vague words are broadly stable, speakers do adjust boundaries within the available range to give the most information in context. ${ }^{1}$ We outline empirical and theoretical consequences of this finding for future work, emphasizing the need to characterize individual differences and contextual variation jointly, as well as the need to explicitly contrast speaker models based on strategic and heuristic choice.

## Experiment

To assess the role of the set of available terms in constraining vague language, we elicit labeling behavior in a task where participants are shown a property value (i.e. probability and hue), and are asked to either choose a corresponding label from a given set of options ( N -AFC), or freely generate a label that corresponds to the presented value. In the $\mathrm{N}-\mathrm{AFC}$ cases, we expect that the distributions will reflect peoples willingness (or lack of willingness) to "stretch" their category assignment of values based on available terms. In the

[^430]

Figure 1: Sample stimuli for the two tasks: Probability (left two panels) and color (right two panels).
free generate cases, we expect that the distributions will reflect people's natural tendencies of assigning terms to values.

## Methods

Participants Three-hundred and sixty individuals from the Amazon Mechanical Turk research pool participated in this study for monetary compensation.

Materials Color. The stimuli for the color condition consisted of 60 equally spaced values sampled from the winHSV240 (hue, saturation, and value) color space. The colors varied along the full range of the hue dimension, while saturation and value were held constant at $90 \% .^{2}$ The set of available vague color words included seven of the eleven universal color terms (red, orange, yellow, green, blue, purple, and pink; Berlin \& Kay, 1969). To create different conditions, we incrementally increased the number of color words available for participants to choose from - starting with three terms and ending with seven terms. We also included a free generate (see Table 1) condition resulting in six conditions for color in total. In addition to the AFCs for each condition, there was also a reject option, indicating that the color value was not described by any of the available color words. The color space was stratified into six regions, so that each participant only saw one stimuli from each region at equal intervals.This design ensured that participants were presented with values that spanned the entire property range.

Probability. The stimuli for the probability conditions also consisted of 60 equally spaced probability values on the range of $0-1$. The vague probability words that could be used to describe the values were selected from a norming phase with a separate set of participants $(\mathrm{N}=32)$. The norming participants were simply asked to provide labels for randomly generated probability values. The six most frequently generated terms were then used here. To match the structure of the color task, the probability task was also comprised of six condi-

[^431]Table 1: List of Available Vague Words by Condition

| Condition | Probability |  | Color |
| :---: | :---: | :---: | :---: |
| 1 | [UL] unlikely, likely | [3-TERM] | red, green, blue |
| 2 | [ULV] unlikely, likely, very unlikely, very likely | [4-TERM] | red, green, blue, yellow |
| 3 | [ULS] unlikely, likely, somewhat unlikely, somewhat likely | [5-TERM] | red, green, blue, yellow, purple |
| 4 | [VS] very unlikely, very likely, somewhat likely, somewhat unlikely | [6-TERM] | red, green, blue, yellow, purple, orange |
| 5 | [ULVS] unlikely, likely, very unlikely, very likely, somewhat unlikely, somewhat likely | [7-TERM] | red, green, blue, yellow, purple, orange, pink |
| 6 | [FG] free generate | [FG] | free generate |

tions ranging from two alternative forced choices (AFC) to six AFCs, and a free generate condition (see Table 1). The option to reject was present in all conditions. The probability space was stratified into six regions, so that each participant only saw one stimuli from each region at equal intervals.
Procedure Participants were told that they would be helping a robot to understand the meaning of vague words by assigning the words to different property values. Participants were first presented with a set of instructions describing the stimuli and the task. For the probability task, they were shown a pie chart with an arrow called a spinner and a shaded region denoting a probability value (Figure 1, top panels). They were informed that their job was to either pick from a given set of words or generate a word that described the likelihood of the spinner landing in the shaded region of the pie. For the color task, participants were presented with a single color patch and were asked to either choose one of the given color words or generate a word to describe the color Figure 1, bottom panels). Each set of instructions was provided immediately before the task that they described. Each participant described 12 unique property values ( 6 probability values and 6 hue values). The conditions and presentation order of values were randomized across participants.

## Results

Probability Results We assessed whether or not participants consistently used the probability words to describe the same probability values across conditions (see Figures 2 and 3, left column), via linear mixed-effects models (lme) using the lme4 package in R (Bates, Mächler, Bolker, \& Walker, 2015). LME models test for significant differences in responses within experimental groups of primary interest (i.e. condition), while accounting for variability that results from factors that are experimentally uncontrolled (e.g. subjects). We followed up the modelling with planned pair-wise comparisons between conditions using a Tukey post hoc analysis, which corrects for family-wise error rates. In the LME models, subjects and stimuli order were always treated as random effects, while condition was treated as fixed. Probability and hue values were treated as the dependent measure and condition was treated as an indicator variable. For
each probability word, we used a single lme model and compared it to the null. We started with a null model of participants and stimuli order and then added condition as a predictor in the alternate models. The null model predicts no difference in the assignment of probability words to values across conditions and the alternate models predict the opposite. Model fit was assessed using a likelihood-ratio test to compare the hypotheses of the null and alternate models. Condition was significant for probability words:likely ( $\beta=66.33, S E=3.01$ ), unlikely $(\beta=21.03, S E=2.84)$, and somewhat likely $(\beta=47.67, S E=4.72)$. Model comparisons for each of these words favored the alternate models (likely: $\chi^{2}(4)=36.77, p<.0001$, unlikely: $\chi^{2}(4)=26.89, p<$ .0001 , and somewhat likely: $\chi^{2}(4)=9.41, p=.02$ ). Planned pairwise comparisons were conducted to identify the conditions where the probability values differed for each word. For readability, we use codes to refer to the specific conditions (See Table 1 for the condition codes and probability terms available in each condition). Results showed a significant difference in the mean values for likely in the UL and ULV conditions ( $p<.001$ ); ULV and ULS conditions ( $p<0.001$ ); and ULS and VS conditions ( $p=0.02$ ). See Figure 4, left panel, for a visualization of the cumulative changes in values for likely across AFC conditions.

Comparisons show that the probability values assigned to unlikely differed in the ULV and FG conditions ( $p<0.01$ ); UL and ULV conditions ( $p=0.01$ ); and ULS and ULV conditions $(p<0.001)$. See Figure 4 , right panel, for a visualization of the cumulative changes in values for unlikely across AFC conditions. A difference in mean values for somewhat likely was observed in the ULVS and VS conditions ( $p<0.01$ ); and a marginal difference inULVS and FG conditions ( $p=.055$ ). We also calculated the percentage of reject option responses in each N -AFC probability condition. In the order of Table 1, the reject option constituted $4 \%, 1 \%$, $1 \%, 1 \%$, and $1 \%$ of the responses. Taken together, the results suggest that not only are the assignment of probability words to values influenced by the set of alternative descriptions that could have been used, but also that the space of probability values do not have a strict partitioning. In other words, a varying number of probability terms can be flexibly used to

Figure 2: Responses from the N -AFC conditions. Labels on the y -axis were the options available to the participants and the x-axis shows the stimuli values. LEFT PANEL: For each plot, the probability terms selected vs. probability values presented to participants. Right PANEL: For each plot, the color terms selected vs. the hue values presented to participants.
describe different values in probability space.

Color Results The most notable difference between the two domains is that the reject option was selected at a much higher rate for color than probability. In the order of Table 1 , the reject option constituted $36 \%, 31 \%, 14 \%, 9 \%$, and $3 \%$ of the responses for each N-AFC color condition. Like in the probability analysis, we used linear mixed-effects models
to assess whether participants consistently used color words to describe hue values across conditions (see Figures 2 and 3, right column). Interestingly, model comparisons only favored the alternate model for the color purple. Again for readability, we use codes to refer to the specific conditions (see Table 1). Planned pairwise comparisons revealed the conditions where hue values for purple were different: 5-TERM and FG conditions ( $p<.01$ ) and 5-TERM and 7-TERM conditions

Figure 3: Responses from the free generate conditions. The y-axis shows the set of labels freely generated more than 5 times and the $x$-axis show the presented values. Probability responses are presented in the left panel and color responses are presented on the right.

Figure 4: Cumulative frequency curves for likely and unlikely across the AFC conditions. The curves show the relative rates of people using likely (on the left) and unlikely (on the right) probability terms given the alternative sets of probability words in each condition.
( $p<.01$ ). Importantly, there were no significant differences in the mean hue values for the remaining colors across conditions (i.e. red, green, blue, yellow, orange, and pink). The results suggest that, unlike some probability words, the assignment of color words to hue values are inflexible and are not influenced by the set of alternative descriptions that were offered to participants. Instead, participants assignments reflect that their preference for color categories already takes into account an alternative set of other color categories. This is further supported by the high rates of the reject option use in the conditions with fewer options for color descriptions.

## Discussion

In this paper, we investigated how people assign vague words to probability and color values as a function of the set of available alternatives. We measured this behavior in two tasks where participants either selected a vague word from a fixed set or freely generated a word to describe values. Results re-
vealed two interestingly opposing behaviors for probability and color.

For probability, words varied in their assignment to probability values when other vague terms were available. For example, likely was assigned to a different set of probability values in the UL condition where only unlikely was available, relative to the ULV condition where very likely and very unlikely were also available or the ULS condition where somewhat likely was available. In contrast, for color, the assignment of vague words to color values was much more rigid. In fact, purple was the only color that varied across conditions. Other words had relatively well-defined categories that did not overlap.

The results suggest that for probability, people are adopting the strategy of using the set of available terms to constrain variability. This is consistent with the well-known framing effect (Tversky \& Kahneman, 1986) where decisions/preferences change as a function of how options are
presented. For color, however, they are not adopting this strategy.

There are two potential reasons why this may be. First, the set of color words used in the task are already constrained to the basic universal color categories. It is possible that people are more flexible when the vague color word is not drawn from the 11 universal terms. For example, teal, which was a freely generated response might shift in its assignment to color values depending on the available options. If blue is present in the set, teal might be selected for more greenish hues, and if green is in the set, teal might be selected for bluish hues. Alternatively, it could be that probability words encode a relative comparison in a way that color words do not (Leffel et al., 2016), and this semantic difference stabilizes the interpretations of color words in context. In other words, color terms come with an intrinsic range of applicability, not just a prototypical or ideal instance of the term.

A possible limitation of this work is in the finding that the distributions for most probability terms are very broad and overlapping (See Figure 2), which might be due to either individual differences or the context provided by the alternative sets manipulation. The current methodology is insufficient to distinguish between these. One way we could assess this would be to build generative statistical models which simulate the behavior of the participants under the two possible stories and compare the simulations to the empirical data. At the same time, this work lays the groundwork for examining future questions such as: how do you represent the applicability of words like likely in ways that explain their constrained variability? And how do speakers combine their sense of what would be a good description with factors like their expectations about how a description will be interpreted?

# Counterfactuals, indicative conditionals, and negation under uncertainty: Are there cross-cultural differences? 

Niki Pfeifer (niki.pfeifer@Imu.de)<br>Munich Center for Mathematical Philosophy, LMU Munich, Germany<br>Hiroshi Yama (yama@lit.osaka-cu.ac.jp)<br>Graduate School of Literature and Human Behavioral Sciences, Osaka City University, Japan

#### Abstract

In this paper we study selected argument forms involving counterfactuals and indicative conditionals under uncertainty. We selected argument forms to explore whether people with an Eastern cultural background reason differently about conditionals compared to Westerners, because of the differences in the location of negations. In a $2 \times 2$ between-participants design, 63 Japanese university students were allocated to four groups, crossing indicative conditionals and counterfactuals, and each presented in two random task orders. The data show close agreement between the responses of Easterners and Westerners. The modal responses provide strong support for the hypothesis that conditional probability is the best predictor for counterfactuals and indicative conditionals. Finally, the grand majority of the responses are probabilistically coherent, which endorses the psychological plausibility of choosing coherence-based probability logic as a rationality framework for psychological reasoning research.

Keywords: argument forms; cross-cultural comparison; counterfactuals; indicative conditionals; negation; probability logic; reasoning under uncertainty

## Introduction

In this paper we study selected argument forms involving counterfactuals and indicative conditionals under uncertainty. The aim is to explore potential cross-cultural differences in human reasoning about conditionals and negation under uncertainty between Easterners and Westerners. There are two possible hypotheses: A universal hypothesis and a cultural differences hypothesis. Like universal grammar (Chomsky, 1957), the human mind is conceived as universal across cultures according to mainstream $20^{\text {th }}$ century psychology. Researchers who agree with this hypothesis usually assume that cultural differences are very small since human reasoning has evolved universally (e.g., Mercier \& Sperber, 2011). So far, cross-cultural differences in reasoning involving negations have been described in the classical-logic based (old) paradigm psychology of reasoning literature (see, e.g., Nisbett, Peng, Choi, \& Norenzayan, 2001; Norenzayan, Smith, Kim, \& Nisbett, 2002; Peng \& Nisbett, 1999; Yama, in press). These previous studies demonstrate that Westerners are inclined to engage in rule-based reasoning whereas Easterners are apt to engage in intuitive or dialectical reasoning. In other words, Easterners are more likely to consider contradictory premises dialectically than Westerners. However, Zhang, Galbraith, Yama, Wang, and Manktelow (2015) report that Easterners are not actually more dialectical when they meet contradictory opinions, but they believe due to cultural reasons that dialectical thinking is wiser than Westerners. Because contradictory premises are not used in this ex-
periment, we do not make predictions concerning whether Easterners reason more dialectical or not (see, e.g., Peng \& Nisbett, 1999). Rather, we explore whether the location of negation in the context of conditionals impacts on reasoning and whether our Japanese sample differs from corresponding data of Western samples. If Japanese people see a stronger cultural value in dialectical thinking, it is plausible to assume that they may hesitate to show stronger confidence in the correctness of their judgments. Moreover, the Japanese language differs from European languages in the location of verb and negation. Usually, the verb is placed at the end of a sentence in Japanese. Furthermore, the term "not" is placed after the negated verb. Thus, the word order of a negated sentence is: complement-verb-not. In spite of these differences, cross-cultural studies on logical reasoning which focus on these differences systematically are rare. Our study presents one of the first attempts (see also Yama, in press) to identify cross-cultural differences within the framework of the new probability-based paradigm psychology of reasoning.

Among the various ways of expressing and using counterfactuals (see, e.g. Declerck \& Reed, 2001), we restrict our investigation of counterfactuals to conditionals in subjunctive mood, where the grammatical structure implies that the counterfactual's antecedent $(A)$ is factually false. For instance, consider the utterance of the following counterfactual in the context of a randomly drawn poker card:

> If the drawn card were to show an ace $(A)$, then it would show spades $(C)$.

The grammatical structure of (1) pragmatically entails that the drawn card is not an ace $(\neg A)$, i.e., the antecedent $A$ of (1) is false. By "indicative conditional" we mean an "if-then" statement of the form If A, then $C$, e.g.,

If the drawn card shows an ace, then it shows spades.
Contrary to the counterfactual (1), the indicative conditional (2) does not imply whether the card actually shows an ace or not. While the core meaning of indicative conditionals was equated with the semantics of the material conditional in the classical logic-based paradigm (or "old") psychology of reasoning (see, e.g., Braine \& O’Brien, 1998; JohnsonLaird, 1983; Rips, 1994; Wason \& Johnson-Laird, 1972), our work is located in the new paradigm psychology of reasoning, where conditionals are interpreted as conditional probability assertions (see, e.g., Elqayam, Bonnefon, \& Over, 2016;

Oaksford \& Chater, 2007; Over, 2009; Pfeifer, 2013). Instead of using (fragments of) classical logic, the new paradigm psychology of reasoning uses probability theory as a rationality framework. Probability as a rationality framework is psychologically and philosophically appealing for many reasons (see, e.g., Pfeifer \& Douven, 2014). Let us mention three of them.

First, probability theory allows for managing degrees of belief instead of restricting belief to the two values true and false as in the case of bivalent classical logic. Thus, probability theory provides a much richer framework to study conditionals. It allows for analysing different psychological predictions concerning conditionals: not only in terms of the material conditional $(A \supset C)$ and the conjunction $(A \wedge C)$ as defined in classical logic, but also in terms of the conditional event $(C \mid A)$, as defined in coherence-based probability logic (see, e.g., Coletti \& Scozzafava, 2002; Gilio, Pfeifer, \& Sanfilippo, 2016; Pfeifer \& Kleiter, 2009). Table 1 presents the truth conditions of these three interpretations. Note that the conditional event cannot be expressed in classical bivalent logic. We hypothesise that the degree of belief in a conditional If $A$, then $C$ is interpreted by a suitable conditional probability assertion $(p(C \mid A))$ and neither as the probability of the material conditional $(p(A \supset C))$ nor as the probability of the conjunction $(p(A \wedge C))$. We will test these three interpretations in the following experiment.

Table 1: Truth tables for the material conditional $A \supset C$ interpretation, the conjunction $\wedge$ interpretation and the conditional event interpretation $C \mid A$ of a (counterfactual) conditional If $A$ (were the case), then $C$ (would be the case).

| $A$ | $C$ | $A \supset C$ | $\wedge$ | $C \mid A$ |
| :---: | :---: | :---: | :---: | :---: |
| true | true | true | true | true |
| true | false | false | false | false |
| false | true | true | false | undetermined |
| false | false | true | false | undetermined |

Second, probability logic blocks so-called paradoxes of the material conditional (see, e.g., Pfeifer, 2014). For example, $\neg A$ ("not-A") logically entails $A \supset C$. The paradox arises, when the material conditional is used to formalize a natural language conditional. Then, for example, the conditional "if it rains today, then I'll be a billionaire tomorrow", follows from the premise "it does not rain today": this inference violates common sense but it is logically valid. In probability logic, the inference from $p(\neg A)=x$ to $p(C \mid A)$ is probabilistically non-informative, i.e., if $p(\neg A)=x$, then $0 \leq p(C \mid A) \leq 1$ is coherent; hence, the paradox is blocked (Pfeifer, 2014). Whether an inference is probabilistically informative or not is a binary question: if the best possible coherent probability bounds on the conclusion coincide with the unit interval $[0,1]$, then the argument form is probabilistically non-informative; otherwise, it is probabilistically formative (i.e., the premise set constrains the probability of the conclusion). The the-
oretical prediction that the paradox is probabilistically noninformative also matches experimental data based on samples involving Westerners (Pfeifer \& Kleiter, 2011; Pfeifer \& Tulkki, 2017b). Note that the paradox is not blocked if the conditional probability (conclusion) is replaced by $p(A \supset C)$ or by $p(A \wedge C)$. A subgoal of this paper is to explore how Japanese participants reason about this paradox.

Third, probability allows for retracting conclusions in the light of new evidence while classical logic is monotonic (i.e., adding a premise to a logically valid argument can only increase the set of conclusions). The suppression effect (see, e.g., Byrne, 1989; Stenning \& van Lambalgen, 2005) illustrates peoples' capacity to retract conclusions if new premises are learned. Moreover, experimental data suggests that most people satisfy basic nonmonotonic reasoning postulates of System P (see, e.g. Benferhat, Bonnefon, \& Da Silva Neves, 2005; Pfeifer \& Kleiter, 2005, 2010). The rules of System P describe formally basic principles any system of nonmonotonic reasoning should satisfy (Kraus, Lehmann, \& Magidor, 1990) and different semantics were developed, including probabilistic ones. Probabilistic semantics postulate that conditionals should be represented by conditional probability assertions (see, e.g., Adams, 1975; Gilio, 2002). Interestingly, inference rules which are (in)valid in System P are also (in)valid in standard systems of counterfactual conditionals (like Lewis, 1973). This convergence shows a close relation between conditional probabilities and counterfactuals. Compared to the big number of psychological investigations on indicative conditionals (for overviews see, e.g., Evans \& Over, 2004; Nickerson, 2015), studies on adult reasoning about counterfactuals are surprisingly rare (Over, Hadjichristidis, Evans, Handley, \& Sloman, 2007; Pfeifer \& Stöckle-Schobel, 2015; Pfeifer \& Tulkki, 2017b). Our study sheds new light by adding a cross-cultural perspective on indicative conditionals and counterfactuals.

Table 2: Task names, their abbreviations and formal structures used in the experiment, where $\neg$ denotes negation, $\rightarrow$ is a placeholder for denoting the indicative conditional or the counterfactual, $\supset$ denotes the material conditional, $\therefore$ denotes "Therefore".

| Task name (abbreviation) | Argument form |
| :--- | :--- |
| Aristotle's thesis \#1 (AT1) | it's not the case that: $(\neg A \rightarrow A)$ |
| Aristotle's thesis \#2 (AT2) | it's not the case that: $(A \rightarrow \neg A)$ |
| Negated Reflexivity (NR) | it's not the case that:( $A \rightarrow A)$ |
| From "Every" to "If" (EIn) | Every $S$ is $P \therefore S \rightarrow \neg P$ |
| From "Every" to "If" (EI) | Every $S$ is $P \therefore S \rightarrow P$ |
| Modus Ponens (MP) | $A, A \rightarrow C \therefore C$ |
| Negated MP (NMP) | $A, A \rightarrow C \therefore \neg C$ |
| Paradox (Prdx) | $\neg A \therefore A \rightarrow C$ |

Table 2 lists the task names, their abbreviations, and their underlying logical form used in our experiment. All argu-
ment forms were investigated previously in the literature on Western samples. Each argument form is suitable for indicative and subjunctive formulations. They are carefully selected to distinguish between the material conditional, conjunction and conditional event interpretation of conditionals. Tasks AT1, AT2, and NR (adapted from Pfeifer, 2012) are about negating conditionals. AT1 and AT2 are contingent (i.e., they are neither tautologies nor contradictions) under the material conditional interpretation of conditionals: specifically, $\neg(\neg A \supset A) \equiv \neg(\neg \neg A \vee A) \equiv \neg A$ and $\neg(A \supset \neg A) \equiv \neg(\neg A \vee$ $\neg A) \equiv \neg \neg A \equiv A$. Since we don't know anything about $(\neg) A$, probability logic predicts for AT1: $0 \leq p(\neg(\neg A \supset A)) \leq 1$; likewise, for AT2: $0 \leq p(\neg(A \supset \neg A)) \leq 1$. For the conditional event interpretation, however, both AT1 and AT2 obtain probability one, since in general coherence requires that $p(A \mid \neg A)=p(\neg \mid A)=0$ for any contingent $A$ and since by the narrow scope reading of conditionals, AT1 is represented by $p(\neg A \mid \neg A)$ and AT2 is represented by $p(A \mid A)$ and 1 is the only coherent assessment for the respective conditional probabilities. Note that there are two ways to negate material conditionals, namely the wide scope negation of material conditionals (i.e., $A \supset C$ can be negated by $\neg(A \supset C)$ ) and the narrow scope negation of material conditionals (i.e., $A \supset C$ is negated by negating its consequent $C: A \supset \neg C$ ). Note that if people interpret $\rightarrow$ by $\supset$ but negate the conditional by the narrow scope interpretation of negation of conditionals, the predictions for AT1 and AT2 coincide with the predictions of the conditional probability interpretation of conditionals (since AT1: $p(\neg A \supset \neg A)=p(\neg \neg A \vee \neg A)=p(A \vee \neg A)=1$ and since AT2: $p(A \supset \neg \neg A)=p(\neg A \vee \neg \neg A)=p(\neg A \vee A)=1)$. To disentangle the conditional probability interpretation and the narrow scope negation of the material conditional interpretation, we added the NR task. The NR task, the narrow scope negation of the material conditional interpretation predicts that the whole unit interval is coherent, since the instruction does not reveal any probabilistic information about $\neg A$ and since $(A \supset \neg A) \equiv(\neg A \vee \neg A) \equiv \neg A$, hence $0 \geq p(A \supset$ $\neg A) \leq 1$, while coherence requires that $p(\neg A \mid A)=0$.

Table 3 lists the normative predictions of the different argument forms. Averaging the percentages of responses in three studies reveals that $73 \%$ of the participants in task AT1, $75 \%$ in task AT2, and $80 \%$ of the participants in task NR responded probabilistically coherently according to the conditional probability interpretation (Pfeifer, 2012; Pfeifer \& Stöckle-Schobel, 2015; Pfeifer \& Tulkki, 2017b).

Task EI (resp., task EIn) connects the basic syllogistic sentence type "Every $S$ is $P$ " with associated conditionals (resp., conditionals involving negations) in the indicative and in the counterfactual form. The motivation for these tasks is to shed light on the hypothesised close relations between quantified statements and conditional probability assertions in the literature (see, e.g. Cohen, 2012; Pfeifer \& Sanfilippo, 2017, submitted). Recent data of Westerners suggest, that in task ASP $73 \%$ of the participants respond that the conclusion holds, whereas $88 \%$ of the participants respond that the conclusion
in task ASnP does not hold (Pfeifer \& Tulkki, 2017b), which corresponds to the normative predictions.

We also investigate the well-known MP and its not logically valid but probabilistically informative counterpart NMP. In a sample of Western participants (Pfeifer \& Tulkki, 2017b), $68 \%$ responded correctly, that the conclusion in task MP holds, and $63 \%$ responded correctly that the conclusion in task NMP does not hold (see also Pfeifer \& Kleiter, 2007).

Although tasks EIn, EI, MP, and NMP do not differentiate among the three considered interpretations of the conditionals, these tasks were selected (i) to test whether the responses of the Japanese sample differs from responses of corresponding Western samples and (ii) to investigate whether there are differences in the responses between the two experimental conditions (i.e., indicative versus counterfactual conditionals).

Finally, as mentioned above, we investigate one of the paradoxes of the material conditional. Western data on Task Prdx indicates that most people ( $87 \%$ on the average) understand that this argument form is probabilistically non-informative (Pfeifer \& Kleiter, 2011; Pfeifer \& Tulkki, 2017b).

## Method

## Materials and Design

We used a $2 \times 2$ between-participants design where we crossed task formulations in terms of indicative conditionals versus formulations in terms of counterfactuals. To control for position effects, we used two random orders (generated by random.org). This resulted in four different task booklets.

Each booklet consisted of a brief introduction, of eight tasks, and of questions about the booklets (task difficulty, whether participants took logic or probability classes and whether they like maths). Furthermore, we included usual demographic questions at the end. The logical forms of the eight tasks are explained in Table 2. We instantiated these logical forms into a cover story which was already used in studies on Western samples (see, e.g., Pfeifer \& Kleiter, 2011; Pfeifer \& Tulkki, 2017b). We adapted and translated this cover story for the Japanese sample.

For each task, the participants were asked to imagine the following situation:

> Hanako works in a factory that produces toy blocks. She is responsible for controlling the production. Every toy block has a shape (cylinder, cube or pyramid) and a colour (red, blue or green). For example:
> - Red cylinder, red cube, red pyramid
> - Blue cylinder, blue cube, ...
> - Green cylinder, ...

Then, for example in task AT1 (indicative conditional), the participants were asked to consider the following sentence:

[^432]（もしおもちゃのブロックが立方体ではないならば，そのおも ちゃのブロックは立方体である，というわけではない。）

The instructions continued by the following questions， which prompt answers in a forced choice format：

> Can Hanako infer at all how sure she can be that the sentence in the box holds? (please tick the appropriate box)
> $\square$ NO, Hanako can not infer how sure she can be that the sentence in the box holds.
> $\square$ YES, Hanako can infer how sure she can be that the sentence in the box holds.

The previous question serves to give the opportunity to re－ spond in a non－informative way and thereby avoid conver－ sational implicatures which could bias the participant to re－ spond in an informative manner．Specifically，we aim to in－ vestigate to what extent the participants are able to distinguish probabilistically informative and non－informative argument forms．The next question prompts a qualitative evaluation of the conclusion of argument forms which are perceived to be probabilistically informative：

If you chose＂YES＂，please tick one of the following answers：
$\square$ Hanako can be sure that the sentence in the box holds．
$\square$ Hanako can be sure that the sentence in the box does not hold．

After each target task，the participants were instructed to rate on a scale their subjective confidence in their response．The corresponding AT1 task involving counterfactuals was formu－ lated in exactly the same way with the difference，that the indicative conditional was replaced by a corresponding coun－ terfactual，as follows：

> | It is not the case, that: If the toy block were not a cube, |
| :--- |
| then the toy block would be a cube. |

（もしおもちゃのブロックが立方体ではなかったとすれば，そのお もちゃのブロックは立方体であるだろう，というわけではない。）

Note that AT1 can be conceived as an inference from an empty premise set．For those tasks involving explicit premises（i．e．，in tasks EIn，EI，MP，NMP，and Prdx），we for－ mulated uncertainties in terms of verbal descriptions（＂極め て確実である＂；＂quite sure＂）．For instance，consider task MP：
（A）．．．quite sure that the toy block is a cube．
（B）．．．quite sure that if the toy block is a cube，then it is red．
Our reason for qualitative premise and conclusion probabil－ ities in terms of verbal descriptions of probabilities（instead of quantitative probabilities）was to reduce the psychological complexity of the probabilistic inference．In this study，we were interested in the interpretation of negations and condi－ tionals but not in the numerical propagation of the probabili－ ties from the premises to the conclusion．

## Participants and procedure

63 Osaka City University undergraduate students participated in this study（mean age $20.02(S D=1.05)$ years， 34 females， 21 males， 8 did not disclose their gender）．Their major sub－ jects included various humanistic fields（ 3 commerce， 5 cul－ ture， 1 geography， 5 history， 4 Japanese， 8 law， 5 linguistics， 1 pedagogy， 2 philosophy， 17 psychology， 2 sociology，and 10 other）．Nobody had ever taken logic classes but two partici－ pants had previously taken some probability classes．At the end of the experiment，participants evaluated the set of tasks as rather difficult（mean $2.76(S D=2.11)$ on a scale rang－ ing from 0 （＂very difficult＂）to 10 （＂very easy＂））． $82.54 \%$ reported that they do not like maths．

All participants were tested at the same time during a les－ son in a course on cultural psychology．For reducing the probability for copy－pasting responses，the booklets were dis－ tributed such that the two task orders and the two formula－ tions of the conditionals（indicative vs．counterfactual）alter－ nated systematically．Moreover，the experimenter announced that the task booklets differ before the participants started with filling in their responses．The booklets were formulated in Japanese，the participants＇mother tongue．

## Results and discussion

We performed Fisher＇s exact tests to compare the response frequencies among the four booklets（task order $1 \times$ task or－ der $2 \times$ indicative conditionals $\times$ counterfactuals）and did not observe any significant differences after performing Holm－ Bonferroni corrections for multiple significance tests．Like－ wise，analyses of variance on the participant＇s confidence ratings in the correctness of their responses did not show statistically significant differences among the four booklets． This replicates previous findings in studies which used West－ ern samples．Specifically，studies on probabilistic truth table tasks（Over et al．，2007；Pfeifer \＆Stöckle－Schobel，2015） and on uncertain argument forms（Pfeifer \＆Tulkki，2017b） did not detect significant difference between indicative con－ ditionals and counterfactuals．Thus，our data speak against cross－cultural differences between Easterners and Western－ ers．This calls for further experiments to clarify whether this interesting negative result is due to a too high dissimilarity of our tasks compared to those in other studies on cross－cultural differences．Or，alternatively，whether cross－cultural differ－ ences are not that strong as they are claimed to be（see，e．g．， Zhang et al．，2015）．

Since there were no significant differences in the responses among the four booklets，we pooled the data for the follow－ ing data analysis $(N=63)$ ．Concerning the interpretation of conditionals，we observed high endorsement rates of the con－ ditional probability hypothesis（see Table 3）．This is strong support for the hypothesis that both indicative conditionals and counterfactuals are best modeled by conditional proba－ bility．

Table 4 presents the mean confidence ratings，which shows how sure the participants are that their responses are correct．

Table 3: Percentages ( $n=63$ ) of "holds" (hld), "does not hold" ( $\neg$ hld), and probabilistic non-informativeness responses ( n -inf; see also Table 2). Predictions based on the conditional probability hypothesis of conditionals are in bold. Alternative hypotheses are indicated in parentheses: $\neg_{\supset}$ (resp., $\supset_{\urcorner}$) denotes wide (resp., narrow) scope negation of the material conditional $\supset ; \wedge$ denotes conjunction. If not specified otherwise, predictions coincide.

|  | AT1 | AT2 | NR | EIn |
| ---: | :--- | :--- | :--- | :--- |
| hld: | $\mathbf{6 5 . 0 8}(\supset \neg)$ | $\left.\mathbf{7 6 . 1 9}\left({ }_{\wedge}\right\urcorner\right)$ | 6.35 | 6.45 |
| $\neg$ hld: | 15.87 | 11.11 | $\mathbf{6 3 . 4 9}(\neg \supset)$ | $\mathbf{6 9 . 3 5}$ |
| n-i: | $19.05(\neg \supset)$ | $12.70(\neg))$ | $30.16\left(\neg_{\wedge}\right)$ | 24.20 |
|  | EI | MP | NMP | Prdx |
| hld: | $\mathbf{8 8 . 8 9}$ | $\mathbf{5 3 . 9 7}$ | 9.52 | $0.00\left({ }^{\circ}\right)$ |
| $\neg$ hld: | 6.35 | 3.17 | $\mathbf{5 2 . 3 8}$ | $17.46(\wedge)$ |
| n-inf: | 4.76 | 42.86 | 38.10 | $\mathbf{8 2 . 5 4}$ |

The confidences are relatively high, with an average value of 7.2 on a rating scale from 0 to 10 .

Table 4: Mean $(M)$ and standard deviations $(S D)$ of the participants' confidence ratings ( $n=63$ ) on a scale from 0 ("very sure that my response is not correct") to 10 ("very sure that my response is correct"; see also Table 2).

|  | AT1 | AT2 | NR | EIn | EI | MP | NMP | Prdx |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| $M$ | 6.77 | 6.86 | 7.20 | 7.71 | 8.02 | 7.18 | 7.02 | 6.82 |
| $S D$ | 1.99 | 2.06 | 2.37 | 1.99 | 1.97 | 2.10 | 2.08 | 1.93 |

## Concluding remarks

Our data suggest that people form their degree of belief in the counterfactual If A were the case, $C$ would be the case by equating it with the corresponding conditional probability of $C \mid A$. This is consistent with the observation in previous experimental work (with Western participants) that people treat the factual statement as irrelevant when they form their degree of belief in a counterfactual (Pfeifer \& Stöckle-Schobel, 2015; Pfeifer \& Tulkki, 2017b, 2017a). This can be justified and explained by the coherence-based theory of nested conditionals (Gilio \& Sanfilippo, 2013, 2014; Gilio, Over, Pfeifer, \& Sanfilippo, 2017, submitted). Given three events $A, B, C$ with incompatible $A$ and $B$ (i.e., $A \wedge B$ is a logical contradiction) the prevision of the conditional random quantity $((C \mid B) \mid A)$ is equal to $p(C \mid B)$ (Gilio \& Sanfilippo, 2013, Example 1, p. 225). Thus, the counterfactual If $A$ were the case, $C$ would be the case can be modeled by the degree of belief in the conditional random quantity $(C \mid A) \mid \neg A$ which equals to $p(C \mid A)$ (i.e., Prevision $((C \mid A) \mid \neg A)=p(C \mid A)$ ). This is an explanation for why people-as experimentally demonstrated in Western
samples and also in our Japanese sample-respond by corresponding conditional probabilities when asked to give a degree of belief in a counterfactual.

Our data suggest a negative answer to the question whether there are cross-cultural differences between Easterners and Westerners w. r. t. reasoning about indicative conditionals, counterfactuals, and their negations. Further experimental work, e.g., involving causal task material (see, e.g. Over et al., 2007; Pfeifer \& Tulkki, 2017a), is needed to substantiate the hypothesis that conditional probability is the universal key ingredient for psychological theories of indicative conditionals and counterfactuals.

The material conditional interpretation of conditionals was the gold standard to evaluate human reasoning about conditionals in the old paradigm psychology of reasoning. Our data do not support the material conditional interpretation. Rather, our results strongly support the conditional probability interpretation of conditionals, which became prominent in the new paradigm psychology of reasoning and which received strong experimental support in recent years (see, e.g., Elqayam et al., 2016; Fugard, Pfeifer, Mayerhofer, \& Kleiter, 2011; Over, 2009). Even though most of the data was collected on Western samples, but given the theoretical plausibility of the the conditional probability interpretation, we think that this is further suggests that universality in human reasoning.

Finally, we note that adaptation of reasoning styles can be one of the universal adaptive strategies across cultures. The question of which aspects of human reasoning are universal, and in how far they are universal, is important and calls for collaborations of psychologists of reasoning and cultural psychologists.

# Abductive, Causal, and Counterfactual Conditionals Under Incomplete Probabilistic Knowledge 

Niki Pfeifer (niki.pfeifer@lmu.de)<br>Munich Center for Mathematical Philosophy, LMU Munich, Germany<br>Leena Tulkki (leena.tulkki@helsinki.fi)<br>Department of Philosophy, History, Culture and Art Studies, University of Helsinki, Finland

#### Abstract

We study abductive, causal, and non-causal conditionals in indicative and counterfactual formulations using probabilistic truth table tasks under incomplete probabilistic knowledge ( $N=80$ ). We frame the task as a probability-logical inference problem. The most frequently observed response type across all conditions was a class of conditional event interpretations of conditionals; it was followed by conjunction interpretations. An interesting minority of participants neglected some of the relevant imprecision involved in the premises when inferring lower or upper probability bounds on the target conditional/counterfactual ("halfway responses"). We discuss the results in the light of coherence-based probability logic and the new paradigm psychology of reasoning.

Keywords: abductive conditionals; causal conditionals; counterfactuals; indicative conditionals; psychological experiment; uncertain argument form; probabilistic truth table task

## Introduction

The probabilistic truth table task was introduced by two independent studies at the beginning of this millennium (Evans, Handley, \& Over, 2003; Oberauer \& Wilhelm, 2003). It serves to investigate how people interpret conditionals under uncertainty. Moreover, it is one of the starting points of the new (probability-based) paradigm psychology of reasoning (see, e.g. Baratgin, Over, \& Politzer, 2014; Elqayam, Bonnefon, \& Over, 2016; Oaksford \& Chater, 2007; Over, 2009; Pfeifer, 2013; Pfeifer \& Douven, 2014), which started to replace the old (classical logic-based) paradigm psychology of reasoning. The probabilistic truth table task was constructed to investigate how people interpret conditionals (i.e., indicative sentences of the form If $A$, then $C$ ). As its name suggests, the task consists of inferring the degree of belief in a conditional based on probabilistic information attached to the truth table cases. What are truth table cases? Let $A$ and $C$ denote two propositions (i.e., sentences for which it makes sense to assign the truth values true or false) like a fair die is rolled and the side of the die shows an even number, respectively. The four truth table cases induced by $A$ and $C$ are: $A \wedge C$, $A \wedge \neg C, \neg A \wedge C$, and $\neg A \wedge \neg C$, where $\wedge$ denotes conjunction ("and") and $\neg$ denotes negation. Classical logic is bivalent, involving only the truth values true and false. Therefore, the conditional defined in classical logic (i.e., the material conditional, see Table 1) is either true or false. The conditional event $C \mid A$ involved in conditional probability ( $p(C \mid A)$ ), however, is not bivalent, as it is void (or undetermined) if its antecedent $A$ is false (see Table 1). Therefore, it cannot be represented by the means of classical logic.

Table 1 presents the truth conditions of the most important psychological interpretations for adult reasoning about indicative conditionals (i.e., conditional event, conjunction, and material conditional). Moreover, it presents the biconditional and biconditional event interpretations, which were reported in developmental psychological studies (see, e.g. Barrouillet, Gauffroy, \& Lecas, 2015).

Psychological evidence for the conditional event interpretation was already observed within the old paradigm psychology of reasoning (see, e.g., Wason \& Johnson-Laird, 1972). The response pattern, which is consistent with the conditional event interpretation was seen as irrational (dubbed "defective truth table"), as it violates the semantics of the material conditional. The material conditional used to be the gold standard of reference for the meaning of indicative conditionals in the old paradigm. However, within the new paradigm psychology of reasoning this response pattern is, of course, perfectly rational (Over \& Baratgin, 2017; Pfeifer \& Tulkki, 2017).

Table 1: Truth tables for the material conditional $A \supset C$, the conjunction $A \wedge C$, the biconditional $A \equiv C$, the biconditional event $C|\mid A$ (i.e., $A \wedge C| A \vee C$ ), and the conditional event $C \mid A$.

| $A$ | $C$ | $A \supset C$ | $A \wedge C$ | $A \equiv C$ | $C \\| A$ | $C \mid A$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| true | true | true | true | true | true | true |
| true | false | false | false | false | false | false |
| false | true | true | false | false | false | void |
| false | false | true | false | true | void | void |

While classical truth table tasks require to respond with truth values, probabilistic truth table tasks require to with respond degrees of belief. Following Pfeifer (2013), we interpret the task as a probability logical inference problem. Specifically, it is formalised as a probability logical argument with assigned degrees of belief in the four truth table cases as its premises and the degree of belief in a conditional as its conclusion. The inference problem consists in propagating the uncertainties of the premises to the conclusion. As an example, consider the conditional probability interpretation of the $(p(C \mid A))$ conditional If $A$, then $C$ as the conclusion. This argument scheme is formalised by:
(A) From $p(A \wedge C)=x_{1}, p(A \wedge \neg C)=x_{2}, p(\neg A \wedge C)=x_{3}$, and $p(\neg A \wedge \neg C)=x_{4}$, infer $p(C \mid A)=x_{1} /\left(x_{1}+x_{2}\right)$.

In argument scheme $(\mathcal{A})$, the fraction $x_{1} /\left(x_{1}+x_{2}\right)$ is the prob-
ability propagation rule for the conditional probability. For different interpretations of the conditional, the probability propagation rules differ. Table 2 presents the corresponding probability propagation rules of the interpretations given in Table 1.

Table 2: Probability propagation rules for the different interpretations of If $A$, then $C$. The premise set $\{p(A \wedge C)=$ $\left.x_{1}, p(A \wedge \neg C)=x_{2}, p(\neg A \wedge C)=x_{3}, p(\neg A \wedge \neg C)=x_{4}\right\}$ entails the respective conclusion (see also Table 1).

| Interpretation | Conclusion |
| :--- | :--- |
| Material conditional | $p(A \supset C)=x_{1}+x_{3}+x_{4}$ |
| Conjunction | $p(A \wedge C)=x_{1}$ |
| Biconditional | $p(A \equiv C)=x_{1}+x_{4}$ |
| Biconditional event | $p\left(C\|\mid A)=x_{1} /\left(x_{1}+x_{2}+x_{3}\right)\right.$ |
| Conditional event | $p(C \mid A)=x_{1} /\left(x_{1}+x_{2}\right)$ |

The main empirical result of classical probabilistic truth table tasks is that the dominant responses are consistent with the conditional event interpretation of conditionals. Moreover, if people solve the task several times, some people shift to the conditional event interpretation during the course of the experiment (see, e.g., Fugard, Pfeifer, Mayerhofer, \& Kleiter, 2011a; Pfeifer \& Stöckle-Schobel, 2015).
A key feature of classical probabilistic truth table tasks is that they present complete probabilistic knowledge w.r.t. the truth table cases: all (point-valued) probabilities $x_{1}, \ldots x_{4}$ are available to the participant (see, e.g., Evans et al., 2003; Oberauer \& Wilhelm, 2003; Fugard et al., 2011a; Pfeifer \& Stöckle-Schobel, 2015). When all probabilities involved in argument scheme $(\mathcal{A})$ are given as point values, for example, it is possible to infer a precise (point-valued) probability of $C \mid A$. Of course, $x_{3}$ and $x_{4}$ are irrelevant for calculating $p(C \mid A)$ in this case. However, as full probabilistic information is usually not available in everyday life, we argue for investigating incomplete probabilistic knowledge. If $x_{1}$ in argument scheme $(\mathcal{A})$ is only available as an imprecise (i.e., interval-valued) probability, i.e., $x_{1}^{\prime} \leq p(A \wedge C) \leq x_{1}^{\prime \prime}$, the probability of the conclusion of $(\mathcal{A})$ is also imprecise, i.e., $x_{1}^{\prime} /\left(x_{1}^{\prime}+x_{2}\right) \leq p(C \mid A) \leq x_{1}^{\prime \prime} /\left(x_{1}^{\prime \prime}+x_{2}\right)$. Table 4 (see below) presents a numerical illustration of the different interpretations of conditionals in the probabilistic truth table task with imprecise premises. Incomplete probabilistic knowledge has not been investigated within the probabilistic truth table task paradigm yet (for an exception, where only indicative conditionals were investigated, see Pfeifer, 2013).

With only a few exceptions (i.e., Over, Hadjichristidis, Evans, Handley, \& Sloman, 2007; Pfeifer \& Stöckle-Schobel, 2015), the important classes of causal conditionals and counterfactuals have not been investigated empirically within the probabilistic truth table task paradigm yet. Causal conditionals are characterized by connecting cause (i.e., the conditional's antecedent) and effect (i.e., the conditional's consequent), like If you take aspirin, your headache will disappear.

Counterfactuals are conditionals in subjunctive mood, where the grammatical structure signals that the antecedent is false. For instance, If you were to take aspirin (A), your headache would disappear $(D)$, which signals that you had not taken aspirin yet $(\neg A)$. This example is a counterfactual version of the above described causal conditional. Of course, there are also non-causal versions of counterfactuals, like If the side of a card were to show an ace, it would show spades.

Traditionally, counterfactuals are interpreted by possible world semantics (most prominently by Lewis and Stalnaker). However, we interpret counterfactuals in terms of coherence based probability logic. In a nutshell, the aforementioned example of a (causal) counterfactual can by interpreted by a (right-)nested conditional, where the antecedent represents the factual statement $\neg A$ and the consequent represents the conditional $D \mid A$. This representation amounts to $(D \mid A) \mid \neg A$, which is a conditional random quantity (because of the pagelimit we refer for the technical details to Gilio \& Sanfilippo, 2013, 2014; Gilio, Over, Pfeifer, \& Sanfilippo, 2017, submitted). It can be proved that the degree of belief in the conditional random quantity $(D \mid A) \mid \neg A$ is also equal to $p(D \mid A)$ (i.e., Prevision $((D \mid A) \mid \neg A)=p(D \mid A)$; see Gilio \& Sanfilippo, 2013, Example 1, p. 225). Therefore, we hypothesize that the participants' degrees of belief in counterfactuals are equal to corresponding conditional probabilities.

Note that the conditional random quantity $(C \mid A) \mid \neg A$ does not coincide with $C \mid(A \wedge \neg A)$, because the Import-Export Principle does not hold (Gilio \& Sanfilippo, 2014). Therefore, as shown by Gilio and Sanfilippo (2014), the counterintuitive consequences of the well-known triviality results (Lewis, 1976) are avoided. By the way, the formula $C \mid(A \wedge$ $\neg A$ ) is unintelligible (in terms of the Ramsey test, you cannot add a contradiction to your stock of beliefs).

To our knowledge, abductive conditionals have not been empirically investigated in the probabilistic truth table task paradigm yet. Abductive conditionals can be conceived as reversed causal conditionals, characterized as follows: the effect is located in the conditional's antecedent and the cause is located in the conditional's consequent. For example, If your headache disappeared, then you took aspirin. Abductive inferences are also known as inferences to the best explanation (for philosophical and psychological overviews on abduction see, e.g., Douven, 2016a; Lombrozo, 2012, respectively). Like indicative and causal conditionals, abductive conditionals can be formulated in indicative and in subjunctive mood.

The aim of the present study is to help to fill the above mentioned research gaps. Specifically, we aim to shed light on the following questions using probabilistic truth table tasks under incomplete probabilistic knowledge: Are there reasoning strategies for inferring lower and upper bounds in the context of incomplete probabilistic knowledge? Is the conditional event interpretation dominant for abductive, causal, and non-causal counterfactuals?

#### Abstract

Method Materials and Design The task material consisted of 18 pen and paper tasks, preceded by 4 examples explaining the answer format. The task sequence consisted of 9 different tasks that were presented twice in the same random order (i.e., task T10 is a repetition of task T1), resulting in the total of 18 tasks. The tasks were designed to test how participants infer about uncertain conditional sentences in four different experimental conditions (see Table 3). All conditions had the same task sequence, with the following variations: For the first two conditions we used a non-causal scenario in both indicative and counterfactual moods. For the other two conditions we used two variations of a causal scenario in counterfactual mood; inference from causes to effects (causal) and inference from effects to causes (abductive). The material was adapted from probabilistic truth table tasks, which involved precise premises (Fugard et al., 2011a; Pfeifer \& Stöckle-Schobel, 2015).

Table 3: Between participant conditions $\mathrm{C} 1-\mathrm{C} 4$ defined by the types and formulations of conditionals, and sample sizes. |  | Type | Formulation | Sample |
| :--- | :--- | :--- | :---: |
| C1 | non-causal | indicative | $\left(n_{1}=20\right)$ |
| C2 | non-causal | counterfactual | $\left(n_{2}=20\right)$ |
| C3 | causal | counterfactual | $\left(n_{3}=20\right)$ |
| C4 | abductive | counterfactual | $\left(n_{4}=20\right)$ |

For the non-causal scenario we used a vignette story about a six-sided die. The story describes that the die was randomly thrown so that the participants did not know which of the sides ended up facing upwards. The sides of the die were illustrated as six squares. Each side had an image of a black or white geometric figure. In tasks T1, T2, T10, and T11 all sides of the die were shown. To introduce incomplete probabilistic knowledge we presented "covered" sides in the rest of the tasks. Covered sides were indicated by a question mark. Here is an example of how we presented the six sides of a die (task T3/T12):

Next, the participants were presented with the question "How sure can you be that the following sentence holds?" (Kuinka varma voit olla siitä, että seuraava lause pitää paikkaansa?). The target sentences were highlighted with a frame to make the scope of the question clear, for example:

[^433]The answer format had two sets of tick boxes in a " $x$ out of $y$ " format for responding interval-valued degrees of belief. The two response boxes were labeled accordingly ("at least" and "at most"); for instance, as follows:

It was explained in the introduction to give point valued responses by marking the same numbers in both response boxes (i.e., lower and upper bounds coincide).

The target sentence in the non-causal tasks was formulated in terms of "If $A$, then $C$ ". In all non-causal tasks the antecedent mentioned a form and the consequent mentioned a color. After completing each task, the participants were asked to rate their confidence in the correctness of their response on a 10 -step rating scale from "fully confident that your answer is incorrect" to "fully confident that your answer is correct".
Apart from the following two differences, the counterfactual task version was identical to the indicative version of the task: (i) we added a factual statement which contradicted the antecedent of the target sentence and (ii) the target sentence was formulated in subjunctive mood. "The form of an upward-facing side of the die is a cube" is an example of a factual statement and the corresponding target sentence is: "if the figure on the upward facing side of the die were a circle, then the figure would be black" (Jos ylöspäin osoittavan kyljen kuvio olisi ympyrä, niin tämä kuvio olisi musta). The suffix -isi in the Finnish original indicates the counterfactual mood.

For the causal and abductive conditions, the tasks were structurally identical to the (non-causal) dice-scenario. However, instead of dice, a vignette story about drugs and their effects created a causal scenario. In the vignette story, six patient reports were shown to the participants. The patient reports were illustrated as six rectangles having a name of a fictional drug and a result of the medication (either "diminishes symptoms" or "no impact on the symptoms"). We used question marks on some patient reports (like in the dice scenario) to introduce incomplete probabilistic knowledge. Here is an example of the patient reports, which contains the same probabilistic information as the above mentioned die-example:

In the causal version of the task material the antecedent denotes the name of a drug and the consequent denotes an effect. In the abductive version the order was reversed: first an effect was presented and then a drug was named. In this way the tasks called for either causal inferences from causes to effects, or abductive inferences from effects to causes. As the material was formulated in counterfactual mood, we added a factual statement to each task, which contradicted the antecedent of the target sentence.

Participants and Procedure Eighty students from the University of Helsinki (Finland) participated in the experiment.

The students were native Finnish speakers with no previous academic training in logic or probability. Each participant was tested individually. The paper and pencil tasks were followed by a short structured interview about how the participants had interpreted the target tasks. Participants were paid $15 €$ for their participation.

## Results and Discussion

We performed Fisher's exact tests to investigate whether the four different versions of the task booklets had an impact on the participants' degrees of belief in the respective target sentences. After p -value corrections for multiple significance tests, we did not observe significant differences between the four conditions and we therefore pooled the data.

Table 5 shows the percentages of responses according to the different interpretations of conditionals. All tasks differentiate between the conditional probability, the conjunction, and the material conditional interpretation. A subset of the tasks differentiates between biconditional and biconditional event interpretations as well. Conditional probability interpretations marked with indices, however, were patterns identified from the data and were not anticipated during the construction of the task material. Therefore, not all tasks differentiate among all interpretations. Table 4 shows the normative answers for each interpretation for the example task discussed in the previous section (see (Die sides)). Both, lower and upper bound responses, had to match the normative lower and upper bounds for the categorization of the responses in Table 5. Since each response box enables 42 different " $X$ out of $Y$ " responses, and since both, lower and upper bound responses needed to match for the classification, the a priori chance for guessing an interpretation was very low (i.e., $\left.1 /\left(42^{2}\right)=0.0006\right)$.

Figure 1: Mean confidence values for tasks T1-T18 by condition. C1-C4 denote the four condition as defined in Table 3.

The task material was designed so that the normative predictions of the three main psychological interpretations of conditionals (i.e., conditional probability, conjunction, and

Table 4: Example of predicted responses where the task consists in inferring the degree of belief in the conditional "If the figure on the upward facing side of the die is a circle, then the figure is black" (i.e., the conclusion), based on the die presented in (Die sides) above (i.e., (Die sides) contains the premises). The index $\bar{l}$ (resp., $\bar{u}$ ) denotes conditional probability responses where the covered sides are ignored for inferring the lower (resp., upper) bound response. These response types are the "halfway lower" and "halfway upper" interpretations, respectively. $\overline{l u}$ denotes conditional probability responses where covered sides are ignored for inferring both bound responses, i.e., the "halfway both interpretation". See also Table 2.

| Interpretation | Predictions |  |
| :--- | :---: | :---: |
|  | at least | at most |
| $p($ black $\mid$ circle $)$ | 1 out of 2 | 2 out of 2 |
| $p(\text { black } \mid \text { circle })_{\bar{l}}$ | 1 out of 1 | 2 out of 2 |
| $p(\text { black \| circle })_{\bar{u}}$ | 1 out of 2 | 1 out of 1 |
| $p(\text { black } \mid \text { circle })_{\bar{u}}$ | 1 out of 1 | 1 out of 1 |
| $p($ circle $\wedge$ black $)$ | 1 out of 6 | 2 out of 6 |
| $p($ circle $\supset$ black $)$ | 5 out of 6 | 6 out of 6 |
| $p($ circle $\equiv$ black $)$ | 3 out of 6 | 4 out of 6 |
| $p($ circle $\\|$ black $)$ | 1 out of 4 | 2 out of 4 |

material conditional) were unique for each task. During the analysis we identified three further response strategies related to the conditional probability interpretation. In what we call halfway lower interpretation (denoted by $p(\cdot \mid \cdot)_{\bar{l}}$ ) the upper bound is the same as in conditional probability, but the lower bound response differs in that the covered sides (i.e., sides marked with question mark) are ignored. Halfway upper interpretation (denoted by $p(\cdot \mid \cdot)_{\bar{u}}$ ) is the same, but in reverse order. In a halfway both interpretation the covered sides are ignored for both bound responses. As these answer strategies are in a sense partial versions of the conditional probability interpretation, we combined their results with conditional probability answers into grouped conditional probability. Notice that the tasks T1,T2, T10 and T11 with full information (i.e., no question marks) have the same value for lower and upper bound answers. Therefore the halfway responses could not be distinguished from the conditional probability answers in these tasks.

Of all 1440 responses, $32.1 \%$ were consistent with standard conditional event responses, $29.9 \%$ were consistent with conjunction responses, and $0.2 \%$ were consistent with material conditional responses. Like the material conditional, also the biconditional and the biconditional event response frequencies play a neglectable rôle in the data $(0 \%-3 \%$ in the four tasks T3, T6, T12, T15 where these interpretations were differentiated). The predominant response strategy in pointvalued tasks (T1, T2, T10 and T11) was consistent with the conditional probability interpretation. In nine out of 14 tasks with incomplete probabilistic information (i.e., tasks involv-

Table 5: Percentages of responses from all four conditions and all 18 tasks (T1-T18; $N=80$ ). "Grouped $p(\cdot \mid \cdot)$ " denotes the sum of all conditional probability responses, including those marked with the indices. The halfway interpretations (indices $\bar{l}$ and $\bar{u}$ ) and the numerical predictions are explained in Table 4. "- -" denotes cases where different conditional probability interpretations cannot be individuated (i.e., in the point value tasks). Similarly, "[- -]" denotes cases where biconditional and biconditional event interpretations cannot be distinguished from the other interpretations. The interpretations are explained in Table 2. "** denotes psychological main interpretations.

ing "covered" sides or patient reports) the predominant answer strategy was conjunction. We also observed shifts of interpretation towards conditional probability: comparing the first three tasks with incomplete information (i.e., T3-T5) to the last three (i.e., T16-T18), the number of conditional probability answers increased from $19 \%$ to $30 \%$, and conjunction
answers decreased from $35 \%$ to $27 \%$. This replicates shifts of interpretations reported in the literature (Fugard et al., 2011a; Pfeifer, 2013).

However, when all the conditional probability response types are grouped together, the resulting set of response strategies is clearly the predominant one in all tasks. $51.5 \%$ of all answers are consistent with the grouped conditional probability responses. $18.1 \%$ were "other" responses, that is, responses that did not fit the grouped conditional probability, conjunction, biconditional, biconditional event, or material conditional. Thus, in total $81.9 \%$ of the data can be modeled by the investigated hypotheses concerning the interpretation of conditionals.

Compared to a previous study that investigated non-causal indicative conditionals under incomplete probabilistic information (Pfeifer, 2013, i.e., similar tasks as in condition C1), our results show lower level of conditional event responses (compared to the previous $65.6 \%$ ), and higher levels of conjunction responses (compared to the previous $5.6 \%$ ). The material conditional responses were similar (previously $0.3 \%$ ). Pfeifer and Stöckle-Schobel (2015) investigated conditionals under complete probabilistic knowledge and used similar tasks as in our conditions C1, C2 and C3. These authors also reported higher levels of conditional probability answers and lower levels of conjunction responses, while material conditional responses were similarly low. The lower levels of conditional probability responses may be explained by the apparent higher complexity of the tasks used in the present experiment. The tasks are more complex (i) because of the combination of using counterfactuals as target sentences in three of four conditions and (ii) because of imprecise probabilities in the premises (i.e., incomplete probabilistic information).

The tendency to give answers that partially coincide with conditional probability has also been found in a previous study which tested non-causal cases in indicative mood with similar task material as we used for condition C1 (Pfeifer, 2013). In that study our halfway lower-interpretation is referred to as "halfway conditional event strategy". However, in the present study we found two completely new strategies: the halfway upper- and the halfway both-interpretation. The halfway upper-interpretation is particularly interesting, as it explains $12.8 \%$ of the total 1120 responses, slightly more than the halfway lower response strategy (i.e., $11.6 \%$ ). Halfway conditional probability responses might unburden the working memory load by ignoring the covered sides (see also Pfeifer, 2013).

Figure 1 shows the results of the confidence ratings. We performed analyses of variance to investigate impacts of the different conditions. After Holm-Bonferroni corrections we observed significant differences within the three tasks T1, T2 and T 10 . The corresponding p -values were $0.006,0.01$, and 0.008 . In each of these tasks-as well as in all other tasksthe condition C 4 had lower mean confidence values compared to the other conditions. The lower confidence may be because of the apparent higher difficulty of the task material in
condition C 4 for two reasons: first, the target sentence was a counterfactual. Because of the inconsistency between the factual statement and the antecedent, many participants reported counterfactuals as puzzling in the post-test interview. Second, abductive tasks required "backward" inference from effects to causes and are incongruent with the more natural if cause, then effect-direction. In general, backward inferences are known to be harder to draw compared to forward inferences (Evans \& Beck, 1981).

## Concluding Remarks

We investigated how people reason about conditionals under incomplete probabilistic knowledge. The novel features in our test design were comparisons of causal and abductive scenarios, as well as counterfactuals under incomplete probabilistic knowledge. One of our main findings is that the dominant response is consistent with the conditional event interpretation of conditionals among all four groups. Moreover, we discovered two major answer strategies, halfway upper and halfway lower conditional event responses, which can be understood as strategies to unburden the working memory load.

Inferentialist accounts of conditionals propose that there should be an inferential relation between the antecedent and the consequent (see, e.g., Douven, 2016b). Thus, when conditionals with inferential relations (e.g., causal or abductive ones) are compared with conditionals where no apparent inferential relation exists (like in our conditions C1 and C2), one would expect significant differences. Our data, however, do not support this inferentialist hypothesis.

The results of our paper broaden the area of inferences where conditional probability seems to be the best predictor for how people reason. We have shown that coherence-based probability logic provides a formalization of the meaning of counterfactuals and provides a rationality framework for reasoning under complete and incomplete probabilistic knowledge. This suggests that it may also be suitable for subclasses of causal reasoning like abductive reasoning, which is important in the studies on (scientific) explanation and learning.

#### Abstract

Do children always conform to a majority's testimony, or do the pragmatics of that testimony matter? We investigate children's reasoning about mapping a novel word to a referent in an object-labeling task. Across four conditions, we modified the testimony in an object-labeling task, to account for pragmatic principles, so that the majority does and does not provide an explicit opinion about the alternative object chosen by the minority. Four- and 5-year-olds were given a choice between an object endorsed by a three-person majority, or one endorsed by a single minority informant. In the unendorsed condition, informants explicitly unendorsed the unchosen object. In the nothing condition, informants said nothing about the unchosen object. In the ignorance condition, informants explicitly expressed uncertainty about the unchosen object, and in the hidden condition, the chosen object was the only one present at the time of the endorsement. Children were most likely to endorse the majority object in the unendorsed condition, in which the majority explicitly stated that the label applied to only one referent, whereas in the hidden condition, where only one object at a time was present in the discourse, children chose objects endorsed by the majority and the minority equally, with the other two conditions intermediate. This suggests that children might not simply have a conformity bias; rather, they are sensitive to the majority's implied intentions when learning from testimony.

Keywords:social learning; social cognition; consensus; testimony; causal reasoning; pragmatics

## Introduction

Learning from others is especially important for young children who are growing up in a complex social world. One way children gain knowledge from others is by learning from testimony. In particular, there is a growing body of literature showing that, similar to adults, children seem to be influenced by the opinions and behavior of a majority group (e.g., Bernard, Proust, \& Clément, 2015; Burdett et al., 2016; for a recent review see Huan, van Leeuwen, \& Edelson, 2013). For example, children recognize and trust a consensus during word learning. Corriveau, Fusaro \& Harris (2009) found that 3 - and 4-year-old children view a consensus as a reliable source of information when learning novel object labels. Children were more likely to prefer novel labels that were endorsed by the majority, and to selectively trust individuals who were previously part of the majority in a subsequent task. Bernard et al. (2015) found that slightly older children (4- and 5-year-olds) also
exhibited a consensus effect, even after the majority was shown to give unreliable testimony about object labels. Children are also more likely to copy the majority's behavior (Haun, Rekers, \& Tomasello, 2012) and action sequences (Herrmann et al., 2013). As well, children seem to overconform in many situations; majority influence trumps direct source knowledge ( Hu et al., 2015), and sometimes even children's own knowledge (Corriveau \& Harris, 2010), or the knowledge of competent individuals (Burdett et al., 2016).

On the other hand, we also know from previous work that children are rational learners; they selectively learn from other people's testimony and evaluate the information they receive (for a review, see Mills, 2013; Sobel \& Kushnir, 2013; Koenig \& Sabbagh, 2013), suggesting that they might not indiscriminately endorse majority opinions. While having a majority bias in word learning is sensible due to the shared, conventional nature of word meanings, in a less socially constructed domain, such as causal learning, children may be less influenced by the majority group (Hu, Buchsbaum, Griffiths \& Xu, 2013). Similarly, children are less willing to agree with the majority's action when learning about tools if the majority endorses a function that is considered inefficient or implausible (Schillaci \& Kelemen, 2013). Additionally, children selectively learn from informants who display other indicators of reliable knowledge, including a history of providing accurate information (e.g., Pasquini et al., 2007), performing actions successfully (e.g., Wilks, Collier-Baker, \& Nielson, 2014), having expertise in the field (Burdett et al., 2016), and having privileged knowledge (Einav, 2014).

Taken together, the current literature about majority influence in children's social learning suggests that children are rational learners, but that the role of consensus widely impacts their reasoning and social learning more generally. Why then do children conform or not conform to the majority? The mechanism that underlies majority influence is still unclear. A bias to copy the majority simply because it is the majority can often be an effective social learning strategy (Laland, 2004; Perreault, Moya, \& Boyd, 2012) Conforming to the majority is a simple strategy that is often sensible and an indication of reliability (Corriveau et al., 2009). Alternatively, children might not only be attending to the number of informants, but also use pragmatic inferences for learning.

Figure 1. The arrow indicates the toy labeled by an informant as the referent of a novel word. The goal of the participant is to infer whether a novel word (e.g., "modi") means the blue toy, the purple toy, or both.

This second line of reasoning is consistent with the literature on using pragmatic cues to guide learning. Grice (1975) proposed that participants in conversation obey the maxims of cooperative communication-be truthful, informative, relevant, and clear. Specifically, the Maxim of Quantity (be informative) and the Maxim of Relevance (be relevant) are both crucial for motivating our hypothesis. To be informative means to give as much information as needed, and no more. To be relevant means to say things that is pertinent to the given context. Children might assume informants are being informative and relevant with their testimony, influencing what they learn.

Frank and Goodman (2014) showed that during word learning, children are indeed sensitive to speakers' communicative intentions, leading children to make inferences that go beyond explicit testimony. This suggests that children can make use of pragmatic principles in word learning inferences. For instance, Figure 1 illustrates a task similar to Frank and Goodman (2014). If the speaker only calls the toy on the right (marked by the arrow) "a modi," children can infer that 'modi' means the blue toy, and not the purple toy, for example, by assuming that speakers are using language relevantly and informatively.

However, in previous testimony research, the majority's opinion of the minority choice has been left ambiguous, and children's pragmatic reasoning abilities were not considered. For example, when the majority suggest that object X is the referent of a novel label or suggest using strategy X (e.g., Corriveau et al., 2009; Haun et al., 2012), this could pragmatically imply that object Y was not a referent or that they should not use strategy Y, otherwise the speaker would have referred to this option as well, in order to be informative (Frank \& Goodman, 2014). Pragmatic inferences may help children reason: "If the majority labeled object X as a modi and did not comment on object Y , they must believe that only object X is the modi. If the majority wanted me to know that object Y is also a modi, then they would have told me, because they had the opportunity to speak about object Y." Accordingly, the language used could imply that the options are mutually exclusive and only one object is a modi, for example, providing additional evidence against the minority opinion.

Given children's sensitivity to pragmatically implied information, we conducted the present study to investigate
how pragmatics can influence the strength of the majority influence in children. We examined 4- and 5-year old children's preference for the majority in an object labeling task. Specifically, we compared children's tendency to conform when the majority does and does not provide an explicit opinion about the minority's choice.

## Pragmatic knowledge versus consensus

In the present study, we investigate children's reasoning about the mapping of a novel word to a referent in an object-labeling task, when presented with a three-person majority and a conflicting minority informant. There were four testimony conditions-the unendorsed condition, the nothing condition, the ignorance condition, and the hidden condition-that varied in the informativeness of the testimony and the relevance of the object(s) present in the situation. In the most explicit case, the unendorsed condition, the majority endorsed one object and unendorsed the other object, while the minority informant provided the opposite testimony. Here, children learn from declarative testimony that makes the extent of the novel label explicit, and no pragmatic inference is needed. We hypothesize that, since the testimony in this condition explicitly states that the labels are mutually exclusive, the testimony provided by the majority group will outweigh the evidence provided by just one minority informant, and children will be more likely to endorse the majority testimony.

In the nothing condition, the informants endorsed one object and said nothing about the other. This condition was intended to replicate previous work, in which the informants' knowledge or belief about the unchosen object was left ambiguous. We predict that children will favour the majority endorsement, because, as in our example (Figure 1), they will make a pragmatic inference that the speakers are using language informatively, and so the majority must believe that the novel label does not apply to the unchosen object, otherwise they would have referred to the unchosen object using the label as well. Therefore, similar to the unendorsed condition, children in the nothing condition will infer that the labels are mutually exclusive. However, we predict that they will endorse the majority less often than in the unendorsed condition since there is additional ambiguity than when the majority explicitly states their opinion.

In the ignorance condition, the informants endorse one object but express uncertainty in their beliefs about the unchosen object. Since the majority provides information with low certainty about the extension of the novel label, their testimony should carry less weight in determining whether the unchosen object can also be referred to using the novel label. Further, the informants' uncertainty suggests that the label may not be mutually exclusive, and could apply to both objects. Thus, children should be less likely to endorse the majority's testimony, compared to the unendorsed and nothing conditions.

Finally, the language used in the testimony for the hidden condition was exactly the same as in the nothing condition, but only one object-the endorsed toy-was present. The
hidden condition relies on the pragmatic understanding that the speaker is being informative and relevant in their testimony, and is therefore only speaking about object that is present in the discourse context. The result is that, if children make this pragmatic inference-speakers cannot comment on objects that they and their communicative partners do not see-then in the hidden testimony, the majority provides no or the least amount of evidence against the minority's choice. On the other hand, if children are not sensitive to the pragmatics of the testimony, then the results for the hidden condition should be the same as the nothing condition, with children endorsing the majority's choice.

Whereas the current literature supports children's conformity bias as a learning strategy, a pragmatic explanation would suggest that children do not indiscriminately conform to the majority. The overarching aim is to show that children are sensitive to pragmatic principles even if they have a general tendency to trust the majority. That is, the extent of children's conformity depends on the pragmatics of the testimony. Specifically, as the majority's testimony becomes more explicit in their negative judgment of the minority's opinion, children will be more likely to adopt the majority's endorsement over the option endorsed by the minority informant. Thus, we predict that the tendency to endorse the majority will decrease over the conditions: unendorsed condition (most majority endorsement); then, nothing condition; then, ignorance condition; and finally, the hidden condition should exhibit the least majority bias. Alternatively, if children do exhibit a global conformity bias, then they should indiscriminately endorse the majority's opinion regardless of the testimony.

## Methods

Participants. Participants were 112 preschoolers, 49 females and 63 males (mean age $=4$ years 8 months; range $=47-71$ months). An additional 23 were excluded from the study because of experimenter error (9), participant distraction (9), failure to make a choice (2), and failure to remember object label (3). Participants were recruited from the University of Toronto database or from public neighbourhood parks and museums.
Participants were randomly assigned among the four
between-subject conditions: the unendorsed condition ( $\mathrm{n}=$ $28, \mathrm{M}=59$ months, range $=50-71$ months, $32 \%$ female), the nothing condition ( $\mathrm{n}=25, \mathrm{M}=57$ months, range $=48-$ 71 months, $40 \%$ female), the ignorance condition ( $\mathrm{n}=31$, $\mathrm{M}=58$ months, range $=47-71$ months, $52 \%$ female), and the hidden condition ( $\mathrm{n}=28, \mathrm{M}=56$ months, range $=48-$ 67 months, $50 \%$ female).
Materials and Procedure. Children were tested individually. In all conditions, each participant participated in two test trials, a modi trial and a dax trial. Each trial featured two novel objects for a total of four unique objects of differing shape and colour in order to reduce extension.

The trial presented first was counterbalanced across participants. The object pairs and side on which each object was presented were held fixed but the object chosen by the majority and minority was counterbalanced.

To begin each condition, children sat at a table across from the experimenter. The experimenter introduced children to two novel objects and explained that they were unknowledgeable about the labels of the objects. The experimenter suggested that the participant watch a film to learn about the objects' label. Participants then watched a pre-recorded film of four female informants evaluating the objects on a 13 " laptop screen.

A film consisted of four video clips, each featuring a female informant sitting by herself at a table with the same novel objects. Informants wore different colour shirts. In the first three clips, the three-person majority each endorsed one object with the novel label, and in the final clip the one minority informant endorsed the other object with the same novel label, repeated three times so that the frequency with which each participant heard the label used to refer to each object was equal. Each clip concluded with the informant picking up the toy they had endorsed. The identity of the minority informant was counterbalanced across participants. Figure 2 displays schema for the videos shown.

In the unendorsed condition, each majority informant endorsed one object while explicitly unendorsing the other object by saying, "That's a modi (pointing to target toy); that's not a modi (pointing to other toy)." In the ignorance condition, each majority informant endorsed one object while expressing uncertainty about the other object by saying, "That's a modi (pointing to target toy); I don't know

Figure 2. Schema of the videos seen by children. (i) Stimuli placement for the Unendorsed, Ignorance and Nothing condition. Testimony from the Nothing condition. (ii) Stimulus placement and testimony from the Hidden condition.
if that's a modi (pointing to other toy)." In the nothing condition, the majority informants endorsed one object and did not comment on the other object by saying, "That's a modi (pointing to target toy)." In the hidden condition the informant sat at the table with only one object and evaluated that object by saying, "That's a modi (pointing to target toy)." In all conditions the minority informant endorsed the other object with the same novel label three times. For instance, in the unendorsed condition the minority informant said "That's a modi (pointing to other toy); that's not a modi (pointing to target toy). Look at that modi (pointing to other toy); that's not a modi (pointing to target toy). It's a pretty cool modi (pointing to other toy); that's not a modi (pointing to target toy)". The minority scripts in the other conditions followed in the same manner.

Once the film ended, the screen turned black and the objects were brought back. The experimenter then asked the participant to identify the referent of the novel label by asking, e.g., "Can you show me a modi?" Participants' first gestural or vocal response was recorded.

## Results

Table 1: Participant scores by condition

|  | Score |  |  |
| :---: | :--- | :--- | :--- |
| Condition | $\mathbf{0}$ | $\mathbf{1}$ | $\mathbf{2}$ |
| $(1)$ Unendorsed | 0 | 4 | 24 |
| $(2)$ Nothing | 3 | 9 | 13 |
| $(3)$ Ignorance | 4 | 8 | 19 |
| $(4)$ Hidden | 6 | 12 | 10 |

Figure 3. Average number of responses (+/- 1 s.e.) endorsing the majority object. There was a significant effect of condition. Children chose the majority's object most often in the unendorsed condition, and least often in the hidden condition. $* * p<0.01 \quad * * * p<0.001$.

Participants were assigned a score $(0,1$, or 2$)$ based on the number of trials in which they endorsed the majority informants' testimony (see Table 1). ${ }^{1}$ Children's mean responses for all conditions are shown in Figure 3. For all conditions, chance level was a mean score of 1 .

[^434]Children chose the majority's referent to the novel object significantly more often than chance in the unendorsed $t(27)$ $=11.15, \mathrm{~d}=4.29, p<.0001)$; nothing $(t(24)=3.09, \mathrm{~d}=1.26$, $p<0.01)$; and ignorance conditions $(t(30)=3.72, \mathrm{~d}=1.36$, $p<0.001)$. In contrast, in the hidden condition, participants were not more likely to adopt the majority's opinion than the minority's $(t(27)=1.11, \mathrm{~d}=0.39, p=0.24)$.

We also found a significant effect of condition on children's tendency to choose the majority object, onefactor ANOVA $F(3,108)=5.3, \mathrm{MSE}=2.39, p<0.01$. Planned two-sample t-tests for independent samples demonstrated that the unendorsed condition was significantly different compared to all the other conditions: unendorsed vs. nothing: $t(51)=-2.45, \mathrm{~d}=0.67, p<0.01$; unendorsed vs ignorance: $t(57)=-2.19, \mathrm{~d}=0.58, p<0.05$; and, unendorsed vs. hidden: $t(54)=4.31, \mathrm{~d}=1.15, p<$ 0.0001. Similarly, children's performance in the hidden condition was significantly different from the ignorance condition, $t(57)=1.92, \mathrm{~d}=0.50, p<0.05$; and, marginally different from the nothing condition, $t(51)=1.61, \mathrm{~d}=0.44$, $p=0.06$. There was no significant difference in children's performance in the nothing condition compared to the ignorance condition, $t(54)=-0.23, \mathrm{~d}=0.06, p=0.41$.

Follow-up polynomial contrasts indicate asignificant linear trend, $F(1,108)=13.67, p<0.001$, partial $\eta^{2}=0.11$. The linear trend suggests that deference to majority decreases across ordered conditions: unendorsed ( $M=1.82$, $\mathrm{SD}=0.074$ ), nothing ( $\mathrm{M}=1.44, \mathrm{SD}=0.711$ ), ignorance ( M $=1.48, \mathrm{SD}=0.724)$, and hidden $(\mathrm{M}=1.11, \mathrm{SD}=.079)$.

## Discussion

To be rational yet efficient social learners, it would be beneficial for children to learn through explicit instruction as well as pragmatic inferences. This study provides the first empirical evidence that children consider pragmatic inferences when learning from testimony provided by a majority and minority group. We examined the effects of the pragmatic cues in informants' testimony on children's tendency to defer to the majority. Our study found that although children tend to be influenced by the majority, they also weigh informants' opinions using pragmatic cues to assess the meaning of their testimony. By assuming that informants are being cooperative in their communicative intent (e.g., Maxim of Quantity; Maxim of Relevance), children are evaluating the pragmatic implications of the language used and making inferences that go beyond the literal meaning of the testimony.

We found that when learning from explicit, declarative testimony, as was the case in the unendorsed condition, 4and 5- year old children were significantly more likely to endorse the majority object-their tendency to endorse the majority option was almost at ceiling. In this condition, the informants' opinions about both of the novel objects were made explicit in thelanguage of the testimony. They endorsed one object using the novel label (e.g., modi) and provided additional evidence that the unchosen object was not a modi. In this case, following the majority is a sensible
strategy since the explicit endorsement of only one object by three people might outweigh the evidence provided by just one minority informant.

There was also a consensus effect in both the nothing condition-replicating the findings in previous work (e.g., Corriveau et al., 2009) - and the ignorance condition. And yet, in these conditions the majority bias was significantly less than in the unendorsed condition, suggesting that children are aware of the additional ambiguity in these conditions. By contrast, children did not exhibit a majority bias in the hidden condition. The crucial difference between these conditions is the pragmatic inferences made, given the ambiguity of the learning situation.

When the speaker's testimony is ambiguous, as in the nothing condition, children might rely on pragmatic cues to infer the speaker's intent. According to the pragmatic account, a crucial step in the inferential process is the assumption that the speaker, in this case, the informants, is being cooperative with their utterance, and has the goal of being informative. Accordingly, if the speaker had wanted to label both objects then they had the ability to do so, as in the unendorsed and ignorance conditions. The fact that the informants only ever labeled one object in the nothing condition led children to infer that the novel label is only applicable to one object in the given situation, leading to the conclusion that the unchosen object is not a referent of the novel label. However, in the hidden condition, only one object was present, invoking a different pragmatic inference than in the nothing condition-the inference that speakers are only discussing objects relevant to the current situation. Consequently, even though the testimony in these two conditions was identical, children's inferences differed. Children in the hidden condition were no more likely to endorse the majority's testimony than the minority's. This suggests that children's inferences from consensus are influenced by their sensitivity to pragmatic cues embedded in the testimony.

A somewhat unexpected finding was that children were also more likely to choose the majority's object in the ignorance condition. In the ignorance condition, we intended for the uncertainty about the extension of the object label to come from the uncertainty in the speaker's knowledge. Since informants expressed low certainty in their testimony, there should be less evidence against the unchosen object being e.g., a modi, and by association, against the minority. However, children might instead have interpreted the statement of ignorance as a comment about the object rather than about the informants' knowledge. Children might have inferred that the majority was certain about one object having many features of e.g., a modi, but was uncertain about the other object due to its ambiguous or hard to categorize appearance. Future work should disambiguate the type of uncertainty being conveyed.

Together, the results go beyond asking whether or not children have a conformity bias, and explore children's sensitivity to pragmatically implied information. Children's tendency to conform might not simply be driven by a 'copy-
the-majority' strategy (Laland, 2004), since they did not conform to the majority equally across conditions. Instead, the extent to which children prefer members of the majority as informants might vary with the pragmatics of the language used in the testimony. Children may not be overestimating the value of the majority's opinions compared to the minority's testimony. Instead, children are sensitive to the language used by informants, and hence, are selective about situations in which they should go with the consensus view. This finding is consistent with previous work suggesting that children are ableto make sophisticated inferences about implicit, intended meaning in speakers' utterances (e.g., Frank \& Goodman, 2014).

An interesting question is whether our results are specific to the use of an object-labeling task. For instance, children may be more likely to conform to a majority in a labeling task because the meanings of words are socially determined (Hu et al., 2013). In addition, labels may have stronger implications due to other constraints on word learning, such as mutual exclusivity-each object has only one category label (Markman, 1989), and the shape bias-differently shaped objects usually have different category labels (Landau, Smith \& Jones, 1988). For example, if an informant labels Object 1 as a modi, this strongly implies that Object 2, which is very differently shaped, is not a modi. This would provide additional evidence against the minority, by suggesting that both objects cannot be modis.

In our experiment, we were able to modify the testimony so that the strength of the implications regarding the novel label for the object(s) varied by condition. However, if children were exclusively following these types of language learning constraints, they should have assigned a novel label to only one object in all conditions. On the contrary, children's performance followed a linear trend and did not favour the majority label in the hidden condition.

However, future work should examine children's endorsements of majority and minority information in other domains such as causal learning (e.g., Hu et al., 2013). Causal tasks do not rely on the conventions and social construction that make learning labels special. Since causal actions on objects might not be mutually exclusive by nature-one causal action does not necessarily imply that the other actions are ineffective-future work can directly examine how making actions appear mutually exclusive using pragmatic principles can affect children's reasoning. We would be interested in children's reliance on consensus during a causal task, and in turn, how they are making pragmatic inferences about the efficacy of each action.

One further question concerns the operationalization of consensus and the presentation of a majority group versus the minority informant. In this paper, we presented the informants individually, and in a sequential manner with the majority group first, similar to previous work by Haun et al. (2012) and Burdett et al. (2016), and importantly, this was held constant across all of the conditions. However, in both Bernard et al. (2015) and Corriveau et al. (2009), the majority and minority informants were all presented
together, and at the same time rather than one after another. It is possible that this difference in the format of majority presentation might change the pragmatics of the situations, for example if children believe that the dissenter in a simultaneous presentation is attempting to correct the majority's misinformation. Future work could compare simultaneous and sequential presentation of the informants to see how this changes children's inferences.

Finally, it is difficult to quantify our predictions without formalizing our assumptions. A Bayesian model could produce quantitative predictions regarding the ordering of our conditions, and the magnitude of the differences between them. This type of model could examine how a rational learner would balance a majority opinion against the pragmatic implications of their testimony, without a conformity bias, and test those predictions against children's behaviour, building on previous models of learning from testimony (e.g., Buchsbaum et al., 2012) and of making pragmatic inferences (e.g., Frank \& Goodman, 2014).

In sum, this research sheds light on how pragmatic principles can inform children's learning from conflicting majority and minority groups. In conditions where the testimony explicitly stated, or pragmatically implied, that the labels were mutually exclusive, children were more likely to adopt the majority's label than the minority's label. However, when the testimony had weaker implications about the labels of the novel objects, children were not more likely to rely on the consensus view. This suggests that children might not simply have a conformity bias. Instead, children can make sophisticated inferences that go beyond the literal meaning of the testimony. By doing so, they consider both the explicit statements made by informants, as well as the pragmatic inferences implied by the majority opinion in their learning from the social world.

## Acknowledgments

We are grateful for all the families for their participation, and to the Computational Cognitive Development lab for their help with data collection. We would especially like to thank Pingki Mazmunder for help with data collection and analysis.This work was supported by the Natural Sciences and Engineering Research Council of Canada, the Canada Foundation for Innovation, and the Connaught Fund.

# A categorical (fixed point) foundation for cognition: (adjoint) corecursion 

Steven Phillips<br>National Institute of Advanced Industrial Science and Technology, Tsukuba, Ibaraki, Japan

#### Abstract

Computationalism has been the pre-eminent framework for models of mind, since the cognitive revolution. However, the plethora of apparently incommensurate approaches seems to undermine hope for a common computational foundation. Category theory provides a mathematically rigorous foundation for computation that includes recursion and corecursion. We show that corecursion unifies various cognitive behaviours for comparison and contrast in a principled and novel way. For instance, Chomsky's merge function is a universal morphism, which has a dual, called comerge. One implication of this work is that corecursion appears to be the rule rather than the (human) exception in contrast to Chomsky's view of recursion.

# Dual-routes and the cost of computing least-costs 

Steven Phillips<br>National Institute of Advanced Industrial Science and Technology, Tsukuba, Ibaraki, Japan<br>Yuji Takeda<br>National Institute of Advanced Industrial Science and Technology, Tsukuba, Ibaraki, Japan<br>Fumie Sugimoto<br>National Institute of Advanced Industrial Science and Technology, Tsukuba, Ibaraki, Japan

#### Abstract

Theories of cognition that posit complementary dual-route processes afford better fits to the data when each route explains a part of the data not explained by the other route. However, such theories must also explain why each route is invoked, lest one can fit any data set with enough routes. One possible explanation is that route selection is based on a least-cost principle: the route that requires fewer cognitive resources (including time) relative to the goal at hand. We investigated this explanation with a dual-route version of visual search, where the target could be identified via opposing (easy or hard forms of) feature and conjunction search conditions. The data support a contextualized version of the least-cost principle in that the cost of computing least-cost also influences route selection: participants assessed alternatives, but only when the cost of that assessment was relatively low.

# The Effect of Economic Scarcity Priming on Perception of Race

#### Abstract

Existing research suggests that White individuals are more likely to categorise biracial faces as Black in conditions of resource scarcity. It has been theorised that this effect is due to in-group boundaries becoming more exclusive in scarce conditions. An alternative explanation refers to implicit socioeconomic association between Black individuals and lower level of resources. These two approaches entail different predictions for Black participants performing the categorisation task. If scarcity prompts greater in-group exclusivity, Black participants should, ceteris paribus, categorise more biracial faces as White. If, however, scarcity invokes socio-economic status associations, Black participants should categories biracial faces in the same way as White participants. Experiment 1, explored the effects of priming on White and Black groups. It provided support for the implicit socio-economic association theory. Furthermore, experiment 2 on Asian sample, provided additional support as Asian participants showed the same pattern of response. The paper discusses implications of these findings.

Keywords: intergroup bias; perception of race; boundary formation; resource scarcity; scarcity priming

## Introduction

Substantial evidence suggests that the perception of race can be influenced by environmental factors (e.g. Davis, 1991; Peery \& Bodenhausen, 2008; MacLin \& Malpass, 2001). This effect was examined by Rodeheffer, Hill and Lord (2012), who primed participants with the concepts of resource scarcity, abundance and neutral control. The priming stimuli included slides with captioned pictures showing relevant concepts. Participants were then presented with twenty composite images of biracial faces generated using $50 \%$ content of White and $50 \%$ content of Black individuals' photographs. The task was to categorise faces as either Black or White. Results showed that participants in the scarcity condition were more likely to categorise faces as Black, relative to the abundance or neutral conditions. There was no significant difference between neutral and abundance conditions. Rodeheffer et al. theorised that, in times of economic crisis, boundaries of in-group categorisation become more exclusive where less people are classified as in-group members.

Results from Krosch and Amodio (2014) support these conclusions. Participants were primed with scarcity, negativity, and neutral conditions. Priming consisted of
subliminal presentation of relevant word primes for 20 ms prior to each trial. Participants subsequently categorised faces as either Black or White. Facial stimuli included morphed pictures of mixed race individuals generated using different proportions of original faces of Black and White people at $10 \%$ increments. The dependent variable was the point of subjective equality, defined as the proportion of original Black face content required for the morphed image to be equally likely to be categorised as either Black or White. Results showed that in the scarcity condition, a given image may have significantly lower proportion of Black content to reach the point of subjective equality. In other words, a higher number of images were identified as Black in the scarcity condition. Consistently with previous explanations of Rodeheffer et al. (2012), authors of the study concluded that in the conditions of resource scarcity the boundaries of in-group categorisation become more exclusive, as participants tended to exclude biracial individuals from the White group in the scarcity condition. However, the study had a certain limitation as a quarter of the sample consisted of Asian participants. The facial stimuli included only images of Black and White individuals and no Asian individuals. The experiment was therefore unable to examine any effect of change of ingroup boundaries since there were no in-group images in the stimuli from the point of view of Asian participants. This may indicate that the effect was driven by other factor. The present study explores this possibility.

The paper thus postulates an alternative theoretical explanation relating to the effect of implicit racial bias, based on presumption that Black people constitute a disadvantaged group with lower level of resources (Gilens, 2003). That is, people's sematic network may include an association between scarcity (or lower socio-economic status) and Black individuals. Activation of the concept of scarcity may therefore result in higher cognitive accessibility of the concept of Black individuals. This in turn increases the probability of a given face to be classified as Black following scarcity priming. Extensive previous literature demonstrated a wide range of similar implicit racial biases, which, more importantly, are exhibited by individuals across different ethnicities, including Black people themselves (e.g. Payne, 2006; Correll, Park, Judd \& Wittenbrink, 2002).

We might therefore reconsider the above evidence from Rodeheffer et al. (2012) and Krosch and Amodio (2014). It is possible that the results were driven not by a change in ingroup exclusivity, but by implicit association between lower level of resources and Black individuals. The present study investigates these two theoretical explanations by testing different ethnic groups. According to the initial account, scarcity yields an increase in exclusivity of the in-group categorisation. If this theory is correct, White participants will show a tendency to exclude biracial individuals from the White in-group, increasing the number of faces being judged as Black. Conversely, Black participants should show the opposite pattern of response. According to the alternative explanation, scarcity priming activates the concept of lower level of resources and increases cognitive accessibility of the associated concept of Black individuals. Similar to other implicit race-related biases, this effect can be expected to occur irrespective of the ethnicity of the participant. Therefore, both Black and White participants will show the same pattern of responses, with increased probability of judging ambiguous faces as Black in the scarcity condition, relative to the neutral condition. As neither of the original studies included Black participants, new data is required to decide between the two hypotheses. Experiment 1 directly tests these predictions by analysing responses from Black and White participants. Experiment 2 further tests the hypotheses by analysing responses from Asian participants. Asian people are out-group members to both Black and White faces included in the stimuli. According to the in-group exclusivity theory, they should be unaffected by scarcity priming, as no change in in-group exclusivity can be observed. According to the socioeconomic account, however, they should exhibit similar response patterns, as the White and Black participants from experiment 1.

## Experiment 1: Black and White participants

In the original studies, participants were White. Given the competing hypotheses (in-group/out-group versus implicit biases), we recruited both Black and White participants. If the group hypothesis is correct, we should expect Black participants to exhibit the opposite in-group behaviour as White participants. If, however, the implicit bias hypothesis is right, we should expect both groups of participants to have the same response patterns.

## Participants

Sixty-four people participated in the experiment ( $\mathrm{N}=64$ ); 40 female, 23 male and 1 person classified their gender as "other". The amount of participants was chosen prior to recruiting the participants, and consequently no direct stopping rule was in place. The age of participants ranged from 18 to 55 (mean $=29.84, S D=8.69)$. Participants were recruited opportunistically from Birkbeck, University of London.

## Design

The experiment included two independent variables: priming (two levels: scarcity and neutral), and group (two levels: Black or White). The experimental design was 2 x 2 mixed with group as the between subject variable and priming as the within subject variable. The dependent variable measured the mean response rate across all trials in both conditions (scarcity or neutral) for each group (Black or White). The scope of possible values ranged from 1.0 indicating that $100 \%$ of 45 images presented were identified as Black to 2.0 indicating that $100 \%$ of images were identified as White. The mean score of 1.5 represents that $50 \%$ of the images were classified as White and $50 \%$ as Black.

## Materials

The experiment used Qualtrics survey software and could be conducted online. The priming stimuli for the scarcity condition were obtained from the Rodeheffer et al. (2012) study, as they were proven to be of sufficient quality to produce priming effects. They consisted of captioned pictures showing economic recession, poverty and scarce resources. The stimuli for the neutral condition included three slides showing pictures of clocks, as there is no reason to assume that images of clocks should prime participants in terms of economic scarcity or abundance. Similarly, in order to replicate and test previous findings, the facial stimuli were obtained from the Krosch and Amodio (2014) study. They included morphed pictures generated from photographs of Black and White individuals at $10 \%$ increments from $10 \%$ Black to $90 \%$ Black $^{1}$.

## Procedure

In accordance with ethical approval requirements, participants consented to their involvement and that they could terminate the experiment at any time if they so desired. First, participants saw slides with neutral priming (images of old-fashioned clocks). Having seen the images, participants were presented with 45 morphed facial images (from Krosch \& Amadio, 2014), one picture per slide. Following Rodeheffer et al. (2012), the instruction read: "If you had to choose, would you describe this person as [Black/White]". Participants indicated their response by clicking one of two radio buttons. Following the first set of pictures, participants were presented with the scarcity priming (caption and images of economic scarcity), and then the second set of 45 pictures. The experiment ended with a page requesting the demographic information, including ethnicity, gender and age. The last page included debriefing. The entire procedure lasted for about 15 minutes.

[^435]
## Experiment 1: Results

Only data of participants who classified themselves as Black or White were analysed. The means and standard deviations are presented in Table 1. The lower the mean response rate, the higher is the bias towards categorising faces as Black (cf. the above description of the design). The descriptive statistics show that in neutral conditions the results were close to the expected value of 1.5 . The results in the experimental conditions were lower, which means that more images were classified as Black.

|  | Black | White |
| :---: | :---: | :---: |
| Neutral priming | $1.51(.06)$ | $1.47(.13)$ |
| Scarcity priming | $1.42(.07)$ | $1.43(.14)$ |

Table 1: Scarcity effect on participant groups

A mixed 2-way ANOVA revealed a significant main effect of priming: $F(1,62)=31.57, p<0.001$. Thus, results varied significantly between the priming conditions across both groups such that more faces were categorised as Black in the scarcity condition. The main effect of group was not significant: $F(1,62)=.28, p=.60$, indicating that both groups had similar response rates across the priming conditions. In addition, there was no significant interaction: $\mathrm{F}(1,62)=.135, \mathrm{p}=.14$. This shows that the effect of priming did not vary as a function of the group variable. In order to further test effects of scarcity within each group separately, two 1 -way repeated measures ANOVAs were performed. The test in the Black group confirmed a significant effect of scarcity: $F(1,33)=9.27, p=.003$. Similarly, in the White group, a significant effect was also obtained: $F(1,29)=23.13, p<.001$ (see fig. 1). This confirms that the main effect of priming in the 2-way ANOVA was driven by significant differences in both groups. As illustrated in Figure 1, results of the experiment were consistent with the poverty priming hypotheses.

Fig. 1: Main results, experiment 1

## Experiment 2: Asian participants

Experiment 1 showed that both Black and White participants rated more faces as Black in scarcity conditions. Experiment 2 pursues this hypothesis by testing Asian participants. As these are out-group members for both Black and White faces, they should, according to the in-group/outgroup hypothesis, be unaffected by the priming. If, however, the implicit socio-economic association hypothesis is correct, Asian participants should respond in a similar way as the Black and White participants in experiment 1. Given these results, we predict the latter hypothesis.

## Participants

Thirty-one people of Asian origin were recruited from Mechanical Turk ( 8 female, 23 male$)^{2}$. In order to ensure Asian origin without priming the participants to consider this as an issue for selection, a pre-screening including a number of filler questions unrelated to race and ethnicity as well as information to identify the respondent's ethnicity and race was conducted to pick out participants with relevant ethnicity. Only Asian participants would subsequently allowed to continue with the actual experiment. The age of participants ranged from 18 to 60 (mean $=30.00, S D=9.55$ ).

## Design, materials, and procedure

As in experiment 1 , scarcity and neutral conditions were independent variables. The design was within-subjects, hence all participants were allocated to both conditions. The experiment used the same dependent measure as in the previous experiment.

## Experiment 2: Results

Only data of participants who classified themselves as Asian were analysed (two participants who passed the qualification test, subsequently identified themselves as mixed-race). The mean response rate in the neutral condition was $1.48(S D=.14)$. This result was close to the chance rate of 1.5 . The outcome in the scarcity condition was $1.43(S D=.13)$, revealing that more pictures were classified as Black. A related sample t-test showed that the effect was significant $(t(30)=2.35, p=.013) .{ }^{3}$ The results from experiment 2 are thus in line with findings from experiment 1 and suggest that scarcity priming invoked implicit socio-economic associations rather than increasing in-group/out-group exclusivity.

[^436]
## Discussion

The outcomes of the experiments demonstrate that priming the concept of resource scarcity changes the perception of race. Participants in the scarcity condition were more likely to categorise biracial faces as Black, relative to the neutral condition. This effect has been shown to exist across all groups included in both experiments. The results provide empirical support for the theory of implicit association between the concept of poverty and Black individuals, yielding more faces to be categorised as Black. The results challenge the original explanation presented by Rodeheffer et al. (2012) and Krosch and Amodio (2014). Here, the shift of perceptual threshold of racial categorisation is based on scarcity-related increase of ingroup exclusivity. This was theorised to facilitate resource allocation towards the ingroup. The present results showed that Black, White, and Asian participants had the same pattern of response, which is contrary to the hypotheses derived from their theory. Thus, the present study confirms that the implicit poverty priming theory has higher explanatory power relative to the reduction of the ingroup inclusivity theory.

The results of the study are of high social significance in terms of intergroup relationships, potentially concerning the distribution of wealth and power, and regarding implicit socio-economic associations. The implicit association between poverty and Black individuals may be related to the stereotype of a Black person as poor and chronically welfare dependent. According to Gilens (2003), media portrayal of poverty has become increasingly "racialized" - it shows disproportionately higher number of Black people depicted as poor. He found that almost $60 \%$ of images in American articles on poverty present Black individuals, whereas around $27 \%$ of the poor are Black. This tendency culminated in articles published in 1962 and 1963 during a broad coverage of welfare system abuses which saw $75 \%$ of images representing Black people. This trend reversed in the early 1980s in the times of economic downturn, with the percentage reduced to $33 \%$. These changes indicate that the media increase the overrepresentation in the negative context of welfare system abuse and the "undeserving" poor. Furthermore, they decrease the overrepresentation when poverty can be justified by overall economic decline. Further studies show that attitudes towards the poor are context dependent, e.g. people are more likely to classify poor senior citizens or medical care receivers as deserving public assistance (Smith, 1987; Cook \& Barrett, 1992). Consistently with these notions, Gilens (1999) established that the representation of Black people among the poor varies as a function of positivity of the context. No images of Black individuals were found in articles on senior citizens. Consistently, the overrepresentation in articles on underclass, urban problems and criminality ranged between $85 \%$ and $100 \%$. It can, therefore, be theorised that the disproportionate representation of Black people among the poor in the media contributes to the establishment of the implicit association. In addition, this effect is magnified by
negative context of the media article, which may bias people's beliefs concerning reasons for Black poverty. Indeed, studies demonstrated that news reports on poor Black children produce more personal attributions relative to news reports on poor White children (Iyengar, 1991). In other words, participants were more likely to attribute Black poverty to alleged negative personal characteristics of Black people, while White poverty is more likely to be explained in terms of structural and social factors rather than personal (e.g. economic crisis, unemployment etc.).

Another socially significant consequence of this implicit association relates to the fact that people tend to behave consistently with the content of activated stereotype. In a classic study, Bargh, Chen and Burrows (1996) examined this notion by priming participants with the concept of elderly people. Results showed that participants walked more slowly following this priming, which is part of the stereotype of senior citizens. In addition, priming participants with the concept of Black individuals resulted in a more aggressive behaviour. These phenomena are consistent with previously outlined theoretical explanations of increased cognitive accessibility of concepts associated with currently activated ideas. The study showed that stereotypes not only affect task performance in laboratory settings but also can affect daily behaviour. Results consistent with this notion were obtained by other studies which used the stereotype threat paradigm. Research showed that priming people with racial or gender stereotypes (e.g. lower mathematic ability of Black people and women, while higher ability of Asians) results in stereotype-congruent behaviour (e.g. Steele, 1997; Steele \& Aronson, 1995; Walton \& Cohen, 2003; Steen, 1987). Further evidence demonstrates that the effects of stereotype activation are not limited to academic or IQ tests only, but also extend to economic decision making. For example, women primed with gender stereotypes are less likely to engage in risky financial activities (Powell \& Ansic, 1997; Schubert, Brown, Gysler \& Brachinger, 1999), and they are less likely to pursue careers traditionally regarded as male (Rudman \& Phelan, 2010).
Collectively, these studies suggest that stereotypes can have a long-lasting effect on a range of aspects crucial for life success, such as education and career choice, which translates into wealth and social status. It can be therefore argued that negative racial stereotypes hinder the prospects of Black people, since people have a tendency to unwittingly act in accordance with the content of internalised stereotypes. Concurrently, socio-cultural stereotyping may be activated by relevant cues such as economic scarcity (as the current studies explore). Black people, therefore, experience double social jeopardy effects of implicit racism of White people and damaging effects of the internalised stereotypes. These phenomena contribute to the continuation of Black poverty, which reinforce stereotypes concerning Black people. It can also be hypothesised that biased media portrayal of Black people as poor and dependent on welfare further magnifies this
effect. This means that the media and other organisations, e.g. charities which advertise fundraising campaigns for people in Africa, should be made aware of the negative effects that this continuing bias has. Due to holding social responsibility, the media articles or advertisement should present a balanced and accurate picture of reality. Issues concerning the relationship between socio-cultural stereotypes, group dynamics, socio-economic power, ethnicity, and cognitive function are complex, multifacetted, and inter-dependent. They relate to very real problems in society, and further studies are warranted to explore these delicate aspects, how they function, and how they relate to one another in much more detail.

## Author contributions

D. L. Pilucik developed the idea of the study, rationale and method, conducted data collection and analysis and wrote manuscript draft. J. K. Madsen provided support with developing the study, critical revision, finalised the manuscript, and prepared it for submission. Both authors approved the final version of the manuscript for submission.

## Acknowledgements

The authors of the study wishes to express their gratitude to Amy Krosch and Christopher Rodeheffer for supplying the stimuli materials (see Krosch \& Amodio, 2014; Rodeheffer et al., 2012).

#### Abstract

Psychedelic substances are used for clinical applications (e.g., treatment of addictions, anxiety and depression) as well as an investigative tool in neuroscientific research. Recently it has been proposed that the psychedelic phenomenon stems from the brain reaching an increased entropic state. In this paper, we use the predictive coding framework to formalize the idea of an entropic brain. We propose that the increased entropic state is created when top-down predictions in affected brain areas break up and decompose into many more overly detailed predictions due to hyper activation of $5-\mathrm{HT}_{2 \mathrm{~A}}$ receptors in layer V pyramidal neurons. We demonstrate that this novel, unified theoretical account can explain the various and sometimes contradictory effects of psychedelics such as hallucination, heightened sensory input, synesthesia, increased trait of openness, 'ego death' and time dilation by up-regulation of a variety of mechanisms the brain can use to minimize prediction under the constraint of decomposed prediction.

Keywords: predictive coding; psychedelics; level of detail; Bayesian networks, Lysergic acid diethylamide, Psilocybin.

## Introduction

A recent review paper (Nichols, 2016) examines both the current scientific knowledge regarding psychedelics as well as the many positive results in clinical experiments using psychedelics to treat depression and addiction. The brain, under the influence of psychedelics, has been described as 'being in more states than usual' (CarhartHarris et al., 2014), based on an increased activity in a number of specific brain networks such as the default mode network. They suggested that this higher variance of activity allows for enhancement of the repertoire of possible states over time, and introduced the term Entropic Brain to describe this higher entropic state. On a more implementational level, the current consensus is that psychedelics cause their effects by being (partial) agonists of serotonin, i.e., 5 -hydroxytryptamine $2 \mathrm{~A}\left(5-\mathrm{HT}_{2 \mathrm{~A}}\right)$ receptors, with particular importance to those expressed on apical dendrites of neocortical pyramidal cells in layer V . The $5-\mathrm{HT}_{2 \mathrm{~A}}$ receptors are excitatory receptors, making the neurons more likely to fire.

In this paper, we combine both these computationallevel and implementational-level insights into a predictive coding account of the effect of psychedelics. We unify notions proposed by Kwisthout, Bekkering, \& van Rooij (2017) regarding the importance of the amount of details or granularity of predictions, and Bastos et al.'s (2012) canonical microcircuits for predictive coding. We propose that the increased entropic state is created when top-down predictions in affected brain areas break up and decompose into many more overly detailed predictions due to hyper activation of $5-\mathrm{HT}_{2 \mathrm{~A}}$ receptors in layer V pyramidal neurons. We demonstrate that this novel, unified theoretical account can explain the various and sometimes contradictory cognitive effects of psychedelics such as hallucination, heightened sensory input, synesthesia, increased trait of openness, 'ego death' and time dilation by up-regulation of a variety of mechanisms the brain can use to minimize prediction under the constraint of decomposed predictions.

In the next section we will introduce the main ideas of the predictive coding account. We will then formulize the Entropic Brain hypothesis into a predictive coding account of the psychedelic phenomenon. In the second part of this paper we will show how this formalization can explain the various and sometimes contradictory cognitive effects of psychedelics.

## A Predictive Coding Primer

In his book "The Doors of Perception" (1954), Aldous Huxley described some of his psychedelic experiences, which led him to propose the idea that perception is a door between things that are known and things that are unknown. This idea turned out prescient of the contemporary predictive coding account of brain processing. According to predictive coding, perception is a continuous process of combining the brain’s previous knowledge with new incoming data by using Bayesian updating, so as to best represent the environmental causes of its sensory input. This enables the brain to predict its sensory inputs. Furthermore, the brain is thought to create a hierarchically ordered model (Friston, 2008). For any
pair of levels, the higher-level will have contextdependent hypotheses predicting the bottom-up signals from lower-levels. The hypothesis that generates the best predictions will determine perception. Calculating which hypothesis generates the best predictions is done by calculating the posterior probability of the hypothesis. The posterior probability combines both the likelihood of the bottom-up input and the prior probability of the hypothesis before receiving the input. This can be seen as an advantageous tactic especially under conditions of noisy unreliable bottom-up data, since previous knowledge can be used to come up with the best hypothesis. The predictions stemming from the best hypothesis inhibit the bottom up incoming data 'explaining it away' (Clark, 2016).

Recently, Kwisthout and colleagues proposed a computational-level distinction between the precision of a prediction and the amount of details or granularity of predictions (Kwisthout \& van Rooij, 2015, Kwisthout et al., 2017). This work has shown that more detailed predictions cause higher prediction errors. This work is based on the idea that higher cognitive functions are better described by categorical probability distributions rather than the traditional Gaussian densities (Friston et al., 2015). An important distinction between Gaussian densities and categorical probability distributions is that in the latter the state space granularity (how detailed are the generative models and the predictions that follow from them) is crucial. Whereas the amount of uncertainty (or precision) in a Gaussian density can be adequately described by its variance, a categorical distribution needs both the state space granularity and the entropy of the distribution to describe its precision (Kwisthout \& van Rooij, 2015).

Bastos et al. (2012) have suggested a 'canonical microcircuit' that provides an implementational-level account of the predictive coding in the brain. The idea of such a canonical microcircuit is that a cortical column contains the circuitry necessary to implements a form of approximate Bayesian inference and that these circuits are replicated with minor variations throughout the cortex. This Microcircuit model is based on evidence showing that superficial pyramidal cells have forward connections to higher areas in the brain hierarchy while deep layers, including pyramidal cells in layer V of the cortex, send back propagating signals to lower areas. Bastos et al. present evidence showing that these backwards connections are inhibitory and can plausibly be seen as implementing the top-down 'predictions' as suggested by the predictive coding framework, while forward connections are plausible realizations of the signals representing 'prediction error'. They further suggest that superficial layers of cortex show neuronal synchronization and spike-field coherence predominantly in the gamma frequencies, while deep layers prefer lower (alpha or beta) frequencies. In essence, they claim that
the top down predictions are communicated by lower alpha or beta frequencies while prediction error is communicated by faster gamma frequencies.

Muthukumaraswamy et al. (2013) found, following administration of Psilocybin, a desynchronization of neural activity especially in the slower alpha and beta rhythms, meaning neurons were acting in a more disjoint and separate way, suggesting that the brain was at a higher entropic state. Using dynamic causal modelling they found that this desynchronization is "likely triggered by $5-\mathrm{HT}_{2 \mathrm{~A}}$ receptor-mediated excitation of deep pyramidal cells" (Muthukumaraswamy et al., 2013, p. 15171). While synchronization of post synaptic neuronal groups creating brain wave oscillations are thought to be needed for communication between brain areas and passing of information, the actual information is thought to be found in the a sparse coding of neuron spiking as very specific timings compared to the oscillations (Fries, 2015).

## A Predictive Coding Account of the Psychedelic State

As we have seen, the effects of psychedelics stem from the $5-\mathrm{HT}_{2 \mathrm{~A}}$ receptors on pyramidal cells in layer V being activated, lowering the threshold of individual neuronal firing and thus desynchronizing the activity of the neuronal population. We discussed above Bastos et al.'s (2012) view that the information communicated by the synchronous activity of these specific cells is likely to represent the brain's top-down predictions. It is known that within the neocortex, $5-\mathrm{HT}_{2 \mathrm{~A}}$ receptors are not distributed equally and different areas have different binding potentials. Higher binding potentials can be found in prefrontal and visual areas while the motor cortex has lower binding potentials (Forutan et al., 2002). Our theory focuses on the dense band of $5-\mathrm{HT}_{2 \mathrm{~A}}$ receptors in layer V pyramidal cells.

Based on Kwisthout et al.'s (2017) notion of state space granularity in predictions, we suggest that hyperactivation of the cells in layer V decomposes the broad categorical prediction that is usually calculated by this neuronal population into sub categories, creating a set of higher detailed predictions. These decomposed predictions stemming from prefrontal, parietal and somatosensory cortex are sent backwards to lower layers of the cortical hierarchy. The decomposed higher detailed prediction that has the highest posterior probability now dominates perception. However, under most conditions, no matter which of the higher detailed decomposed predictions best fits the data, it will still fit less data than the 'usual' broad prediction. This will cause a higher level of bottom up prediction error. As we shall see in the second part of the paper, the compensatory mechanisms called to deal with this higher level of prediction error can explain the wide variety of psychedelic effects.

Figure 1. The predictive coding account assumes that the brain generates predictions using a cascading hierarchy of generative models, processing only that part of the inputs that was unpredicted. Under normal circumstances one might predict to observe animals or plants, and interpret the inputs in a likewise manner (left panel). We suggest that after administration of psychedelics these predictions become more decomposed, leading to more fine-grained, very specific predictions, each of which has a fairly low probability. This will in general lead to a higher prediction error and unstable predictions (right panel). Figure adapted from Clark (2016).

To clarify further what a decomposed set of predictions means, imagine a person walking in the forest receiving some sensory input (Figure 1). Under regular conditions the set of her predictions might be P (Animals) $=0.4$, $P$ (Plants) $=0.6$. The relatively low entropy of these predictions can be computed to be $H=-\sum p_{i} \log _{2}\left(1 / p_{i}\right)=$ 0.97 bits. This means there is relatively little uncertainty regarding these possible predictions. Now let us imagine this person is under influence of psychedelics. Under this condition her set of predictions will be decomposed, for instance: $\mathrm{P}($ Birds $)=0.2, \mathrm{P}($ Dogs $)=0.1, \mathrm{P}($ Butterfly $)=$ $0.09, \mathrm{P}($ Elf $)=0.01, \mathrm{P}($ Trees $)=0.3, \mathrm{P}($ Grass $)=0.6$, P (Flowers) $=0.1$. As we can see, the main categorical predictions of 'Animals' and 'Plants' break up, each into more detailed sub categories. These decomposed predictions bring about a higher entropic state, $\mathrm{H}=-\sum \mathrm{p}_{\mathrm{i}}$ $\log _{2}\left(1 / p_{i}\right)=2.49$ bit. In most cases this will result in higher prediction error from lower layers as these decomposed predictions 'explain away' less of the prediction error from lower layers than normal. The 'extra' predictions being activated are likely to be dependent on a subject's personal experiences and history. In general we should expect a flattening of the prediction distribution, and well-established prediction categories that contain many subcategories will be affected more than predictions with fewer subcategories.

## The importance of bottom-up data in this process

A known concept in the psychedelic community is "set and setting". The mind's set can be compared to the brain's predictions while setting considers the environmental data. When precise environmental data combines with decomposed higher detailed predictions the result will be a uniquely clear perception. This type of perception is commonly described by users and can be read in Aldus Huxley's (1954) description of the vividness
of Red Hot Poker flowers he perceived while under the influence of psychedelics. However, due to environmental changes and noise, this clear perception is not likely to stay stable over time. The noisier the bottom-up signal, the more the top-down predictions influence perception (Seth, 2014). Under decomposed predictions, lowering precision of sensory data can result in misclassification of the data. The brain's best explanation for the imprecise 'noisy' data might be one of the sub-threshold predictions that got activated. This will result in a 'hallucination'. Psychedelics are known to both obscure and distort perceptual data as well as add clarity and give the sense of enhanced resolution. These two different sides of the psychedelic state are dependent on the precision of the bottom-up data, i.e., the noisiness of the setting. The more noisy the bottom-up data is, the more likely hallucinations will be.

## Prediction error minimization and the psychedelic state

Under normal conditions the brain can decrease prediction error in several ways (Friston et al., 2012; Kwisthout et al., 2017). It could update predictions; lower prediction error by intervening in the world or it may update the causal model that generated the predictions. In this section, we explore how upregulating these mechanisms, in order to deal with the increased prediction error caused by decomposed predictions, can explain many of the documented psychedelic effects. We will investigate the effects of prediction updating, active inference, changing the weight of predictions, and long-term learning effects.

## Updating the predictions

As we have explained, in the case of decomposed predictions, a smaller amount of sensory inputs will be explained by any specific prediction. This will cause
increased prediction errors. One mechanism the brain might use to minimize prediction error is to change the prediction distribution. However, as the predictions remain decomposed no prediction will be enough to explain away the prediction error for long and so once again the distribution will change and perhaps this time the probability of an otherwise unlikely input becomes the leading prediction and affects perception. This constant revising of the probability distribution will lead to a destabilization of perception. Objects, scenes and even abstract thoughts will 'morph' and change at a rapid speed; however, each percept reflects the best possible prediction at that moment. A room might look bigger or smaller or the prediction of the light condition might change causing colors to morph. This can be the cause of individuals reporting a tendency to see "multiple viewpoints" (Sessa, 2008).

Predictions from other layers of the brain hierarchy that were not affected by activation of the $5-\mathrm{HT}_{2 \mathrm{~A}}$ receptors can be upregulated by either increasing their relative strength or lowering their level of detail. This will cause the predictions from these layers to enforce their predictions on more of the incoming data. Google's deep neural network 'deep dream' ${ }^{1}$ (originally created for identifying images) illustrates how this might happen. By allowing different layers of the network to strengthen their predictions these networks were able to produce hallucinatory effects. Strengthening predictions of lower layers (that identified lines) created images with amplified lines, while increasing predictions from higher level abstract layers (e.g., identifying buildings) created images with 'imaginary' buildings being imposed on the original picture. Further proof that this is actually happening in the brain can be seen in the work of Bressloff et al. (2001). Their simulated attenuated low-level predictions of the visual system (V1) and found remarkable resemblance with geometrical hallucinations drawn by people on LSD. This shows that increased predictions from V1 are likely to be behind the specific geometrical visual hallucination. Furthermore, Carhart-Harris et al. (2016) found that increased cerebral blood flow (CBF) in the visual cortex as well as a greatly expanded functional connectivity profile in V1 correlated strongly with subjects' ratings of visual hallucinations. It is impossible to know at the moment whether the increase in CBF is due to increased predictions errors, upregulating of predictions, or both.

## Acting on the Environment

Another mechanism of minimizing prediction error is intervening in the world (i.e., acting on the environment) (Brown, Friston, \& Bestmann, 2011). This changes the actual inputs and sets some of the model's parameters and thus decreases uncertainty. Changing the brain's input can happen both in a passive way, for instance by moving one's eyes, or by actively moving objects in the environment. Since $5-\mathrm{HT}_{2 \mathrm{~A}}$ receptors are not as prevalent

[^437]in the primary motor cortex, top-down prediction from that area wouldn't be as affected and this mechanism is likely to remain intact even under the influence of Psychedelics. This can explain why hallucinations seem to grow stronger while sitting still and can help influence harm reduction policies. By creating motor output, for instance while walking or dancing, the mechanism of active inference (in which motor output minimizes proprioceptive prediction error between the expected and actual position of one's limb, bringing the actual position closer to the expected position; see, e.g., Brown et al., 2011) might enable the brain to lower prediction errors stemming from other parts of the brain too.

## Changing Weight of the Prediction Error

While chemical tolerance to Psychedelics drugs should not exist more than a few days after ingestion (Leshner, 2001) many experienced users will admit that the first few experiences feel stronger than later experiences and increased dosage is needed to reach the same state. This might happen as a result of the brain's attempt to minimize prediction error by lowering the weight of the prediction error or attributing this higher prediction error to 'inherent' noise that does not need to be explained. An example of inherent noise that the brain learns to ignore can be seen in a fair coin toss (Kwisthout et al., 2017). Even if you guess the coin will land on 'heads' and then it actually lands on 'tails' no surprise will follow. The brain has learnt that this type of stochastic noise is inherent to a fair coin toss. The same could happen under extended use of psychedelics. The brain could learn that this state is inherently noisier and lower the weight of the prediction error. We can only postulate that this might happen through affecting the dopamine system which has been implicated in precision weighting of prediction error (Friston et al., 2012).

## Long Term Learning Effects

Within the predictive coding framework the model constructed by the brain is considered to be encoded in the network connectivity. Changes in this connectivity will lead to long term learning. While learning effects in humans after administration of $5-\mathrm{HT}_{2 \mathrm{~A}}$ agonists have not directly been studied in the last decades an interesting study in rabbits has found that agonists at the $5-\mathrm{HT}_{2 \mathrm{~A}}$ receptor including LSD enhanced associative learning at doses that produce cognitive effects in humans (Harvey, 2003). Using the predictive coding framework, depression, addiction and obsessive compulsive disorders have been suggested to stem from overly strong and narrow predictions from certain networks that get 'stuck' (Edwards et al., 2012) and aren't updated based on the bottom-up data. Momentarily decomposing these predictions by $5-\mathrm{HT}_{2 \mathrm{~A}}$ agonists, especially with a combination of supportive bottom-up information coming from a therapeutic setting, might lead to long term model updates. This could be the reason behind the success of
recent clinical trials that have used $5-\mathrm{HT}_{2 \mathrm{~A}}$ agonist to treat these disorders.

A long term model update that psychedelic are known to cause is increasing the trait of 'openness' (MacLean, Johnson, \& Griffiths, 2011). The mechanism we suggest to explain this is as follows. A higher prediction error state caused by administration of $5-\mathrm{HT}_{2 \mathrm{~A}}$ agonists coupled with a positive rewarding setting, leads to surprise becoming a more sought after state. Interest in exploring the unknown and trying new things might grow and people might be 'motivated to enlarge their experience into novel territory' which is what defines the trait of openness (DeYoung et al., 2009).

## Psychedelics research findings reinterpreted

In the following section we will re-interpret previous findings in psychedelics research in light of our theoretical account and see how our account can clarify and shed further light on these results.

Kometer et al. (2006) presented so-called Kanizsa triangles to subjects after administration of psilocybin. These shapes are perceived as complete triangles and circles rather than the complex shapes that they actually are, because of a top-down learnt prediction. Viewing this shape under normal conditions has been shown to evoke a unique change lowering of voltage as measured on the skull $170 \mathrm{~ms}^{2}$ after presentation of this stimulus. Following administration of Psilocybin, Kometer et al. found a decrease in strength of this ERP suggesting a lower strength of these predictions. This is in accordance with the model of decomposed predictions, since decomposed predictions will indeed cause each prediction to be weaker than normal. This same experiment also found desynchronization of alpha band activity which we have discussed previously.

In a behavioral experiment, Spitzer et al. (1996) found increased indirect semantic priming after administration of Psilocybin. They claim their data suggests that Psilocybin leads to an "increased availability of remote associations and thereby may bring cognitive contents to mind that under normal circumstances remain nonactivated" (Spitzer et al., p. 1056). This would indeed be expected if broad categorical 'semantic' predictions are decomposed, activating many more detailed semantic predictions, and allowing for more remote associations to be activated.

Another well-documented effect is known as 'Time Dilation' in which subjective time seems to slow down. A few minutes can subjectively be perceived as taking much longer. Here we postulate that subjective sensation of time is dependent on the amount of prediction error and possibly prediction updates the brain makes in order to minimize prediction error. This idea is based on Ulrich (2006) who discovered that the extent to which a stimulus can be predicted affects time perception, with unexpected

[^438]stimuli perceived as longer. Similarly, Tse et al. (2004) found that a stimulus which stands out as different from all the others in a series appears to last longer than the other stimuli. An increase of prediction updates might cause the subjective feeling that more time has passed. This is similar to the common feeling that the first day of a journey to another country seems longer because it is filled with so many new experiences and so many prediction updates must happen in that day.

The last phenomenon we would like to touch upon is the notion of 'Ego death' many psychedelic users report. Apps \& Tsakiris (2013) describe a predictive coding account of the neural and computational basis of selfrecognition. Here, one's body is recognized as the most likely "me". This probabilistic inference arises through the integration of information from hierarchically organized unimodal systems in higher-level multimodal areas. As we have seen, the brain's attempt to minimize increased prediction error induced by psychedelics breaks down this hierarchical structure which might lead to a total inability to distinguish between environment and self and the unique perception of 'oneness' described by many experiencing 'ego loss'. While Apps \& Tsakiris' account deals with the 'minimal self', we postulate looking at the 'higher ego' as a collection of high-level relatively inflexible predictions regarding the future behaviour of the 'self-organism' in a variety of situations. Following administration of $5-\mathrm{HT}_{2 \mathrm{~A}}$ agonists these predictions will break up based on the subjective pieces of information compromising this category. This relaxation of otherwise rigid predictions about the self might explain positive results for treatment of depression and addiction after administration of psychedelics that have been reported (Nichols, 2016).

## Conclusions

In this paper we presented a computational theory explaining the effects of psychedelics in terms of the predictive coding account of cortical processes. Our theory further explicates the Entropic Brain hypothesis (Carhart-Harris et al., 2014) in terms of predictive coding. We proposed that administration of psychedelics cause the brain to make overly detailed (i.e., decomposed) predictions of the inputs it receives, leading to an increased prediction error. Crucially, while dopamine is considered to modulate precision weighting of prediction errors (Friston et al., 2012), our theory suggests that serotonin might have a role in modulating the granularity ("level of detail") of predictions. Our theory explains how a simple lowering of the excitation threshold of the pyramidal neurons in layer V in prefrontal, parietal and somatosensory cortex (caused by administration of 5$\mathrm{HT}_{2 \mathrm{~A}}$ agonists) in fact decomposes predictions from those areas, causing increased prediction errors from lower levels in the brain hierarchy. The brain's attempts to minimize these increased prediction errors by active inference, prediction updating, modulation of the weights
of prediction errors, or model revision can explain several (and sometimes contradictory) cognitive effects of psychedelics such as hallucination, heightened sensory input, synesthesia, increased trait of openness, 'ego death' and time dilation.

# Repetition improves memory by strengthening existing traces: Evidence from pairedassociate learning under midazolam 

Vencislav Popov (vencislav.popov@gmail.com)<br>Lynne Reder (reder@cmu.edu)<br>Department of Psychology, Carnegie Mellon University, Pittsburgh, PA, USA

#### Abstract

Here, we examined how repetition under midazolam, a benzodiazepine that prevents the storage of novel associations, affects cued-recall performance of paired-associates. We contrasted word pairs that were initially studied and tested repeatedly without any successful recall prior to the midazolam injection, with other pairs that were studied for the first time after the injection of midazolam. According to our SAC (Source of Activation Confusion) memory model, repetition leads to strengthening existing memory traces rather than creating multiple traces for each repetition. As such, it predicts that repetition under midazolam should benefit only pairs that were originally studied prior to the midazolam injection. This prediction was confirmed. The results suggest that memory traces for pairs studied prior to the midazolam injection were strengthened under midazolam. However, word pairs that had not been studied prior to the injection were not bound in long-term memory because midazolam prevents the formation of new associations.

Keywords: memory strength; paired associate learning; episodic memory; practice; midazolam;

Repetition improves memory performance across the board. Beneficial effects of repetition have been found on most measures of explicit memory such as single-item and paired-associates recognition (e.g., Challis \& Sidhu, 1993; Reder et al., 2000), free recall (e.g., Challis \& Sidhu, 1993; Underwood, 1969), and cued recall tasks (Meltzer \& Constable, 2005; Reder et al., 2007; Reder, Liu, Keinath, \& Popov, 2015). However, despite more than a century of research on repetition effects, there is no consensus about the mechanism through which practice affects memory (Criss \& Koop, 2015; Hintzman, 2010, 2011; Osth \& Dennis, 2015; Pavlik \& Anderson, 2005).

Two major types of theories have been proposed to explain repetition effects. Cumulative-strength models (CSMs) suggest that memory traces differ in strength or familiarity, and this strength increases with repetition and decays with time (e.g., Murdock, Smith, \& Bai, 2001; Pavlik \& Anderson, 2005; Reder et al., 2000; Wickelgren, 1972). In these models, recognition and recall are a function of strength and greater strength leads to better memory performance. In contrast, multiple-trace models (MTMs), usually equated with global matching models (GMMs, Criss \& Koop, 2015), state that each repetition of an item is encoded separately in memory (Bower, 1967; Brown, Neath, \& Chater, 2007; Hintzman, 1984; Lansdale \& Baguley, 2008; Osth \& Dennis, 2015). This leads to redundant memory traces, each of which has some probability of being retrieved during test. Interestingly, while both CSMs and MTMs co-exist in the current literature, several proponents of each class believe that certain
empirical findings have conclusively ruled-out the alternative models (Criss \& Koop, 2015; Hintzman, 2011).

When it comes to CSMs, some researchers have argued that they are incompatible with findings from judgments of frequency (JOF) and judgments of recency (JOR) tasks (Flexser \& Bower, 1974; Hintzman, 2010, 2011 Hintzman \& Block, 1971). Many CSMs in the past have assumed that the estimation of frequency, recency and duration of events is based on a single strength dimension (Hintzman, 2011). As a result, these models predict that, for example, if an event is repeated it should also appear to be more recent and to have lasted longer. That is not the case studies have shown that participants can easily discriminate the frequency, recency and duration of repeatedly studied items (Flexser \& Bower, 1974; Hintzman, 2010, 2010; Hintzman \& Block, 1971).

This line of work seems to provide strong evidence against CSMs, and yet, they are still popular in modeling recognition and recall. Hintzman (2011) refers to this as "the fallacy of cumulative strength", and suggests that the CSMs are still popular because most theorists focus on recognition memory and recall, while ignoring tasks such as JOR and JOF. However, the same criticism can be directed at conclusions from JOR and JOF tasks - the fact that a single strength dimension cannot explain behavioral patterns in such tasks does not mean that repetition effects on recognition and recall memory are not due in part to cumulative strengthening of existing memory traces. It only indicates that memory representations also include rich contextual information, which is an assumption shared by most current dual-process CSMs.

Similarly, when it comes to MTMs and GMMs, other researchers maintain that they cannot account for the divergent patterns of the list-length effect (LLE) and the list-strength effect (LSE) on free recall and recognition (Criss \& Koop, 2015; Shiffrin, Ratcliff, \& Clark, 1990). The LLE shows that increasing the number of different items on a study list decreases free recall, cued recall and recognition performance. Similarly, the LSE shows that increasing the number of repetitions on some items leads to worse free recall for the non-repeated items. However, the LSE generally has no effects on overall performance in recognition tasks. Critics of GMMs have argued that they are fundamentally incompatible with this pattern of results (Criss \& Koop, 2015). This is because GMMs assume that the same mechanism is involved when the number of different items increases and when some items on a list are repeated. Specifically, they both lead to the creation of additional memory traces and to increased global signal variance, which causes interference during retrieval. As such, GMMs supposedly predict that LSE and LLE should always occur together.

However, multiple proponents of GMMs have questioned both the reliability of the pattern of LSE and LLE effects on recognition (Dennis \& Humphreys, 2001; Murdock \& Kahana, 1993) and the inability of GMMs to account for it (Murdock \& Kahana, 1993; Osth \& Dennis, 2014, 2015). Furthermore, despite the fact that most MTMs are also GMMs, a multiple-trace model does not have to depend on global matching for memory decisions, which would make it easier to fit the pattern of LSE and LLE results. For example, even though our Source of Activation Confusion model (SAC; Reder et al., 2000) is a cumulative-strength model, the dual processes that allow it to account for the divergent pattern of LLE and LSE results would allow it to do the same even if each item repetition created a novel episodic trace (Cary \& Reder, 2003; Diana \& Reder, 2005).

In summary, the major problem with contrasting CSMs and MTMs has been that they make similar predictions when it comes to most memory tasks. One way to overcome this would be to attempt to disrupt the mechanism that is responsible for repetition effects in a specific model such as SAC, to make predictions how that will affect behavioral performance and to evaluate how well the model fits the data. To achieve that, we examined how repetition affects cued-recall under midazolam. Midazolam is a benzodiazepine that creates temporary anterograde amnesia by preventing the storage of new associations in LTM (Ghoneim, 2004; Reder et al., 2006), but it does not impair pre-existing memory traces (Ghoneim, 2004) or their strengthening, as evidenced by its limited effect on repetition priming (Hirshman, Passannante, \& Arndt, 2001; Hirshman, Passannante, \& Henzler, 1999).

We compared cued-recall performance for paired-associates that were studied for the first time (control pairs) under midazolam and a subset of the pairs that were studied both before the midazolam injection and re-studied after the injection (practice pairs). The subset of interest were those pairs that had not been recalled on any of the tests that preceded the re-study session under midazolam. Given that midazolam prevents the storage of new associations in LTM, SAC predicts that the recall of control pairs should be at floor levels; performance on practice pairs that were never recalled correctly was an open question. SAC assumes that pairs that had never been correctly recalled might still have subthreshold episodic traces in LTM. If repetition of the pair leads to the strengthening of this sub-threshold episodic trace, as SAC originally assumes, then we would expect greater recall of practice pairs compared to control pairs. If, however, repetition leads only to the creation of additional memory traces, then no advantage should be observed for practice compared to control pairs under midazolam, because midazolam will prevent the storage of the new traces in LTM.

## Method

The data of interest involve a subset of conditions from a larger study previously reported in Reder et al. (2007) and Reder et al. (2006; study 2). For clarity, we will describe the full design.

## Participants

Thirty-one healthy individuals from the Pittsburgh community participated in this experiment. Each participant was screened by a doctor and received $\$ 150$ upon completion.

## Procedure, materials and design

The study took place in two sessions on two separate days. We used a within-subject double-blind cross-over design where the drug condition (saline vs midazolam) was randomly assigned to one of the two days for each participant. Each session consisted of three separate study-test list cycles. The saline/midazolam injection was administered over a 2-min period between Lists 1 and 2. Participants began the study phase of List 2 immediately after the injection.

During each list, participants saw all of the 45 high-frequency word pairs in the following sequence: Study - Test1 and Restudy1 - Test2 and Restudy2. During the initial study phase, each word pair was presented for 3 seconds preceded by a fixation cross for 1 second. After all 45 pairs were studied, participants completed a self-paced cued-recall test for all 45 pairs in a different random presentation order. Test trials began with a 500 ms fixation cross, followed by the presentation of the first word in a pair and a question mark prompting participants to respond. Participants were asked to recall the correct word and type it on a laptop keyboard or press the return key to move to the next trial. Regardless of the accuracy of their response, participants saw the correct answer for 2.5 seconds after each response, which gave them an opportunity to restudy the pairs again. When all 45 pairs were tested and restudied the test-restudy phase was repeated one more time, which concluded the procedure for the first list. This study-testandrestudy1-testand-restudy2 procedure was repeated for two more lists, each of which took approximately 17 min . to complete. On each list, the 45 study pairs were split into 3 conditions with 15 pairs per condition - control pairs, which were unique for each list, practice pairs, which were the same 15 pairs on all 3 lists, and interference pairs, which had the same words on all 3 lists, but the cue words were assigned to different response words on each new list. The order of word pairs in each list, study and test sessions was randomly determined.

## Data analysis and logic for the current study

Only a small subset of conditions was relevant for this study (see Figure 1). Specifically, we looked at cued recall performance on List 2 Test 2 for those control and practice pairs for which participants had failed to recall the response word on all previous tests. The control pairs were unique to each list, and as such the ones we selected were previously studied and tested only once at the beginning of List 2 . The practice pairs were previously studied and tested twice on List 1 as well. We analyzed only those practice pairs which participants failed to recall on all three occasions (L1T1, L1T2 and L2T1).

We focused on the second test of List 2 (L2T2), rather than on the first test on List 2 for the following reason. Even though the injection was administered before the beginning of the second list, practice pairs were restudied immediately after their second test on List 1 (L1T2). Thus, if we observed improved recall for practice pairs on L2T1, it might have been due to the restudy

Figure 1. Visualization of the procedure for the subset of conditions relevant for this study. Small boxes represent the phases of each list (study, cued recall, or restudy), and whether the test was successful. Shown are the subsequent phases only for the relevant trials. The first row shows the procedure for practice pairs; the second shows the procedure for the control pairs. List $1 \& 2$ are shown in separate columns.
session that occurred prior to the injection rather than due to strengthening during the study session of List 2 under midazolam.

In summary, we selected control and practice pairs that showed no evidence of being learned up until L2T1 in either drug condition (midazolam or saline). These pairs were then restudied immediately following that test, and were then tested on L2T2. For control pairs, $75 \%$ qualified for analysis in the saline condition and $99 \%$ in the midazolam condition. For practice pairs, $32 \%$ qualified under saline and $41 \%$ under midaz. We analyzed accuracy on L2T2 as function of pair type (control vs practice) and drug condition (midazolam vs saline) using a logistic mixed effects regression with participants and items as random intercept effects. We compared alternative models with and without each of the main effects and interactions. A Bonferroni correction was applied to all post-hoc tests ( $\mathrm{n}=4$ ).

## Results and discussion

The overall recall for each list collapsed over the two tests in a list are presented in Figure 2 and the results for the subset of trials of interest are presented in Figure 3. Control pairs were recalled less accurately than practice pairs, $\Delta \mathrm{AIC}=-22, \chi^{2}(1)=24.12, \mathrm{p}<$ .001. Word pairs were recalled less accurately under midazolam compared to saline, $\Delta \mathrm{AIC}=-172, \chi^{2}(1)=174.32, \mathrm{p}<.001$. There was a significant interaction between drug condition and type of pair, $\Delta \mathrm{AIC}=-17, \chi^{2}(1)=19.27, \mathrm{p}<.001$. Post-hoc comparisons revealed that practice pairs were recalled significantly more accurately than control pairs in the midazolam condition ( $z=6.72$, $\mathrm{p}<.001$ ), but not in the saline condition $(\mathrm{z}=2.30, \mathrm{p}=.09)$. Finally, both practice and control pairs were recalled more accurately in the saline compared to the midazolam condition ( $z=9.97, p<.001$ and $\mathrm{z}=4.56, \mathrm{p}<.001$, respectively for practice and control pairs). These results are consistent with the view that repetition can strengthen existing memory traces, because only pairs that were initially studied prior to a midazolam injection benefited from additional study under midazolam. These practice pairs were recalled more often than control pairs, which were studied for the first time after the midazolam injection, even though both showed no evidence of learning prior to the final test.

Despite the fact that practice pairs had not been recalled on any of the 3 previous tests, it is possible that an initial association for them was stored during List 1 . It seems reasonable to conclude that even though these associations were inaccessible, they must have been registered in LTM since they were strengthened under midazolam while the control pairs were not. Midazolam is known to block the formation of new associations but there is no evidence that it inhibits strengthening of existing traces. On the contrary, implicit memory is spared under midazolam (Hirshman et al., 2001), and the model presented below already assumes that implicit memory is based on strengthening the same representations involved in familiarity-based recognition (Reder, Park \& Kieffaber, 2009).

An alternative explanation of these data consistent with multiple-trace theories might be that even if no traces were strengthened under midazolam for practice pairs, the pre-existing sub-threshold traces might be spontaneously recovered in a probabilistic way (Brown, Neath \& Chater, 2007). We believe this is unlikely, given that each practice pair analyzed here failed to be recalled on all 3 previous tests. Additionally, we can directly estimate what is the probability of recovery with a multinomial processing tree model (Erdfelder et al., 2009), where at each test there is one of the following possibilities: 1) successful recall of the target due to study/restudy, $r=\mathrm{P}$ (success on test $\mathrm{n} \mid$ fail on test $\mathrm{n}-1$, or when $\mathrm{n}=1$ ), 2) failing to recall a previously recalled target, $f=\mathrm{P}($ failed recall on test $\mathrm{n} \mid$ success on test $\mathrm{n}-1), 3$ ) spontaneous recall of a previously unrecalled target regardless of restudy benefit, $u=\mathrm{P}^{\prime}($ success on test $\mathrm{n} \mid$ fail on test $\mathrm{n}-1)$. We estimated these probabilities from performance on the control pairs on the two tests on List 1 (data not used in the previous analyses):

$$
\begin{array}{lll}
P(\text { success T1 \& success T2) } & =r *(1-f) & =0.42 \\
P(\text { success T1 \& fail T2) } & =r * f & =0.04 \\
P(\text { fail T1 \& success T2) } & =(1-r) *(r+u) & =0.29 \\
P(\text { fai T1 \& fail T2) } & =(1-r) *(1-r-u) & =0.25
\end{array}
$$

Here, successful recall following a failed recall is a combination of reencoding benefit $r$ and a spontaneous recovery $u$. This analysis showed that the probability of successful recall due to (re)encoding was $r=0.46$, the probability of forgetting a previous encoding was $f=0.09$, and the probability of spontaneous
recovery of a forgotten encoding was $u=0.07$ (similar values were obtained if we consider all sequential pairs tests on all three lists for practice pairs in the saline condition, $u=0.089$ ). One-tailed $t$ tests showed that the benefit of restudy under midazolam (Fig 3), was significantly higher for practice pairs, but not for control pairs. Thus, spontaneous recovery of previously forgotten items cannot account for our results.

Figure 2. Cued-recall performance during acquisition, collapsed over the two tests (black points and solid lines) and model fits (white points and dashed lines) in all lists for control and practice pairs as a function of drug condition.

Figure 3. Accuracy on L2T2 for control and practice pairs that were not recalled correctly on any of the previous tests as a function of whether the L2 items were studied under saline or under midazolam. Horizontal red line shows the probability of spontaneous recovery of a forgotten item without strengthening.

To demonstrate that CSMs can fit the data not only verbally, but quantitatively as well, we fit a SAC model (Reder et al., 2000) on a trial-by-trial basis separately for each participant. In general, SAC posits that semantic, episodic and contextual information is represented as a network of interconnected concepts, event and context nodes varying in strength. Each node has an activation value that increases when a node is perceived or when it receives activation from other nodes. This activation decays with time according to a power law to a base-level resting activation that also is strengthened or decays with experience. When new information is studied, two processes occur. First, the current and the resting level activation values of the corresponding preexisting concept nodes are increased. Second, if this is the first occurrence of the
study episode, a new event node is created and it gets associated with the corresponding concept nodes, as well as with the general and specific context nodes. If, however, the study event has occurred previously, the existing event node and its links with the concept and context nodes are strengthened instead.

Retrieval in SAC is based on the activation of the event and concept nodes and the process differs slightly between free recall, cued recall and recognition. During free recall, the general context node and the list node are activated and they spread activation to all episode nodes connected to them. During cued-recall or recognition, the concept node(s) for the cue(s) is also activated and it spreads activation to all episode nodes connected to it. Spreading activation is multiplied by the strength of each association, and divided by the sum total strength of associative links emanating from the sending node. This represents competition for retrieval. Finally, if an episode node's activation passes the retrieval threshold, an item is recalled (free and cued recall) or recollected (recognition). For recognition, if no episode node passes the threshold, the strength of the cue concept node is evaluated. If it passes its retrieval threshold, a familiarity-based response is made.

The majority of parameters in the model were imported from previous studies. Consistent with the fact that midazolam prevents the storage of novel associations in LTM, in the current simulation we manipulated the probability of encoding an episode node. During the first presentation of each word pair there is a certain probability that participants will fail to encode the event node due to inattention, fatigue or insufficient working memory (see Reder et al., 2007). In models of other studies, this value has been constant, but in the current implementation, we allowed it to vary between the saline and the midazolam conditions. The optimal value for the saline condition was estimated from the data ( $p=$ 0.35 ), while the encoding probability for the midazolam condition changed with time elapsed since the injection (see Table 1 for parameter estimates and descriptions, and Table 2 for full model specification). Immediately after the midazolam injection the encoding probability was 0 , reflecting the inability to store new associations at maximum potency, and it gradually increased to half of the encoding probability in the saline condition in 31 minutes (drug halflife for memorial effects, Albrecht et al., 1999).

The overall model fit for all conditions is presented in Figure 2, and the fit for the specific subset of interest is overlaid on Figure 3. Importantly, the model was fit by predicting a single value for each participant - their overall cued-recall performance and by minimizing the RMSE between the predicted and the observed value. Given that the model had no information about the performance in each condition, we obtained a surprisingly good fit for the split by conditions ( 16 summary data points per participant; $\mathrm{RMSE}=0.139, \mathrm{R}^{2}=0.8$ ). The model demonstrates that the beneficial effect of repetition under midazolam can be explained entirely by the strengthening of preexisting memory traces that were previously below the retrieval threshold.

One could question why practice pairs were not recalled better than control pairs in the saline condition, given that they should benefit both from strengthening a pre-existing trace as well as from creating novel associations for pairs that were previously unlearned, while control pairs benefit only from forming new associations. Indeed, while the overall fit of the model was quite
good, the model predicts that there should be a repetition advantage for the subset of analyzed practice pairs even in the saline condition (Figure 3). The behavioral data showed a small effect in that direction, which was not significant after correcting for multiple comparisons $(\mathrm{p}=.09)$. One possibility is that this is due to a selection bias - the practice pairs selected for analysis were those that showed no evidence of learning in three previous tests ( $\sim 32 \%$ ), thus they were generally hard to learn. Note that the control pairs we analyzed were those that had not been recalled on only 1 previous test ( $\sim 76 \%$ ) so they were probably not as difficult to learn. The greater difficulty of the selected practice pairs might have offset the relative repetition benefits under saline (as seen from Fig 2, practice pairs do benefit more under saline than under midazolam). Another possibility is that there were only few observations per cell, and the resulting noise might have obscured the effect in the saline condition. Despite this, the key prediction, namely the comparison between control and practice pairs under midazolam, was quite robust.

In summary, the current study provides evidence that one mechanism through which repetition benefits memory is the strengthening existing memory traces. Despite this result, we do not wish to argue that no additional information beyond strength is stored in memory with each repetition of an event. Based on JOR, JOF, LLE and LSE results reviewed in the introduction, and the results presented here, it is reasonable to conclude that repeated experiences affect memory through a multitude of mechanisms that include both strengthening of previously encoded traces that match in content, as well as storing novel traces to represent the unique features of the repeated experience. What part of that information is accessed likely depends on the nature of the task being performed. While accurate judgments of recency and frequency might require accessing and comparing information across multiple memory traces, recognition and recall can depend on the strength of any one of those traces.

Table 1 SAC model parameters

| Par | Description | Value |
| :---: | :---: | :---: |
| Imported parameters |  |  |
| $A_{\text {boost }}$ | Value added to current activation when an item is perceived | 40 |
| $p_{\text {decay }}$ | Exponential decay constant for current activation | 0.8 |
| $d_{\text {node }}$ | Power-law decay constant for base-level activation | 0.175 |
| $c_{\text {node }}$ | Power-law growth constant for base-level activation | 25 |
| $d_{\text {link }}$ | Power-law decay constant for link strength | 0.12 |
| Clink | Power-law growth constant for link strength | 25 |
| $b_{\text {freq }}$ | Exponent for Kucera and Francis word frequency norms for estimating pre-existing base-level activation | $1 \quad 0.4$ |
| $l_{\text {freq }}$ | Exponent for Kucera and Francis word frequency norms for estimating preexisting link fan | 0.7 |
| Estimated parameters |  |  |
| $P_{\text {baseline }}$ | Baseline probability of encoding an event node for a new word pair | 0.35 |
| $\sigma_{\text {episode }}$ | Standard deviation of the episode node activation | 1 |
| $T_{\text {episode }}$ | Retrieval threshold for episode node activation | $\begin{gathered} 2.9 \pm \\ 1.6^{*} \end{gathered}$ |

[^439]Table 2 SAC model equation

| Equation | Description |
| :---: | :---: |
| $B_{0}=K F^{b_{\text {freq }}}$ | Preexisting base-level activation; a function of Kurcera \& Francis word frequency |
| $B=B_{0}+c_{\text {node }} \sum t_{i}^{-d_{\text {node }}}$ | Current base-level activation is a function of preexisting base-level activation and time since each presentation of a stimulus. $t_{i}$ is the time since the $i$-th presentation |
| $S_{\text {cue,episode }}$ $=c_{l i n k} \sum t_{i}^{-d_{l i n k}}$ | Current strength of the link from the cue to the episode node is a function of time since each presentation of the stimulus. $t_{i}$ is the time since the $i$-th presentation |
| $A_{\text {cue }}=B+A_{\text {boost }}$ | Current activation of the cue is a function of base-level activation and a perceptual boost |
| $A_{\text {input }}=A_{\text {cue }} \frac{S_{\text {cue } e \text { episode }}}{\sum S_{\text {cue }}}$ | The input to an episode node due to spreading activation from the cue is a function of the cue activation level, the strength between the cue and the episode node, and the fan of the cue |
| $A_{\text {episode }}=\ln \left(B+A_{\text {input }}\right)$ | Current activation of the episode node is the natural logarithm of the sum of the base-level activation and the received spreading activation |
| $\begin{aligned} & P_{\text {encoding }} \\ & =P_{\text {baseline }} *(1 \\ & \left.-C \times 2^{-\frac{t_{\text {injection }}}{t_{h l}}}\right) \end{aligned}$ | The probability of encoding the episode node is a function of the baseline probability, whether a the drug was saline $(\mathrm{C}=0)$ or midazolam ( $\mathrm{C}=1$ ), the time since the injection and the half-life of the drug. |
| $\begin{aligned} & P_{\text {retrieval }} \\ & =N\left(A_{\text {episode }} \mid \sigma_{\text {episode }},\right. \\ & \left.\quad \tau_{\text {episode }}\right) \end{aligned}$ | The probability of retrieval of the episode node is the area to the left of the activation value under a standard normal distribution with the threshold as the mean. |

#### Abstract

Although an understanding of fractions is a critical precursor for other mathematical concepts, including proportional reasoning, algebra, and success in STEM fields, surveys of mathematics education in the United States indicate that school-age children lack age-appropriate math skills and proficiency. Thus, understanding the critical precursors of fraction knowledge is important for the development of instructional materials. The aim of the present study was to examine whether instructional format affected children's learning and transfer of fraction concepts, and whether individual variables such as executive function and math knowledge moderated these effects. Six- to 8 -year-old children participated in a longitudinal, pre/post test design, in which they received a fraction-training intervention. Critically, we manipulated the extent to which real-world instruction was grounded in visual vs. symbolic representations. We find that $1^{\text {st }}$ and $2^{\text {nd }}$ graders were able to learn fraction concepts following this intervention, despite having no formal fraction education. The extent to which the instructional stimuli were grounded in visual vs. symbolic representations affected children's proportional reasoning knowledge in a transfer task, and condition effects were moderated my children's working memory and prior math knowledge. This work has implications for instructional design and curriculum development in the classroom.

Keywords: Numerical cognition, fractions, proportional reasoning, education, learning.

## Introduction

An understanding of fractions is a critical precursor for other mathematical concepts, including probability, proportional reasoning, algebra, and much of the STEM fields (Bailey, Hoard, Nugent, \& Geary, 2012; Department of Education, 1997). In fact, early fraction knowledge predicts the acquisition of algebraic knowledge well into middle and high school. However, surveys of mathematics education in the United States indicate that school-age children lack age-appropriate math skills and proficiency (NAEP, 2009; NCES, 2010; Siegler et al., 2012; also see Hurst \& Cordes, 2016). Thus, improving students' math knowledge and reasoning ability about proportions early in a child's education is important. Furthermore, understanding what instructional format may best lead to both the learning and transfer of difficult math concepts (i.e., proportions) should be a fundamental component of instruction and curriculum development.

The aim of the present study was to examine whether the instructional format in which fraction concepts are taught would affect the learning and transfer of novel fraction concepts (Core Curriculum; New Common Core Mathematics Standards, 2000), as well as whether individual variables such as executive function and prior math knowledge would moderate any observed effects. On the one hand, one approach to teaching mathematics to young children involves the use of concrete instantiations, such as vibrant, perceptually-rich visual displays or realworld contextualized examples (e.g., Van de Walle, 2007), presumably because these high-contrast items are attentiongrabbing, motivating, and often found in a child's natural environment (NCTM, 2000). Perceptually rich education materials are abundantly available and often populate children's classrooms in an effort to keep children interested in the materials being taught (Peterson \& McNeil, 2012). Even teachers prefer perceptually rich materials (Peterson \& McNeil, 2012), as they presumably increase children's engagement in the task at hand.

On the other hand, much work suggests a "less is more" approach to teaching children about difficult math concepts. This work suggests that perceptually rich or concrete materials may hinder mathematics concept learning (and perhaps problem solving and computation) because extraneous perceptual information gets integrated into representation of the target concept (e.g., Kaminski \& Sloutsky, 2009, 2013; Kaminski, Sloutsky, \& Heckler, 2009; McNeil \& Fyfe, 2012; Mix, 1999, 2008; Peterson \& McNeil, 2012; Posid \& Cordes, 2014). For example, Posid and Cordes (2014) asked young children (3-6 years) to decide which of two arrays contained a target number of items, where half of the arrays were homogenous in makeup (e.g., all of the same kind of animal) and the other half of the arrays were heterogeneous in make-up (all different animals). They found that children were less accurate when arrays were heterogeneous in make-up, particularly when the task was more difficult (when children were asked to find a larger target numerosity), and that this homogeneity advantage remained present across development (Posid \& Cordes, 2014; also see: Mix, 1999, 2008). Similarly, Kaminski \& Sloutsky (2013) taught young children (kindergarten through second grade) to read bar graphs, while manipulating whether the graphs contained colorful and irrelevant information or monochromatic bars. They
found that the children trained on graphs with irrelevant colorful features often tried to use that extraneous perceptual information incorrectly, decreasing their overall accuracy compared to their peers who were trained on monochromatic bar graphs (Kaminski \& Sloutsky, 2013). Together, these studies suggest that these more perceptually rich concrete instantiations over-communicate information to the learner, compared to their generic counterparts, thereby hindering learning from the relevant mathematical structure or relations at hand.

The impact of perceptual information when learning about proportions or fractions is even less known. In one study, Kaminski and Sloutsky (2009) investigated kindergarteners' ability to identity proportions across two sets of stimuli, which varied in their degree of concreteness of the instantiations. Children in the concrete condition failed to compare novel proportions while children in the generic condition successfully compared novel proportions, following a sparse training and no instruction. These findings suggest that simple proportional relations can be learned following generic instantiations, while concrete instantiations do not promote this same type of learning.

In this vein, young children's learning of fractions may also benefit from more generic instantiations. Specifically, fractions are traditionally introduced as symbols (e.g., 1/2), where visual representations may add extraneous information that could be interpreted ambiguously or incorrectly. For example, additional visual information could (a) add a layer of perceptual richness by conveying concept-irrelevant information and/or distracting information to the learner from the specific math concept to-be-learned, (b) add extraneous conceptual information, such as sharing, when real-world instantiations such as the use of a pizza pie are used, or (c) add a combination of the two. Thus, the present study addresses whether symbolic or visual instantiations in particular provide pre-fraction learners with a better ability to learn about novel fraction concepts. Because little work has addressed whether perceptual or conceptual visual instantiations may be detrimental to the young learner, the present study utilizes minimalistic, black-and-white stimuli (perceptually but not conceptually rich) to begin to address this important research question.

## Overview of the Current Study

The aim of the present study was to examine whether instructional format affected children's learning and transfer of fraction concepts, and whether individual variables would moderate any observed visual vs. symbolic instantiation effects. Critically, we manipulated the extent to which real-world instruction was grounded in visual vs. symbolic representations, while incorporating actual educational practices into the training paradigm (material, context, multi-session lessons). First and second graders participated in a pre/post-test design in which they received fraction instruction over several intervention sessions (Ordinal Comparisons, Addition and Subtraction, Decomposition), followed by a test of transfer (Fraction and Proportional Reasoning).

## Method

## Participants

Seventy-three $1^{\text {st }}$ and $2^{\text {nd }}$ grade children ( $M_{\text {Age }}=6.9$ years) participated in this study. Children were tested in their own elementary school during regular school hours. All children were tested in a quiet room with a single female experimenter.

## Materials

Pre- and Post-Test: Fraction Battery.
The fraction pre- and post-test batteries were identical and consisted of three fraction-knowledge tasks, which asked participants to make judgments about either symbolic or visual fraction information (also see Hurst \& Cordes, 2016; Polinsky, Posid, \& Sloutsky, 2017; Posid \& Sloutsky, 2015, 2017). The first task was an Ordinal Task, in which participants were asked to judge which of two sets was numerically larger and included visual fraction comparison (e.g., $2 / 3$ vs. $1 / 3$, represented as black-andwhite circles divided into three equal parts, with two parts and one part shaded, respectively) and a symbolic fraction comparison (e.g., $2 / 3$ vs. $1 / 3$ ). Children next completed a Matching Task, in which they matched either a symbolic fraction (e.g., $1 / 3$ ) to a visual fraction (e.g., a black-andwhite circle divided into three parts with one part shaded) or vice-versa. Children then completed an Addition and Subtraction Task, in which they were asked to add visual fractions (e.g., black-and-white circles) or symbolic fractions (e.g., $1 / 4+2 / 4$ ). Due to the difficulty level of the Matching Task and Addition/Subtraction Task, four answer choices were offered in a multiple-choice format. For all fraction tasks in the pre-/post-test battery, only fractions $<1$ were used (e.g., $2 / 3$ but not 4/3).

## Fraction Training:

The fraction training intervention consisted of three sessions, which were identical in content and instruction across conditions. Each training session consisted of two parts: one-on-one guided instruction between the child and experimenter followed by a block of practice problems used to measure immediate learning. Importantly, although the content and instruction was consistent across conditions, children participated in one of three training conditions: (1) Visual Only (black-and-white circles only; $n=22$ ), (2) Symbols Only (symbolic fractions only; $n=25$ ), or (3) Visual + Symbols (both black-andwhite and symbolic fractions shown side-by-side; $n=23$ ). The instruction and practice block were exclusively run in the child's randomly assigned condition (see Figure 1).

The first training task was an Ordinal Comparison task, in which children were instructed on how to compare two fractions with either the same denominator (e.g., $1 / 4$ vs. $2 / 4$ ) or same numerator (e.g., $1 / 4$ or $1 / 8$; Figure 1). Critically, the fraction instruction throughout all three training tasks was meant to address two concepts prevalent in the fraction-learning literature to date. First, children were taught to use counting to identify and manipulate the numerators and denominators presented, as children notoriously demonstrate a "whole number bias" when
learning about fractions (e.g., DeWolf \& Vosniadou, 2014; Hurst \& Cordes, 2016; Ni \& Zhou, 2005; Obersteiner, van Dooren, Van Hoof, \& Verschaffel, 2013 Obersteiner, Van Hoof, Verschaffel, \& Van Dooren, 2016; Polinsky et al., 2017). Second, children were taught about fraction magnitude knowledge, specifically as it relates to the partwhole concept (e.g., Siegler, Thompson, \& Schneider, 2011; Stafylidou \& Vosniadou, 2004). This instruction and feedback was followed by a block of practice trials in which children continued to compare fractions, but without scaffolding or feedback from the experimenter.

The second training task was an Addition and Subtraction task, in which children were taught how to systematically add or subtract two fractions. Children were shown a correct strategy for solving this type of fraction problem. This was followed by a practice block, in which children continued to add and subtract fractions, but without the input and feedback from the experimenter.

Finally, children completed a Fraction Decomposition task, in which they were asked to add or decompose a series of fractions (e.g., $1 / 6+2 / 6+1 / 6$; Figure 2). The instruction was similar to that of the addition and subtraction task, with step-by-step instructions on how to identify the fractions, recognize that the denominator (or total number of pieces) was the same using counting, and then add the numerators (or shaded number of pieces) to find the answer. Again, this was followed by a block of practice trials in which children continued to decompose fractions, but without the instruction and feedback of the experimenter.

Figure 1. Examples of the Stimuli used in the Test portion of the Training Sessions.

## Transfer Task:

The transfer task was used to measure children's fraction and proportion knowledge, and consisted of a series of visual questions. Included questions asked children to make judgments related to either probability (e.g., "If you were to roll a dice, what is the probability that that it would land on a 2?" or "If you were to reach into this box of candy without looking, what is the probability that you would randomly pick out a cherry piece?) or fractions
(e.g., "Can you express the triangles as a fraction of the entire set?" or "If you were to reach in to one of two fish tanks, are hoping to pick a fish of a certain color, which fish tank should you reach into?").

All tasks were administered on a Macintosh laptop. These programs were created using RealBasic software, which also recorded participants' reaction time and answers during the tasks.

## Procedure

Pre/Post-Test Fraction Battery:
The procedure consisted of three phases: The Ordinal Task, the Matching Task, and the Addition/Subtraction Task. The Ordinal Task consisted of three blocks: natural number comparisons (warm up), visual fraction comparisons, and symbolic fraction comparisons. All fractions were $<1$ so as to match the visual and symbolic fractions featured in the second and third blocks. Each block in the Ordinal Task consisted of 32 trials, for a total of 96 trials. The Matching Task consisted of three blocks of 12 trials each, for a total of 36 trials. The Addition/Subtraction task consisted of four blocks of 12 trials each, for a total of 48 trials.

## Fraction Training:

The procedure consisted of three training sessions: Ordinal Comparisons, Addition and Subtraction, and Decomposition. The Ordinal Comparisons training session consisted of two phases: Same Denominator comparison training and Same Numerator comparison training. Each instruction phase consisted of two examples, followed by a block of 10 test questions ( 20 total test trials). The Addition and Subtraction training session consisted of two phases: Addition and Subtraction. Each instruction phase contained two examples, followed by a block of 20 test trials ( 40 total test trials). The Decomposition training session consisted of two phases of Decomposition instruction (fractions whose sum was $<1$ and fractions whose sum was $>1$ ), each followed by one blocks of test trials, plus a final block of "intermixed" test trials, for a total of 30 test trials.

## Transfer Task:

The transfer task consisted of seven blocks of proportional reasoning and fraction reasoning picture problems and included: (1) spinner proportions, (2) dice rolling, (3) determining the proportions of shapes in a set, (4) determining the proportion of candy in a bowl, (5) interpreting a pie graph, (6) representing a set of shapes as a fraction, and (7) determining the proportion of fish in a fish tank (for a total of 36 Transfer Task questions). The transfer task was administered approximately 2 weeks after post-test. It was also given in multiple-choice format due to the difficulty of the task itself and for consistency of testing format across sessions.

## Results

The present study examined three outcome variables of interest: (1) Learning at Training: Did children perform above chance on the test trials following each intervention
session? That is, did they learn the information they had just practiced with the experimenter? (2) Pre-Post Test Gains: Did children improve on our Fraction Battery from Pre-Test to Post-Test? (3) Transfer Task: Did children perform above chance on our Transfer Task? Critically, we examined the impact of Training Condition (Visual+Symbol, Visual Only, Symbols Only) on all three of these variables of interest. Finally, we examined the role of individual variables as moderators of Condition effects on our dependent variables.

## Learning at Training

Results indicate that young children were able to learn fraction concepts despite having no formal instruction in the classroom, as indicated by their above-chance performance during each phase of training (vs. chance: Ordinal: $p<.001$, Cohen's $d=2.8$; Addition/Subtraction: $p<.001$, Cohen's $d=2.4$; Decomposition: $p<.001$, Cohen's $d=4.4$; Figure 2). A moderate - but non-significant ( $p$ ' $s<.2$ ) -- trend demonstrated the impact of children's experimental condition across these tasks. That is, children's performance in the Symbols-Only and Visual+Symbols conditions were similar across the three day-of training tasks; however, children's accuracy in the visual-only condition was lower.

Figure 2. Accuracy on the test trials of each Fraction Training Session by Condition. Error bars reflect Standard Error of the Mean.

## Pre- to Post-Test Gains

We also assessed whether children made substantial gains from pre- to post-test within our Fraction Battery. For the purposes of this analysis, difference scores were created for each participant (post - pre) for each portion of the Fraction Battery (Ordinal, Matching, and Addition/Subtraction; pre-test: no effect of Condition: $p>.1$ ), such that each participant had a single difference score for each task representative of any gains made. Then, an average of these difference scores was created to identify children's total gains across the training tasks. A significantly positive difference score (versus zero) would indicate significant gains made by that participant.

Children demonstrated significant gains between pre- and post-test $(t(69)=10.6, p<.001$, Cohen's $d=2.6)$. Notably, condition differences were not observed in any of our three tasks within the Fraction Battery ( $p$ ' $s>.1$ ),
suggesting that, at least for $1^{\text {st }}$ and $2^{\text {nd }}$ graders, any instructional format can promote learning of these difficult math concepts.

## Transfer Task

Performance accuracy on the Transfer Task was calculated for questions pertaining to Proportional Reasoning and Fraction Reasoning. Overall, children performed abovechance on both types of questions in the Transfer Task (Proportional Reasoning: $p<.001$, Cohen's $d>.1$; Fraction Reasoning: $p<.001$, Cohen's $d>2.5$; Figure 3). Condition differences were observed for the Proportional Reasoning portion of the Transfer Task $(F(2,63)=6.5, p=.003)$, such that children in the Visual+Symbol condition outperformed their peers in both the Visual Only and Symbols Only conditions. Of note, children in the Visual Only and Symbols Only conditions performed significantly abovechance, and out-performed a secondary sample of untrained controls whose accuracy did not exceed chance-level $(t(6)=1.7, p=.15$, Cohen's $d=1.4)$. In contrast, no Condition effects were observed for the Fraction Reasoning questions ( $p>.7$ ), mirroring the lack of Condition effects observed in the pre- to post-test gains.

## Individual Variability

A series of regression analyses were run in order to investigate whether individual variables predicted children's performance across our dependent variables. Each regression model tested the following independent variables: pre-fraction knowledge (as assessed through our pre-test Fraction Battery), prior Math Knowledge (assessed through a portion of the Woodcock Johnson and a 3-minute speeded arithmetic test administered at pre-test), Inhibitory Control (assessed through a numerical stroop task administered at pre-test), Working Memory (assessed through a serial ordering task administered at pre-test), and the child's grade in school.

Children's accuracy during the day-of training tasks (composite score) was significantly predicted by their grade in school (Beta $=.224, p=.06$ ), prior math knowledge (Beta $=.573, p<.001$ ), and their pre-test fraction knowledge (Beta=.253, $p=.04$; Model: $R^{2}=.416, p<.001$ ). Children's performance at post-test was significantly predicted by children's prior math knowledge (Beta=.566, $p<.001$; Model: $R^{2}=.401, p<.001$ ), while children's pre- to post-test gains were significantly predicted by their grade in school (Beta $=.382, \quad p=.009$ ), working memory (Beta=.306, $p=.012$ ), and pre-test fraction knowledge (Beta $=.485$, $p=.001$; Model: $R^{2}=.220, p=.014$ ). Additional SEM modeling was conducted to examine whether our significant predictors specifically moderated any effects of Condition on our dependent variables. We find that prior math knowledge does moderate the effects of Condition on children's day-of training accuracy ( $p=.02$ ) and post-test fraction performance ( $p=.002$ ), while working memory moderated children's gains from pre- to post-test ( $p<.001$ ).

Finally, regression and SEM modeling were conducted for children's performance on the Transfer Task. Specifically, children's accuracy on the proportional
reasoning portion of the Transfer Task was significantly predicted by their grade in school (Beta=.227, $p=.059$ ), Condition (Beta $=.222, \mathrm{p}=.064$ ), inhibitory control (Beta $=.250, \quad p=.038$ ), and pre-test fraction knowledge (Beta $=.257$, $p=.086$ ). Again, secondary SEM models indicated that both math knowledge and working memory individually and significantly moderated performance on the Transfer Task. Specifically, children with High working memory did not show Condition differences, while those with low working memory did (Low WM: $F$ (2, $28)=9.0, p=.001$; High WM: $F(2,27)=1.7, p=.206)$. These children benefited most from Visual+Symbol. Like working memory, children with high math knowledge did not show Condition differences on the Transfer Task, whereas children with low math knowledge did. These children benefited most from Visual+Symbol (Low Math: $F(2,26)=4.7, p=.019$; High Math: $F(2,29)=1.7, p=.1)$.

Figure 3. Accuracy on the Transfer Task by Condition. Error bars reflect Standard Error of the Mean.

## Discussion

The aim of the present study was to examine whether instructional format affected children's learning and transfer of fraction concepts, as well as to investigate whether individual variables such as executive function and math knowledge moderated any effects of visual vs. symbolic instantiations. Results indicate two important patterns of performance. First, using real-world instructional stimuli from the current Core Curriculum (Core Curriculum; New Common Core Mathematics Standards, 2000), children as young as $1^{\text {st }}$ and $2^{\text {nd }}$ grade successfully learned new fraction concepts, as indicated by their above-chance performance on day-of training, in their gains observed from pre- to post-test on our Fraction Battery, and their above-chance performance on the Transfer Task. Because an understanding of fractions is an important precursor for other mathematical concepts, including probability, proportional reasoning, algebra, and much of the STEM fields (Bailey, Hoard, Nugent, \& Geary, 2012; Department of Education, 1997), it is critical that elementary school children are involved in a curriculum that employs these critical foundations in fraction education. Although previous surveys of mathematics education in the United States suggest that children lack age-appropriate math skills (NAEP, 2009; NCES, 2010; Siegler et al., 2012; also see Hurst \& Cordes,
2016), the present study suggests that current curriculum is utilizing content that may help close this gap in years to come.

Second, and more importantly, the present study finds that the instructional format in which the to-belearned concepts are presented to children is important. Specifically, those children in the Visual+Symbol condition faired best both during immediate learning within our intervention sessions and in our test of transfer two weeks following post-test. Of note, children in the Visual only condition never out-performed their peers in either of the other two conditions, suggesting that less is not necessarily more when teaching children about new and conceptually challenging fraction concepts. Moreover, children who were low in math knowledge and low in working memory at pre-test benefited most from the Visual+Symbol condition, suggesting that the redundant perceptual information was particularly helpful.

The findings from the present study suggesting that "less" is not "more" when teaching children about new fraction concepts is interesting given much work suggesting that extraneous perceptual information may interfere with children's ability to learn mathematical concepts or make mathematical reasoning judgments (e.g., Kaminski \& Sloutsky, 2009, 2013; Kaminski et al., 2009; McNeil \& Fyfe, 2012; Mix, 1999, 2008; Peterson \& McNeil, 2012; Posid \& Cordes, 2014). This pattern of findings could be accounted for by two explanations. First, perhaps either fractions themselves or novel fraction concepts are a stand-alone category. That is, perhaps "less is more" when children are learning about whole numbers or non-fraction numerical concepts. However, this is unlikely given ample research to suggest that both children and adults demonstrate a whole number bias, especially when learning about or solving fraction problems that are novel or difficult (e.g., see DeWolf \& Vosniadou, 2014; Hurst \& Cordes, 2016; Ni \& Zhou, 2005; Obersteiner et al., 2013; Obersteiner et al., 2016; Polinsky et al., 2017). That is, when solving fraction or proportion problems, children often apply their intuitions about whole numbers to fraction concepts (for example, they might say that $1 / 4+1 / 4=2 / 8$, as they incorrectly assume that you should add the numerators and the denominators, as you would if you were adding whole numbers).

Another explanation for the seemingly divergent pattern of findings observed in the present study comes from the nature of the stimuli used in the study itself. Although condition differences emerged, the stimuli were more perceptually impoverished than those used in previous work reporting "less is more" during mathematical learning and reasoning (Kaminski \& Sloutsky, 2009, 2013; Kaminski et al., 2009; McNeil \& Fyfe, 2012; Mix, 1999, 2008; Peterson \& McNeil, 2012; Posid \& Cordes, 2014). Specifically, the conditions in this study varied by whether the instantiations contained visual vs. symbolic vs. visual + symbolic information. However, the visual stimuli were always black-and-white circles, while the symbolic stimuli were a single monotone color (e.g., black). In contrast, real-world mathematics education
includes much more diverse and vibrant displays, the use of 2D and 3D objects, the use of "interesting" pictures and colors (e.g., a pizza pie to represent a pie graph or visual fraction; Peterson \& McNeil, 2012), and so on. Therefore, perhaps the "perceptually impoverished" framework employed in the present study muted the real-world effects of varying concrete vs. generic instantiations when teaching children about fractions and proportions. Currently, work from our laboratory is exploring this variation to visual vs. symbolic instantiations, through the use of a perceptually rich training paradigm. We are currently exploring whether similar Condition effects and individual moderators will emerge when perceptually rich (e.g., pizza pies rather than black-and-white circles, Sesame Street-like numbers with colors and eyes, etc.) stimuli are used in a similar training intervention.

Figure 4. Perceptually rich instantiations of the stimuli used in the present study.

In conclusion, the present study utilized a realworld fraction training intervention and finds that children can learn fraction information prior to formal education, using instructional material from the current Core Curriculum. Importantly, although all children demonstrated gains following training, those who received redundant perceptual information tended to out-perform their peers following immediate learning and in a transfer test of proportional reasoning. Additionally, children's prior math knowledge and working memory moderated our observed effects, indicating these should be taken into consideration when children are taught novel or difficult fraction concepts. This work has implications for instructional design and curriculum development in the classroom.

#### Abstract

A classic discussion about visual imagery is whether it affords reinterpretation, like discovering two interpretations in the duck/rabbit illustration. Recent findings converge on reinterpretation being possible in visual imagery, suggesting functional equivalence with pictorial representations. However, it is unclear whether such reinterpretations are necessarily a visual-pictorial achievement. To assess this, 68 participants were briefly presented 2-d ambiguous figures. One figure was presented visually, the other via manual touch alone. Afterwards participants mentally rotated the memorized figures as to discover a novel interpretation. A portion $(20.6 \%)$ of the participants detected a novel interpretation in visual imagery, replicating previous research. Strikingly, $23.6 \%$ of participants were able to reinterpret figures they had only felt. That reinterpretation truly involved haptic processes was further supported, as some participants performed co-thought gestures on an imagined figure during retrieval. These results are promising for further development of an Enactivist approach to imagination.

Keywords: visual imagery; haptic imagery; gesture; enactivism; the imagery debate

## Introduction

Early phenomenological observations concerning voluntary visual imagery suggested that nothing new can be discovered in visual imagery that was not present in the intention to imagine to begin with (Sartre, 1940). This fits Descriptivist renderings of visual imagery (Pylyshyn, 2002), where visual imaginings have a fixed mode of presentation, and are "images under a description" (Fodor, 1975, p. 191). This view gained substantive empirical traction (in part) by research showing that when participants memorized an ambiguous figure under a particular percept (e.g., duck), they were unable to discover an alternate novel interpretation (e.g., rabbit) when retrieving the ambiguous figure in visual imagery (Chambers \& Reisberg, 1985; Slezak, 1991). These results were obtained even though the memory of the figure was detailed enough to draw it out, and which allowed for subsequent ambiguity detection when perceiving the drawing.

Subsequent research within the ambiguity detection paradigm showed that the previous studies may have employed too difficult ambiguity examples (e.g., duck/rabbit figure), and failed to properly inform
participants by providing an ambiguity example (Brandimonte \& Gerbino, 1993; Finke, Pinker, and Farah, 1989; Hyman \& Neisser, 1991). One of those studies showed an ambiguity detection rate of $40 \%$ with slightly less complex figures as the classic duck/rabbit figure and providing an ambiguity example (Peterson, Kihlstrom, Rose, \& Glisky, 1992). Some shortcomings of previous studies that found positive findings were resolved by Mast and Kosslyn (2002), who noted that participants might have been alerted by the ambiguity of the figures during perception as they were shown an ambiguous figure before memorizing the target figure. In their study they found that $44 \%$ of the participants were able to detect an alternative interpretation while excluding possible confounds of ambiguity detection in perception rather than imagery.

In a recent study we have expanded upon this research (Kamermans, Pouw, Mast, \& Paas, under review). Participants in Mast and Kosslyn's (2002) study were provided partial visual cues of the ambiguous figure during imagination. Therefore, it could not be fully excluded that some raw sensory information is necessary for ambiguity detection via imagery to occur, allowing for the possibility that ambiguity detection via imagery alone is impossible after all. In our previous study however, we found that ambiguity detection is possible without visual cues as well ( $30 \%$ detection rate), while excluding other possible confounds such as ambiguity detection during perception rather than retrieval in imagery.

The ambiguity detection paradigm has been primarily regarded as being important for The Imagery Debate. This is because, in contrast to the Descriptivist approach, the other contender in The Imagery Debate - the Quasi-pictorial account (Kosslyn, 2002) - explicitly argues for the possibility of ambiguity detection. On such an account, visual imaginations are constituted by internal representations that are experienced as and function like pictorial representations (drawings, diagrams, etc.). As such, analogous to pictures, the representational content of visual images are not intrinsically fixed, rather the mental image preserves the "raw" visual-pictorial information of the previously seen object which is open to reinterpretation.

In summary, there is converging evidence that visual imagination allows for similar re-interpretative feats as pictorial representations (Mast \& Kosslyn, 2002; Kamermans et al., under review). Such evidence has been
mainly interpreted as a win for the Quasi-pictorial account over the Descriptivist account (Mast \& Kosslyn, 2002). Yet, although reinterpretation in mental imaginings might afford similar feats as pictorial representations (e.g., drawings), it need not be the case that imagination functions exactly like visual-pictorial representations. In fact, imagery-based reinterpretation need not be visual-pictorial at all.

## Enactive Imaginings

Indeed, Quasi-pictorial and Descriptivist accounts of mental imagery are not the only game in town (Foglia \& O'Regan, 2016). There are also views that promote an Enactive view of sensory perception and imagination (Hurley, 2002; O'Regan \& Noe, 2001; Thomas, 1999) ${ }^{1}$. Our conception of the Enactive position in relation to imaginings, is that imaginings are something we do rather than an internal state; the success of an imagining is not (primarily) mediated by internally stored knowledge of properties of the object imagined, but rather by a pre-reflective understanding of sensori-motor relations that would hold if the object would be present. The enactive logic is that since perception is an accomplishment of an active embodied system (Gibson, 2014) so too must perceptual imagination be constituted in a practical understanding of the sensori-motor relations that would hold when perceiving some object.

Evidence closely in par with an Enactive view concerns findings that show a functional role for eye-movements in visual imagination (Brandt \& Stark 1997; Laeng \& Teodorescu 2002; Spivey \& Geng, 2001). Note, that the functional role eye-movements seem to have in visual imagination is achieved even though eye-movements themselves do not provide visual information in a classic sense at all, e.g., eye-movements also occur and affect visual imagery when eyes are closed (Spivey, Tyler, Richardson, \& Young, 2000). Note as such that although the Quasi-pictorial account could be invoked here to explain the eye-movements (as the eye-movements interact with supposed internally stored visual information of the object), it is difficult to explain the function of eye-movements which provide no visual information in the classic sense. It is precisely because an Enactive view does not adopt a classic view of perception that it is able to recognize that (pre-reflective knowledge of) bodily movements constitute perception and imagination (O’Regan \& Noe, 2001; Hurley, 2002). Imagination, on such a construal, involves being attuned to sensori-motor potentialities of a particular object imagined (Thomas, 1999; O'Regan \& Noe, 2001). In visual imagery this attunement seems to be achieved in part through reenacting eye movements (a co-constituent of visual perception).

[^440]
## Present study

In the current study participants memorize two figures in succession for 30 seconds. Both of these figures have an alternate interpretation when rotated 180 degrees (i.e., figures are ambiguous). One of these figures is provided visually, the other via touch alone (i.e., haptic perception). It is then assessed whether participants are able to find the alternate interpretation for each figure in their imagination by mentally rotating the memorized figure.

As a further extension of the possibility of ambiguity detection in visual imagery we assess here whether participants can perform visual reinterpretations without being provided with an ambiguity example (cf. Kamermans et al., under review). However, the most important extension relative to previous research that we emphasize in this article, is the assessment of whether ambiguity detection can be performed in haptic imagery as well. That is, similar to visual imagery, can ambiguity be detected upon a mental imagining that is based on an ambiguous figure that was explored via touch?

Importantly, it could be that feeling a figure allows for ambiguity detection in imagery only insofar participants are able to reconstruct visual information based on this haptic perception. If true, ambiguity detection is always performed on visual information. On such a construal it is plausible that ambiguity detection rates of visually perceived figures, is greater than when haptically perceiving figures. After all, if ambiguity detection is a visual achievement, having had direct visual access as opposed to second-hand access (visual reconstruction via haptic perception) would improve the quality of the mental image, and hence improve reinterpretability. Therefore, next to assessing the possibility of ambiguity detection per condition individually, we will assess possible differences in detection rate between the haptically and visually perceived figures that would be predicted if reinterpretation in imagery is strictly a visualpictorial achievement.

Additionally, in light of an Enactive approach to sensory perception and imagination, and our previous theoretical efforts concerning the cognitive function of co-thought gesture (Pouw, de Nooijer, van Gog, Zwaan, \& Paas, 2014), we anticipated to observe co-thought (i.e., silent) handgestures that enacted interaction with the object during haptic imagery. That is, similar to research showing that eye-movements appear to co-constitute visual imagination, so too might manual movements co-constitute haptic imagery processes. Therefore, in the current study we explored manual gestures that occur when retrieving the haptically (as well as visually) memorized figure.

## Method

## Participants \& Design

Sixty-eight participants were tested (61 female, Mage = 20.03 years, $S D a g e=3.36$ years, range 17-37 years) ${ }^{2}$. Recruitment targeted both Dutch and non-Dutch students all of whom received instructions in English. The participants were enrolled in courses taught in English at the Erasmus University Rotterdam. All of the participants took part in the experiment for course credits.

The study had a within-subject design (Visual vs. Haptic Condition; order counterbalanced) using two test figures counterbalanced over condition assignment. Ambiguity detection rate was the main dependent variable. Additionally we assessed co-speech and co-thought gesture occurrences.

## Materials

Test Figures Two ambiguous test figures were cut out from high density foam sheets, similar to Kamermans et al. (under review). The figures were designed by Leo Burnett (2015) for the "Upside Down" campaign retrieved from Google images and further modified by us. Each figure had two readily perceivable interpretations (see figure 1). An alternate interpretation could be discovered by rotating the figure 180 degrees.

Figure 1. Line drawings of the seal/doe, and the penguin/giraffe test figure. As can be seen, one interpretation always showed the body of an animal and the second interpretation the head of a different animal.

Video Recording Performance was recorded using a JVC Everio GZ-MG130 camcorder, to assess gesture occurrence and inspection of the behavioral data when necessary.
Demographics and Control Questions Participants reported their age, sex, and native language. To assess participants' beliefs about the nature of the experiment the following questions were included: "What do you think was the purpose of the current study? (If you have no idea, no answer is necessary)", and "What do you think the researchers are expecting to discover with the current study? (If you have no idea, no answer is necessary)". Finally, the experimenter would explicitly ask participants who reported reinterpretation of one or two figures whether they had noticed the alternate interpretation during memorization or newly discovered it in visual imagery.

[^441]
## Procedure

Participants were tested individually and were told that they took part in a study about visual memory and memory of touch. The experiment consisted of a memorization phase and a testing phase.

In the memorization phase two figures were presented successively (order counterbalanced). Participants were informed that they would be given 30 seconds to inspect the figure and memorize it. In the Visual Condition versus the Haptic Condition participants were only allowed to see or touch the figure, respectively. For the Haptic Condition participants felt the contours of the figure which was presented under a card-board box that prevented visual inspection of the figure. The respective figure assigned to the haptic condition was horizontally attached via velcrotape on a wooden base. The wooden base was shown to participants as to inform them how the figure would be placed on top of it (it was stressed that the wooden base was not the object of inspection). Participants were informed not to move the figure on the wooden base (experimenter ensured that orientation of the figure was not altered, which was assessable via an opening in the card-board box at the experimenter side).

After each presentation of a figure, the participants were asked what they had seen or felt (depending on condition) and the experimenter noted down the response. If participants reported a) two or more distinct interpretations or b) only the interpretation that belonged to the 180 degree alternative orientation, the associated testing phase would be skipped as ambiguity was detected prematurely (a) or signaled (b) during memorization.

After memorizing the two figures, in the subsequent testing phase participants mentally retrieved the memory of each figure consecutively (order of retrieval counterbalanced). They retrieved figures with their eyes closed, as to ensure that visual input during retrieval was consistent between participants. Once participants indicated that they had brought back their memory of the respective figure, the experimenter would inform them that this figure had another interpretation next to the interpretation they already gave. Participants were told that the alternate interpretation could be discovered by rotating the mental image 180 degrees. Participants were given no time restrictions in discovering the alternate interpretation (reaction times were timed however, but were not of special interest).

## Performance and Scoring

An answer was considered correct in case the same interpretation was given by another participant in the respective condition (visual or haptic) of the memorization phase. For example, the answer "cow" for the head (doe) orientation of the seal/doe figure in the haptic condition would be considered correct if another participant had reported the same answer in the memorization phase for the haptic condition and the same orientation. For the main
confirmatory analysis, we chose for checking answers in the congruent modality because the crucial research question is about the continuity between perception and imagination, and this is distorted if both modalities will track properties of objects idiosyncratically.

Note therefore, participants were primarily their own raters in this study, minimizing post hoc experimenter decisions. However, similar to our procedure in Kamermans et al. (under review) we decided that in two cases answers should be counted as correct/incorrect even though these specific interpretations were (not) named by other participants. Namely, we counted as correct "Walrus/Seal" in the haptic condition for the figure seal and the "letter Y" (which partially overlapped with "Y stick") as an incorrect combination in the haptic condition for the figure seal. Note, that these post-hoc choices do not affect interpretation of the results.

## Results

## Interpretations

In Table 1 all the interpretations are given that overlapped between participants in the perception and testing phase (and therefore scored correct).

Table 1: Overlapping (re)interpretations

| Visual Condition <br> Giraffe | Deer, Giraffe <br> (Baby) cow |
| :--- | :--- |
| Doe | Penguin, Bird |
| Penguin | Seal |
| Seal |  |
| Haptic Condition | Tree, Flower |
| Giraffe | Deer, Aeroplane, Bird, Propeller |
| Doe | Penguin, Fish, Human Being |
| Penguin | Sea Lion, Walrus/Seal*, Bird |
| Seal |  |

Note. Overlaps between perception during memorization and mental retrieval of figures between participants. Asterisk pertain to post-hoc decision (1 instance).

## Exclusion

A total of 46 (34\%) out of 136 ambiguity detection trials were excluded as there was either premature ambiguity detection (10/46) or an interpretation was given during memorization that did not match the orientation that the figure was given in (36/46). However, we will exclude each participant data if on any of the two trials within participants premature ambiguity detection was obtained as this signals awareness of ambiguity during the memorization phase, 34 participants were excluded (50\%). The total sample to assess ambiguity detection rates per condition thus consists of participants who were not aware in any of the trials of ambiguity in the figures during memorization, ensuring that ambiguity detection ensued in imagery. Note that such high exclusion rates are common in ambiguity detection research as to maximally control for ambiguity detection during perception rather than imagery (see e.g., Mast \& Kosslyn, 2002).

## Descriptives

Retrieval time Participants in the haptic condition had an average of $23.88(S D=19.51)$ seconds to provide an interpretation or abort attempt. Participants in the visual condition took on average 27.68 ( $S D=21.23$ ) seconds.
Haptic Imagery vs. Visual Imagery As the descriptives show in Table 2, it seems that ambiguity detection is possible both when the figure is memorized and identified visually as well as through touch alone. Furthermore, four participants were able to detect ambiguity in both the haptic and visual conditions, and seven participants only detected ambiguity in the visual $(\mathrm{n}=4)$ or the haptic $(\mathrm{n}=3)$ conditions. Thus data is almost completely symmetrical across conditions and our planned within subjects-test for a binary outcome reflects this, McNemar $p>0.99$.

Table 2: Overall detection rate

|  | Visual | Haptic |
| :--- | :--- | :--- |
| Doe/Seal | $1 / 12(8.3 \%)$ | $6 / 22(27.3 \%)$ |
| Giraffe/Penguin | $6 / 22(27.3 \%)$ | $2 / 12(16.6 \%)$ |
| Total | $\mathbf{7 / 3 4}(\mathbf{2 0 . 6 \%})$ | $\mathbf{8 / 3 4}(\mathbf{2 3 . 6 \%})$ |

Haptic-Visual Imagery: Effects of Crossmodal Scoring However, it could be noted that since each condition (visual vs. haptic) has its own rating system that this could affect/distort our interpretation in significant ways. As such we performed an additional exploratory re-analysis where we counted any interpretation correct if it was named in the visual or the haptic memorization phase (see Table 1). This revealed a McNemar significance test $p=.227$, with a detection rate of $38.2 \%$ for the visual condition and $23.6 \%$ for the haptic condition (table 3). Thus, note that the more lenient scoring system slightly inflated detection rates in the visual condition but not to a degree that the null-hypothesis could be rejected.

Table 3: Overall detection rate

|  | Visual | Haptic |
| :--- | :--- | :--- |
| Doe/Seal | $3 / 12(25 \%)$ | $6 / 22(27.3 \%)$ |
| Giraffe/Penguin | $10 / 22(45.5 \%)$ | $2 / 12(16.6 \%)$ |
| Total | $\mathbf{1 3 / 3 4}(\mathbf{3 8 . 2 \%})$ | $\mathbf{8 / 3 4}(\mathbf{2 3 . 6 \%})$ |

Exploratory: Gesture occurrence During testing we observed that participants adopted spontaneous gestures during the testing phase when retrieving and interpreting the figure even though participants kept their eyes closed during retrieval. Firstly, participants used co-speech gestures when providing an interpretation (often accompanied by a description) of the figure $44 / 68$ ( $64.7 \%$ ) in the haptic condition and slightly less in the visual condition, 36/68 ( $52.9 \%$ ). Perhaps, such co-speech gestures solely fulfill communicative purposes, as the interpretation needed to be communicated to the experimenter. However, we also found that a select few performed gestures in silence (i.e., cothought gestures), as-if feeling the contours of the previously felt figure (3 participants in the haptic condition) and more pointing-and-tracing gestures in the visual
condition ( $n=3$ ), e.g., tracing the contours of the figure on the table. Further note that when premature ambiguity detection is controlled for (sample $=34$ ) we found that $20 \%$ (4/20) of those who gestured in the haptic condition detected ambiguity whereas $28.5 \%$ (4/14) of those did that did not gesture. Furthermore, $23.5 \%$ (4/17) of gesturing participants in the visual condition detected ambiguity as opposed to $17.6 \%$ (3/17) for non-gesturing participants.

Figure 2. Example co-thought gesture in haptic trial

## Discussion

The current results replicate previous research showing that ambiguity detection in visual imagery is possible (Mast \& Kosslyn, 2002; Kamermans et al., under review), i.e., when memorizing a figure under a particular percept this figure can be discovered to have another interpretation by re-inspecting it in visual imagery. This finding further extends this research in that ambiguity detection in visual imagery is possible without showing participants an example of an ambiguous figure after memorization (in contrast to Kamermans et al., under review). Further research could employ more direct comparisons of the effect of providing an ambiguity example or not after memorization on ambiguity detection rates (for a discussion on this see Peterson et al., 1992).

More importantly however, we have shown that ambiguity detection of a figure in mental imagery is possible even when the figure is explored via manual touch alone, as evidenced by the approximate $23.6 \%$ detection rate in the haptic condition ("approximate" barring different coding schemes). The important question is whether this shows that ambiguity detection was (solely) performed via haptic imagery, or whether exploring a figure via touch results in visual images upon which reinterpretation could be performed. This is a question that this study does not address directly.

However, in speculative vain it is striking that we did not find statistically significant differences in a within-subject test on ambiguity detection for visually or haptically explored figures. If ambiguity detection is solely performed in the visual modality of imagination, one would predict that having direct visual access to an ambiguous figure would support the quality of that imagination - hence inflating
ambiguity detection - relative to figures that were only haptically perceived. However, even bearing this in mind it does not exclude that ambiguity detection was not achieved via visual imagery.

On the other hand however, we do find evidence that reinterpretation of imagined haptically explored figures is likely to involve some haptic processes, or at least at times, given that a few participants were manually reenacting manipulating an (imagined) figure. This directly relates to eye-movements (i.e., "ocular reenactments") during visual imagery. These eye-movements reenact perceptual affordances of previously seen figures. In the current example, manual reenactments seem to exploit manual affordances of previously felt figures. In sum, we find it an attractive hypothesis that - at minimum - a cross-modal visual-haptic imagination is performed when reinterpreting previously felt figures. This is in par with a host of studies showing that haptic and visual perception are co-informative (e.g., Lacey, Campbell. Sathian, 2007; Wallraven, Bülthoff, Waterkamp, van Dam, \& Gaissert, 2014).

## A New Imagery Debate?

As mentioned, discovery of a novel re-interpretation of a visual imagining has been regarded as supporting the Quasipictorial account of visual imagery (Mast \& Kosslyn, 2002) and refuting the Descriptivist assumption that visual imagery is necessarily fixed under an original perceptual ascription (Chambers \& Reisberg, 1985; Pylyshyn, 2001). However, on our reading, ambiguity detection can also be accounted for within an Enactive framework, where the achievement reinterpretation requires a skill-full act that is inherently unstable because of the lack of direct access (O'regan \& Noe, 2001; Thomas, 1999). This constraint of imagery as inherently unstable may actually have some explanatory power over the Quasi-pictorial account. Note, for example that only a small portion (not more than $38 \%$ ) of the current sample is able to reassign meaning to a mental imagining ${ }^{3}$. This is striking as there is reason to believe that the current figures are relatively easy and memorized up to a point that participants can accurately draw them, as previous research with shorter memorization times and more complex figures has shown (Chambers \& Reisberg, 1985). Thus, if it were the case that ambiguity detection depends on internally represented pictorial information, reinterpretation rates should be much higher. If however, the achievement of gaining access to a previously seen or felt object via imagining consists in an effortful skill-based employment of a coalition of sensory systems, then it is not surprising that ambiguity detection is as difficult as it is. It does not require a mere retrieval and re-inspection of internally represented visual-pictorial imprints, but an attunement to sensori-motor

[^442]contingencies when interacting with an object. Further note, that the proposed multimodality of imagery does not apply to haptic ambiguity detection alone, as our findings show that even in cases where participants reinterpret a figure in visual imagery, non-communicative gestures are recruited that exploit affordances of the figure as if it were visually present (e.g., by tracing the contour on the table during retrieval with eyes closed).

Before concluding, some shortcomings need to be shortly stressed (as to invite further research). Firstly, no causal relation can be inferred from manual action and haptic imagery at this point. We are currently performing a study that manipulates manual enactment to ascertain its role in (haptic) imagery. Secondly, although results signal that haptic processes may be directly involved in ambiguity detection of previously felt figures, the current design does not exclude the possibility that ambiguity detection is purely a visual achievement. This is because haptic perception might induce visual construals which allow for visual reinterpretation. Additionally, as mentioned by a reviewer, current participants remembered two figures that were alike in their representation of an animal body/head. This likeness might interfere with memorization of both figures, perhaps making comparison between haptic/visual conditions more problematic.

To conclude, we have provided evidence that reinterpretations in mental imagery can be achieved when figures are memorized visually or via manual touch alone. We have argued on the basis of a) the observed manual enactments during imagery, as well as b) the lack of observed differences between visual and haptic ambiguity rates, that ambiguity detection might not be purely visualpictorial. Instead, we have speculated that visual and/or haptic imagery is mediated by a pre-reflective understanding of the sensori-motor relations that would hold were the object present.

#### Abstract

Categorical and coordinate stimulus processing were hypothesized by Kosslyn (1987) to be lateralized visual tasks, differentiated by task-relevant spatial frequencies. Slotnick et al. (2001) directly tested Kosslyn's hypothesis and concluded that the lateralization presents only when tasks are sufficiently difficult. Our differential encoding model is a three layer neural network that accounts for lateralization in visual processing via the biologically plausible mechanism of differences in connection spread of long-range lateral neural connections (Hsiao, Cipollini, \& Cottrell, 2013). We show that our model accounts for Slotnick's data and that Slotnick's analysis does not convincingly explain their results. Instead, we propose that Kosslyn's initial hypothesis was based on an incorrect assumption: categorical and coordinate stimuli are not solely differentiated by spatial frequencies. The results that our model captures cannot be reproduced by Ivry and Robertson's (1998) Double Filtering by Frequency theory, which is driven solely by lateralized spatial frequency processing.

Keywords: Differential encoding; hemispheric asymmetry; spatial frequency processing; categorical vs. coordinate

## Introduction

The human brain is composed of two largely disconnected hemispheres that communicate via a bridge of neural connections known as the corpus callosum. The level of relative disconnection and redundancy suggests that, for some cognitive processes, it may be advantageous for each hemisphere to specialize and reduce redundancy. This functional specialization, or "lateralization," occurs in many diverse cognitive facilities in humans (Stephan et al., 2003) and non-humans alike (Rogers \& Andrew, 2002). Examples in humans include fine motor skills and language processing, both of which are left hemisphere dominant (Knecht et al., 2000). Of particular interest to us is visual lateralization. Past studies have shown visual lateralization in processing stimuli ranging from frequency gratings to facial recognition (e.g. Ivry \& Robertson, 1998; Sergent, 1985).

Navon's (1977) hierarchical letters are one visual stimulus showing lateralization. These consist of a large, "global" letter (e.g., "T") that is composed of small, "local" letters (e.g., "F"). Sergent (1982) showed an advantage in identifying the local level target (the letter F in the above example)
presented when flashed in the right visual field/ left hemisphere (RVF-LH), and the reverse (the letter T in the above example) in the left visual field/ right hemisphere (LVF-RH). She concluded that the LH performs better with high spatial frequency (HSF) stimuli, whereas the RH does better with low spatial frequency (LSF) stimuli. Kitterle, Christman, and Hellige (1990) directly tested this hypothesis with frequency gratings and showed that the lateralization was driven by task demands, rather than purely by stimulus properties.

Inspired by Sergent's (1982) theory, Ivry and Robertson (1998) proposed their Double Filtering by Frequency (DFF) theory to explain these asymmetric processing results. DFF theory proposes that the hemispheres identically first select the frequency bands relevant to the task, but then are biased so that the left hemisphere preferentially processes HSFs, and the right hemisphere LSFs. DFF theory also accounts for data suggesting that frequency processing differences between the hemispheres are not absolute, but instead are relative to the frequency band relevant for solving the task (Christman, Kitterle, and Hellige, 1991). Finally, their model accounts for the categorical and coordinate spatial relations proposed by Kosslyn (1987) and Kosslyn, Koenig, Barrett, Tang, and Gabrieli (1989), described below. However, there is no neurological basis for the core mechanisms of the DFF theory, nor is there a developmental explanation of how or why this phenomenon would emerge (see Cipollini, 2014 for further discussion).

Kosslyn (1987) and Kosslyn et al. (1989) argued that humans process visual stimuli using two distinct types of spatial relations. Coordinate relations rely on an absolute, metric basis; for example, the statement "the glass of water is 3 inches from my hand" defines a coordinate judgment of one's hand and the glass of water. In contrast, categorical relations rely on abstract, relative terms. The statement "the glass of water is on top of the table" does not tell us exactly where the glass is, only its relative position to a table. In his 1987 paper, Kosslyn observed a RVF-LH advantage for categorical relation judgments and a LVF-RH advantage for coordinate relation judgments in response time. Other work (e.g. Hellige \& Michimata, 1989) provided further support for this hy-
pothesis with more varied types of stimuli (e.g., a bar and dot stimulus).

However, Sergent (1991) found that this lateralization effect presented only when stimuli were degraded, and several analyses have noted that the lateralization only presents in right-handed people (Slotnick, Moo, Tesoro, \& Hart, 2001). Other researchers likewise found weak or inconclusive evidence for lateralization of categorical and coordinate stimuli, especially for the LH advantage on categorical stimuli (Okubo \& Michimata, 2002). Nevertheless, researchers generally agree that a distinction exists, even if it is weaker than originally thought (see Jager \& Postma, 2003 for a review).

In light of these conflicting data, Kosslyn and colleagues now argue that lateralization in categorical and coordinate stimuli results from a differential frequency processing, potentially based on lateralization in neuronal receptive fields (see Baker, Chabris, \& Kosslyn, 1998; Kosslyn, Chabris, Marsolek, \& Koenig, 1992). In support of this hypothesis, Okubo and Michimata (2002) showed that the RH coordinate advantage, but not the LH categorical advantage, was eliminated by contrast balancing, which removes low spatial frequency information without degrading stimuli.

## Slotnick et al. (2001) revisit Categorical / Coordinate

Of particular interest here are the experiments and results of Slotnick et al. (2001). In past experiments, researchers flashed stimuli in one visual field or the other, leaving room for interhemispheric interference. To isolate lateralization effects, Slotnick et al. ran a clinical study on 134 subjects, each of whom had at least one hemisphere temporarily deactivated by an intracarotid injection of sodium amobarbital.

Using the same stimuli as in Kosslyn et al. (1989), Slotnick et al. (2001) sought to reproduce their results in subjects with deactivated hemispheres. In addition, they added a new stimulus type, paired squares, which was designed to resist "categorization" of coordinate tasks, whereby a subject on later trials during an experiment learns a coordinate task (e.g., is the plus more than two inches from the minus) and turns it into a categorical task (Slotnick et al., 2001). This explanation had been proposed to explain the weakening of the RH advantage on coordinate stimuli. The paired squares coordinate stimulus forces the subject to make a direct metric comparison between the two parts of the stimulus.

Unlike the original paper, Slotnick et al. (2001) measured results by classification error, rather than reaction time. Though the results generally aligned with Kosslyn's hypothesis, one coordinate experiment did not show the expected RH dominance, instead showing lateralization opposite of that in the original paper. The authors noted that distances between components of their figures (e.g. the blob and dot), were larger in their experiments than in Kosslyn et al. (1989). Difficulty has been reported to modulate lateralization in other experiments (e.g. Sergent, 1985), and so they posited this made the task too easy to show proper lateralization. Consequently, post-hoc they stratified the tasks by difficulty and found that only when a task is sufficiently difficult does later-
alization arise as expected.

## Differential Encoding Model

Figure 1: Taken from Hsiao, Cipollini, and Cottrell (2013), this diagram shows the autoencoder models with varying connection spreads and symmetric connections. Notice the left hemisphere's hidden units connect to a more spread out set of neurons on average, while maintaining the same number of connections.

Competing with DFF theory is our Differential Encoding (DE) theory (Hsiao, Shahbazi, \& Cottrell, 2008; Hsiao, Cipollini, \& Cottrell, 2013). It is inspired by an anatomical difference in the auditory system's long range lateral connections (LRLCs). On average, a LH neuron connects to neighbors generally farther from itself than the RH neurons do (Galuske, Schlote, Bratzke, \& Singer, 2000). The DE model hypothesizes these LRLCs as the driving factor behind visual lateralization as well. Compared to the DFF theory, the DE model has the advantage of having neurodevelopmental and neuroanatomical plausibility (Cipollini, 2014).

Computationally, the Differential Encoding model is a standard 3-layer neural network which can be thought of as a recurrent neural network unrolled one step in time. The first set of connections is a sparse autoencoder, trained on natural images, to represent how a stimulus might be transformed in the early stages of the brain using low level processing such as Gabor filters. Each neuron in the autoencoder corresponds to a spatial location, and it connects to 5 other neurons generated randomly from a Gaussian centered around the neuron itself. The LH and RH networks vary by the standard deviation, or sigma parameter, of the Gaussian, to mimic the lateralized connection spread of the LRLCs, seen in Figure 1.

Note that this differs from a Gaussian receptive field. A network with Gaussian receptive fields has fixed connections, and the strength of the connections are determined by a Gaussian. In the DE model, the lateral connections themselves are stochastic and determined by randomly sampling from a Gaussian, and the strength of the connections are learned by training.

In Hsiao, Cipollini, and Cottrell (2013), the authors show that the autoencoder in the DE model reconstructs natural images in accordance with the predictions of Sergent (1982). Specifically, the RH model reconstructs low spatial frequency (LSF) components of a stimulus better, whereas the LH model reconstructs HSF components better.

Once trained, each hemisphere's hidden units are then con-

Figure 2: These are the stimuli from Slotnick et al. (2001). Note that paired squares only had a coordinate task, whereas blob/dot and plus/minus have both categorical and coordinate.
nected to a task-specific output unit that is trained by the delta rule to learn some task. In this way, the information represented by the hidden layer is tested as to what tasks it is best at. We have found in many experiments that the LH model is better at tasks that require HSFs, and vice-versa for the RH model (Hsiao, Cipollini, \& Cottrell, 2013).

In addition to the autoencoder properties outlined above, the model has accounted for Sergent's (1982) data, as well as Kitterle, Christman, and Hellige's (1990) data showing task dependence of lateralization (Hsiao, Cipollini, \& Cottrell, 2013). This suggests the DE model has the very frequency encoding properties that Sergent (1982) hypothesized. As Kosslyn and colleagues have suggested (e.g., Baker, Chabris, \& Kosslyn, 1999), the distinction between categorical and coordinate stimuli may stem from lateralized frequency processing. Therefore, we test the network on Slotnick et al. (2001)'s stimuli to further establish the relationship between our model and frequency lateralization, as well attempt to reach parity with the DFF on these stimuli.

## Materials and Methods

Our stimuli mimic those of Slotnick et al. (2001)
The stimuli used in the 2001 study can be seen in Figure 2. There are three types of stimuli: blob/dot, plus/minus, and paired squares. All three stimulus types involve coordinate tasks. Blob/dot requires an evaluation of how far apart the blob and dot are, and plus/minus likewise requires an evaluation of how far apart the plus and minus are. The paired squares task, in contrast, requires judging whether the two sets of paired squares are equidistant or not. The former two stimulus types also have categorical tasks. The blob/dot categorical task requires evaluating whether the dot is on the blob or off of it, and the plus/minus categorical task requires evaluating whether the plus is on the right or the left. There is no categorical task for paired squares.

For the plus/minus and blob/dot coordinate stimuli, "near" configurations were those where the distance between the plus and minus or blob and dot measured smaller than a reference distance of 2 inches; the "far" configurations were larger than 2 inches. In our model, the reference distance was 5.5 and 6 pixels for plus/minus and blob/dot respectively.

Slotnick et al. (2001) hypothesized that these tasks are harder when the distance between stimulus components are close to the reference distance of 2 inches. They defined "hard" configurations as those where the distance between
stimulus components fell within the range of $[1,3]$ in inches, i.e. within one inch from the reference distance of 2 inches. "Easy" configurations were those outside of this range. In our model, "hard" configurations were those where the distance fell within 2 pixels of the reference distance, and "easy" were the other stimuli. Stratifications for paired squares coordinate and the two categorical tasks were less principled and will be explored below.

## Simulation Procedure

The simulation was implemented in MATLAB. All code is open source ${ }^{1}$. Input images were implemented as bitmaps, following the images published in the original paper as best possible. To accomplish this, plus/minus and paired squares images were $34 \times 25$ pixels. Due to the need for increased resolution, blob/dot images were $68 \times 50$ pixels. Due to the varying resolutions, the experiment sizes had different hyperparameters. Of particular interest, the $34 \times 25$ images had a RH and LH standard deviation (sigma) of 4 and 10 pixels respectively; the $68 \times 50$ had 4 and 15 . In both cases, each neuron had five connections per hidden unit, with one hidden unit corresponding to each pixel of the image. Our train and test data were the same, so to prevent overfitting, we used heavy regularization. Specifically, we used a relatively high amount of dropout of 0.7 (Srivastava, Hinton, Krizhevsky, Sutskever, \& Salakhutdinov, 2014) and introduced noise on the input.

The human experiment used 100 LH subjects and 124 RH subjects; however, 54 hemispheres of patients deemed abnormal or otherwise compromised (e.g. those with parietal lobe tumors) were excluded (Slotnick et al., 2001). We followed the same analyses done in the human experiment, and in an attempt to roughly match statistical power, we instantiated each hemisphere in our computational model 100 times. Instantiations with outlier performance were discarded, so there were slightly fewer than 100 instantiations for the final results.

## Results and Discussion

The output of the DE model is a real-valued number between 0 and 1 , where 0 and 1 represent the target labels (e.g. off/on for categorical blob/dot). Error is measured as the sumsquared error (SSE) between the model's output and the true label. In Slotnick et al. (2001), they measure mean percent error in classification. The different measurements means $y$ -

[^443]

Figure 3: Differential Encoding (left) results follow the overall Slotnick et al. (2001) results for task x hemisphere interactions, which can be seen as the slope of each line. Note that since hemispheric performance, not absolute performance, was relevant, $y$-axes were re-scaled to emphasize slope.
axes are not directly comparable, but in this experiment we are concerned with the relative performance of hemispheres on each task. We simply compare the slopes in Figure 3 to see how well the DE model fits the human data.

From Figure 3, it is clear that the DE results do not follow the human data perfectly, but the key concepts are captured. Categorical blob/dot, coordinate blob/dot, and categorical plus/minus all showed the expected LH advantage. Coordinate plus/minus shows no LH advantage ( $F_{1,195}=0.0669$, $p>0.75$ ), and categorical plus/minus has a stronger LH lateralization than it ( $F_{1,391}=12.96, p<0.001$ ). Crucially, the anomalous result in the original paper persists: categorical blob/dot is not more LH-dominant than coordinate blob/dot ( $F_{1,396}=1.200, p>0.25$ ), as it was in Kosslyn et al. (1989).

Paired squares on first glance appears to have reverse lateralization as in the human data. However, paired squares was extremely volatile, and that advantage disappears or reverses spontaneously. Statistically, lateralization was nonsignificant: there are large error bars for paired squares, and the repeated-measures anova of this data reveals this same non-significance ( $F_{1,198}=0.115, p>0.9$ ). Slotnick et al. (2001) reported this stimulus had only marginal statistical significance ( $p<0.1$ ) in their results as well. Therefore, while we plan to investigate this stimulus further, for now, we are less concerned that it did not show LH dominance.

The middle and bottom rows in Figure 3 show the results of the human data and the DE model for easy and hard subsets respectively. Our model replicates the results well. Before further analyzing the results, we take a closer look at Slotnick
et al.'s (2001) difficulty stratification, to understand what relationships across difficulty are crucial to replicate.

## Revisiting Slotnick et al. (2001)

Slotnick et al. (2001) directly measured lateralization in subjects who had a hemisphere temporarily deactivated as part of a presurgical evaluation for treatment of intractable epilepsy. This meant the authors only ran their experiments once. When their data contradicted Kosslyn's results, they ran a post-hoc analysis of the data to explain their results. The crucial takeaway was that lateralization presented only if the task is difficult enough.

We find reasons to doubt Slotnick et al.'s conclusions. First, there are critical inconsistencies in their figures. If the easy and hard instances of a task both lateralize in the same direction, then combining all trials together should as well. Yet, as shown in Figure 3, coordinate plus/minus overall does not lateralize, though its easy and difficult subsets did. This discrepancy is never addressed in their paper.

In addition, most of the stratifications between easy and hard were not built in a principled manner and therefore lack validity. Slotnick et al. (2001) state that the stratification of the paired squares task was an empirical heuristic, as there was no neat way of differentiating easy and hard stimuli. Similarly, they note that no analogous concept of difficulty exists for categorical stimuli, so they just used the same division as their coordinate counterparts.

The coordinate blob/dot results are both internally consistent and well-principled, but the other tasks are not. The overall results of Slotnick et al. (2001), matched by our compu-

| Task | Blob/Dot | Plus/Minus | Paired Squares |
| :---: | :---: | :---: | :---: |
| Coordinate |  |  |  |
| Categorical |  |  | Not Applicable |

Figure 4: Frequency preferences of the DE model for each task. Y-axis is network accuracy, while x-axis marks the center of the frequency window on which a bandpass filter is applied. If spatial frequencies drive categorical and coordinate processing, we should see better performance on categorical tasks at HSFs and vice-versa at LSFs. We do not see this pattern.
tational modeling, are not adequately explained by difficulty stratification. We now look for an alternate explanation.

## Spatial frequency selectivity within the DE model

Kosslyn and colleagues (e.g. Baker, Chabris, \& Kosslyn, 1999) concluded that categorical and coordinate processing lateralized according to preferential frequency processing. As originally hypothesized in Sergent (1982), the LH is thought to outperform the RH in processing HSFs and vice-versa for LSFs. Numerous experiments have shown lateralization as a function of filtering stimuli to specific frequency windows (e.g. Sergent, 1985). The Differential Encoding model has also shown this same differential frequency processing (Hsiao, Cipollini, \& Cottrell, 2013).

To examine whether spatial frequency differences drove results on these five tasks, we tested the model with different bandpass filters for each task. Specifically, all networks trained on the same, unchanged image patches to learn the same features, simulating typical visual experience. However, the perceptron was trained and tested on stimuli run through a bandpass filter window of size four and eight CPI, for $34 \times 25$ and $68 \times 50$ images respectively. This would allow us to empirically deduce which frequencies the network best responded to. Results were agnostic to a host of parameter choices, including sigma, dropout, and bandpass width (within reason), so we believe the results are general to the task, and not specific to anything about our network setup.

Per Kosslyn's hypothesis, we expected to see lateralization in accordance with task type: there should be increased categorical performance on HSFs and likewise for coordinate and LSFs. Figure 4 shows the results. Coordinate paired squares
is almost parabolic with a minimum around 10 CPI . Coordinate plus/ minus is largely agnostic to frequencies, whereas categorical shows bimodal preference, with the global minimum at HSFs. Categorical blob/dot performed equally well at the windows centered from 10 to 18 CPIs, whereas coordinate performed best in the window centered at 10 CPIs and was locally parabolic around that area. Beyond roughly 20 CPI, critical image features are lost and in both cases the networks perform poorly.

There is no unified trend of stimulus type and frequency. Considering the DE model both captures the critical relationships outlined in Slotnick et al. (2001) and accounts for spatial frequency filtering (Hsiao, Cipollini, \& Cottrell, 2013), it appears something besides frequency underlies the categorical and coordinate dichotomy. We plan to explore this further via contrast balancing (Okubo \& Michimata, 2002).

## Conclusion

We show in this paper that the DE model both replicates human data on the categorical and coordinate dichotomy and doesn't behave strictly in accordance with spatial frequencies. This calls into question the hypothesis about spatial frequencies driving coordinate and categorical lateralization. It also provides a point of differentiation between DFF theory and the DE model. Limited to spatial frequency information, DFF would be unable to replicate the conflicting data in Slotnick et al. (2001) as the DE model does.

In addition, we have shown in other experiments that DE models of a larger sigma encode more information at higher spatial frequencies, and vice-versa for smaller sigmas. Furthermore, stimulus size mediates this relationship: as image
size increases, so too does the point where the LH networks outperform the RH networks. We are pursuing this as an explanation for the relative frequency effect, noted in Christman, Kitterle, and Hellige (2001).

The DE model already accounts for faces and the categorical and coordinate results. If we can account for the relative frequency effect, we have superseded the DFF with a model that is biologically grounded and is informative about experiments to run in biology and psychology.

#### Abstract

Refutation texts are beneficial for removing misconceptions and supporting comprehension in science. Whether these beneficial effects hold true in the domain of statistics is, however, an open question. Moreover, the role of refutation texts for the accuracy in judging one's own comprehension (metacomprehension accuracy) has received little attention. Therefore, we conducted an experiment in which students with varying levels of statistical misconceptions read either a standard text or a refutation text in statistics, judged their text comprehension, and completed a comprehension test. The results showed that when students read the standard text, having more misconceptions resulted in poorer text comprehension and more inaccurate metacomprehension as indicated by overconfident predictions. In contrast, when students read the refutation text, the number of misconceptions was unrelated to text comprehension and metacomprehension accuracy. Apparently, refutation texts help students to pay attention to inaccuracies in their knowledge and, thereby, can promote self-regulated learning from texts.

Keywords: metacomprehension accuracy; misconceptions; procedural and conceptual understanding; text comprehension

In higher education, statistics has become a central part in many fields of study to enable students to deal with quantitative information (Ben-Zvi \& Garfield, 2004). At the same time, in higher education, students are increasingly expected to engage in self-regulated learning (Cassidy, 2011). For example, in statistics, students often need to advance their knowledge by reading statistics textbooks. However, such learning can be challenging, especially when students have to understand complex statistical concepts, such as covariance, about which they frequently have false ideas in the form of misconceptions. Such statistical misconceptions differ in fundamental ways from the normatively correct conceptions and, thus, can strongly hamper the comprehension and application of statistics (Liu, 2010).

## The Role of Misconceptions for Text Comprehension and Metacomprehension

Text comprehension is a process by which learners actively construct a mental representation of the information provided in a text (Kintsch, 1998). As usually not all possible relations are explicitly stated in a text, the construction of a mental representation requires learners to use their prior knowledge to infer within-text and knowledge relations (McNamara \& Magliano, 2009).

However, when learners possess inaccurate prior knowledge in the form of misconceptions, comprehension can be hampered because misconceptions can trigger false inferences. For example, Kendeou and van den Broek (2005) examined the online processes taking place when learners with misconceptions read texts. Their findings showed that learners with misconceptions used and integrated their prior knowledge with textual information as did learners without misconceptions. Yet, the content of their inferences was contaminated by their misconceptions. This, in turn, resulted in an inappropriate mental text representation after reading. In line with these findings, research in reading and science education shows that misconceptions often hinder memory and comprehension of text (see, e.g., Guzzetti et al., 1993).

When learning from reading texts, it is also important that learners accurately monitor and judge their own comprehension, which is known as metacomprehension accuracy (Dunlosky \& Lipko, 2007). Accurate metacomprehension affects the extent to which learners effectively self-regulate their learning. For example, only a learner who accurately monitors that a text is not yet sufficiently understood to perform well on a comprehension test might decide to further study the material (e.g., Thiede, Anderson, \& Therriault, 2003). Research, however, indicates that learners are often overconfident when monitoring their text comprehension. This is particularly true for learners' predictions, that is, their judgments of comprehension after
they have read a text but before they have taken a comprehension test (e.g., Maki et al., 2005).

Recently, Prinz, Golke, and Wittwer (2017) found that misconceptions produced overconfident predictions. More precisely, their results showed that statistical misconceptions not only impeded the comprehension of a statistics text but also led to inaccurate self-assessments of text comprehension as indicated by overconfident predictions. Apparently, when learners have misconceptions, they are likely to construct a flawed mental text representation. At the same time, when self-assessing their text comprehension, learners tend to focus on the amount of textual information they can retrieve from memory while neglecting whether this information is correct. Consequently, learners with misconceptions are likely to overestimate their actual comprehension (see also Dunlosky, Rawson, \& Middleton, 2005).

In sum, research indicates that learning from standard texts mainly elicits superficial understanding and monitoring when learners hold misconceptions. To overcome these difficulties, it is important that learners become aware of their misconceptions and revise their understanding, a process called conceptual change.

## The Role of Refutations for Text Comprehension and Metacomprehension

Conceptual change occurs when learners modify their existing prior knowledge to include new information (e.g., Chi, 2008). This requires that the existing prior knowledge is identified as inadequate and the new information is understandable, plausible, and useful (Posner et al., 1982). Usually, conceptual change is demanding because a strongly held misconception impedes the recognition of its inconsistency with the correct information provided in a text (Otero \& Kintsch, 1992). A promising instructional approach to inducing conceptual change is the use of refutation texts (Guzzetti et al., 1993). Refutation text passages typically comprise three elements: First, a commonly held misconception is described. Second, a cue that explicitly states that the misconception is in fact inaccurate is presented. Third, the scientifically correct explanation that directly refutes the misconception is provided (Tippett, 2010).

Research has shown that refutation texts in science domains are indeed more beneficial for restructuring incorrect prior knowledge than standard expository texts (e.g., Ariasi \& Mason, 2011; see also Guzzetti et al., 1993; Tippett, 2010). Studies that investigated the processes taking place when reading refutation texts found that refutation texts are effective because misconceptions and correct conceptions are presented in close proximity, thereby increasing the likelihood of simultaneous activation. Only after such coactivation, further conceptual change processes, like the experience of a cognitive conflict, the evaluation of one's current conceptions, and the establishment of coherence in one's knowledge, can take place (e.g., Ariasi \& Mason, 2011; van den Broek \& Kendeou, 2008). Whether refutation texts
prove effective in promoting conceptual change and enhancing comprehension also in statistics is not yet clear. Learning in statistics typically involves the acquisition of both concepts and procedures (Ben-Zvi \& Garfield, 2004). Therefore, it is also an open question whether refutation texts not only benefit the learning of statistical concepts but also the learning of statistical procedures.

With regard to metacomprehension, the role of refutation texts is largely under-researched. An exception is a study conducted by van Loon et al. (2015) that revealed no beneficial effects of refutation texts on monitoring accuracy because learners remained overconfident when predicting their comprehension. However, the texts about misconceptions used in the study were rather short and there was only one comprehension question per text. Therefore, predictions were related exclusively to the comprehension of information about a single misconception. Hence, it is unclear whether refutation texts would promote metacomprehension accuracy when judgments do not focus exclusively on misconceptions. In literature on conceptual change, it has often been theorized that refutation texts increase learners' metacognitive awareness of their own conceptions in relation to the scientific conceptions (e.g., Ariasi \& Mason, 2011). Thus, it seems plausible to assume that refutation texts can support learners in reflecting about their misconceptions, thereby increasing metacomprehension accuracy.

## The Present Study

We investigated to what extent a refutation text compensates for the detrimental impact of misconceptions on text comprehension and metacomprehension accuracy in the domain of statistics. More specifically, we focused on the topic of covariance and examined comprehension and metacomprehension accuracy with respect to both conceptual and procedural aspects of covariance.

The first research question addressed whether the type of text would moderate the effect of misconceptions on text comprehension. We expected that when reading a standard text, more misconceptions would lead to poorer conceptual and procedural text comprehension, whereas this relationship would not be apparent when reading a refutation text.

The second research question concerned whether the type of text would moderate the effect of misconceptions on metacomprehension accuracy. We hypothesized that when reading a standard text, more misconceptions would lead to greater overestimation of conceptual and procedural text comprehension, whereas this detrimental effect would not be apparent when reading a refutation text.

## Method

## Participants and Design

A total of $N=53$ university students ( $M=25.04$ years, $S D=$ $2.42,59 \%$ female) participated in this study. The study had
two independent variables. The first independent variable was categorical and referred to the type of text: Participants read either a standard text or a refutation text about the statistical concept of covariance. The second independent variable was metric and referred to the number of misconceptions about covariance. Dependent variables were text comprehension and metacomprehension accuracy referring to conceptual and procedural aspects of covariance.

## Material

The statistics text about covariance was adapted from a statistics textbook written by Bortz and Schuster (2010). This text existed in two versions: a standard text version and a refutation text version. Both versions addressed conceptual aspects of covariance such as its different directions, explained procedural aspects of covariance such as how it is calculated, provided the formula for computing covariance, and contained three graphs to illustrate positive, negative, and no covariance. In addition, the refutation text contained information challenging four common misconceptions about covariance (i.e., covariance implies causality, covariance is a standardized statistic, covariance is related to the slope of the fit line, and zero covariance proves the absence of any association; see, e.g., Prinz et al., 2017). More precisely, for each misconception, the three typical elements of a refutation text passage were provided: First, the misconception was described. Second, the incorrectness of the misconception was explicitly stated. Third, the scientifically correct explanation was given (Tippett, 2010). In contrast, the standard text only provided the scientifically correct explanation for each misconception. Without the graphs and the formula, the standard text included 515 words and the refutation text included 638 words. We did not equate the length of the two text versions to keep the manipulation unconfounded with other variations (e.g., the inclusion of additional or repetitive information in the standard text; cf., e.g., Diakidoy, Mouskounti, \& Ioannides, 2011).

## Measures

Misconceptions Misconceptions about covariance were assessed by 15 questions, with each question addressing one particular misconception. We collected these misconceptions on the basis of a comprehensive literature review (Prinz et al., 2017). For example, one question referred to the misconception that covariance does not depend on measurement units but represents a standardized statistic:

In a study, sports scientists from a university determined the covariance between the height and the time for a $100-\mathrm{m}$ dash of 20 sprinters. In his calculation, sports scientist A quantified time in seconds. When his colleague, sports scientist $B$, checks again, he quantifies time in milliseconds. Which of the following statements about the covariances calculated by the two sports scientists is correct?
$\square$ The two sports scientists will receive the same covariance because it does not matter if they use different measurement units (misconception).
$\square$ Both calculations will yield no covariance because one cannot calculate covariance from time data (wrong).
$\square$ No statement about the two covariances can be made because it is unknown if the variables time and height are linear (wrong).
$\square$ Sports scientist B will obtain a higher covariance than sports scientist A because milliseconds yield bigger numbers than seconds (correct).
All questions had a single-choice format with four response options. One option represented the correct answer, one option represented the particular misconception, and the two remaining options represented incorrect answers but not a particular misconception. The number of misconceptions was determined by counting how many times participants selected the response option that represented a misconception. Thus, they could record a maximum number of 15 misconceptions.

Text Comprehension Text comprehension referred to both conceptual and procedural comprehension of covariance. Conceptual comprehension was assessed by eight inference questions that had a single-choice format with four response options. Of the eight questions, four questions addressed misconceptions about covariance as already described. These were the four misconceptions that were targeted in the text. For these questions, one response option represented the correct answer, one response option represented the particular misconception, and the two remaining response options represented incorrect answers but not a particular misconception. Another four questions addressed further conceptual attributes of covariance but not specifically misconceptions. For these questions, one response option represented the correct answer and three response options represented incorrect answers but not a particular misconception. The participants received 1 point for each correct answer. Thus, they could achieve a maximum number of 8 points in the conceptual comprehension test.

Procedural comprehension was assessed by four openended questions that required the participants to perform calculations regarding covariance. They received 1 point for each correct answer. Thus, they could achieve a maximum number of 4 points in the procedural comprehension test. Interrater agreement on the procedural comprehension questions was high, Cohen's $\kappa=.98,95 \%$ CI [0.95, 1.00].

To facilitate the interpretation of participants' performance on the conceptual and procedural comprehension questions, we converted the number of conceptual and procedural comprehension questions correct into percent correct.

Metacomprehension Accuracy Before completing the comprehension questions, participants predicted the number of questions they would presumably answer correctly. They made their predictions for the conceptual and procedural
questions separately. Metacomprehension accuracy was calculated by taking the signed difference between participants' judged number of questions correct (converted into percent correct) and their actual number of questions correct (converted into percent correct). Hence, a positive value indicated overconfidence because participants would assume to answer more comprehension questions correctly than they actually did. For example, a value of +.10 means that participants assumed to provide $10 \%$ more correct answers to the questions than they actually did. In contrast, a negative value indicated underconfidence and a value of zero indicated a perfectly accurate judgment.

## Procedure

In the experiment, first, the participants completed the misconceptions test about covariance. Second, they accomplished a reading skills test serving as a filler task to remove the contents of the misconceptions test from working memory. Third, the participants read the statistics text about covariance. They were informed that their conceptual and procedural comprehension of the text would be tested after reading. Fourth, the participants predicted their conceptual and procedural text comprehension. To do so, they were informed about what kind of knowledge the two types of comprehension questions would require. Fifth, they answered the conceptual and procedural comprehension questions.

## Results

To statistically test our hypotheses, we performed multiple regressions. We centered all predictor variables to maintain meaningful estimates of the main effects. In case of a statistically significant interaction effect, we computed simple slopes analyses following the approach suggested by Richter (2007) to investigate the pattern of the interaction. According to this approach, the categorical predictor text type was dummy coded and entered in two complementary regression models to estimate the regression parameters. As before, the metric predictor number of misconceptions was entered in the regression models in centered form. When testing directional hypotheses, we used one-tailed tests. Table 1 displays descriptive statistics for misconceptions and the dependent variables as a function of text type.

Table 1: Descriptive statistics.

| Variable | Refutation text$(n=27)$ |  | Standard text$(n=26)$ |  | Total sample$(N=53)$ |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | M | SD | M | SD | M | SD |
| NoM | 4.74 | 1.66 | 4.15 | 1.38 | 4.45 | 1.54 |
| CC | . 62 | . 19 | . 65 | . 20 | . 63 | . 19 |
| PC | . 59 | . 32 | . 65 | . 34 | . 62 | . 33 |
| Accuracy CC | . 07 | . 19 | . 07 | . 18 | . 07 | . 19 |
| Accuracy PC | -. 10 | . 37 | -. 14 | . 31 | -. 12 | . 34 |

Note. $\mathrm{NoM}=$ number of misconceptions; $\mathrm{CC}=$ conceptual comprehension; $\mathrm{PC}=$ procedural comprehension.

The refutation text group and the standard text group did not significantly differ from each other with regard to the number of misconceptions, $t(51)=-1.40, p=.167, d=0.39$.

## Text Comprehension

As displayed in Table 2, the multiple regression with conceptual comprehension revealed a marginal significant main effect of misconceptions and a significant interaction effect between text type and misconceptions.

Table 2: Predictors of conceptual comprehension.

| Predictor | $b$ | $S E b$ | $t(49)$ | $p$ | $\Delta R^{2}$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Constant | 0.62 | 0.03 | 24.64 | $<.001$ |  |
| Text type | -0.01 | 0.05 | -0.18 | .857 | .01 |
| NoM | -0.03 | 0.02 | -1.88 | .066 | .03 |
| Text type x NoM | 0.09 | 0.03 | 2.73 | .005 | .13 |

Note. $R^{2}=.17, F(3,49)=3.26, p=.029 . \mathrm{NoM}=$ number of misconceptions.

Simple slopes analyses showed that, in the standard text group, the regression coefficient $b$ for number of misconceptions was $-0.08(S E=0.03)$ and significantly different from zero, $t(52)=-3.01, p=.002, \Delta R^{2}=.03$. This means that an increase of one misconception led to a decrease of $8 \%$ in conceptual text comprehension. In contrast, in the refutation text group, the regression coefficient for number of misconceptions was not significant, $b=0.01, S E=0.02, t(52)$ $=0.64, p=.527, \Delta R^{2}=.03$. Thus, there was no significant effect of misconceptions.

As shown in Table 3, the multiple regression with procedural comprehension also revealed a significant interaction effect between text type and misconceptions.

Table 3: Predictors of procedural comprehension.

| Predictor | $b$ | $S E b$ | $t(49)$ | $p$ | $\Delta R^{2}$ |
| :--- | ---: | ---: | ---: | ---: | ---: |
| Constant | 0.61 | 0.05 | 13.38 | $<.001$ |  |
| Text type | -0.04 | 0.09 | -0.45 | .654 | .01 |
| NoM | -0.03 | 0.03 | -1.08 | .287 | .01 |
| Text type x NoM | 0.11 | 0.06 | 1.75 | .043 | .06 |

Note. $R^{2}=.08, F(3,49)=1.38, p=.260 . \mathrm{NoM}=$ number of misconceptions.

Simple slopes analyses showed that, in the standard text group, the regression coefficient $b$ for number of misconceptions was $-0.09(S E=0.05)$ and significantly different from zero, $t(52)=-1.85, p=.036, \Delta R^{2}=.01$. Thus, an increase of one misconception led to a decrease of $9 \%$ in procedural text comprehension. In contrast, in the refutation text group, the regression coefficient for number of misconceptions was not significant, $b=0.02, S E=0.04, t(52)$ $=0.51, p=.611, \Delta R^{2}=.01$, indicating that there was no significant effect of misconceptions.

## Metacomprehension Accuracy

As shown in Table 4, the multiple regression with metacomprehension accuracy of conceptual comprehension revealed a marginal significant interaction effect between text type and misconceptions.

Table 4: Predictors of metacomprehension accuracy of conceptual comprehension.

| Predictor | $b$ | $S E b$ | $t(49)$ | $p$ | $\Delta R^{2}$ |
| :--- | ---: | ---: | ---: | ---: | ---: |
| Constant | 0.08 | 0.03 | 3.05 | .004 |  |
| Text type | -0.01 | 0.05 | -0.14 | .892 | $<.01$ |
| NoM | 0.02 | 0.02 | 0.84 | .406 | .01 |
| Text type x NoM | -0.05 | 0.04 | -1.35 | .092 | .04 |

Note. $R^{2}=.04, F(3,49)=0.73, p=.541$. NoM $=$ number of misconceptions.

Simple slopes analyses showed that, in the standard text group, the regression coefficient $b$ for number of misconceptions was $0.04(S E=0.03)$ and marginally significantly different from zero, $t(52)=1.43, p=.081, \Delta R^{2}$ $=.01$. Hence, an increase of one misconception resulted in $4 \%$ greater overestimation of conceptual text comprehension. In contrast, in the refutation text group, the regression coefficient for number of misconceptions was not significant, $b=-0.01, S E=0.02, t(52)=-0.38, p=.703, \Delta R^{2}=.01$. Thus, there was no significant effect of misconceptions.

As can be seen in Table 5, the multiple regression with metacomprehension accuracy of procedural comprehension revealed no significant main effect or interaction effect.

Table 5: Predictors of metacomprehension accuracy of procedural comprehension.

| Predictor | $b$ | $S E b$ | $t(49)$ | $p$ | $\Delta R^{2}$ |
| :--- | ---: | ---: | ---: | ---: | ---: |
| Constant | -0.11 | 0.05 | -2.28 | .027 |  |
| Text type | 0.01 | 0.10 | 0.13 | .897 | $<.01$ |
| NoM | 0.03 | 0.03 | 1.05 | .300 | .02 |
| Text type x NoM | -0.06 | 0.06 | -0.94 | .177 | .02 |

Note. $R^{2}=.03, F(3,49)=0.56, p=.643 . \mathrm{NoM}=$ number of misconceptions.

## Discussion

A large body of literature demonstrates positive learning effects from reading refutation texts compared with reading standard expository texts. However, little is known about whether refutation texts are also favorable for learning in statistics and for producing accurate self-assessments of comprehension. Thus, the present study is the first to address these questions.

First, the results showed that a refutational statistics text can compensate for the detrimental impact of misconceptions on text comprehension. When students read a standard text about covariance, a higher number of misconceptions about covariance led to poorer conceptual and procedural
comprehension of the text. In contrast, when students read a refutation text about covariance, there was no effect of misconceptions on text comprehension. This result extends prior research by showing that refutation texts can prevent the adverse impact of misconceptions in statistics as well.

Importantly, the beneficial effect of the refutation text was demonstrated for both conceptual and procedural comprehension. Research in mathematics education widely acknowledges the view that conceptual and procedural knowledge are iteratively related to each other, with increases in conceptual knowledge leading to subsequent increases in procedural knowledge and vice versa (e.g., Rittle-Johnson \& Schneider, 2015). Accordingly, in the present study, conceptual and procedural comprehension were quite strongly associated, $r=.46, p=.001$. Therefore, when students read the refutation text, their misconceptions were no longer predictive of both their acquisition of conceptual understanding and procedural skill.

Second, the findings showed that a refutational statistics text can compensate for the detrimental impact of misconceptions on metacomprehension accuracy with regard to conceptual comprehension. When students read a standard text about covariance, a higher number of misconceptions about covariance led to greater overestimation of conceptual comprehension. In contrast, when students read a refutation text about covariance, there was no significant effect of misconceptions on the accuracy with which they judged their conceptual comprehension. In accordance with the interpretation given by Prinz et al. (2017; see also Dunlosky et al., 2005), when reading a standard statistics text, students with a higher number of misconceptions likely constructed a flawed mental text representation. At the same time, when self-assessing their text comprehension, these students might have focused on the amount rather than on the correctness of the textual information they could access from memory. Accordingly, they might have more strongly overestimated their conceptual comprehension. However, when reading a refutational statistics text, the students might have been more inclined to assess the quality of the textual information they could retrieve from memory. This might have been the case because refutation texts promote the coactivation of misconceptions and the scientifically correct conceptions (van den Broek \& Kendeou, 2008), thereby increasing the likelihood of knowledge evaluation and reflection in the context of conceptual change processes. Note, however, that the interaction effect between text type and misconceptions as well as the regression slope of misconceptions in the standard text group only approached the $10 \%$ level of statistical significance. As suggested by power analysis, this likely is the result of insufficient power to detect rather small effects. This is also supported by the findings of Prinz et al. (2017) that revealed a negative effect of misconceptions on metacomprehension accuracy of conceptual comprehension in the case of a standard text when using a sample of 49
participants. Therefore, future research should replicate the findings presented here while using larger sample sizes.

Contrary to expectation, however, the type of text and misconceptions did not affect metacomprehension accuracy of procedural comprehension. It can be assumed that the refutation text failed to coactivate procedural comprehension and, thus, decreased the likelihood that students would closely evaluate this type of comprehension. Yet, online measures such as think-aloud protocols could help to clarify the mechanisms proposed to underlie the effects observed in this study.

In sum, this study showed that refutation texts can compensate for detrimental effects of misconceptions on text comprehension and metacomprehension accuracy in the domain of statistics. Refutation texts appear to promote students to pay attention to inaccuracies in their knowledge, enhancing their self-regulated learning.

#### Abstract

There is an ongoing debate over the psychophysical functions that best fit human data from numerical estimation tasks. To test whether one psychophysical function could account for data across diverse tasks, we examined 40 kindergartners, 38 first graders, 40 second graders and 40 adults' estimates using two fully crossed $2 \times 2$ designs, crossing symbol (symbolic, non-symbolic) and boundedness (bounded, unbounded) on free number-line tasks (Experiment 1) and crossing the same factors on anchored tasks (Experiment 2). Across all 8 tasks, $88.84 \%$ of participants provided estimates best fit by a mixed log-linear model, and the weight of the logarithmic component ( $\lambda$ ) decreased with age. After controlling for age, the $\lambda$ significantly predicted arithmetic skills, whereas parameters of other models failed to do so. Results suggest that the logarithmic-to-linear shift theory provides a unified account of numerical estimation and provides uniquely accurate predictions for mathematical proficiency.

Keywords: cognitive development; numerical cognition; number-line estimation; psychophysical function

## Introduction

In this paper, we aimed to address an ongoing debate on the psychophysical functions that link numbers to their magnitude estimates and to provide a unified framework for understanding seemingly-conflicting data from a variety of studies (Barth \& Paladino, 2011; Cohen \& Sarnecka, 2014; Opfer, Thompson, \& Kim, 2016; Siegler \& Opfer, 2003; Slusser, Santiago, \& Barth, 2013). Specifically, we sought to test whether models that fit data from old research methods could accurately predict data from new methods that differed in small increments that were thought to be psychologically meaningful. Finally, we aimed to test whether models that best accounted for numerical magnitude estimates also provided the best predictors of educational outcomes.

The classic theory about developmental change in numerical estimation is that the representation of numerical magnitudes follows a logarithmic-to-linear shift (Siegler \& Opfer, 2003; Siegler, Thompson, \& Opfer, 2009). Because this shift occurs for different numbers at different times (e.g., for $0-100$ number-lines before $0-1000$ number-lines), this change is thought to come from experiences that children have in school with symbolic numbers (Siegler \& Opfer,
2003). This account was originally based on a single version of the number-line task, which is the symbolic bounded free branch in the taxonomy in Figure 1.

Figure 1: Taxonomy of number-line tasks. Branches connected by solid lines were examined in previous studies. Ones connected with dashed lines are new.

Two alternative accounts were recently proposed. One is the proportional-judgment account, claiming participants adopt proportion judgment strategies when estimating numerical magnitudes (Barth \& Paladino, 2011; Slusser et al., 2013). The other is the measurement-skills account, claiming that data from number-line tasks arise from task-specific measurement skills (Cohen \& Blanc-Goldhammer, 2011; Cohen \& Sarnecka, 2014). Like the classic theory, these accounts also depended only on specific sets of number-line tasks (symbolic bounded anchored for proportional-judgment account; symbolic unbounded free for measurement-skills account (see Figure 1).

## 1. Symbolic vs. Non-symbolic

One potentially important variable is whether numerical magnitudes are presented symbolically or non-symbolically. For the log-to-linear shift account, this variable is important because symbolic numbers are presented to children in number-lines in school, on rulers, and in arithmetic lessons. Most studies have focused only on the symbolic magnitude estimates, though with different psychophysical functions being proposed (Barth \& Paladino, 2011; Cohen \& Sarnecka,

2014; Opfer et al., 2016; Siegler \& Opfer, 2003; Slusser et al., 2013).

In contrast, when Dehaene et al. (2008) presented Amazon indigene with non-symbolic numeric magnitudes, they found that a mixed log-linear model (MLLM, see Figure 2A) provided a better fit to number-line estimates than alternatives. Among these alternatives, however, the power models proposed by Slusser et al. (2013) and Cohen \& BlancGoldhammer (2011) were not included.

## 2. Bounded vs. Unbounded

Another potentially important feature of number-line estimation is whether an upper endpoint is provided (bounded) or not (unbounded). Like symbols, the use of a numeric upper bound may make the task easier because it provides an additional reference point against which to estimate the target number. On the other hand, Cohen and his colleagues have claimed that the unbounded task is actually easier because subjects need only to add incremental units, whereas the bounded task requires subtracting from the endpoint at the upper bound. For this reason, they suggested that extensions of cyclic models (CPMs, see Figure 2C) provide best fitting models for estimates in the bounded condition and that scallop power models (SPMs, see Figure 2D) provides best fitting for estimates in the unbounded condition (Cohen \& Blanc-Goldhammer, 2011; Cohen \& Sarnecka, 2014). Though Cohen and colleagues did not include the mixed log-linear model among the alternatives tested, Kim and Opfer (in press) found the MLLM was a better predictor of estimates than CPMs and SPMs for symbolic bounded free and unbounded free number-line tasks.

## 3. Free vs. Anchored

A third potentially important variable is whether subjects are given the numeric magnitude of the half-way point on the number-line (anchored) or not (free). Like the use of an upper bound, Opfer et al. (2016) have argued that the anchored task provides an additional reference point that should increase linearity of estimates. On the other hand, Slusser et al. (2013) have argued that the task reveals changes in proportional reasoning, and they showed that children's symbolic bounded anchored number-line estimates were better fit by one of three adapted cyclical power models (CPMs) (Hollands \& Dyre, 2000) than a simple logarithmic model. Subsequent studies, however, found the MLLM provided a better fit to both symbolic bounded free and symbolic bounded anchored number-line estimates than mixtures of the CPMs (Opfer et al., 2016), which was called MCPM1 (see Figure 2B) in Kim and Opfer (in press)'s study.

## The Current Study

In this study, we manipulated all three variables orthogonally to systematically test the mixed log-linear model against its competitors on 4 previously examined tasks and 4 novel tasks. Thus, we tested all the branches shown in Figure 1,
with symbolic bounded free (SBF), symbolic unbounded free (SUF), non-symbolic bounded free (NBF), non-symbolic unbounded free (NUF) tasks in Experiment 1 and symbolic bounded anchored (SBA), symbolic unbounded anchored (SUA), non-symbolic bounded anchored (NBA), nonsymbolic unbounded anchored (NUA) tasks in Experiment 2. At the end of Experiment 2, we also administrated a battery of math tests, including addition and subtraction, to each subject to determine which model parameters best predicted addition and subtraction proficiency. This issue has educational significance, but it also tests the key cognitive process claim of the measurement-skills account, viz. that unbounded number-line estimates are easier than the bounded ones because they require addition skills rather than subtraction skills.

Figure 2: Illustrations of predicted estimates from the mixed log-linear model (A), the mixed cyclic power model 1 (B), the mixed cyclic power model 2 for bounded condition ( C ) and the mixed scallop power model for unbounded condition (D).

## Experiment 1: Free Numerical Estimation

## Methods

Participants Participants were 40 kindergartners ( $\mathrm{M}=5.98$ years; $47.5 \%$ female), 38 first-graders ( $\mathrm{M}=7.13$ years; $50 \%$ female), 40 second-graders ( $\mathrm{M}=8.09$ years; $57.5 \%$ female) and 40 adults ( $\mathrm{M}=20.1$ years; $50 \%$ female).
Materials and procedure Participants were administered four different number-line tasks using a 2 (symbolic/non-
symbolic) by 2 (bounded/unbounded) fully-crossed design Order of tasks was determined by a balanced Latin square.

In symbolic conditions, participants were presented with 20 number-lines, with a number on each endpoint of the line. The to-be-estimated numerals were evenly sampled from 0 to 30. On each trial, numbers were shown 2 s followed by random-noise mask. In non-symbolic conditions, procedure was similar, except that endpoints of lines and to-beestimated numbers were dot arrays. Sizes of dots were controlled on $50 \%$ of trials, while areas covered by dots were controlled on the other $50 \%$.

In bounded conditions, endpoints of the line were 0 and 30 (symbolic condition) or 0 and 30 dots (non-symbolic condition). In the unbounded condition, endpoints were 0 and 1 (symbolic condition) or 0 and 1 dot (non-symbolic condition). The instructions for the unbounded condition were taken from Cohen and Sarnecka (2014).

## Results

1. Logarithmic-to-linear-shift theory accurately predicted median estimates and individual differences. We first fit median estimates for all four number-line tasks and age groups using MLLM. Across all tasks and age groups (Figure 3), fit of MLLM was very high ( $\mathrm{R}^{2}=.93 \sim 1$ ). Analyses of the weight of logarithmic component ( $\lambda$ ) revealed that with age, estimates changed from logarithmic patterns to linear ones, with $\lambda$ decreasing from kindergartners to adults across all tasks (Figure 3). As expected, $\lambda$ in non-symbolic conditions was higher than in symbolic ones. Also, $\lambda$ in unbounded conditions was higher than in bounded ones regardless of symbolic format, which argues against the view that "the unbounded task requires less mathematical sophistication than the bounded task does" (Cohen and Sarnecka, 2014). To test whether individual performance revealed the same pattern, we computed $\lambda$ for individual participants' data and conducted a mixed ANOVA, with symbolic format and boundedness as within-participant factors and age group as a between-participant factor. Results showed a main effect of symbolic format, $F(1,154)=74.19$, $p<.001$, boundedness, $F(1,154)=86.32, p<.001$, and age group, $F(3,154)=39.08, p<.001$. An interaction between symbolic format and boundedness, $F(1,154)=4.17, p<.05$, indicated that the effect of symbols was greater for the bounded tasks.

To test whether logarithmicity of estimates represented a stable pattern of individual differences, we correlated individual participants' $\lambda$ among all tasks. Results showed that individual participant's $\lambda$ among all the four number line tasks positively correlated (with correlation coefficient . 70 ( $p<.001$ ) between SBF and SUF tasks; .45 ( $p<.001$ ) between SBF and NBF tasks; 35 ( $p<.001$ ) between SBF and NUF tasks; .49 ( $p<.001$ ) between SUF and NBF tasks; .39 between SUF and NUF tasks; and $.54(p<.001)$ between NBF and NUF tasks).

| NUF | 100 | 100 | 100 | 100 | 100 |

Table 2: Partial correlation between $\lambda$ in MLLM and math score after controlling for age across the free number line tasks.

| MLLM |  | Partial correlation |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | Addition |  | Subtraction |  |
|  | SBF | $\lambda$ | -. 40 | *** | -. 27 | *** |
|  | NBF | $\lambda$ | -. 27 | *** | -. 19 | * |
|  | SUF | $\lambda$ | -. 36 | *** | -. 24 | ** |
|  | NUF | $\lambda$ | -. 17 | * | -. 17 | * |

2. Model comparison. We next compared the fit of MLLM to that of its competitors: MLLM vs MCPM1 and MCPM2 for the bounded conditions and MLLM vs MSPM for the
unbounded ones. The proportion of individual children who were best fit by the mixed log-linear model (MLLM) using AICc was calculated.

As illustrated in Table 1, estimates of $68 \%$ to $100 \%$ of participants were best fit by mixed log-linear model (MLLM) among all four free number line tasks. In the bounded condition, none of the MCPMs was the best fitting model for the majority of any age or task combination. In unbounded condition, we replicated the findings from Kim and Opfer (in press), with MLLM providing a better fit for $100 \%$ of participants' estimates compared to MSPM.
3. Predicting the mathematical performance. We next conducted partial correlation analysis between individual participant's addition and subtraction performance (which were tested in Experiment 2) and the best-fitting parameter values from the models when controlling for age. The addition score was the sum score of simple and complex addition problems, and the subtraction score was the sum score of simple and complex subtraction problems.

As shown in Table 2, the logarithmicity parameter $\lambda$ of the MLLM predicted both addition and subtraction performance across all tasks after controlling for age. In contrast, the correlations among the model parameters of the MLLM competitors were very small, inconsistent, and not expected by the theories that generated the models. Specifically, for bounded conditions, the negative correlation between the absolute value of $\beta \mathrm{s}-1$ of the MCPMs and math performance was found in only a few of number line tasks, with the absolute value of $\beta_{2 \mathrm{CPM}^{-}} 1$ of MCPM1 negatively correlating with addition for the symbolic bounded free number line task $(r(156)=-.18, p<.05)$, the absolute value of $\beta_{\mathrm{SBCM}^{-1}}$ of MCPM2 negatively correlating with addition and subtraction for the non-symbolic bounded free task $(r(156)=-.17, p<.05$ for addition; $r(156)=-.17, p<.05$ for subtraction). Also, only the absolute value of s-1 in MCPM2 negatively correlating with subtraction was found in symbolic bounded free task $(r(156)=-.17, p<.05)$. For the unbounded condition, the negative correlation between the absolute value of $\beta_{\mathrm{MSPM}}-1$ in MSPM and addition was only found in symbolic unbounded free task ( $r(156)=-.18, p<.05$ ). These finding suggests that MLLM uniquely predicts math performance, regardless of tasks or age groups.

## Experiment 2: Anchored Numerical Estimation

## Methods

Participants Participants in Experiment 2 were the same as in Experiment 1.
Materials and procedure Participants received the same 2 (symbolic/non-symbolic) by 2 (bounded/unbounded) number line tasks as in Experiment 1, except that information was given about the location of 15 (or 15 dots) in each of the four tasks. Order of tasks followed a Latin square. After that, 200 arithmetic problems were presented for participants to solve as quickly as possible: simple addition, simple subtraction, complex addition and complex subtraction. For simple
addition problems, each of the addends was a one-digit number and the sum was no more than 10 (e.g., $5+3,2+1$ ). For simple subtraction problems, the difference was less than 10 and both minuend and subtrahend were one-digit numbers (e.g., 9-3, 8-2). For complex addition problems, sums were bigger than 10 but less than 30 , and addends were one- or two-digit numbers (e.g., $4+16,14+15$ ). For complex subtraction problems, differences were bigger than 10 but less than 30 , with the minuend a two-digit number and the subtrahend one- or two-digit numbers (e.g., 16-5, 25-11).

## Results

1. Logarithmic-to-linear-shift theory accurately predicted median estimates and individual differences. We first fit the median estimates for all four number line tasks and age groups using MLLM. As shown in Figure 4, across all tasks and age groups, the fit of MLLM was uniformly high $\left(R^{2}=.93 \sim 1\right)$. Analyses of $\lambda$ revealed that with age, estimates changed from logarithmic patterns to linear ones, with $\lambda$ decreasing from kindergartners to adults (Figure 4). As with Experiment $1, \lambda$ in non-symbolic conditions were higher than in symbolic ones, and $\lambda$ in unbounded conditions were higher than in bounded conditions regardless of symbol. We also computed $\lambda$ for individual participants' data. The mixed ANOVA results again showed a main effect of symbolic format, $\quad F(1,154)=83.17, \quad p<.001$, boundedness, $F(1,154)=21.20, p<.001$, and age group, $F(3,154)=19.63$, $p<.001$.

To test whether the logarithmic-to-linear-shift theory could also capture individual differences, we correlated individual participant's $\lambda$ among tasks. The results showed that individual participant's $\lambda$ among all the four number line tasks positively correlated (with correlation coefficient .81 ( $p<.001$ ) between SBA and SUA tasks; $.61(p<.001)$ between SBA and NBA tasks; . 48 ( $p<.001$ ) between SBA and NUA tasks; . $54(p<.001)$ between SUA and NBA tasks; . 43 ( $p<.001$ ) between SUA and NUA tasks; and .61 ( $p<.001$ ) between NBA and NUA tasks.
2. Model comparison. We next examined whether MLLM is the best model compared to other competitors. According to the previous studies (Cohen \& Sarnecka, 2014; Opfer et al., 2016; Slusser et al., 2013), we compared the fit of MLLM, MCPM1, and MCPM2 on individual data for the bounded condition (which included SBA and NBA tasks). Since the unbounded anchored number-line tasks were new in this study, we compared the fit of all the four models for the unbounded condition (which included SUA and NUA tasks). The proportion of individual children who were best fit by the mixed log-linear model (MLLM) using AICc was calculated.

As illustrated in Table 3, the estimates of $63 \%$ to $100 \%$ of participants were best fit by mixed log-linear model (MLLM) among all four anchored tasks across all age groups. Specifically, in the bounded condition, no matter what types of symbol were given, against to the proportional account and subtraction or division-skill account, none of the MCPMs was the best fitting model for the majority. In the unbounded condition, our results showed that estimates of $65 \%$ to $98 \%$

|  | MLLM |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- |
|  | K | 1 | 2 | A | All |
| SBA | 85 | 63 | 63 | 68 | 70 |
| NBA | 93 | 97 | 100 | 93 | 96 |
|  |  |  |  |  |  |
| SUA | 88 | 74 | 68 | 65 | 73 |
| NUA | 98 | 97 | 95 | 93 | 96 |

Table 4: Partial correlation between $\lambda$ in MLLM and math score after controlling for age across the anchored number line tasks.

|  |  | Partial correlation |  |  |  |  |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :---: | :---: | :---: | :---: |
|  |  |  | Addition |  |  |  |  |  |  | Subtraction |
| MLLM |  |  |  |  |  |  |  |  |  |  |
|  | SBA | $\lambda$ | -.29 | $* * *$ | -.20 | $*$ |  |  |  |  |
|  | NBA | $\lambda$ | -.22 | $* *$ | -.15 |  |  |  |  |  |
|  | SUA | $\lambda$ | -.30 | $* * *$ | -.22 | $* *$ |  |  |  |  |
|  | NUA | $\lambda$ | -.24 | $* *$ | -.20 | $*$ |  |  |  |  |

Note. ${ }^{*} p<.05,{ }^{* *} p<.01,{ }^{* * *} p<.001$
of participants were best fitting by MLLM when compared the fitting of all the four models. All these results suggest the logarithmic-to-linear-shift account for all the anchored numerical magnitude representation, regardless of boundedness or symbolic format.
3. Predicting the mathematical performance. Similar with Experiment 1, we also conducted partial correlation analysis
between individual participants' addition and subtraction performance and the best-fitting parameter values from the models when controlling for age. As shown in Table 4, $\lambda$ in the MLLM predicted both addition and subtraction performance across almost all the anchored number line tasks after controlling for age. However, for bounded condition, the negative correlation between the absolute value of $\beta \mathrm{s}-1$ of the MCPMs and math performance was only found for the symbolic bounded anchored task, with absolute value of $\beta_{2 \text { CPM }^{-1}}$ in MCPM2 negatively correlating with addition and subtraction ( $r(156)=-.26, p<.001$ for addition; $r(156)=-.26$, $p<.001$ for subtraction). The finding suggests that MLLM uniquely predict math performance, regardless of tasks or age groups.

## Discussion

Our experiments indicate that the logarithmic-to-linear shift account provides a unified framework that can account for data coming from a broad array of numerical estimation tasks. Specifically, we found a mixed log-linear model was the best fitting model for the vast majority ( $88.84 \%$ ) of children and adults. This finding held regardless of whether the symbolic format was symbolic or non-symbolic, whether the task was bounded or unbounded, and whether an additional reference was given or not. These results replicate those reported in Opfer et al. (2016) and Kim and Opfer (in press), as well as extending them to 4 novel number-line tasks. Finally, we found that with education, individuals acquire more substantial prior experience with symbolic numbers than non-symbolic dots, with more logarithmic compression shown in non-symbolic than symbolic condition. Also, the additional reference points (either midpoints or bounded endpoints) can increase the linearity of estimates. Thus, the classic number line task (SBF) is not an outlier in eliciting logarithmic pattern of estimates. Of the eight tasks, the highest logarithmicity was observed in kindergartners' estimating non-symbolic unbounded free (NBF) task and the lowest was in SBA.

Our results also showed that the logarithmic weight $(\lambda)$ was not fixed, but depended on the developmental history and prior experiences of the subject, leading to lower $\lambda$ values from kindergartners to adults. These findings met the overarching principle of the logarithmic-to-linear shift theory, which holds that the representation of numerical magnitude will change from the logarithmic pattern to linear one with age and experience (Opfer et al., 2011; Opfer \& Siegler, 2007; Siegler \& Booth, 2004; Siegler \& Opfer, 2003; Thompson \& Opfer, 2008).

Finally, individual differences were stable across the eight tasks: children whose estimates were more logarithmic in one task were also more logarithmic in the other seven tasks, $r(156)=.35 \sim .81, p<.001$. This would not be expected if the eight tasks elicited radically different estimation strategies, and it suggests that the logarithmic-to-linear theory provides an accurate picture for mental representation of all kinds of numerical estimations.

## Implications for alternative accounts

Broadly, our results undercut key claims of the proportionjudgment and measurement-skills accounts. A key claim of the proportion-judgment account is that developmental change involves a change in the degree of bias and use of implicit reference points. In this view, the degree of bias $(\beta)$ was thought to gradually converge on 1 , and more reference points would be utilized by the participants, "from an unbounded power to a one-cycle proportional to a two-cycle proportional version of the model" (Slusser et al., 2013, p.5). If these views were correct, the weights for 0 -cyclic power model ( $w_{1}$ ) and 1-cyclic power model ( $w_{2}$ ) in MCPM1 would be expected to decrease with age and the weight for 2-cyclic power model $\left(w_{3}\right)$ would be expected to increase -at the very least among the bounded tasks in Experiment 1 and 2. However, we found no support for this developmental pattern among any of our eight tasks. Additionally, there was no stable pattern of individual differences in the degree of bias and use of reference points. Given the relatively poor fits of these models, this lack of predictive power might not be surprising, but it does warrant caution about the psychological meaning of the parameter values.

Our results also provide robust evidence against the measurements-skills account. First, according to Cohen and Sarnecka (2014), "the implicit addition needed for the unbounded task is less mathematically sophisticated than the implicit subtraction needed for the bounded task, [therefore] children should perform better on the unbounded task at a younger age" (p. 1643). Against this contention, we found greater accuracy for bounded than unbounded tasks regardless of age, symbolic format, or provision of anchors. Far from being easier, the unbounded tasks were more difficult and actually yielded the highest logarithmicity scores. Even more critically, the parameter values of the models associated with this account (subtraction and scallop bias) were thought to track general subtraction and addition skill. If so, one would expect them to predict subtraction and addition skill when subjects actually performed subtraction and addition. However, we found no evidence that this was the case. Again, given the relatively poor fits of these models, its lack of predictive power should not be surprising.

## Acknowledgments

We would like to thank the administrators, teachers, students, and parents in Columbus for their involvement on the project. Also, we would like to thank Ariel Lindner and Rebecca Zagorsky for help with data collection. Partial support for this project was provided by a grant from the Institute for Educational Sciences (IES R305A160295).

#### Abstract

Several theories about Theory of Mind (ToM) have been proposed. The most well-known of these are Theory Theory and Simulation Theory, although alternative and hybrid theories do exist. One such theory, proposed by Bach (2011, 2014), is based on the Structure-Mapping theory of analogy, which has been shown to play a key role in cognitive development. There is evidence that children are more likely to pass false belief tasks when trained using stories that are easy to compare via structural alignment, as opposed to stories that are difficult to compare in this way (Hoyos, Horton \& Gentner, 2015). This paper shows how a computational model based on Bach's account can provide an explanation for the Hoyos et al. training study and proposes directions for future research on human subjects.

Keywords: analogy; theory of mind; false belief; structuremapping; cognitive modeling

## Introduction

The mechanisms behind Theory of Mind (ToM) have been hotly debated for decades. According to one popular theory, Theory Theory, children are little scientists who develop theories about others' beliefs (e.g. Gopnik \& Wellman, 1992). Another theory, Simulation Theory, suggests that children play out scenarios as if they were the agents involved (e.g. Goldman, 1992). Other accounts include hybrid theories (e.g. Bach, 2011), which attempt to combine aspects of Theory Theory and Simulation Theory (see Related Work).

Another important question is how ToM is learned and when. Interestingly, several studies have shown that at least some aspects of ToM can be improved via brief intervention (e.g. Hoyos et al., 2015; Hale \& Tager-Flusberg, 2003; Lohman \& Tomasello, 2003). This paper considers one such study and models how analogical generalization may lead to improved performance on the false belief tasks tested. The model generates testable predictions for future work.

We begin by discussing the theories that underlie our model, the Structure-Mapping Theory of analogy (SMT; Gentner, 1983) and Bach's (2011) structure-mapping account of ToM, along with our computational models of analogical matching and generalization used in the model. We then summarize a ToM training study (Hoyos et al., 2015) and describe how our model explains the performance
improvements provided by training. We close with related work and future directions.

## Background

We base our model on the Structure-Mapping approach to Theory of Mind proposed by Bach (2011, 2014). Because understanding Structure-Mapping Theory (SMT; Gentner, 1983) is essential to understanding this theory and our model, we describe it first. This is followed by a description of Bach's theory. Finally, we describe the computational models of SMT processes that we are using.

## Structure-Mapping Theory

Structure-Mapping (Gentner, 1983) is a theory of analogy and similarity. Under SMT, relational/structural similarity is emphasized over similarity based on features alone. Humans' ability to see these structural similarities across dissimilar cases is a key aspect of higher order cognition, which suggests that structural similarity is used in everyday reasoning. SMT proposes that comparison involves the alignment of elements between two cases, called a base and a target.

Consider a common pedagogical analogy: "A cell is like a city. The city government controls the city. The nucleus controls all the cell's activities. A power station provides electricity. A mitochondrion is like the power station." (Chang \& Forbus, 2015). In this example, the cell acts as a target and the city acts as a base. Structural representations of the two are aligned to form a mapping. SMT predicts that the cell maps to the city, the nucleus maps to the government, control of the cell maps to control of the city, and the mitochondrion maps to the power station (Fig. 1). What about providing electricity? Because of the match between the mitochondrion and the power station, we can infer that the mitochondrion does something like providing electricity. This conclusion is called a candidate inference.

SMT can be extended to include analogical generalization (Kuehne et al., 2000). As a person is exposed to alignable cases, generalizations are formed. For example, we can form a generalization between the city and the cell. This would state that "Something like a city or cell has something like a city government or nucleus that controls it and something like

Fig. 1: A visual representation of SMT. Entities are shown as rectangles. Relationships are in diamonds. Dotted lines show correspondences between the two cases. Dashed lines show the candidate inference.
a power station or a mitochondrion that gives it energy." Eventually, generalizations become abstract schemas that can represent, for example, a single type of event. They can be stored in long term or working memory.

## SMT Theory of Mind

Bach $(2011,2014)$ has proposed that ToM is developed via structure-mapping. He proposes that two forms of base domains are used. The first are abstract schemas built up over time. The second are events from autobiographical memory. This provides a hybrid model: Mappings to the schema domain correspond to theories as described in Theory Theory models, and mappings to the autobiographical domain correspond to simulation. For example, to decide whether a person who arrived 15 minutes late to a flight that was delayed by 10 or a person who arrived 15 minutes late to a flight that left on time would be more upset, a person might retrieve an abstract schema that says "people are very upset when they narrowly miss their goal" or they might simulate how they would feel if they were the person in question by mapping to an autobiographical memory. Bach argues that simulation tends to happen when the general heuristic has not yet been formed, and involves complex combinations of cases (see Bach, 2011 for specifics).

Because we do not attempt to model a complete Theory of Mind in this paper, we assume a simplified version of Bach's theory. Our model focuses on the learning aspect, so we assume that heuristic-like abstractions have not yet been formed. Thus, only concrete autobiographical memories are retrieved from long term memory. Generalizations are formed in working memory, which we propose as a mechanism by which schemas are learned.

## SME and SAGE-WM

The Structure Mapping Engine (SME; Forbus et al., 2016) implements the analogical mapping process of SMT. SME compares a base and target case, both represented in predicate calculus, and computes one or more mappings that align statements and entities. Each mapped expression receives an initial score, which is propagated to its children. Thus, highly
nested expressions have high scores. The score of a mapping is the sum of the scores of its constituents. Thus, mappings between cases that have high structural similarity receive higher scores. Mappings also include candidate inferences that project missing information from one case to the other.

In this model, we deliberately do not model retrieval from long-term memory, to avoid the cost of providing enough distractors to make this challenging, and instead assume that retrieval finds reasonable autobiographical memories. However, we have proposed (Kandaswamy et al., 2014) that analogical generalization also occurs in working memory, what we call interim generalizations. The SAGE-WM model ${ }^{1}$ keeps a list of generalizations and recent examples. Given a new example it uses SME to compute a score between the probe and each generalization in turn, ordered by recency. If the score is over a pre-determined threshold, the probe is assimilated into the generalization. If no generalization is above threshold, the new example is compared to each outlier in turn using SME, again ordered by recency. If any mapping is above threshold, a new generalization is formed. Otherwise the probe becomes a new ungeneralized example.

## Learning Theory of Mind

Several studies have shown that Theory of Mind can be acquired in part using experimental interventions (e.g. Lohman \& Tomasello, 2003; Hale \& Tager-Flusberg, 2003; see Hofmann et al., 2016 for meta-analysis). However, most of these studies involve extended training. On the other hand, there is evidence that ToM can be acquired much more quickly when training examples are highly structurally alignable. In particular, a study by Hoyos et al. (2015) showed that structurally alignable unexpected contents-style stories can improve children's performance on false belief tasks, given just three training examples. In this paper, we examine and model the results of this experiment.

## Modeling Task

In the Hoyos et al. (2015) study, children were first given a false belief pre-test containing one unexpected contents task (UC), one verbal false belief task (VFB), and one unexpected location task (UL). In the UC task, a container (e.g. a cookie box) is shown to have unexpected contents (e.g. grass) and participants are asked to predict what someone who has never seen inside would think the container contains. In VFB participants are told another child holds a false belief (that they think an item is somewhere it is not) and asked to predict where the child will look for the item. Finally, in UL, participants are told a story where one child places an object in a location and leaves the room. Another child then moves the object, and the participants are asked to predict where the first child will look for the object when they return.

Those who passed all three tests were excluded from the study. The remaining children were split into two groups: high alignment and low alignment. Both groups were

[^444]presented with three stories in the style of an UC task, in a repetition-break pattern: the main character in the first two stories held a true belief (e.g. she thought that there was cereal in a cereal box, and there really was cereal inside), while the character in the last held a false belief (e.g. she thought there were crayons in the crayon box, but there were really rocks). The difference was that the stories heard by children in the high alignment condition were very similar, in terms of both structure and linguistic content. The stories heard by children in the low alignment condition, on the other hand, differed on both counts. Following training, all children were tested on the same three tasks (UC, VFB, UL) as before.

Hoyos et al. found that children in both conditions made significant gains from pre- to post-test. Importantly, they found that the children in the high alignment condition made significantly higher gains than those in the low alignment condition. Hoyos et al. concluded that structural alignment aids false belief understanding. Furthermore, they, like Bach (2011, 2014) postulated that analogical comparison is "instrumental in children's understanding of mental states and their relation to the factual world." In this paper, we propose a mechanism for how structural alignment during learning can aid in false belief understanding and forming a complete Analogical Theory of Mind.

## Learning Analogical Theory of Mind

The mean performance increase by children in the high alignment group was 0.75 out of 3 possible, with significant gains made in all three of the false belief tests. Yet few children learned more than one. On the other hand, children in the low alignment condition made an average of 0.23 gains. Only gains in the UC task were significant. Since all of the training examples were variants of UC, it is not surprising that this was the easiest task to learn. However, learning ToM requires the ability to transfer to other tasks, as was the case with children in the high alignment condition. The process of making gains in UL and VFB tasks must, then, be different than the process of only gaining UC.

We argue that analogical comparison in working memory alone leads to gains in the UC. That is, immediate recall of the training examples themselves is sufficient to cause gains. In contrast, a generalization between a training example and an autobiographical memory retrieved from long term memory leads to transfer to the other two tasks, VFB and UL. The violation of expectation generated during training causes the child to probe long term memory for a case of similar surprise. What exactly they find surprising about the training-that something other than what they expected was inside the box, that the character in the story was incorrect in her guess, or something else-affects the case that is retrieved from long term memory. This in turn affects which of UL and VFB the child is able to answer.

## A Computational Model

Our model, like Bach's theory, is based in SMT, using SAGE-WM for reasoning and learning.

## Our Model

A simplified English version of each training and testing example from Hoyos et al. (2015) was semi-automatically encoded using a natural language understanding system (EA NLU; Tomai \& Forbus, 2009). Although syntax was simplified, overall structure and word choices were consistent with the original stories. Figure 2 shows a partial representation of a true belief story. Events are represented in the neo-Davidsonian style: a reified event with role relations connecting it to other constituents. The conjunction of statements about an event participates in causal relations. In English, Figure 2 states that because it is not the case that there is a seeing event in the box by Kim, Kim thinks that there is a containment event wherein the box contains cereal.

During training, the appropriate examples were passed into SAGE-WM in the order that the children in the corresponding condition saw them (true belief, true belief, false belief). The threshold for whether or not a probe was generalized was set to 0.01 . If the incoming example matched to an example already in working memory with a score greater than 0.01 , the model asked whether the match was correct. This corresponds to feedback in the Hoyos et al. (2015) experiment. When told it was correct, the model assimilated the examples into a generalization. Its behavior when told it was incorrect, on the other hand, depended on its calculation of surprise. Surprise occurs when the model encounters an incorrect match whose score is the same order of magnitude as the previous correct match. We propose that this comes out of the repetition break structure of the story order (Hoyos et al., 2015; Loewenstein \& Heath, 2009): the high similarity to the interim generalization leads to a strong expectation of sameness, and the violation leads to a search for recategorization. When surprised, the model probes long term memory for an alternative case to align with.

Figure 3 gives a visual representation of our model. In the high alignment condition (a), the first true belief story is stored in working memory. The second true belief story is then matched to the first, and an interim generalization is formed. When the false belief story comes in, it too matches to the generalization. Due to violated expectations, long term

```

Fig. 2: A partial representation of a true belief story. This statement represents the phrase "Kim thinks that the box contains cereal because Kim has never seen inside the box".
memory (dotted line) is probed. Long term memory is a collection of generalized and specific cases that represent memories formed over time. If a case is retrieved, an interim generalization between the match and the false belief case is created and stored in working memory (b).

In the low alignment condition (c), on the other hand, no generalization is formed between the two true belief cases. This leads to them being stored as separate cases in working memory. When the false belief case comes in, it matches to the first true belief case, but no element of surprise is present when the model is corrected. For this reason, long term memory is never probed, and working memory consists of only the three training examples (d). The contents of working memory during testing predict the questions that the child is able to answer.

Testing proceeded as follows: cases were again encoded semi-automatically using EA NLU. These cases were given to the model which retrieved the most similar case from working memory and generated candidate inferences by analogy. The candidate inferences correspond to what the model predicts is missing from the test cases (e.g. what the agents will do). These candidate inferences were manually inspected to determine whether any could result in correctly answering the test questions.

Fig. 3: A visual representation of our model of training in the Hoyos et al. study. (a) shows training in the high alignment condition. (b) is a representation of working memory after high alignment training. (c) and (d) show low alignment training and the consequent working memory, respectively. Cases that are structural matches to the probe are bold.

## Results

The model behaved as predicted. In the high alignment condition, the model generalized the true belief cases with a normalized match score of 0.075 . It then matched the false belief to the generalization with a score of 0.066 , which corresponds to the child incorrectly predicting that the character in the story knows what is in the box. The model was then informed that this match was incorrect. Because the similarity scores it had encountered were within the same order of magnitude, it searched long term memory for another match. It then retrieved one of two memory cases that matched with a normalized score of 0.083 or 0.066 , and created an interim generalization between it and the false belief case. We used stories intended to approximate a memory a child might have (e.g. thinking that a magician put a ball inside of a hat, only to find the hat empty) to model what might plausibly be retrieved. Depending on the case retrieved, the model was then able to answer VFB or UL. Correctness was evaluated based on the candidate inferences generated from the best mapping between the test case and the contents of working memory. For example, to correctly answer "Where is Nora going to look for her ball?" (UL) the mapping must produce a candidate inference stating that there might be a looking event, in which Nora looks for her ball in the appropriate location.

In the low alignment condition, on the other hand, the second true belief case matched to the first with a very low similarity score of 0.0014 , well below threshold. For this reason, the model did not form a generalization between them. When the false belief case was compared, it had a match score of 0.066 with the first true belief case. Similar to the high alignment condition, the model was informed that this was not a correct match.

Because the previous match score was of a different order of magnitude, the model did not look into long term memory, and instead stored the false belief case alongside the two true belief cases. When the UC case came in, the false belief case was retrieved. The mapping generated a candidate inference that would allow the model to properly answer "What does she think is in the box?" This candidate inference stated that not having looked inside the cookie box would cause the agent to believe that it contained something analogous to crayons in the crayon box from the training example. That is, cookies.

Note that this retrieval is due to recency in working memory: the UC test case lacks the explanation present in the training cases about why a person holds a certain belief (e.g. "Kim thinks that the cereal box contains cereal because Kim has never looked inside the box."), so the first true belief case had the same match score. If that case had been retrieved, the model would not have been able to answer UC correctly.

## Discussion

Our model gives one explanation for the results of the Theory of Mind training study presented in Hoyos et al. (2015). It also suggests that an important step in ToM development is generalizing belief-state cases in long term memory. In the
training studies, understanding that the training cases can, and indeed should, be assimilated to long term memory with belief-state interpretation cases is crucial. In other words, children may be accumulating experiences that require reasoning about belief states in long term memory, but these memories remain inert until a surprising event-such the one experienced by the high alignment participants in the Hoyos et al. study-stimulates their retrieval and begins the process of creating schemas that can be used in future ToM reasoning. This predicts that children in the high alignment condition of Hoyos et al. (2015) are more likely to retain what they have learned than the children in the low alignment condition: the children in the high alignment condition were more likely to access those experiences from long term memory and form a generalization with them.

In addition, our model predicts that reversing the order of training examples would cause children in both conditions to fail. In the low alignment case, when the most recent training example is retrieved, children would match the UC task to a true belief scenario, and answer incorrectly. Children in the high alignment case would similarly fall back on retrieval of the most recent case, as they would not experience the surprise caused by the repetition break structure.

Previous studies (e.g. Hale \& Tager-Flusberg, 2003; Lohmann \& Tomasello, 2003) have suggested that experience plays a role in ToM development. Our model provides a concrete explanation for how these experiences might lead to ToM and provides further suggestions for human subject experiments.

## Related Work

## Theories of Theory of Mind

Here, we summarize the best-known ToM theories.
Theory Theory One of the most popular takes on ToM is Theory Theory, which views the child as a scientist with regard to interpreting other people's mental states (e.g. Gopnik \& Wellman, 1994). The child begins with a naïve theory about others, sometimes referred to as a folk psychology, which she modifies and adapts as evidence that supports or refutes the theory is observed. The theory gradually develops from only understanding desire states, to belief states, to how belief and desire states influence each other and behavior (Bartsch \& Wellman, 1995).

Simulation Theory Under the Simulation Theory view, a child mentally simulates events in order to predict others' actions and beliefs (Goldman, 2006), and develops by improvement in simulation abilities (Flavell, 2004). Criticisms of Simulation Theory include that errors made by both children and adults are not consistent with those predicted by Simulation Theory accounts (Saxe, 2005) and that simulation is not sufficient for describing observed developmental patterns (Perner \& Howes, 1992).

Modular Theories Another common account is that ToM can be explained as a single cognitive module. Scholl and Leslie (1999) list six characteristics of modules: they are domain-specific, their behavior is, at least in part non-
voluntary, their processing is fast, their outputs are shallow and highly constrained, they are often located in a particular region of the brain, and their processes may be impairedand selectively impaired-by neural damage. Importantly, according to Scholl and Leslie, modularity theories "intend to capture only the origin of the basic ToM abilities" (1999). In this sense, modularity theories do not necessarily compete with other theories of ToM discussed here.

Hybrid Theories Several hybrid theories have been proposed to bridge the gap between Theory Theory and Simulation Theory. Some, which Bach (2011) calls dividedhybrid models, alternately assign aspects of Theory of Mind to simulation or theorizing, depending on which is better supported by empirical data (e.g. Heal, 1996). This approach, as Bach notes, avoids discussion of acquisition. It is unclear how a child learns to use simulation for some tasks and theory for others, and how simulation and theory develop concurrently. Other hybrid theories, which Bach (2011) calls dynamic-hybrid models, focus on continued development. Bach's model falls under this category. Like other dynamichybrid theories, Bach's allows for development and changes to ToM not only throughout childhood, but into adulthood. This includes switching between theorizing and simulating to complete the same tasks at different points in development. As psychologists continue to find evidence of ToM shifts throughout adulthood (e.g. Hess, 2006), dynamic-hybrid theories become more and more plausible.

## Computation Models of Theory of Mind

Hiatt and Trafton (2010) implemented a model of Theory of Mind using the ACT-R cognitive architecture (Anderson, 2007) that learned to perform the Sally-Ann task. It extracted facts out of the scenario and was asked several false belief questions about what it saw. It was rewarded for answering correctly and punished for answering incorrectly, leading it over time to inhibit true belief responses, producing a learning curve consistent with developmental data. However, unlike our model, the training they used did not follow from an empirical training study. We note that the children in the Hoyos et al. (2015) study were able to learn aspects of false belief after seeing just three examples, only one of which actually was a false belief situation.

Goodman et al. (2006) modeled ToM via two Bayesian networks that respectively represent a naïve and expert theory in a Theory Theory account. They propose the models as competing hypotheses in the Sally-Anne task, and show how, during training, the expert theory becomes preferred over the naïve theory. The need to hand-code both theories in the system's starting endowment makes it more of a computational level model (Marr, 1982), whereas we provide a process-level model of learning. Furthermore, our model is consistent with the evidence from the training study presented by Goodman et al. (2006), which shows that surprise can improve children's ToM performance.

## Future Directions

Our results provide evidence that structure-mapping is indeed a plausible process-level mechanism (Marr, 1982) for ToM and how it is learned. As such, our future work will look toward developing a complete computational Theory of Mind, including both the theory and simulation aspects of Bach's theory, using SAGE as the underlying mechanism.

# A Theory of Resonance: Towards an Ecological Cognitive Architecture 

Vicente Raja<br>University of Cincinnati, Cincinnati, OH, United States

#### Abstract

This paper may be seen as a blueprint for an ecological cognitive architecture. Ecological psychology, I contend, must be complemented with a story about the role of the CNS in perception, action, and cognition. Such a story must be a theory of resonance compatible with the main tenets of ecological psychology. I offer here the two main elements of such a theory: a framework (Anderson's neural reuse) and a methodology (multi-scale fractal DST).

#### Abstract

Humans possess rich knowledge of the structure of the world, including co-occurrences among entities, and covariation among their discrete and continuous features. But how people learn, infer and predict this structure is not well understood. Here we explore everyday scene understanding as a case study of people's structural knowledge and reasoning. We introduce a probabilistic model over scene graphs that can learn the relational structure of objects and their arrangements and support inference and generation. Our model was able to learn the underlying structure of real-world scenes, and use it for inference and compression. In two human psychophysical experiments we found that a corresponding computational cognitive model was able to explain how people learn novel scene distributions and use it for classification and construction. Our work represents the first computational theory of human scene understanding that can account for people's rich capacity for learning and reasoning about structure.

#### Abstract

The predominant view concerning determinants of analogical retrieval is that it is preferentially guided by superficial cues. In order to test the cognitive plausibility of a structural similarities-based retrieval, we constructed a story-recall task in which life-like scenarios shared structural correspondences. In Experiment 1, we showed that such structural similarities induce retrievals when the participant had several source candidate situations sharing superficial similarities with the target cue. Experiment 2 was designed to test whether the encoding was sufficiently oriented on structural similarities to drive retrievals, even if the participants possess only one source candidate situation with superficial matches in memory. The results of the two present experiments lead us to conclude that in some contexts, abstract encoding induces a superiority of structural similarities over superficial ones in retrieval. Further implications for analogical retrieval approaches are discussed.

Keywords: Analogy; analogical retrieval; structural similarity; abstract encoding; story-recall task

## Introduction

Analogy has been identified as a key process to perceive the conceptual structure of a new situation by importing it from a familiar analog representation (Gentner, 1983; Gick \& Holyoak, 1983). Most studies are consensual that the mapping process permitting this transfer is preferentially based on structure rather than surface correspondence. In other words, when comparing two analogs, subjects do not rely on similarities in terms of objects or object attributes, but instead tend to focus on common abstract relations. Figure 1 provides an illustration of a target cue story sharing a structural correspondence with a superficially dissimilar analog source candidate situation ("making a deal to avoid a bad situation"), and a surface correspondence with a superficially similar disanalog source candidate situation belonging to the same semantic domain (raptors, tailfeathers, etc).

Target cue story
Karla, an old hawk, lived at the top of a tall oak tree. One afternoon, she saw a hunter on the ground with a bow and
some crude arrows that had no feathers. The hunter took aim and shot at the hawk but missed. Karla knew the hunter wanted her feathers so she glided down to the hunter and offered to give him a few. The hunter was so grateful that he pledged never to shoot at a hawk again. He went off and shot deer instead.

Superficially dissimilar analog source candidate situation Once there was a small country called Zerdia that learned to make the world's smartest computer. One day Zerdia was attacked by its warlike neighbor, Gagrach. But the missiles were badly aimed and the attack failed. The Zerdian government realized that Gagrach wanted Zerdian computers so it offered to sell some of its computers to the country. The government of Gagrach was very pleased. It promised never to attack Zerdia again.

Superficially similar disanalog source candidate situation Once there was an eagle named Zerdia who donated a few of her tailfeathers to a sportsman so he would promise never to attack eagles. One day Zerdia was nesting high on a rocky cliff when she saw the sportsman coming with a crowsbow. Zerdia flew down to meet the man, but he attacked and felled her with a single bolt. As she fluttered to the ground Zerdia realized that the bolt had her own tailfeathers on it.

Figure 1: Situations sharing different types of similarity in Gentner, Ratterman \& Forbus (1993)

Types of similarity implicated in the retrieval of a source representation in memory are the main issues debated in the literature. The predominant view is that the retrieval of a source candidate situation critically depends on superficial similarities, whereas the influence of structural similarities seems more peripheral (Gentner, 1983; Gentner, Ratterman \& Forbus, 1993; Gick \& Holyoak, 1983; Trench \& Minervino, 2015). In Gentner and Colhoun's (2010) words: "Relational retrieval can be said to be the Achilles' heel of our relational capacity. There is considerable evidence that
similarity-based retrieval, unlike the mapping process, is more influenced by surface similarity than structural similarity." However, opposite assertions have arisen in the literature, attributing a major influence to structural similarities, even overcoming that of surface similarities (Blanchette \& Dunbar, 2000; Dunbar \& Blanchette, 2001; Hofstadter \& Sander, 2013; Kretz \& Krawczyk, 2014). The aim of this paper is to demonstrate that structural matches have a greater influence than superficial ones in the retrievals of life-like situations. This will be shown by creating a competition between source candidate situations sharing either exclusively superficial or structural similarities with the target cue (Figure 2 illustrates this intended feature composition). Before considering the current experiments, we report the major findings stemming from several experimental paradigms.

|  | Analog source <br> candidate situations | Disanalog source <br> candidate situations |
| :---: | :---: | :---: |
| Structural similarity | X |  |
| Superficial similarity |  | X |

Figure 2: Correspondences between target cues and critical source candidate situations intended in Experiment 1 and 2

## Analogical Problem Solving

In the problem solving domain, a common experimental design to study analogical retrieval via analogical transfer is the source-target paradigm (Gick \& Holyoak, 1983; Holyoak \& Koh, 1987). A source problem situation is first proposed with its solution, then an analog target problem is given to be solved. To measure the role of surface correspondence in access, the surface of the source problem is manipulated to either match or not with the target one. The retrieval is considered to have occurred when the participant detects similarities between the target problem and the source problem without further hints from the experimenter, leading to the transfer of the resolution procedure from the source to the target. Results have shown that retrieval is high when the source is both superficially and structurally similar to the target. More precisely, the similarities in terms of the problems' story theme have appeared to be a crucial determinant in access (Ross, 1987). Inversely, superficially dissimilar analog source problems are seldom retrieved by the participants (Gick \& Holyoak, 1983). Studies on problem solving have also demonstrated that structural similarities can, in certain circumstances, have a role in retrieval: when two source analogs are presented jointly to be compared, their critical solution principle can be retrieved when faced with the target (Catrambone \& Holyoak, 1989). Also, retrievals are reported to be more frequent when the two superficially dissimilar analog problems share structural similarities at a less abstract level (Holyoak \& Koh, 1987).

## Story-Recall Paradigm

Another frequently used paradigm is the story-recall task (Gentner et al., 1993; Wharton, Holyoak \& Lange, 1996; Catrambone, 2002). A set of short text stories are presented as source candidates for the retrieval before the introduction of target cue situations which share various similarities with them (Figure 1). Within a problem solving paradigm, the problems generally share the same structure since it is the transfer of an abstract solution being investigated. This is not systematically the case in the story-recall paradigm since the situations are chosen to create a competition between source candidate situations possessing exclusively the surface or exclusively the structure in common with the target cue (Gentner et al., 1993). This paradigm showed superficially similar disanalogs were retrieved significantly more often than superficially dissimilar analogs, leading to the conclusion that superficial similarity is the main factor implicated in access.

Wharton, Holyoak, Downing, Lange, Wickens \& Melz (1994) argued that the minor role attributed to structural matches in story-recall tasks could be due to the fact that only one source candidate, the superficially similar disanalog, shares some semantic features with the target cue. One can note that in real-life conditions, several source candidate situations, corresponding in superficial features with the perceived situation, are generally available in memory. The authors observed that structural similarities may play a certain role in access because when the analog source candidate also shares some superficial similarities, it is better retrieved than the concurrent source candidate possessing only superficial similarities with the target cue. Structural similarities also seem to play a certain role in access when they are implemented without superficial matches: the retrieval of a superficially dissimilar source candidate is higher when it shares structural features with the target cue (Wharton et al., 1996). However, the role of structural similarities in access has only been shown when two source candidates shared the same amount of surface correspondence. Hence, the reviewed works did not demonstrate the superiority of structural similarities in access, since it would require showing that superficially dissimilar analogs are better retrieved than superficially similar disanalogs.

## Production Paradigm

Challenging the ecological nature of traditional experimental conditions (unfamiliar source and target situations, short familiarization time, restrained pool of source candidates), further research focused on the retrieval of situations encoded prior to the experiment in real-life conditions (Blanchette \& Dunbar, 2000; Dunbar \& Blanchette, 2001; Kretz \& Krawczyk, 2014). With this configuration, a high structural overlap was generally observed between the source and the target cue situation. For instance, expert discourse in scientific domains (politics, biology, economics) exhibited predominance for structural analogies, though sometimes also sharing a superficial
correspondence. Those findings were replicated in experimental conditions with a production paradigm, where participants who were allowed to select their own sources of analogy retrieved significantly more semantically distant analogs than superficially similar analogs (Blanchette \& Dunbar, 2000). In other words, those findings not only advocate for the major role of structural similarity but also for the weak impact of superficial similarity when accessing an analog. However, Trench \& Minervino (2015) pointed out that the sources provided by the participants could be invented rather than real memories, and that superficially dissimilar analogs could be more common in memory than superficially similar ones. They tested the potential that while controlling the availability and number of the two types of concurrent source candidates, findings obtained from usual source-target and story-recall paradigms would be replicated when the participant generates analogical retrievals from her or his own experiences. They proposed target situations with either superficial and structural, or solely structural similarities with their memories. In accordance with prior findings, participants more often proposed superficially similar analogs than superficially dissimilar ones. In another study using this paradigm, situations retrieved by management consultants provided with target situations embodying an original negotiation principle manifested only superficial matches (Gentner, Loewenstein, Thompson \& Forbus, 2009). Contrary to previous studies using the production paradigm, this experiment reflects a marginal tendency to access structurally similar source situations. These results, in sharp contrast with the ones obtained by Dunbar and Blanchette (2000), indicate that the natural settings of the encoding condition of one of the analog is not in itself the critical parameter influencing the type of retrieval. Namely, whereas it probably promotes the abstract encoding of this analog situation, the access to its structural matches with the other analog which is still provided by the experimenters is not guaranteed.

## Encoding through abstract concepts

When faced with a target cue situation, the fail to retrieve an analog situation is generally interpreted as a defect of abstract encoding of the two situations (Gick \& Holyoak, 1983; Gentner et al., 2009). If the participant is unable to grasp the structure of the situations, the abstract similarities could not be used as a cue to retrieve. Indeed, only if the participant is incited to compare either two source analogs or two target analogs, he might extract a schema sufficiently abstract, and subsequently perceive this schema in a superficially dissimilar analog, in the context of the retrieval.

However, even if the schema extracted from the situation is not abstract enough so that the similarities introduced between the analogs by the experimenter will be detected, it cannot be claimed that the encoding of a situation is purely concrete and literal (Hofstadter \& Sander, 2013). Whereas a wealth of stimulations is permanently available in our environment, one has to select the properties relevant to make sense of the situations. This cannot be done by processing
every perceptively available superficial piece of information. Instead, the situation's understanding depends on the properties (whether perceptual or abstract) that are compatible with the conceptual structure in construction and on the neglect of those which are not.

We suggest that familiar concepts' evocation during the encoding is a critical point to account for the abstract information raised by perceived situations. This idea is congruent with findings revealing that source analog problems that participants usually fail to retrieve in experiments are better accessed by expert participants (Novick, 1988). When experts have a familiar concept to highlight the abstract properties of these situations, the novice does not have this conceptual door toward the structure. This reveals that the novice participant has not elaborated the specific concept that allows for the encoding of the structure of complex problem situations necessary for the structurallybased retrieval of this type of situations. However, it is very likely that he/she has acquired an expertise in daily-life situations, where one systematically has to deepen the encoding until elementary abstract concepts are established, such as "making a deal", "bad faith", "lie", "authenticity", "prosocial behavior" and so on, to produce adapted behaviors. The activation of these concepts should highlight the structure underlying some daily-life situations in a way that elicit structurally-based retrieval. Whereas most studies have focused on abstract inter-domain analogies that a novice could rarely access, we aim at investigating analogies between situations inspired from social scenarios that can be experienced in different domains of daily-life.

## Experiment 1

In order to demonstrate the superiority of structural similarities over superficial similarities in retrieval, we conducted a first experiment where those two types of similarities were in competition in the retrieval of a source situation candidate. In that way, a story-recall task was used so as to control for the highlighting of the structure underlying both the analog source candidate situation and the target cue situation.

## Method

## Material

Social scenarios inspired from Wharton et al. (1996) involving life-like contexts were used. Although the objects of the analog situations were clearly divergent, they shared very similar role at the required level of abstraction for making sense of the stories. In the analog pair reported in Figure 3 for instance, both stories relate the setting of a social competition between two characters (rival cookers or classmates) having the same goal (turnover or seducing someone) and an unusual way to put an end to it by helping the competitor to enhance her/his critical ability (improve Lorenzo's pizza dough or looking after Diane's appearance). If those situations are not directly taken from the participant's
experience, $\mathrm{s} /$ he still can use her/his general knowledge about social relations to encode such scenarios.

In order to make sure that the two types (superficial or structural) of similarities with the target cue were never confounded in a same source situation, superficially similar source stories structure clearly diverge from the target ones. In this way, contrasting with previous works (e.g. Gentner et al., 1993), disanalogs are not modified versions of a same structure story, but describe structurally different scenarios.

Wharton et al. (1994) noticed that when semantic correspondence was not only present between the source disanalog and the target cue, the artificial saliency of the superficial matches decreased and resulted in a weaker influence on access. In their experiment, the concurrent superficially similar source candidates were the analog and the disanalog. As previously indicated, we aim at isolating the influence of structure and surface similarities by implementing them in different source candidates. Hence, we multiplied the number of source candidates sharing surface features with the target cue by introducing three superficially similar disanalogs. To respect a symmetry between the number of semantically close and distant source candidates, we also introduced three superficially dissimilar source candidate situations (the analog sharing structural correspondence, and two unrelated distractors).

## Target cue story

Luigi holds a pizza truck in a very popular place. Lorenzo, another ambulant pizzaiolo, has placed his truck just beside Luigi's and is detrimental to his turnover. Luigi realizes the dough of Lorenzo's pizzas is bland. Luigi spontaneously gives his personal recipe to Lorenzo so as he can enhance the quality of his product. Since then, his pizza dough is amazingly tasty. The same evening, Lorenzo declares to Luigi that in order to show him how much he found his intention was nice, he will move his truck in another sector, far from this one.

Superficially dissimilar analog source candidate situation
Julie is in love with Victor, her classmate, and she is getting closer to him in order to seduce him. But Diane joins the class in the middle of the year and also has a crush on Victor. Julie remarks that Diane was not very aware of her style and proposes her some relooking advices, showing her fashion photos and taking her for shopping. Diane now looks very cute and chic. Diane is so grateful that she tells Julie that she would stop flirting with Joe.

## Superficially similar disanalog source candidate situation

In a market place, the truck called « At Alessandro \& Fabio's » has various choices of homemade pizzas. The important clientele going there is fond of the authentic atmosphere steaming from this stand held by the two happy

[^445]looking men in Italian traditional suits. However, once they will have left this selling space, the two men will go to another market place after taking care of wearing German traditional clothes to sell sausage specialties. The sign will display «At Hans and Hendrich's ».

Figure 3: Examples of stories used in the Experiment 1

## Procedure and experimental design

The first two pages of a booklet presented the 6 source stories, then a blank page separated them from the last page comporting the target cue situation. Under each source story was a 5 points scale inviting participants to assess the ease they had to imagine the scene while reading it. As recommended by Wharton et al. (1996), this was done to promote a deep treatment of the situations. The dependent variable was the source retrieved during the reading of the target cue situation.

It was indicated that the task took around 10-15 minutes to fulfill but no time limitations was imposed. After they agreed to participate, participants were given the booklet. They were invited to read the instructions available in the first page. The target cue situation was presented on the last page, followed by the solicitation to indicate if they were reminded of one of the previous situations. If it was the case, they had to restitute any element they could remember about it.

## Participants

34 participants ( 25 women and 9 men, mean age 23.8 years) accepted to take part in the experiment in University libraries (Paris 5 and Paris 8). They were all fluent French speakers.

## Results and discussion

Access credit was attributed to the source candidate for which the participant recalled word content. If content word from more than one source was reported, the source containing the more content words in common was credited. If the participant explicitly reported more than one source despite the instruction, his response was excluded. 3 responses were not analyzed for this reason.

Analyses were drawn on a comparison between the superficially and structurally similar source candidates that were retrieved. Structurally similar source candidate situations were much more retrieved (84.61 \%) than superficially similar disanalog source candidate situations (15.39 \%, see Figure 4). This difference reaches high significance $\left(X^{2}(1, N=29)=12.46 ; P<0.001\right)^{1}$.

In real-life condition, one generally has in memory multiple source candidates sharing similarities in terms of superficial objects with the target cue situation. The results reveal that when a pool of semantically similar source candidate situations is available in memory, but those situations do not preserve the structure of the target cue, the
retrieval is preferentially guided by structural matches with sources of a distant semantic domain. However, our results cannot help us identifying whether the structural matches of daily-life scenarios are sufficiently blatant to drive the retrieval when only one concurrent source candidate belongs to the same semantic domain as the target cue. Experiment 2 was designed in order to answer this question.

Figure 4: \% of retrievals of structurally versus superficially similar source candidates in Experiment 1

## Experiment 2

## Method

## Material

Six source candidate situations were proposed before the target cue situation (taken from experiment 1): 4 unrelated stories (distractors), one superficially similar disanalog story (taken from Experiment 1) and a superficially dissimilar analog story (taken from Experiment 1, c.f. Figure 3). Hence, the design was more similar to the one used in traditional recall tasks (Gentner et al., 1993), though it differs in the isolation of structural or superficial similarities in different source candidate stories that are in competition.

## Procedure and experimental design

The procedure and experimental design were the same as in Experiment 1.

## Participants

67 students ( 52 women and 15 men, mean age 20.8 years) accepted to take part in the experiment during a class (University Paris 8).

## Results and discussion

3 responses could not be interpreted since several source candidate situations were reported despite the instruction asking for only one.

[^446]Again, analyses were focused on the comparison between surface and structure similarities-based retrievals. As illustrated in Figure 5, the superficially dissimilar analog source candidate was significantly more retrieved than the superficially similar disanalog source candidate (respectively $81.25 \%$ and $\left.18.75 \%, X^{2}(1, N=62)=22.41, p<0.001\right)^{2}$.

These results share a similar pattern with the ones obtained from Experiment 1. This comparison induces that the presence of multiple situations belonging to the same semantic domain as the target cue was not a determinant factor promoting the superiority of structural similarities in retrieval. Instead, the fact that our stimuli depicted daily-life situations might have been a critical parameter so that the participants may have rely on the abstract structures of the scenarios as retrieval cues.

Figure 5: \% of retrievals of structurally versus superficially similar source candidates in Experiment 2

## Conclusion

In Experiment 1, the superiority of structural similarities in retrieval was observed while the source analog was in competition with several source candidates sharing exclusively surface features with the target cue. As noted by Wharton et al. (1994, 1996), providing participants with only one source candidate sharing objects with the target cue may provoke its retrieval. However, in Experiment 2, providing participants with only one surface matching source candidate in competition with the superficially dissimilar analog did not reduce the proportion of structural similarity-based retrievals. Thus, structural similarity-based retrievals are predominant when the situations experimentally provided are close to the ones that are encountered in daily-life.

Experimental studies have widely converged on the conclusion that retrieval is driven by superficial similarities. However, as the analog situations that have been mainly studied are unfamiliar for the participants, the latter conclusion cannot be applied to the more ecological retrievals that are processed in daily-life. Indeed, in analogical problem
solving, analog problems share a highly abstract resolution principle (Gick \& Holyoak, 1983; Ross, 1987). Alternatively, the nature of retrieval can be better informed when meaningful structural similarities are set between situations potentially encountered by the participants in their familiar environment. Under these conditions, the participant's knowledge allows to encode familiar relations that constitute cues for retrieving former episodes, while surface features may be neglected (Novick, 1988; Hofstadter \& Sander, 2013). Indeed, a filter has to operate in order to identify the relevant properties constitutive of a concept that allows to make sense of the situation.

Some authors have claimed that the commonly observed surface similarity-based retrieval was not so detrimental to our cognition since situations sharing surface generally also share structure (the kind world hypothesis; Gentner \& Medina, 1998; Trench \& Minervino, 2015). It is noticeable indeed that objects in our environment usually interact in regular ways and have typical relations (Bassok, Wu \& Olseth, 1995). For instance, situations involving two pizzaioli in the same place potentially induce very closed relations, such as a competition between them (Figure 3). Two situations sharing both surface and structure can only be more structurally similar than two surface dissimilar situations sharing only structure at a certain level of abstraction. Yet, it has been taken as granted for advocating the superficially driven retrieval view that retrievals of structurally and superficially similar situations were more frequent than only structurally similar ones (Trench \& Minervino, 2015). An attempt to introduce a source candidate sharing only surface and no structure with the target cue has been made in storyrecall paradigms (Gentner, 1993). Yet, a closer look at the stimuli (Figure 1) makes apparent that the superficially similar disanalog source candidate situations systematically still shared some relational features with the target cue (Wharton et al., 1996). Their structures are highly similar (making a deal to avoid a bad situation) until opposite conclusions at the end of the stories (betrayal or respect of the deal). However, a set of objects still can induce a heterogeneous panel of relations (e.g. two pizzaioli: rivalry, friendship, etc), while different types of objects can induce very similar relations (e.g. a loving couple can also induce the relation rivalry for instance, c.f. Figure 3). In our experiments, dissociating object similarities and similarities in terms of familiar relations into different source candidate situations demonstrated that it is not the objects in themselves that drive access, but rather the familiar structural relations that link them.

# Improving a Fundamental Measure of Lexical Association 

## Gabriel Recchia (glr29@cam.ac.uk)

Paul Nulty (pgn26@cam.ac.uk)

Cambridge Centre for Digital Knowledge, CRASSH, Alison Richard Building, 7 West Rd<br>University of Cambridge, Cambridge CB3 9DP, United Kingdom

#### Abstract

Pointwise mutual information (PMI), a simple measure of lexical association, is part of several algorithms used as models of lexical semantic memory. Typically, it is used as a component of more complex distributional models rather than in isolation. We show that when two simple techniques are applied-(1) down-weighting co-occurrences involving lowfrequency words in order to address PMI's so-called "frequency bias," and (2) defining co-occurrences as counts of "events in which instances of word $_{1}$ and word ${ }_{2}$ co-occur in a context" rather than "contexts in which word ${ }_{1}$ and word $_{2}$ co-occur"-then PMI outperforms default parameterizations of word embedding models in terms of how closely it matches human relatedness judgments. We also identify which downweighting techniques are most helpful. The results suggest that simple measures may be capable of modeling certain phenomena in semantic memory, and that complex models which incorporate PMI might be improved with these modifications.

Keywords: semantic spaces; word space models; semantic memory; semantic networks; computational models

## Introduction

Pointwise mutual information (PMI) is a simple measure that plays an important role in many computational models that approximate human judgments of lexical association or semantic relatedness. Such "semantic space" models typically take the form of algorithms that process a corpus of written language, such as Wikipedia or TASA, and construct quantitative representations of the words they encounter on the basis of lexical co-occurrence statistics. The resulting 'lexical representations' (e.g., numerical vectors) are intended to correspond roughly to semantic representations in the human mind, at least at some level of abstraction. Of particular interest is the degree of association that exists between related (and unrelated) words in any such model. This quantity is computed in a manner appropriate to the model at hand, e.g. cosine similarity between two lexical vectors in a vector space model, or Kullback-Leibler divergence between distributions of words over topics in a topic model. Such computationally estimated associations can then be compared to behavioral data that provides evidence of the actual degree to which people perceive particular words to be related, e.g., human judgments of the semantic relatedness of large numbers of word pairs.

Such correlations with behavioral data are frequently used to argue in favor of particular models of human semantic memory (Griffiths, Steyvers, \& Tenenbaum, 2007; Jones \& Mewhort, 2007; Bullinaria \& Levy, 2007), but
lexical associations derived from semantic space models have many other applications as well. For example, a range of semantic space models-including one method that has been recently shown by Levy \& Goldberg (2014) to be implicitly factorizing a matrix of PMI scores-have recently been employed to study associative processing in high-level judgment, modeling phenomena such as the conjunction fallacy and naturalistic judgment problems (Bhatia, 2017). PMI or explicitly PMI-based methods have been used to cluster terms syntactically and semantically (Bullinaria \& Levy, 2007, 2012), recognize synonyms (Turney, 2001), automatically identify clusters that correspond to different senses of a word's meaning (Pantel \& Lin, 2002), extract linguistic collocations from text (Manning \& Schütze, 1999), and identify patterns of relationships between symptoms in dementia (Mitnitski, Richard, \& Rockwood, 2014), among many other applications.

Because of the range of applications to which PMI and PMI-based methods are applied, any modifications that improved PMI's ability to model human semantic judgments would potentially have benefits for the wide range of computational methods in which it is a component. Furthermore, if a slight modification of some neurally plausible algorithm such as PMI was to produce lexical associations that were as good as those produced by state-of-the-art models (in terms of correlation to human data), it would be worth investigating as a possible computational simplification/abstraction of some process actually taking place within human semantic memory. Finally, simple, computationally efficient yet accurate means of estimating lexical associations are useful within the field of artificial intelligence, as they can more readily be scaled up to larger datasets than can methods that take longer to compute. For all of these reasons, simple measures of lexical association are worthy of closer investigation.

PMI is traditionally defined as follows (Church \& Hanks, 1989):

$$
\operatorname{PMI}(x, y)=\log _{2} \frac{P(x, y)}{P(x) P(y)}
$$

This formulation "compares the probability of observing $x$ and $y$ together (the joint probability) with the probabilities of observing $x$ and $y$ independently (chance)" (Church \& Hanks, 1989, p. 77). Estimating these probabilities is commonly done in a straightforward manner: $\mathrm{P}(x, y)$ is estimated by dividing the number of "contexts" (documents, windows of text, etc.) in which $x$ and $y$ co-occur by the total number of contexts in the corpus, and $\mathrm{P}(x)$ is estimated by
dividing the number of contexts containing $x$ by the total number of contexts in the corpus (and likewise for $\mathrm{P}(y)$ ) (Manning \& Shütze, 1999; Turney \& Pantel, 2010).

## Strengths and Weaknesses of PMI

PMI is a component of many different algorithms that have been fit to behavioral data in the psychological literature. For example, a slight variant of it (PPMI, or 'positive PMI,' which differs only in that negative values are set to zero) has been used directly in lexical vector components in models such as 'PPMI Cosines' (Bullinaria \& Levy, 2007, 2012), and as a preprocessing step to be applied to a matrix prior to singular value decomposition or other matrix factorization techniques. Some algorithms that initially seemed to have little to do with PMI are more linked to it than they first appeared. For example, consider the SGNS algorithm of the popular word embedding tool word2vec (Mikolov, Sustskever, Chen, Corrado, \& Dean, 2013), which has been recently used in studies of metaphor perception and associative processing (Agres et al., 2016; Bhatia, 2017), and is responsible for the Google Word2Vec dataset recently described as one of several "data sets with potential relevance for cognitive science" in a recent survey (Goldstone \& Lupyan, 2015, Table 2). Although this algorithm is typically conceived of as a shallow neural network, its core mathematical operations have been shown to be implicitly factorizing the "well-known word-context PMI matrix from the word-similarity literature, shifted by a constant offset" (Levy \& Goldberg, 2014, p. 2177). The same appears to be true of an alternative embedding method known as noise-contrastive estimation (Levy \& Goldberg, 2014). In fact, much of the advantage that "predictionbased ${ }^{1 "}$ models such as word2vec's SGNS initially seemed to hold over more traditional distributional models (Baroni, Dinu, \& Kruszewski, 2014) appears to be due to word2vec's exploitation of 'hyperparameters' -i.e., miscellaneous operations such as smoothing and subsampling (Levy, Goldberg, \& Dagan, 2015). When these more traditional vector space models are enhanced with analogous hyperparameters, they tend to do as well as prediction-based models (Levy et al., 2015).

Given the ubiquity of PMI in computational models of semantic relatedness, it seems that this measure must be capturing something important. Yet the measure is wellknown for its weaknesses. The most fundamental of these is "frequency bias," PMI's tendency to over-weight cooccurrences involving low-frequency words (Levy et al., 2015; Manning \& Shütze, 1999; Turney \& Pantel, 2010). One way to think about the cause of this problem is that although probability estimates are more accurate when they are made on the basis of lots of data (e.g., frequent words) than on sparse data (infrequent words), the formula for PMI

[^447]does not account for this fact. On the contrary, the less frequent the words, the lower the denominator and the larger the result. Thus a chance co-occurrence between two rare words that each occur only once in a large corpus will result in an exceedingly high PMI. Because Zipf's law entails that any corpus will have many more infrequent than frequent lexical types, this problem is pervasive.

## Addressing PMI's Weaknesses

Given the fundamental difficulties inherent in estimating cooccurrence probabilities from infrequent words, various adjustments to PMI have been proposed to mitigate the problem. Here we consider one commonly proposed solution (down-weighting co-occurrences involving lowfrequency words in some way, to counter PMI's tendency to over-weight them), and one solution that we have not previously seen proposed (adjusting how 'co-occurrences' are defined/counted).

Down-weighting. The probabilities in the denominator of the PMI formula naturally down-weight co-occurrences involving frequent words. This is a desired property; without the denominator, the most "associated" words with virtually any term would be "the," "of," and many other words that occur very frequently across the board. As previously mentioned, however, PMI (and PPMI) have the opposite problem, in that the words these measures deem to be most semantically related to a word $w$ "are often extremely rare words, which do not necessarily appear in the respective representations of words that are semantically similar to w" (Levy et al., 2015, p. 213).

As such, several modifications to PMI have been proposed, many of which are enumerated in Table 1. The ultimate goal of all of these is to cause low frequency words to be ranked less highly than in the standard PMI formula. Some further adjustments have been proposed which rely on information other than the co-occurrence counts and frequencies of the words whose association is being calculated. Because these rely on additional information, there is sometimes a fine line between such modifications of PMI and novel distributional models, and they often have additional parameters. Yet other measures, such as $\mathrm{PMI}^{2}$, have been shown to be monotonic transformations of other measures already appearing in Table 1 (Evert, 2005). We confine our comparisons in Study 1 to only the simplest measures, i.e., measures that, when computing the degree of association between words $w_{1}$ and $w_{2}$, rely only upon the corpus-wide counts $f\left(w_{1}\right)$ and $f\left(w_{2}\right)$, and the co-occurrence counts $f\left(w_{1}, w_{2}\right)$.

Counting. It is clear that there is variation in the literature with respect to the manner in which the probabilities involved in PMI are estimated. For example, several researchers report estimating $\mathrm{P}(x)$ the as frequency of $x$ divided by the number of words in the corpus (Church \& Hanks, 1989; Islam \& Inkpen, 2008), while others use the number of documents in which $x$ appears divided by the
number of documents in the corpus (Manning \& Shütze, 1999; Turney, 2001; Turney \& Pantel, 2010). Similarly, many authors mention that they use the "number of cooccurrences" of $x$ and $y$ to estimate $\mathrm{P}(x, y)$, without specifying exactly what counts as a "co-occurrence." A reasonable assumption is that in some cases this is shorthand for "the number of contexts/documents in which $x$ and $y$ co-occur," and indeed this seems to be approach of some authors who spell out their calculations in detail (Manning \& Shütze, 1999; Turney, 2001; Turney \& Pantel, 2010). A more literal interpretation of "number of co-occurrences"-and perhaps the one intended by at least some of the authors who have used this phrase-would be that this refers to the number of co-occurrence events. For example, in the sentence context "Tiger, tiger, burning bright," the word type tiger can be conceived of as cooccurring with bright twice (one co-occurrence for each instance of tiger $)^{2,3}$. We will refer to this method of cooccurrence counting as "event-based counting," as contrasted from the "context-based" method of counting the number of contexts/documents in which $x$ and $y$ appear together. Event-based counting attends to the information available in the corpus at a more fine-grained level than does context-based counting, as it distinguishes between contexts in which word pairs might appear many times and contexts in which they might appear together only a single time. As such, it can be seen as increasing the overall amount of evidence about word associations that go into the estimation of the probabilities.

## Study 1

Down-weighting and event-based counting each have the potential to address PMI's frequency bias-the former by compensating for the fact that rarer words provide weaker evidence, and the latter by bolstering the overall amount of evidence that the measure takes into account. In Study 1, the success of each approach is evaluated individually and in combination. Table 1 provides the formulae for each of the down-weighting methods surveyed in the previous section, with citations provided in footnotes. Some methods, namely $\mathrm{SCI}, \quad \mathrm{SCI}_{\text {sig }}$, and context distribution smoothing, are asymmetric and distinguish between a cue word $x$ and a response word $y$.

In theory, either context-based or event-based counting could be used with any one of these measures. With contextbased counting, $P(x, y)$ is estimated by dividing the total number of contexts in which $x$ and $y$ appear together by a constant factor, namely the total number of contexts in the corpus (Turney \& Pantel, 2010). Analogously, with eventbased counting, it makes sense to divide the number of co-

[^448]occurrence events in which $x$ and $y$ appear together by the total number of co-occurrence events in the corpus $\sum_{i}^{N} \mid$ context $_{i} \mid\left(\mid\right.$ context $\left._{i} \mid-1\right)$. In practice, however, the specific value here is irrelevant, as it merely serves to scale all PMI scores by a constant factor.

Analogously, to estimate the 'global' or 'corpus-wide' probability $\mathrm{P}(x)$ of observing a word, we can either count the total number of contexts in which $x$ appears (contextbased counting), or we can count $x$ 's raw frequency - the total number of times $x$ appears anywhere in the corpus (event-based counting), and divide the result by the relevant constant factor (number of contexts, or number of cooccurrence events).

Some of the measures in Table 1 call for the use of cooccurrence frequencies $f(x, y)$ or global frequencies $(f(x)$, $f(y))$. These are counted as previously described, except that they are not divided by a constant factor.

Table 1: Methods for down-weighting PMI scores.

| Method | Formula |
| :---: | :---: |
| "Discount factor" ${ }^{4}$ | $\left(\frac{f(x, y)}{f(x, y)+1}\right)\left(\frac{\min (f(x), f(y))}{\min (f(x), f(y))+1}\right) p m i$ |
| $\mathrm{SCI}^{5}$ | $\frac{P(x, y)}{P(x) \sqrt{P(y)}}$ |
| $\mathrm{PMI}_{\text {sig }}{ }^{5}$ | $\sqrt{\min (P(x), P(y))}\left(\frac{P(x, y)}{P(x) P(y)}\right)$ |
| $\mathrm{SCl}_{\text {sig }}{ }^{5}$ | $\sqrt{\min (P(x) P(y))}\left(\frac{P(x, y)}{P(x) \sqrt{P(y)}}\right)$ |
| gmean ${ }^{6}$ | $\frac{f(x, y)}{\sqrt{f(x) f(y)}}$ |
| Context distribution smoothing ${ }^{7}$ | $\log \left(\frac{P(x, y)}{P(x) \frac{f(y)^{\alpha}}{\sum_{i} f(i)^{\alpha}}}\right)$ with $\alpha=0.75$ |

## Method

Word pair lists were obtained for all semantic relatedness tasks evaluated in Recchia and Jones (2009), namely the tasks of Miller \& Charles (1991), Resnik (1995), Rubenstein \& Goodenough (1965), and Finkelstein et al. (2002). Because the latter task conflates judgments of semantic similarity (\{car, truck\}) with judgments of semantic relatedness (\{car, road\}), we used the version of this task that had been partitioned into the so-called "WordSim Similarity" and "WordSim Relatedness" subsets (Agirre et al., 2009). Also included was an additional similarity task, SimLex-999 (Hill, Reichart, \& Korhonen, 2014) and two additional relatedness tasks referred to in the literature as

[^449]MEN (Bruni, Boleda, Baroni, \& Tran, 2012) and MTurk (Radinsky, Agichtein, Gabrilovitch, \& Markovitch, 2011).

Raw PMI scores as well as each of the down-weighting metrics in Table 1 were calculated for every word pair in each relatedness and similarity task ${ }^{8}$, using a version of the Westbury Lab Wikipedia Corpus (Shaoul \& Westbury, 2010) with punctuation removed and capital letters converted to lower case. The resulting corpus contained 3,035,070 documents and approximately 1 billion words. Each metric was computed with context-based counting as well as with event-based counting as described in detail on the previous page. Rather than a window size, terms were treated as 'co-occurring' if they appeared in the same document (i.e., Wikipedia article).

Additionally, to get a sense of how these metrics stack up against what are perhaps the most popular distributional models today-the word2vec CBOW and SGNS modelswe trained each word2vec model on the same corpus using the default settings recommended by Google ${ }^{9}$, and used the resulting vectors to estimate semantic relatedness in the standard manner (e.g., computing cosines between 300dimensional vectors). Comparing to distributional models whose parameters have not been optimized for the tasks at hand is in some ways an unfair comparison. Nevertheless, word2vec's 'off-the-shelf' parameters are the ones most frequently employed when word2vec is used in real-world settings. As usual, Spearman rank correlations were computed between each metric and the human judgments provided by each relatedness and similarity task.

## Results

Down-weighting methods. The only down-weighting methods tested that were consistently as good as or better than the standard PMI formula were the discount factor of Pantel \& Lin (worse performance than raw PMI on 1 of the 8 tasks when using context-based counts, 2 tasks when when using event-based counts) and the "context distribution smoothing" of Levy et al. (worse performance than raw PMI on only 1 task, irrespective of counting method employed). All other down-weighting methods exhibited worse performance than raw PMI on over half of all tasks regardless of counting method. Table 2 illustrates Spearman rank correlations between human judgments and these best-performing down-weighting methods using context-based counting, event-based counting, and the two word2vec models.

Counting methods. Restricting ourselves to the downweighting methods that produced reliable improvements, event-based counting resulted in higher correlations to human data than did context-based counting on all tasks except for SimLex-999. Across all tasks, using event-based

[^450]rather than context-based counting increased correlations by an average of 2.7 points for context distribution smoothing, 4.2 points for the discount factor, and 4.9 points for raw PMI scores.

Table 2: Correlations with human judgments of semantic relatedness (tasks 1-5, 7) and similarity (6, 8).

| Task number (see Note below) |  |  |  |  |  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :--- | :--- | :--- | :---: |
| Method | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |  |
| CDS, Context | .68 | .75 | .58 | .83 | .82 | .32 | .64 | .73 |  |
| DF, Context | .63 | .75 | .51 | .85 | .81 | .30 | .57 | .66 |  |
| PMI, Context | .62 | .74 | .50 | .84 | .78 | .30 | .57 | .66 |  |
| CDS, Event | $\underline{.72}$ | $\underline{.81}$ | .58 | $\underline{.87}$ | $\underline{.86}$ | .27 | $\underline{.68}$ | .76 |  |
| DF, Event | .70 | .79 | .55 | .86 | .83 | .29 | .66 | .72 |  |
| PMI, Event | .70 | .79 | .55 | .86 | .82 | .29 | .66 | .72 |  |
| SGNS | .71 | .77 | .64 | .82 | .75 | .30 | .62 | .75 |  |
| CBOW | .67 | .71 | .56 | .73 | .67 | .32 | .47 | .72 |  |

Note. CDS: context distribution smoothing, DF: discount factor; PMI: unmodified PMI; SGNS: word2vec skip-grams with negative sampling; CBOW: word2vec 'continuous bag of words'; "Context" and "Event" refer to the counting method used. Task numbers refer to the judgments of semantic relatedness/similarity compiled by 1 : Bruni et al. (2012); 2: Miller \& Charles (1991); 3: Radinsky et al. (2011); 4: Resnik (1995); 5: Rubenstein \& Goodenough (1965); 6: Hill et al. (2014); 7: WordSim-Relatedness (Agirre et al., 2009); 8: WordSim-Similarity (Agirre et al., 2009). The highest correlation for each task appears in bold.

## Discussion

Down-weighting and event-based smoothing both confer advantages when PMI is used to estimate semantic relatedness judgments. Specifically, the combination of context distribution smoothing (CDS) and event-based counting performed best for all datasets except for two. Each of these was a dataset on which the various versions of PMI all performed poorly. When SimLex-999 was constructed (Hill et al., 2014), respondents were given explicit instructions about the difference between similarity and relatedness, and told to judge similarity only. PMI has no mechanism for distinguishing between related and similar terms, and does not detect relationships between paradigmatically related terms (which tend to be similar) as well as SGNS does. It is not clear why all metrics did well on WordSim-Similarity, but one reason may be that Agirre et al. (2009) did not specifically instruct participants to rate word pairs based on their similarity. Rather, they created WordSim-Similarity with the original judgments from Finkelstein et al. (2002), which had instructions that conflated relatedness and similarity, but they excluded related word pairs that did not share a formal similarity relation (synonymy, antonymy, hyponymy, etc.)

Why does context distribution smoothing work? Given that the $\sum_{i} f(i)^{\alpha}$ term is constant for any fixed value of $\alpha$,
the only thing that really seems to distinguish CDS from the other discounting methods is its use of $\alpha$ (set to .75) in the exponent of $f(y)$. Furthermore, since $\mathrm{P}(y)$ is estimated by dividing $f(y)$ by another constant, context distribution smoothing is closely related to the much more poorly performing SCI metric of Washtell \& Markert (2009), $\frac{P(x, y)}{P(x) \sqrt{P(y)}}$, which merely raises $\mathrm{P}(y)$ to the power of .5 rather than 75 .

Why would there be anything special about .75 ? One possibility is that this value strikes the proper balance between raising $\mathrm{P}(y)$ to the value of 0 (which would ignore the frequency of $\mathrm{P}(y)$ and result in a measure that was highly correlated with $y$ 's frequency), versus raising $\mathrm{P}(y)$ to the value of 1 (yielding PMI, which is known to give outsize values to infrequent words and is thus likely inversely correlated with frequency). In other words, down-weighting may be optimal when it yields a measure that is neither positively nor negatively correlated with word frequency. This possibility is briefly explored in Study 2.

## Study 2

To find the $\alpha$ for which CDS yields a correlation with word frequency as close to zero as possible, $\alpha$ was fit so as to minimize the absolute value of the Spearman rank correlation between word frequency ${ }^{10}$ and CDS. Because there is no reason in this context to modify $\mathrm{P}(\mathrm{y})$ but not $\mathrm{P}(\mathrm{x})$, the same was done for a generalization of the gmean measure, "simple" smoothing, defined simply as $\log \left(\frac{P(x, y)}{P(x)^{\alpha} P(y)^{\alpha}}\right)$. Finally, the value of $\alpha$ that maximized correlations to human data was determined for both measures. Event-based counting was used in all cases due to its superiority over context-based counting in Study 1.

Table 3 illustrates the values of $\alpha$ that minimized the absolute value of the correlation between the measure and word frequency, while Table 4 shows values of $\alpha$ that maximized correlations with human judgments.

Table 3: Values of $\alpha$ that minimized absolute value of correlations with word frequency (Study 2)

Task number (see Note below Table 2)

| Measure | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| CDS | .85 | .77 | 1.0 | .76 | .78 | .74 | .77 | .72 |
| Simple | .91 | .82 | 1.0 | .79 | .85 | .84 | .84 | .82 |

Table 4: Values of $\alpha$ that maximized correlations with human judgments (Study 2)
Task number (see Note below Table 2)

| Measure | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| CDS | .77 | .80 | .52 | .80 | .74 | .97 | .76 | .74 |
| Simple | .85 | .81 | .76 | .81 | .81 | 1.0 | .84 | .87 |

[^451]
## Discussion

For CDS, the values of alpha that minimized the absolute value of the measure's correlation to word frequency (median .77) were not far off from the values of alpha that maximized correlations to human judgments (median .765), with the greatest discrepancies being on those tasks on which CDS did not perform well in Study 1 (\#3 and \#6). The same was true of simple smoothing (medians .84 and .825 , respectively). This suggests that explicitly finding ways to minimize the degree to which lexical measures of association are confounded with word frequency and other covariates could be a promising path toward improving their ability to model human data. Other future directions could include more in-depth exploration of why $\alpha$ so closely corresponds to those values that maximized correlations to human judgements. For example, if an experimental study showed that the same was true of study participants making judgments about the relatedness of words in an artificial language, even when this value was not equal to .75 , this would provide better evidence that the human mind employs some process that makes an explicit correction for lowfrequency events analogous to that proposed by CDS.

It should not be concluded from the results of Studies 1 and 2 that PMI is more effective in isolation than distributional models such as word2vec. It should also be noted that not all datasets are independent. For example, the word pairs in Miller \& Charles (1991) and Resnik (1995) are subsets of Rubenstein \& Goodenough (1965), so it is unsurprising that a measure that does well on one would do well on all three. Even so, the fact that the use of eventbased counting and CDS down-weighting causes PMI to generally outperform word2vec on its default settings suggests that PMI may be a better abstraction of human relatedness judgments than it is commonly understood to be. Furthermore, given that PMI has so many different applications within cognitive science and is a component of so many models of lexical processing, any improvements to this measure have the potential to improve model fits across a wide range of computational studies of cognition.

# Priming the production of implications 

Alice Rees (reesa34@cardiff.ac.uk)<br>Department of Psychology, Tower Building, 70 Park Place<br>Cardiff, CF10 3AT UK<br>Lewis Bott (Bottla@cardiff.ac.uk)<br>Department of Psychology, Tower Building, 70 Park Place<br>Cardiff, CF10 3AT UK

#### Abstract

We present two experiments investigating the production of implicit constructions. Using a confederate scripting paradigm we find that after making an inference participants were more likely to subsequently produce an implicature. This effect occurred at a global and a local level and was unaffected by the perceived role of the conversational partner. Our findings demonstrate that the choice of whether to be implicit is determined by the activation levels of representations specific to implicatures and that inference and implications have overlapping processing representations.

Keywords: Priming; Scalar Implicatures; Speech Production; Inferring

## Producing implications

During conversations speakers have to make a variety of decisions about the message they wish to convey. These decisions include what lexical material to include, what syntactic forms to use, and whether or not to communicate explicitly or implicitly. When communicating implicitly the onus is on the listener to enrich the utterance to reach the speaker's intended meaning.

Research into language production has predominantly focused on speaker's choices of explicit material. That is, their choices of which lexical items to use or which syntactic constructions to use (e.g. Bock \& Levelt, 1994; Levelt, Roelofs, \& Meyer, 1999; Pickering \& Branigan, 1998). In this paper, we focus on the speaker's decision to be implicit or explicit in their speech. Consider the following:

1. A: "Did John eat the cookies?"

B: "He ate some of them."
=> John ate some but not all of the cookies.
2. A: "Have you met Lucy's new boyfriend? He's handsome and intelligent!"
B: "He's handsome."
=>He's not intelligent.
In these exchanges B's utterance conveys more than what is explicitly coded. In (1) B's utterance leads to the inference John ate some but not all of the cookies. This inference arises through the following steps (based on Grice, 1989): (i) speaker A recognises that B could have said "he ate all of them." (ii) Since B did not say this, and assuming B is cooperative, A can infer that "he ate all of them" is not true; (iii) combining what is said with the negation of the
alternative leads to the inference that "John ate some but not all of the cookies." Similar reasoning can be used for (2). Speaker B could have said "Yes, I agree" or "He is handsome and funny." By not saying these A could infer that B thinks Lucy's boyfriend is not handsome. The result of this reasoning process was termed implicatures by Grice (1989).

Since Grice's seminal work, implicatures have been analysed in great detail. For example, there are analyses from the perspective of theoretical semantics (e.g., Chierchia, 2004), acquisition (e.g., Noveck, 2001), clinical disorders (e.g. Chevallier, Wilson, Happé, \& Noveck, 2010), and sentence processing (e.g., Bott \& Noveck, 2004). What all previous work has in common, however, is that they are from the perspective of the listener, and not the speaker. Here we ask how the speaker makes the choice about whether to make an implication ${ }^{1}$.

## Why imply?

Why does a speaker imply when they could be explicit? One reason is that using implicatures is efficient for a speaker. Since articulation is much slower than speech preparation processes, reducing the amount of material to be articulated reduces this articulatory bottleneck and arguably minimises speaker effort while maximising their benefits (Grice, 1989; Horn, 2004; Levinson, 2000; Wheeldon \& Levelt, 1995). Another reason is that implicatures are used out of politeness. Implicatures can be used to maintain face (Bonnefon, Feeney, \& Villejoubert, 2009; Brown \& Levinson, 1987; Feeney \& Bonnefon, 2013; Goffman, 1967; Holtgraves \& Perdew, 2016). In face threatening contexts listeners interpret the use of implicatures as a speaker's attempt at politeness.

Efficiency and politeness provide intuitive explanations for why people use implicatures. However, it is unclear how these socio-pragmatic factors interact with the language processor. One possibility is that social factors modulate the activation of representations specific to the implicature process. That is, there are representations specific to implicatures and the activation of said representations underlie the production and comprehension of implicatures. We present two experiments to investigate this.

[^452]
## Implicit representations

During conversations interlocutors tend to repeat linguistic structures that they have recently heard or produced. This repetition is known as structural priming (e.g. Bock, 1986). Structural priming occurs throughout the language system in production (Brennan \& Clark, 1996; Bock, 1986; Levelt \& Kelter, 1982; Branigan, et al, 2000; 2005) and comprehension (Sturt, Keller, \& Dubey, 2010; Thothathiri \& Snedeker, 2008), and in different languages (Hartsuiker \& Westenberg, 2000; Scheepers, 2003). There is a general consensus that successful priming of a particular structure indicates the presence of a corresponding representation within the language system whereas unsuccessful priming indicates the absence of such a representation (Branigan, Pickering, Liversedge, Stewart, \& Urbach, 1995; Pickering \& Ferreira, 2008).

Priming is not restricted to explicit linguistic forms; Raffray, Pickering, Cai, \& Branigan (2013) found that after encountering a coerced sentence individuals were more likely to subsequently produce a coerced sentence than after a fully-formed sentence. Sentences involved coercion are ambiguous. For example, "The author finished the book" is ambiguous; the verb finish requires a complement that specifies an event. For a comprehender to interpret the sentence they must undertake an enrichment process which coerces the noun into the correct semantic type. Since individuals were more likely to subsequently produce a coerced sentence after comprehending or producing a coerced sentence than after a full-formed sentence Raffray et al. suggested that there are distinct representations corresponding to coerced and full-form sentences i.e. there are distinct representations involved in implicit and explicit language. While the sort of implicit language used by Raffray et al. is very different to Gricean implicatures, their study nonetheless demonstrates that it is possible to prime the choice between using more or less linguistic material.

Further support comes from Bott and Chemla (2016). They showed that that after deriving a Gricean enrichment participants were more likely to subsequently derive an enrichment. This held both within and between enrichment categories. They suggested that there was a mechanism which underlies the derivation of enrichment and after making an enrichment these mechanisms retain some activation which increases the likelihood of making a subsequent enrichment. However, their findings relate to comprehension (and not production), and so do not illustrate how the speaker chooses between an implicit and an explicit construction.

The success of communication can, in part, be ascribed to priming. Representations that are shared between the comprehension and production system reciprocally activate each other so that after comprehending a particular structure the speaker is more likely to use that structure. Consequently interlocutors develop similar representations of linguistic structures and thus become aligned via priming (Pickering \& Garrod, 2004). We propose that the same
occurs for the production of implicit and explicit constructions. There are specific representations which underlie implicit communication and the activation level of these determines whether or not a speaker produces an implicit construction. Thus in a dialogue if one speaker is using implicit constructions it is likely that their conversational partner will also produce implicit constructions since the representations used to comprehend the utterance will have an activation advantage over other representations that were not used. Thus these representations can be primed. We test this using a confederate-scripting priming paradigm adapted from Branigan, Pickering \& Cleland, 2000).

## Experiment 1

A participant and a confederate took turns describing and identifying a referent card from a set of four. These cards consisted of rectangles containing either one or two images (see Figure 1). Cards were displayed on two separate screens (one for the participant and one for the confederate), and neither party could see each other's screen. The referent card was identified to the speaker by being embedded in a bold square, but not to the listener. The task for the speaker was to communicate to the listener which of the cards was the referent card.

The structure of the images in the display were the same on each trial. Figure 1 shows the structure (left panel) and an example trial. The experimental cards were the A and AB cards. Here, one of the images was duplicated (a pencil in the example). This meant that to communicate that the A card was the referent, the speaker could choose between an implicit construction, "The card with the pencil," in which they relied on the listener making an inference, or an explicit construction, "The card with the just the pencil," in which a modifier removed the ambiguity about which image was the referent. Whether the participant (as speaker) chose an explicit or an implicit form was the dependent measure.

There were two forms of priming. The first was a between subjects manipulation in which one group of participants were exposed to predominantly implicit constructions and the other to predominantly explicit constructions. The second was a within-subjects manipulation in which the sequence of trials was designed to prime an implicit or an explicit construction from the participant.

Our hypotheses were as follows. If there are representations corresponding to implicatures, and if they can be activated or deactivated during conversation, we expect more explicit constructions in the explicit global priming condition than in the implicit condition. Similarly, if implicature representations can be activated at a local level, trials in which the confederate uses an implicit construction should be followed by more implicit constructions than trials where the confederate used an explicit construction.

Figure 1. Example trials. Left panel shows the object structure. Right panel shows an example trial.

## Method

Participants. 35 Cardiff University undergraduate students participated for either payment or course credit.
Materials and Design. On each trial the interlocutors were presented with four cards, each containing one or two images. Images were organized in the same structure (see Figure 1). Both interlocutors would see the same set of four cards however, on prime trials the confederate's screen would also display the description to use. The confederate's descriptions always named a single image, e.g. in Experimental trials the confederate would describe the AB card as "The card with the $[\mathrm{B}]$ ". Experimental trials referred to either the A or the AB card and filler trials referred to the C or DE card.

All trials were organized into pairs such that the confederate described a prime trial and the participant described a target trial. For experimental items there were A , and AB primes and targets, thus there were 4 primetarget combinations. There were 8 examples of each combination resulting in 32 experimental pairs. Filler items were 32 pairs of C and DE trials. An additional 8 practice pairs were presented at the start of the experiment to allow participants to get used to the experimental procedure. Consequently there were 32 experimental pairs +32 filler pairs +8 practice pairs $=144$ items in total.
Items were presented in a fixed pseudorandom order. Experimental pair presentation was alternated with filler pairs. To prevent any findings from being attributable to order effects we reversed the presentation order of the pairs to make two separate lists.

The dependent variable was the construction used by participants to describe the card in target trials. Responses which used a single, unmodified referent were coded as implicit and responses that used two referents or a modified single referent were coded as explicit.

Global priming. Global priming tested whether participants would imitate the conversational style of their partner. Since the A item was duplicated across the A and AB cards, describing the A card was potentially ambiguous. The confederate could either use an implicit description "The card with the $[\mathrm{A}]$ ", which required the participant to derive an inference (A and nothing else), or use an explicit description "The card with just the [A]". In the implicit condition the confederate described the A card implicitly, using an unmodified referent. In the explicit condition the confederate always used a modifier.

Local priming. Local priming tested whether we could prime the implicature representations on a trial by trial basis. This was achieved by manipulating the sequence of prime-target trials. There were two prime types (A cards, AB cards) and two target types (A cards, AB cards), thus there were four prime-target sequences: $\mathrm{A}-\mathrm{AB}, \mathrm{A}-\mathrm{A}, \mathrm{AB}$ $>\mathrm{AB}, \mathrm{AB}->\mathrm{A}$. In the implicit condition the confederate's description of A cards required participants to make an implicature and consequently raised the activation levels of the implicature representations. The confederate's descriptions of AB cards, conversely, blocked the implicature (since there was no card equivalent to $B$ and nothing else) and therefore lowered the activation levels of the implicature representations. Consequently A->A sequences should yield higher proportions of implicature production (unmodified single referent descriptions) than $\mathrm{AB}->\mathrm{A}$ sequences. The reverse should hold for $\mathrm{A}-\mathrm{AB}$ descriptions; rates of implicatures should be high following A trials, participants would avoid unmodified single item descriptions for AB cards and instead use a conjunction ("The card with the scooter and skateboard").

## Procedure

The confederate was a female native-English speaking student from the Cardiff University student population. The participant and confederate were sat at opposite sides of a table facing a computer screen. They could not see the other person's screen. The confederate and participant were told that they were "playing a game where they will take turns describing and identifying cards. The same set of cards will be displayed on both computer screens. If you see one with a bold border it is your turn to describe. To make a guess about which card your partner was describing press one of the four keys corresponding to the position of the card on the screen. Do not speak to your partner except to describe the card". Participants were not allowed to describe the position of the card on the screen but, if they needed their partner to, they could ask for their partner to repeat their description.

## Results

Each participant produced 32 target responses. Of the 1120 responses 22 were excluded due to experimenter error. To ensure that participants were paying attention to the confederate's descriptions we looked at key press responses to prime trials. Participants selected the correct card $98 \%$ of the time. Therefore we can be confident that they were paying attention to the confederate.

Data underwent a logit transformation and were analysed using a $2 \times 2 \times 2 \times 2$ Mixed ANOVA. Prime type (A-card and AB -card) and target type (A-card and AB-card) were within-subjects factors and description form (implicit and explicit) and list were between-subjects factors.

Global priming. Participants adopted the conversational style of their partner. When their partner was using implicatures, participants were more likely to also use implicatures $(\mathrm{F}(1,31)=125.11, p<.001)$.

Figure 2. Proportion of implicit responses in implicit and explicit group.

Local priming. We also manipulated which card was described. Whilst there was no effect of prime $(\mathrm{F}(1,31)=$ $1.98, \mathrm{p}=.169)$ or target $(\mathrm{F}(1,31)=1.88, \mathrm{p}=.180)$ there was an interaction between prime and target $(\mathrm{F}(1,31)=$ $8.08, \mathrm{p}=.008$ ). When participants had to describe an A-card target they produced more implications after they had made an inference (A-prime). When participants had to describe an AB target they produced fewer implications after they had made an inference. This is consistent with there being specific representations involved in producing implicatures.

Figure 3. Proportion of implicit responses to A and AB targets by participants in implicit group.

## Discussion

The results suggest that there are representations corresponding to implicatures that can be activated and deactivated during conversation. After comprehending an implicature the representations involved had an activation advantage over other representations that were not used. Consequently these implicature representations were more likely to be used in subsequent speech production. After cancelling an implicature, the implicature representations' activation was suppressed thereby reducing the likelihood of them being used for subsequent production.

## Experiment 2

Experiment 1 used a confederate as the interlocutor. However, we have no way of knowing whether participants believed our deception. Our results could therefore be a
consequence of participants believing that the conversational partner was an experimenter. In Experiment 2 we tested this by manipulating whether the partner was presented as an experimenter or another participant.

There is range of evidence suggesting that the participant could be influenced by the interlocutor's speech characteristics and social status (e.g. Bergen \& Grodner, 2012; Grodner \& Sedivy, 2011; Holtgraves \& Yang, 1990; 1992). For example, Grodner \& Sedivy showed that listeners were less likely to derive an inference when their interlocutor was judged to be an unreliable speaker. We therefore reasoned that our manipulation could have several possible effects on participants' utterances. One was that participants might imitate their partner more in the experimenter condition. Since the partner would be in a position of authority, participants may feel that the best strategy would be to do exactly as the experimenter did. Previous work has shown that imitation is more likely when the partner has higher authority (e.g. Bandura \& Kupers, 1964; McGuigan, 2013). Alternatively, there may be less imitation in the experimenter condition. Since the partner would now be in the participant's social outgroup, there would be less pressure to conform (e.g. Bourgeois \& Hess, 2008; Yabar et al. 2006).

Orthogonal predictions can be reached about the overall levels of implicit language use. Participants might choose to use more implications overall in the experimenter condition. Since the experimenter would generally be in a position of knowledge, there would be little risk of miscommunication by using implications. Alternatively, participants might use fewer implications because if the partner were the experimenter, participants might feel they have to be particularly informative and precise in their responses.

The basic design was exactly the same as Experiment 1. The only difference was that one group of participants were told that the partner was an experimenter and in the other group they were not. In the latter group, there was an experimenter and a confederate, whereas in the former group one experimenter played the role of both experimenter and conversational partner.

## Method

Design and materials were the same as in Experiment 1. Participants. 35 Cardiff University undergraduate students participated for either payment or course credit. Partner manipulation. There were two roles that the conversational partner could play: participant or experimenter. When the conversational partner took the role of a participant the participant was unaware of their partner's involvement in the experiment, just as in Experiment 1. However, when the conversational partner took the role of experimenter, the participant was fully aware of this. The experimenter informed the participant that they would be playing a communication game together and instructed the participant of their task.

## Results

Each participant produced 32 target responses. Of the 1280 responses 49 were removed due to experimenter error.
Partner role. Numerically, participants produced more implicit descriptions when they knew their conversational partner was the experimenter compared to when they thought their partner was another participant (see Fig. 1). Despite the numerical difference this was not statistically significant $(\mathrm{F}(1,36)=1.13, p=30$. $)$. However, experiments investigating social influences often have a larger sample than that of Experiment 2. It is possible that our manipulation was not strong enough, or that our sample size is too small. This is borne out following a Bayesian analysis (Dienes, 2011; 2014; Rouder et al., 2009). Using the default JZS prior we obtained a Bayes Factor of 0.4. This indicates that our data may not be sensitive enough to draw a strong conclusion about the partner role manipulation.

Figure 4. Proportion of implicit descriptions in implicit and explicit group with confederate as participant or experimenter.

There was no interaction between interlocutor role and conversational style $(F(1,36)=.13, p=.73, \mathrm{BF}=0.3)$.
Global priming. We replicated the findings from Experiment 1. Participants in the implicit condition produced more implicit utterances than those in the explicit condition $(\mathrm{F}(1,36)=45.72, p<.001,95 \% \mathrm{CI}=1.97-$ 3.65). This was found irrespective of interlocutor role. The global priming effect was found both when the interlocutor was the experimenter $(\mathrm{F}(1,16)=19.25, p<.001,95 \% \mathrm{CI}=$ $1.53-4.39)$ and the participant $(\mathrm{F}(1,16)=30.06, p<.001$, $95 \% \mathrm{CI}=1.65-3.68$ ).
Local priming. As in Experiment 1 there was no effect of prime $(\mathrm{F}(1,32)=.016, p=.90)$ or target $(\mathrm{F}(1,32)=3.58$, $\mathrm{p}=.068$ ). However, there was an interaction between prime type and target $(\mathrm{F}(1,32)=6.64, p=.015)$. Following an Acard prime participants descriptions of A-card targets were more implicit but when the target was an AB-card descriptions were more explicit.

The general pattern of results was the same when taking each partner role separately. However, there was no significant interaction when the partner was a participant ( F $(1,16)=3.01, p=.10, \mathrm{BF}=0.5)$ or when the partner was an experimenter $(\mathrm{F}(1,16)=4.18, p=.058, \mathrm{BF}=0.4)$. The Bayes Factors give no reason to suggest that these nonsignificant results were anything else but a lack of power.

## Discussion

The main findings from Experiment 1 were replicated: Participants were more likely to produce implicit constructions when their interlocutor was using implicit constructions than when they were using explicit constructions. These effects were shown for local and global priming manipulations.
There appeared to be no influence of the social status of the conversational partner. We found no significant main effects or interactions of the partner manipulation. Global priming effects occurred regardless of the partner role, and local priming effects showed similar patterns in both conditions but were narrowly nonsignificant. Overall, we can conclude that the priming effects we observed in Experiment 1 were not due to particular strategies adopted by participants disbelieving that the partner was another participant.

## General discussion

We presented two experiments demonstrating that the production of implicatures can be primed. After comprehending an implicature participants were more likely to subsequently produce an implicature. This effect was replicated across two studies and was found both within and between participants. Whilst implicatures are an ostensibly pragmatic phenomenon these experiments suggest that there are distinct representations underlying implicatures and it is the activation levels of these representations that are responsible for the production of implicatures.
Previous research has suggested that socio-pragmatic factors influence the decision about whether to use implicit constructions. For example, people might use implicit language to be more polite or to be more efficient (e.g. Holtgraves \& Yang, 1990, 1992; Levinson, 2000). Whilst these factors are likely to be important, our experiments show that they cannot be the only factors involved. In Experiment 1 we did not manipulate any social factors yet participants systematically varied their choice of construction across conditions. In Experiment 2 we manipulated the social status of the conversational partner but found no difference in rates of implicature production as a consequence. Taken together the experiments suggest that there are distinct representations underlying implicatures and their use is not determined entirely by socio-pragmatic factors. Instead, we propose that socio-pragmatic factors may modulate the activation levels of the implicature representations but further work is needed to address this.
Finally, the priming effects we demonstrate speak to the interaction between deriving an inference and producing an implication. Inferring and implying must necessarily use different representations (since one involves comprehension and the other production) but if they were entirely separate we would not have observed priming effects. That deriving an inference primes the production of an implication shows that the representations involved in the two processes overlap. Exactly which representations are used in both, and
which are restricted to the individual processes, is a topic for future research.

## Conclusion

Our study makes three novel contributions. We have shown (1) that people can be primed to produce Gricean implicatures (2) that there are factors other than the sociopragmatic that determine whether a speaker uses an implicit construction (3) that inferring and implying share overlapping mechanisms.

# How could a rational analysis model explain? 

Samuli Reijula (samuli.reijula@helsinki.fi)<br>TINT / Social and Moral Philosophy<br>PO BOX 24, 00014 University of Helsinki, Finland

#### Abstract

Rational analysis is an influential but contested account of how probabilistic modeling can be used to construct nonmechanistic but self-standing explanatory models of the mind. In this paper, I disentangle and assess several possible explanatory contributions which could be attributed to rational analysis. Although existing models suffer from evidential problems that question their explanatory power, I argue that rational analysis modeling can complement mechanistic theorizing by providing models of environmental affordances.

Keywords: probabilistic modeling; rational analysis; scientific explanation; mechanism; affordance

## 1. Introduction

During the past two decades, probabilistic modeling has become one of the most visible strands of cognitive modeling alongside connectionism, dynamical systems, and rule-based approaches. Curiously, against the general trend in the psychological sciences where theorizing is increasingly anchored in neuroscience findings, probabilistic modeling of higher cognition has been a characteristically top-down endeavor. Without making any substantial commitments about the underlying cognitive mechanisms, probabilistic modeling has been applied to complex aspects of human cognition, which still largely remain beyond the reach of mechanistic research methods. Models of human memory, categorization, causal learning, concept learning, and conditional inference, to mention a few applications, often show an impressive fit to empirical data, and the novel analyses of cognitive capacities provided by the models appear to have shed new light on the nature of the studied phenomena.

However, how does that shedding light actually occur how do such computational probabilistic models explain? Although probabilistic modeling, in principle, does not rely on any particular method of explanation (and not all models aim to be explanatory), modelers often refer to the idea of rational analysis as the account of how and why their models help us understand the mind (Anderson 1990; Oaksford \& Chater 2007). The striking claim made by rational analysis (RA) modelers is that by treating higher cognitive capacities as forms of inductive inference, we can predict behavior, and explain a lot about human cognition without making any assumptions about the underlying representations and processes. This agnosticism about implementation is typically justified by making reference to a rationality assumption: We know that human agents tend to be well-

[^453]adapted to their environment, and hence a careful analysis of the cognitive task encountered by the mind, coupled with an assumption of the optimality of human behavior in the task, results in a putatively powerful methodology of prediction and explanation.

However, it is a widely-held view in the philosophy of science that explanations, also in the cognitive sciences, should track causal mechanisms, and the way that RA purports to sidestep the evidential and explanatory problems arising from the causal complexity of cognition has given rise to a strongly polarized debate (see, e.g., Jones \& Love 2011). On the one hand, the way that the new mathematical methods in probabilistic modeling can capture the interplay of structure and learning in human thought has led to the emergence of an exciting research paradigm. On the other hand, the proponents of non-mechanistic (or even noncausal) explanation need to show when and how it is that such models genuinely explain rather than only redescribe or merely formally unify various phenomena (see Colombo \& Hartmann 2017). Failing to do that, rational analysis could simply be seen as the last breath of the autonomist dream of studying the mind independently from the brain.

The goal of this paper is to advance the debate by disentangling various explanatory contributions which can be attributed to RA models. By relying on the influential contrastive-counterfactual account of explanation, I distinguish between three possible explanatory contributions: Uncovering (a) constitutive dependencies in cognitive systems (i.e. dependencies between parts and wholes), (b) environment-behavior dependencies, and (c) environmentoptimal behavior dependencies. ${ }^{1}$ I argue that often the option (c) best describes the nature of the new understanding provided by RA models: In many cases, RA models should be interpreted as being explanatory not of human behavior as such, but of environmental affordances. Consequently, well conducted modeling of environmental affordances can complement mechanistic theorizing by providing resources for understanding the possible space of behavior of agents.

## 2. Probabilistic modeling and rational analysis

### 2.1 Procedure of rational analysis

The idea of rational analysis modeling dates back to John Anderson's work on human memory and categorization in The Adaptive Character of Thought (1990). Having already worked on his ACT* cognitive architecture, the new methodology put forward in the book reflected Anderson's
increasing worries that the research methods of the time could not really uncover cognitive mechanisms. Lacking a clear picture of what it is that cognitive mechanisms do (i.e. what the psychological explananda are), the available evidence of cognitive processes and their neural implementation was insufficient to uncover the mechanistic architecture of the human mind (Anderson 1990, pp.23-26). Compared to bottom-up research strategies, rational analysis begins from the other end:

> [...] We can understand a lot about human cognition without considering in detail what is inside the human head. Rather, we can look in detail at what is outside the human head and try to determine what would be optimal behavior given the structure of the environment and the goals of the human. (Anderson 1990, p.3)

According to Anderson, careful mathematical modeling of the environment and task structure combined with an assumption about the optimality of human behavior leads to a new self-standing research strategy for understanding the mind: "As this book is evidence, a rational analysis can stand on its own without any architectural theory" (ibid.). By providing a precise model of what the mind does, rational analysis can constrain the search space for cognitive mechanisms, and, putatively, put the scientific study of the mind on a firm foundation.

This view of the role of computational modeling immediately brings to mind Marr's (1982) account of multilevel theorizing. However, whereas Marr provides no systematic account of how computational-level theories are to be constructed, RA modeling has predominantly proceeded according to the six-step cycle proposed by Anderson (1990, p.29):

1. Specify precisely the goals of the cognitive system
2. Develop a formal model of the environment to which the system is adapted
3. Make minimal assumptions about computational limitations
4. Derive the optimal behavior function, given items 1 through 3
5. Examine the empirical evidence to see whether the predictions of the behavior function are confirmed
6. Repeat, iteratively refining the theory

These steps embody an account of how a large part of probabilistic cognitive modeling is done. However, two further assumptions of RA should be made explicit. First, the derivation of optimal behavior in steps 2-4 typically employs probability calculus (not logic) as the normative baseline theory of rational behavior. Secondly, the link between model predictions (step 4) and observed behavior of humans (step 5) is formed by an assumption about the optimality of the observed behavior (see quoted passage above).

[^454]Below I illustrate this process with an example. However, a comment on the status of the approach in cognitive science is in place: Obviously, not all probabilistic modelers endorse the rational analysis framework (see Brighton \& Gigerenzer 2008; Danks 2015; Frank 2013). Focusing on RA is useful for two reasons, however. The approach is undeniably influential, and its core commitments have been endorsed by a large group of well-known modelers (e.g., Anderson 1990; Oaksford \& Chater 1994; Griffiths \& Tenenbaum 2009). A further advantage of focusing on RA has to do with the fact that often the theoretical commitments of mathematical modelers can be hard to pin down. In some cases, the ambiguities are surely due to the modelers themselves not being clear about where their commitments (about how to understand explanatoriness, optimality, etc.) lie. Rational analysis is a clear account of the conceptual foundations of probabilistic cognitive modeling, and provides a starting point, or at least a foil, for explicating such commitments.

To illustrate the rational analysis process, I now briefly introduce Mike Oaksford and Nick Chater's $(1994,2007)$ analysis of the Wason selection task.

### 2.2 The information gain model

Wason selection task is one of the most famous laboratory experiments discussed in the literature on human rationality. In the original form of the task, participants are given four cards, each of which has a letter on one side and a number on the other. The participants' task is to determine whether the rule "If there is a vowel on one side of the card (p), then there is an even number on the other side (q)" holds. More precisely, they are asked to select those cards which must be turned over to discover whether the rule is true or false. The famous finding from the task and its several replications is that only a small minority (less than $10 \%$ ) select the correct cards (vowel, odd number) corresponding to the falsifying instance. That is, judged in the light of logic, most participants fail to perform in a rational way.

Oaksford and Chater (O\&C) challenge the irrationality claim by arguing that logic-based theories of inference and rationality misrepresent the participants' behavior in the task. O\&C's own information gain model suggests that people's apparently irrational way to test a hypothesis should actually be seen as optimal strategy for uncertainty reduction. The gist of O\&C's reinterpretation is that instead of engaging in deductive reasoning, participants interpret the task as an inductive one. They do not try to falsify the rule, but instead they try to determine which of two hypotheses holds:
a) Independence model, $\mathbf{M}_{\mathbf{I}}: \mathrm{P}(\mathrm{q} \mid \mathrm{p})=\mathrm{P}(\mathrm{q})$ or
b) Dependence model, $\mathbf{M}_{\mathrm{D}}: \mathrm{P}(\mathrm{q} \mid \mathrm{p})$ is high, higher than $\left.\mathrm{P}(\mathrm{q})\right)^{2}$

Being initially equally uncertain about both hypotheses, participants aim to reduce this uncertainty as much as possible by turning as few cards as possible.

The rational analysis proposed by O\&C relies on three core principles:

1) Higher cognition can be modeled as probabilistic (Bayesian) computation.
2) The likelihoods and prior probabilities required by the model can be acquired from the analysis of the environment structure.
3) Behavior of human agents constitutes an optimal response to the task.

The model is constructed roughly as follows. To formalize the idea of uncertainty reduction, O\&C adopt the optimal data selection paradigm, and interpret uncertainty reduction as optimizing expected information gain. Information gain $I_{g}(D)$ from turning over a card $(\mathrm{D})$ is defined as $I\left(M_{i} \mid D\right)$ $I\left(M_{i}\right)$ where the Shannon information ${ }^{3} I\left(M_{i}\right)$ can be derived from the probabilities of the hypotheses before and after observing data, $P\left(M_{i}\right)$ and $P\left(M_{i} \mid D\right)$. The required posteriors can be obtained by the Bayes' rule from the likelihoods $P\left(D \mid M_{i}\right)$ and the prior probabilities of the hypotheses. Reflecting initial ignorance, the priors were set to 0.5 and hence the rest of the crucial model specification is built into the likelihoods, which reflect the nature of the four-card task. Oaksford and Chater (1994) show in detail how the required likelihoods can be read off the contingency tables describing the two hypotheses.

From these derivations, it follows that the base rates of $p$ and $q$ have a central role in determining which behavior is optimal. They describe how frequently positive instances of the antecedent and consequent of the rule appear in the environment. Qualitatively, the expected information gain from each of the four cards turns out to depend on the base rates $\mathrm{P}(p)$ and $\mathrm{P}(q)$ in the following way:

| $\mathrm{P}(\mathrm{q})$ is small | $\rightarrow \mathrm{p}$ card is informative |
| :--- | :--- |
| $\mathrm{P}(\mathrm{p})$ is large | $\rightarrow$ not- q card is informative |
| $\mathrm{P}(\mathrm{p})$ and $\mathrm{P}(\mathrm{q})$ are small | $\rightarrow \mathrm{q}$ card is informative |
|  | (not-p card is not informative) |

How should these base rates, then, be determined? Instead of attempting to somehow measure them in relevant environments for different kinds of rules, O\&C cite various intuitively plausible justifications for their rarity assumption: Relying on the observation that categories in language cut the world quite finely, and that properties that figure in causal relations tend to be rare, the assumption states that, generally, $\mathrm{P}(p)$ and $\mathrm{P}(q)$ are small in most situations. Under rarity, O\&C conclude, the $q$ card is more informative than the not- $q$ card. Hence, the model suggests that the highest expected information gain is achieved by turning over the $p$ and $q$ cards, exactly as the majority of the participants do. In fact, with $\mathrm{P}(p)=0.22, \mathrm{P}(q)=0.27$, the model shows a very good fit to experimental data from the Wason task. Hence, by changing the normative model of rational behavior, O\&C were able to explain away irrationality, and to show that
participants' behavior in experiments is actually close to optimal.

The model has received critical attention in the literature (see Oaksford \& Chater 2009), but it serves our current purposes well. The model specification and the modeling assumptions are conceptually on a par with those in more complex Bayesian models: The complexity often pertains to the number of variables involved, the structure and generation of the hypothesis space, and in many cases advanced numerical methods are needed for solving the model. These mathematical sources of complexity do not, however, change the fundamental conceptual architecture of a model. What is common to all RA models is that none of their main components (hypothesis space, likelihood function, priors) are interpreted in a psychologically realistic way as mental representations (Jones \& Love 2011). Instead, they stand directly for properties of the environment. Furthermore, empirical data about the properties of human cognition is not fed into the model specification to calibrate or to constrain the model. Instead, behavioral data enters only in step 5 of RA (see above) as a means for testing model predictions. In this sense, the information gain model is an illuminating example of the theoretical and conceptual assumptions made in rational analysis modeling.

## 3. What rational analysis models fail to explain

There is no consensus in philosophy (or in the sciences) about what scientific explanation is, or what makes a theory explanatory. However, a shared starting point for many accounts of scientific explanation has been to distinguish explanation from other epistemic activities (e.g., description and prediction) by pointing out that explanations offer information of a specific kind. Explanations show how or why something happened or obtains. According to an influential approach (Woodward 2013), the knowledge that allows one to answer such questions concerns change-relating counterfactual dependencies between the relata in the explanation, the explanans and the explanandum. That is, explanations show how (the state of) some things depend on (the state of) other things.

This contrastive-counterfactual account of explanation suggests that explanatory information has generally the following form:
\{CC $\} y[y$ '] because of $x[x$ '] (variable Y takes the value y instead of $y$ ' because $X$ has the value $x$ instead of $x$ ')

According to the contrastive-counterfactual account, being able to explain means that one is able to correctly answer what-if-things-were-different questions, i.e. questions about how changes in explanantia variables influence the state of the explanandum variable. In addition to being a sufficiently general account of explanation, the contrastivecounterfactual account suits the purposes of this article well, because it does not necessarily tie the notion of explanation

[^455]to that of causation. That is, although the 'because' in $\{\mathrm{CC}\}$ is typically understood as referring to a causal dependency, the account does not rule out the possibility of there being also non-causal explanations (Woodward 2013; Pincock 2015; Rice 2015): If a suitable analysis of invariant dependency in non-causal contexts (e.g., for mathematical dependencies) can be found, the contrastive-counterfactual account can be applied to non-causal explanations as well. Hence, the account of explanation casts the net wide enough to give RA models a fair chance of being explanatory.

A further advantage of treating explanations as answers to questions is that it allows us to sharpen the explananda, i.e. to make more precise the possible explanatory claims arising from RA models. I suggest that there are at least three different kinds of objective dependencies that RA models could be said to track: (1) constitutive dependencies between parts and wholes, (2) environment-behavior dependencies, and (3) environment-optimal-behavior dependencies. In the rest of this section, I argue that often RA models do not have genuine explanatory import with respect to the two first kinds of dependencies. The more promising third option is discussed in section 4.

### 3.1 Constitutive what-ifs

The notion of mechanism has acquired a central position in the philosophical debates on scientific explanation. A clear expression of the mechanistic viewpoint has recently been given in the model-to-mechanism mapping (3M) requirement by Kaplan and Craver (2011). According to the requirement, dynamical and mathematical models in systems- and cognitive neuroscience can be explanatory only if there is a mapping between elements in the model and elements in the mechanism for the phenomenon. As the example discussed above suggests, rational analysis models provide no such mapping. They are agnostic about algorithmic and implementation level details, and intentionally so. They clearly do not track constitutive dependencies. Does this mean they cannot be explanatory?

As Kaplan and Craver themselves admit, their argument ultimately relies on shared norms about explanatoriness in the neuroscience community, and their account of explanation as uncovering multi-level mechanisms reflects these norms. If such norms do not hold among probabilistic cognitive modelers, it is not obvious why they, based on this argument alone, should abide by the 3 M requirement.

The contrastive-counterfactual account suggests a more positive reply to Kaplan and Craver's argument: RA models obviously do not provide information about constitutive and causal dependencies in multi-level mechanisms, but this does not rule out the possibility of them tracking some other kinds of objective dependencies, for example, those holding between relata described in purely computational-level terms. Furthermore, a proponent of RA need not (and should not) claim that adding mechanistic detail never improves a computational explanation. To defend the explanatoriness of RA models, a far weaker claim suffices, one stating that it is possible to learn about objective explanatory dependencies
without always relying on information about cognitive mechanisms.

### 3.2 Environment-behavior what-ifs

A second kind of explanatory question answered by an RA model could be: "How would the behavior of the cognizer change when the cognitive task changes in some particular way?" That is, the model could uncover objective dependencies between properties of the environment and the behavior of cognizers. For example, O\&C's model can be used to derive predictions about what the behavior of the participants in the Wason task would be, were $\mathrm{P}(p)$ and $\mathrm{P}(q)$ to take some range of values.

It is here that the optimality assumption of RA becomes crucial. To predict how human behavior would change in response to changes in the task, without knowing anything about the algorithms and processes producing the behavior, RA relies on the assumption that humans are well-adapted to their environments: If we assume that human behavior is close to optimal across a large variety of environments, the predictions derived from the RA model (step 4 of the RA procedure) should in fact apply to that behavior. Optimality forms the link between the normative theory and observed behavior.

Given that human (ir)rationality has been the topic of a longstanding debate in philosophy and psychology, it is not surprising that the optimality assumption has drawn a lot of criticism (Jones \& Love 2011). Although proponents of RA are correct in arguing that some degree of rationality of target behavior is required for us to even perceive it as intentional action, such modest levels of rationality hardly license the strong optimality assumptions of RA models. Neither do evolutionary arguments provide support for strong optimality claims: Natural selection is a source of design and adaptedness, but not necessarily of globally optimal solutions - merely a local comparative advantage is sufficient for evolutionary solutions to survive.

Being aware of these problems, proponents of RA have avoided evolutionary defenses of the optimality assumption. Instead, they often justify optimality by relying on analogies to behavioral ecology and economics, where similar assumptions are commonly made (Chater et al. 2003). However, such analogies break down due to a crucial dissimilarity between these fields. Unlike in cognitive science, both in biology and economics the rationality claims typically concern aggregate behavior, not that of individual agents. Hence, I do not see how appealing to economics or biology could be a viable way to justify optimality assumptions in RA modeling.

These problems with the general defenses of the optimality assumption suggest that perhaps optimality should be examined more locally. Now, what kind of evidence should be obtained to justify the optimality claim in the case of a particular cognitive task? It seems that to support a claim about there being an objective dependency between environment and behavior, we should gather data about human behavior in a task across a range of parameter values
describing various different environmental states. In other words, if human behavior fits the predictions of the model across a range of conditions, that would appear to be rather strong evidence of optimal performance.

However, the existing RA models rarely make use of such cross-environmental data. First of all, many models do not rely on any actual measurements of environment parameters. Instead, they use plausible-sounding assumptions or analogies. For example, Anderson (1990, ch. 2) relied on data about library borrowings to model usage of memory structures, and Griffiths et al. (2007) use Google PageRank to predict fluency of recall. Models devoid of good quality empirical data should be considered as toy models (at best), incapable of uncovering the actual properties of cognitive environments. Furthermore, Marcus and Davis (2013, table 1) suggest that Bayesian modelers have been selective in choosing the results that they report from experimental tasks, only reporting results where human behavior follows the model predictions and ignoring cases where behavior is not optimal. ${ }^{4}$

That said, in the large literature on the information gain model, predictions from the model have been tested against human performance under different base rates and different framings of the task (e.g., descriptive vs. deontic; Oaksford \& Chater 2007, Ch.6). Although the empirical findings remain inconclusive, such systematic variation of the task parameters should be used to produce evidence of a robust explanatory environment-behavior dependency. ${ }^{5}$

## 4. Rational analysis and the logic of the situation

Finally, let us examine the epistemic value of an RA model if we drop the optimality assumption. Assume that we have a model with a (i) well-specified task structure, (ii) parameter values based on measurements of the environment, and (iii) an empirically informed account of computational costs and cognitive limitations. What such a model could do is it could link combinations of parameter values to best possible behavioral choices in those situations. Is this not a kind of objective change-relating dependency? However, consider what the relata of such a dependency are. The model tells what the optimal behavior would be, given a particular combination of environmental conditions and computational limitations. Such counterfactuals do not say anything about actual human behavior. Instead, they can be seen as increasing our understanding of the environmental affordance, or, the logic of the situation (Popper 1963). ${ }^{6}$

What mathematical models of affordances (of the opportunities that the environment offers for the agent) can help us understand is the possible space of action for cognitive agents. Models of affordances show what a hypothetical rational agent would do in different situations.

[^456]For what kind of purposes could such information be useful? First, were we to design artificial cognitive systems with a particular cognitive task in mind, these systems should approximate the optimal behavior specified by the model. For example, in the selection task, if we are interested in reducing our uncertainty, O\&C's model tells us something non-trivial, i.e. which information sources to examine given the base rates of $p$ and $q$.

Secondly, as in economics, rational models can obviously act as normative baselines to which human behavior can be compared. As Sloman \& Fehrbach (2008) argue, often it is just as interesting to discover that behavior does not conform to the rational norm as to see that it does. Finding out when and how complex systems malfunction is often an efficient way to learn about the underlying processes.

However, in neither one of these cases are RA models used to directly explain human behavior. Instead, the model functions as an inferential aid which helps to chart the possible space of action for agents, when faced with a particular task. Herein lies perhaps the hardest evidential problem faced by rational analysis. How do we know what the mind really does in some situation; where do the functional hypotheses in step 1 of RA come from? For example, how would O\&C defend their Bayesian construal of the selection task against an adamant falsificationist? The currently available empirical evidence can hardly decide the issue: Where $O \& C$ see optimal behavior, the falsificationist sees well-known inferential blunders. Marcus and Davis (2013) have argued that similar problems of model selection plague several other RA models as well.

The difficulty seems to come down to the fact that the cognitive tasks and the affordances available to an organism depend on its "life space" - not the physically objective world in its totality, but reality filtered through the organism's needs, drives and perceptual apparatus. Therefore, we should not think that the researcher's intuitions are necessarily a reliable guide to what the tasks faced by different aspects of the human cognition really are. Ad-hocness in task specification, in turn, raises serious worries about the relevance of $R A$ modeling: Constructing detailed mathematical models of potential affordances is of little interest unless such affordances can be shown to be ones actually offering themselves to the human mind.

This worry suggests that the six-step rational analysis modeling cycle introduced in section 2.1 should not proceed independently from knowledge originating from mechanistic research: As both the connectionist rivals of RA and proponents of multi-level mechanistic explanation have argued, functional hypotheses (step 1 of RA) in cognitive science must be formulated in an iterative process between bottom-up and top-down research strategies (see McClelland et al. 2010; Bechtel \& Richardson 2010). In particular, knowledge of perceptual capacities and embodiment

[^457](informing step 2), as well as of the computational constraints of organisms (step 3) mostly originate from the bottom-up research on the mind-brain, and this knowledge should be allowed to constrain RA models. In this sense, Anderson's and O\&C's claims about the self-standing explanatory role of RA are not vindicated by my analysis.

However, neither can bottom-up research strategies stand on their own, or at least they fail to reach high enough. The discussions on mechanistic explanation often have a reductionist bias, and understanding the environments within which cognitive mechanisms function has not received sufficient attention. Here RA models can complement mechanistic theories of cognition by providing precise mathematical models of the task and the environment. For example, as Chater et al. (2003) point out, a correctly formulated rational analysis can show why it is that some simple heuristic can be successful in solving a computationally complex task.

## 5. Conclusions

I have argued that given a sufficiently broad account of scientific explanation, there are several possible ways in which probabilistic modeling could increase our understanding of the mind. However, the strictly computational-level approach embodied in the six-step formula of rational analysis has led to theorizing which often fails to reliably uncover genuine explanatory dependencies. The shortcomings of RA are evidential in nature: The data, and the way it is used in model construction, often cannot support the counterfactual inferences needed explaining human behavior.

My new proposal about the epistemic role of RA models is that they can be understood as models of environmental affordances. Interpreted in this way, the models do not actually provide information about the mind works, or even hypotheses about actual cognitive functions (cf. Marr 1982; Zednik \& Jäkel 2014). Instead, they help to chart the possible cognitive space of action for an organism. The nature of the explanatory contribution of such information is best worked out as a part of a non-reductionist mechanistic research programme.

# Randomness in binary sequences: Conceptualizing and connecting two recent developments 

Stian Reimers (stian.reimers@city.ac.uk)<br>Department of Psychology, City, University of London<br>Northampton Square, London EC1V 0HB, United Kingdom

#### Abstract

Recent theoretical research has shown that the assumptions that both laypeople and researchers make about random sequences can be erroneous. One strand of research showed that the probability of non-occurrence of streaks of repeated outcomes (e.g., HHHHHH) is much higher than that for a more irregular sequence (e.g., HTTHTH) in short series of coin flips. This tallies with human judgments of their likelihood of occurrence, which have conventionally been characterized as inaccurate and heuristic-driven. Another strand of research has shown that patterns of hits and misses in games like basketball, traditionally seen as evidence for the absence of a hot-hand effect, actually support the presence of the effect. I argue that a useful way of conceptualizing these two distinct phenomena is in terms of the distribution of different sequences of outcomes over time: Specifically, that streaks of a repeated outcome cluster whereas less regular patterns are more evenly distributed.

Keywords: randomness; rationality; hot hand fallacy, gambler's fallacy.

## Introduction

One of the more important things that organisms must do to prosper is to identify, extract, and act on patterns in the environment. At a perceptual level, detecting potential threats in a noisy and ambiguous environment is crucial for survival. At a higher level, the ability to detect patterns of events over time or space, such as the presence of absence of prey in different locations at times, the changes in temperature or weather, and so on, allows an organism to predict the future state of the world, and adapt behavior accordingly. In a more contemporary environment, anyone able to detect behavioral patterns in markets, organizations or individuals would be able to exploit that knowledge to their benefit.
In order to detect patterns, an organism has to separate signal from noise. As such, one would expect organisms to accurately represent the absence of a signal, that is, randomness. A poor representation of what random patterns look like would make it harder to spot the times when patterns contain information.
As such, it is surprising that across a wide range of research procedures, people are systematically poor at representing randomness (for reviews see, Nickerson, 2002, 2004; Bar-Hillel \& Wagenaar, 1991; Falk \& Konold, 1997; Rapaport \& Budescu, 1992). For example, people underestimate the frequency of 'streaks' or 'runs' of a particular outcome (such as getting five heads in a row when flipping a coin repeatedly), and treat such streaks
when they appear as evidence for non-randomness. Related, people rate sequences of binary outcomes containing negative serial dependency (that is, an alternation rate between outcomes of greater than .5 ), as being more random than truly random sequences.

One reason why people may be poor is that many properties of random sequences are counterintuitive. For example, relative wait times for different sequences of binary outcomes violate transitivity (see, e.g., Nickerson, 2007).

In this paper I focus on sequences of binary, Bernoulli i.i.d. events such as coin flips (which could come down H or T ), and behaviors which may be modelled by them, such as basketball shots (which could come down as a hit $-\mathrm{X}-$ or a miss - O).

## Representativeness and probability of occurrence

One of the most influential studies to demonstrate an apparent bias in perception of randomness was that of Kahneman and Tversky (1972). In their studies, they asked participants about the relative frequency of occurrence of different birth orders of girls (G) and boys (B) in families with six children in a hypothetical city. They found that participants estimated that there would be many fewer examples of a precise sequence of BGBBBB relative to a precise sequence of GBGBBG. (Of course all precise sequences of birth orders are equiprobable). To examine whether this finding was a result of just the relative frequency of B and G , Kahneman and Tversky also compared estimates of the relative frequency of BBBGGG and GBGBBG, finding that the former was seen as significantly less probable than the latter. Thus, both the relative frequency of outcomes, and the order in which outcomes occur appear to be important in judging the probability of occurrence.

Traditionally, findings of this nature have been explained in terms of heuristics and biases, specifically a misapplication of a representativeness heuristic (but see, e.g., Gigerenzer, 1996; Ayton \& Fischer, 2004): People believe that the properties of short sequences of random outcomes should be representative of those seen in longer sequences (e.g., equal proportions of outcomes, an absence of structure or compressibility), and sequences that share those properties are deemed more probable.

However, recently Hahn and Warren (2009) observed that in situations where one looks for patterns of outcomes in a
finite sequence of, for example, coin flips, different sequences have different probabilities of occurrence.

To give a concrete example (used by Hahn and Warren, 2009), compare the probability of non-occurrence of a HHHH vs HHHT in a sequence of 20 coin flips. The streak of a repeated outcome $(\mathrm{HHHH})$ is around twice as likely not to occur relative to HHHT. The argument made by the authors is that if people use previous experience of merely the occurrence (at least once) or absence of a particular string to judge the probability of occurrence in the future, then they would be quite accurate to say that HHHH would be less likely to occur in a sequence of 20 coin flips than HHHT.
This was also extended to account for the gambler's fallacy: If experience dictates that HHHH is less likely to occur than HHHT, then an individual who sees HHH and is asked to be on whether the next observation is H or T , would with some justification bet on $T$.
Although there is ongoing discussion about the extent to which or circumstances under which Hahn and Warren's theory predicts judgments (Reimers, Donkin \& Le Pelley, 2017), the observation that different strings of outcomes have different probabilities has meant that researchers have needed to reconsider what normative baselines for randomness judgement should be, and potentially turn what previously appeared to be a clear bias into a slight misapplication of a genuine property of the environment.

## The hot-hand-fallacy fallacy

A second challenge to researchers' assumptions about normative baselines has been seen with the hot hand effect.
The hot hand effect is a phenomenon - accepted as selfevidence by many sports participants and spectators - that players go through periods when their performance varies consistently over time, having streaks when they are 'hot', and during that period of time their performance is consistently better than usual, as measured by, for example, the proportion of baskets or putts they manage to sink. If the hot hand were real, it would mean that probability of success had positive autocorrelation: Following a streak of hits, a person would be more likely to score another hit.

Despite popular belief in the hot hand phenomenon, the effect has until recently been seen as a fallacy. Gilovich, Valone and Tversky (1985) examined the performance of professional and amateur basketball players, and argued that there was no evidence for a hot hand effect. They operationalized a hot hand effect in basketball shooting as a difference between the probability of getting a hit (scoring from a free throw) after a streak of $k$ consecutive hits (X) and the probability of getting a hit after a streak of $k$ successive misses ( O ), for example, $\mathrm{p}(\mathrm{X} \mid \mathrm{XXX})>$ $\mathrm{p}(\mathrm{X} \mid \mathrm{OOO})$. The logic, which appears superficially entirely reasonable, was that if the probabilities of a hit after $k$ hits and a hit after $k$ misses were identical in a well-power study, then that provided evidence for the absence of a hot-hand effect. Across several studies, they found no difference in
probabilities, so concluded that the hot-hand effect was a fallacy.

Recently this conclusion has been challenged. Miller and Sanjurjo (2016) note problems with measures traditionally used to support the absence of a hot hand effect (see Rinott and Bar-Hillel, 2015 for less technical overview of an earlier version). Specifically, they prove that if one were to calculate the strength of the hot hand effect for players individually along the lines of calculating $\mathrm{p}(\mathrm{X} \mid \mathrm{XXX})$ / $[p(X \mid X X X)+p(X \mid O O O)]$, and then take the average across individual, that average would be less than .50 . So if a wellpowered study shows a mean proportion of around .50 , then rather than being evidence against a hot hand effect, it is in fact substantial evidence for such an effect.

Miller and Sanjurjo (2016) prove the counterintuitive finding that that in any finite binary sequence, the mean proportion of streaks of length $k$ that are followed by a repetition of the same outcome is on average lower than the proportion of streaks of length $k$ that are followed by the opposite outcome. They note that for $k=1$, the effect is entirely driven by a sampling-without-replacement effect, such that in, say, a short sequence of coin flips where the number of heads and tails is expected to be identical, choosing to look at outcomes following a H removes a H from the sample, meaning that the probability of all other observations, including the next one being a T is slightly greater than .5 .

More relevant for this discussion is the effect where $k>1$. Here, Miller and Sanjurjo note that the effect is driven much more by the extent to which sequences of outcomes can overlap with each other (or show autocorrelation, in the terminology of Guibas \& Odlyzko, 1981). They note that some sequences of outcomes can overlap with themselves: For example the sequence HHH can partially overlap with itself such that in a series of five coin flips, it is possible to observe three overlapping instances: HHHHH; conversely, the sequence HTT cannot overlap at all, and so can only occur once in a series of five coin flips. They note that because overall the expected number of occurrence of HHH and HTT must be identical, HTT must be observed in a greater number of series of five coin flips to compensate for the fact that HHH can occur multiple times within a single series. As such, they prove that

## Variance of occurrences in short sequences

Here, in contrast to Miller and Sanjurjo's (2016) formal proof, a stochastic approach to this issue is taken, in part to make the relationship between the findings of Hahn and Warren (2009) and Miller and Sanjurjo (2016), and in part to attempt to show how the varying distribution of observations of different sequences of outcomes in a longer series of binary outcomes can account for both findings.

This is not the first attempt to relate these two phenomena. In recent iterations of their working paper, Miller and Sanjurjo have attempted to account for the gambler's fallacy as well as the hot hand fallacy, by assuming a degree of insensitivity to sample size. Sun and

Figure 1: Raster plot of the occurrence of strings of HHHH or HHHT across 1,000 simulated coin flips. The horizontal dimension gives the flip from the first on the far left to to the last on the far right.

Wang (2010) note that different forms of waiting time for sequences of outcomes vary differently with outcome. Thus, the mean inter-observation gap is the same for all sequences of a single length, whereas the expected waiting time from first flip of a coin is much greater for some sequences of outcome (such as HHHH) than others (HHHT), and that the variances in these two forms of waiting time vary substantially.

The argument presented here is based on the observation that the variance of the number of trials between observations of a given sequence of outcomes varies. Specifically, the observations made by Hahn and Warren, and those made by Miller and Sanjurjo are both consequences of the same property of random sequences, specifically that within any finite sequence of equiprobable binary outcomes, the distribution of frequency-ofoccurrence for 'streaks' (i.e. repetitions of the same outcome, like HHHH ) is much wider than that for nonstreaks (like HHHT).

To compare the distribution of two sequences of outcome HHHH and HHHT, across 1,000 simulated coin flips, see Figure 1. As both Hahn and Warren (2009) and Miller and Sanjurjo (2016) note, although the total number of occurrences of HHHH and HHHT is approximately equal, HHHH tend to cluster more than HHHT, with several overlapping occurrences together, and then large gaps between them. One way of explaining this it is that we know that overall frequency of HHHH and HHHT must be on average identical. However, immediately after flipping HHHH , there is a $50 \%$ chance of flipping another head, giving another instance of HHHH , and then a $50 \%$ chance of another, and so on. This leads to clusters of consecutive overlapping instances of HH H . Conversely, after flipping HHHT, it takes a minimum of four more flips to get HHHT again. This means that HHHT cannot cluster in the same way.

The consequence is that for shorter sequences of, say, 100 random binary outcomes, the frequency of HHHT will be fairly consistent, whereas the frequency of HHHH will be much more variable. This can be seen in Figure 2, in a simulation of 10,000 runs of 100 coin flips. Here, the string HHHT appears between 3 and 9 times on $95 \%$ of runs of 100 flips. HHHH only appears between 3 and 9 times on $67 \%$ of runs.

Hahn and Warren's theory explains the fact that people seem to think HHHH is less likely to occur than HHHT, by
looking at the difference in the probability of nonoccurrence of a string (or conversely the probability of its occurring at least once). Although they use shorter runs for their examples, the same pattern is observed: In Figure 2, the string HHHH is much more likely not to occur than HHHT is. In fact, although it is hard to see from the graph, the probability of HHHH's non-occurrence is around 100 times that of HHHT. This is - of course - a consequence of the fact that the mean of the frequency-of-occurrence distribution for HHHH is the same as that for HHHT, but the variance is much greater. Hahn and Warren suggest that when making judgments, people, whose experience is limited to short runs of outcomes, might attend to whether a string occurs or not, but not attend to the number of times it occurred. This means that they will see HHHT occurring in a lot more runs than they will HHHH , and will rate it more probable.

Conventional analysis of Gilovich et al.'s hot hand data used the logic that in the absence of a hot hand effect, the average proportion of players' shooting successes would be the same following three successes as following three failures. Miller and Sanjurjo note that this is not the case. The observation I make here is that this is a direct consequence of the distribution of frequency-of-occurrence in 100 binary outcomes being much wider for streaks than non-streaks is that the proportion of XXXX from \{XXXX, $\mathrm{XXXO}\}$ (or, by symmetry $\{\mathrm{XXXX}, \mathrm{OOOX}\}$ ) is less than . 5 .

To give a concrete example, if every day your grocer randomly gives you either 3,4 or 5 apples, and either 2,3 , 4 , 5 , or 6 oranges, and each day you work out what proportion of the fruit you were given is apples, you will find that, averaging across many days, the proportion of apples is greater than .5 , even though the total number of apples and oranges you receive is on average identical.
(If this is not obvious, consider the case where the grocer always gives you 4 apples, and also randomly gives you either 0 or 8 oranges. Half the time you leave with a bag that contains $100 \%$ apples; half the time you leave with a bag that contains $33 \%$ apples, so overall, the proportion of fruit in your bag that is apples averages $67 \%$. However, the overall number of apples and oranges you receive will be the same.)

Thus, in general, if one draws a sample from two distributions which have the same mean but different variances, and then looks at the proportion of the combined outcome that comes from each distribution, the expected

Figure 2: Distribution of frequency-of-occurrence for two different strings of outcomes in 10,000 simulated sequences of 100 coin flips
proportion from the lower variance distribution will be greater than that for the higher variance distribution.
This phenomenon can be seen more generally in Figure 3, which takes a normal approximation of the frequency-ofoccurrence distributions shown in Figure 2, with equal

Figure 3: Simulated samples drawn from distributions with a common mean, Color indicates the mean proportion of the sum of the two samples that comes from the y sample
means, capping at 0 , and varying the SD of the two frequencies-of-occurrence. The color indicates the mean proportion of outcome y , averaged across 50,000 simulated trials of each of 100 random binary outcomes. Where SDs are equal, then of course $p(y)=p(x)=.5$. Where $S D(y)>$ $\mathrm{SD}(\mathrm{x}), \mathrm{p}(\mathrm{y})<\mathrm{p}(\mathrm{x})$, and vice versa. A circle indicates the approximate point where $\mathrm{SD}(\mathrm{x})=\mathrm{SD}(\mathrm{HHHH})$ and $\mathrm{SD}(\mathrm{y})=$ SD(HHHT).

Replacing HHHH and HHHT with XXXX and OOOX, it is clear that, as Miller and Sanjurjo (2016) note, it is not correct to assume that, in the absence of a hot hand effect, the expected proportion of successes following $k$ successes, averaged across a large set of players, should be .5 . Rather, it is significantly lower, as a direct consequence of the distribution of frequency-of-occurrence for XXXX being broader than that for OOOX.

## Conclusion

The argument presented here is that both Hahn and Warren (2009) and Miller and Sanjurjo's (2016) findings can be explained the same way: In sequences of random binary outcomes, streaks of the same outcome (whether heads, HHHH, or successes, XXXX) cluster more than nonstreaks (HHHT, OOOX); this leads to a broader distribution of frequency-of-occurrence of streaks in finite sequences of random binary events relative to non-streaks. This both increases the chance of the non-occurrence of a streak (which H\&W argue makes people think justifiably that HHHH is less likely to occur than HHHT and other nonstreaks) and reduces the average proportion of XXXX among observations of $\{\mathrm{XXXX}$ and OOOX\} (which Miller and Sanjurjo convincingly argue means that evidence for a hot hand effect has been overlooked).

There are potentially interesting implications from these observations for the kinds of cognitive representation that would mediate the biases seen here. For example, an agent that counted the total number of occurrences of different strings of outcomes would see that the number of occurrences of, say, HHHH and HHHT were identical, so should rate them as equally probable. An agent that discarded all information about the frequency of occurrence of a string and recorded only whether or not it was observed (at least once) in a particular set of connected outcomes would of course perceive HHHT as more common than HHHH. Similarly, an agent that, rather than counting the number of occurrences of a string, instead encoded only the relative frequency of different strings, as a proportion of the total number of observations across occasions, would also conclude that HHHT was more frequently observed than НННH.
(Of course the overlapping of streaks described above may account for the biases seen here in more superficial ways. Chater (2014) argues that cognitive segmentation processes may differentially mask the frequency of occurrence of different strings. For example, a sequence of TTHHHHHHTT might be parsimoniously chunked as two tails - six heads - two tails, underplaying the three overlapping occurrences of HHHH within the sequence.)

Overall it seems clear that an examination of the distribution of frequency-of-occurrence for different strings of binary outcomes, allows one to create a parsimonious and intuitive account for two important recent theoretical observations, both of which have implications for the study of rationality.

#### Abstract

Face-to-face communication is a rich, natural form of communication that incorporates multimodal behavioral cues belying meaning and intention. However, computer-mediated communication (e.g., texting) removes many of the multimodal cues in face-to-face communication (e.g., vocal prosody). Recent research has suggested that punctuation might mimic vocal prosody in text (Gunraj et al., 2016), but there is no clear indication of what the overall effects may be. Therefore, the current study investigates the use of punctuation to express intonation. We first replicate Gunraj and his colleagues by showing that a single word ending in a period promotes the appraisal of negative affect. Interestingly, we extend this research by demonstrating that intonational punctuation has the potential to increase social distance, which our preliminary results suggest may occur through processes of emotional contagion and interactive alignment.

Keywords: pragmatics; texting; emotion contagion; interactive communication

## Introduction

With an increased reliance on technology during communication, mistaking the tone of a message may be common. Though mistakes are possible, numerous interesting studies suggest that some aspects of text may help interlocutors interpret conversational (i.e., affective) tone (e.g., lexical choices, punctuation, character features, emoticons; Byron \& Baldridge, 2007; Gunraj et al., 2016; Niederhoffer \& Pennebaker, 2002; Riordin \& Kreuz, 2010).

While these studies have touched on many features of text, less is known regarding the impact of pragmatic tone as indicated by punctuation (i.e., intonational punctuation), on lexical style matching during texting conversations. In the current study, we evaluate the effect of a sender's punctuation use as a paralinguistic cue to emotional tone, and its effect on a receiver's tendency to align their tone and texting preferences with the sender.

## Conveying Tone of Voice in Text

Face-to-face (FFC) communication benefits from the use of multimodal nonverbal cues like eye gaze, vocal prosody, and shared attention (e.g., Banziger \& Scherer, 2005; Burgoon et al., 1995; Knapp et al., 2013). One common area that most strongly affects text-based communication (TBC) is its unimodality. This unimodality is typically confined to linguistic, typographical, and/or grammatical cues, making TBC less rich in non-verbal cues found in FFC (e.g., Byron \& Baldridge, 2007; Kruger et al., 2005). However, a large body of research demonstrates that language users adapt to and make use of the communication medium to convey richer information about their message. For example, interlocutors make use of vocal spelling ("yeaaaaaaah"), non-standard spelling ("ermahgerd"), emoticons, and manipulated grammatical markers ("..."); all of these typographic cues have the potential to indicate tone of voice (Harris \& Paradice, 2007; Riordan \& Kreuz, 2010).

More recently, Gunraj et al. (2016) found that the use of a one-word response followed by a single period in TBC (relative to written communication) was perceived by participants to be rude and insincere. In fact, the use of typographical cues is adaptive, as it may aid in the decoding of an ambiguous message (e.g., when information is missing; Byron \& Baldridge, 2005; Derks et al., 2008; Harris \& Paradice, 2007; Lo, 2008; Riordan et al., 2014; Walther \& D'Addario, 2001). Though conventional multimodal nonverbal cues are absent from TBC, interlocutors have the potential to interpret a sender's intentions beyond the literal meaning.

## Faster but Ambiguous Messages

In a texting context, language users are constrained by the texting medium, in which their messages are typically fast, agrammatical, and largely ambiguous (for review see

Ling \& Baron, 2007). When an interlocutor lacks the relevant cues, one might rely more heavily on their own representations of the world (i.e., egocentric perspective). When this information is decoded incorrectly or the message is overly ambiguous, miscommunication has the potential to follow shortly behind.

Ambiguity has the potential to make receivers (listeners) of a message uncomfortable with uncertainty. However, listeners may handle this uncertainty by making predictions about a speaker's (sender's) intentions (Uncertainty Reduction Theory; Berger \& Bradac, 1992). Interlocutors essentially make predictions to decode ambiguous information by relying on nonverbal cues (e.g., paralinguistic cues) presented by a communication partner (Byron \& Baldridge, 2007). From this account, the receiver evaluates typographic cues (e.g., capitalization, emoticons, etc.) in the message to determine the sender's intentions.

Subsequently, the receiver attempts to synthesize known personality traits with the typographic cues to derive the correct intention. For example, when vocal tone is absent from the sender, a receiver reading a text message may construct an egocentric "tone" representation, similar to that of representing verbally produced "tone" in a face-to-face conversation -- as a means to reduce ambiguity, promote successful communication and decrease social distance (Byrne, 1971; Chartrand \& Bargh, 1999; Dennis \& Valacich, 1999). This leads one to question how a receiver's representation of tone is integrated in a deprived texting environment. More specifically, do interlocutors use similar communicative mechanisms to decrease social distance, when the cards are stacked against them?

## Convergence in Interpersonal Communication

A large amount of research has shown that lexical style matching during communication has the potential to decrease social distance (Byrne, 1971; Bernieri \& Rosenthal, 1991; Chartrand \& Bargh, 1999; Niederhoffer \& Pennebaker, 2002). However, recent research has shown that alignment need not always occur to promote positive communication outcomes (Fusaroli et al, 2012). In fact, these researchers show that though interlocutors have a proclivity to converge linguistically, dyads that adapted and diverged linguistically improved performance on a task i.e., more is not always better (Giles \& Coupland, 1991). It is possible, that under emotional contexts, one would be more likely to converge linguistically and para-linguistically during positive interactions and strategically diverge in negative interactions to decrease social distance (Paxton \& Dale, 2013). Currently, the utility of behavioral convergence and divergence during communication as a potential means to promote pragmatic interpretation, has been less well established in an emotional texting context.

When texting, the receiver of the message automatically colors the message with their interpretation of the sender's tone. If the sender produces emotionally valenced non-verbal cues, then the receiver might produce a similarly valenced response. Hatfield et al. (1994), for example, showed that interlocutors emotions tended to align when interacting with a social other. Additionally, it has also been argued that interlocutors prime each other (at various levels of the interaction), to promote effort saving communication behaviors (phonological to pragmatic priming: Dijksterhuis \& Bargh, 2001; Garrod \& Pickering, 2004). But what if the very nature of the intonational punctuation cue intends to increase social distance? Does the receiver of such a message diverge emotionally or with intonational punctuation? Or will the receiver follow suit and respond reciprocally (e.g., Theory of Reciprocity; McCroskey \& Richmond, 2000), further breaking down the conversation and increasing social distance?

The purpose of the current study is to determine the effect of intonational punctuation on a texting conversation. There are three main goals: (1) As a replication of previous studies, do interlocutors process punctuation for affective intent?, (2) Given intonational punctuation matching, will intonational convergence occur equally across positive and negatively valenced communication? and (3) What are the effects of punctuation alignment on the perception of conversational sincerity? We expect to see intonational punctuation impacting the perceived sincerity, and thus impacting the reciprocal use of punctuation to match conversational tone. We evaluate convergence through a distributional analysis, rather than time series analysis (Paxton et al., 2016). This allowed for the preliminary establishment of alignment, at the global level.

## Method

## Participants

Twenty Kent State University undergraduate students (females $=11$, mean ${ }_{\text {age }}=19.5 \mathrm{yrs}, \min _{\text {age }}=19 \mathrm{yrs}$, $\max _{\text {age }}=$ $23 \mathrm{yrs}, \mathrm{sd}=1.30$ ) participated in return for a $\$ 5$ gift card. One participant was excluded, because the program crashed half-way through the experiment. All participants were native speakers of English, with normal to normal-corrected vision and no diagnosed speech or hearing impairments.

## Materials

All stimulus presentations and data collection were controlled by a Matlab, Psychtoolbox-3 program, that recorded computer-mouse clicks. All participants were seated in front of a 21 -inch iMac computer screen in a sound-attenuated booth.

## Stimuli

The pseudo-confederate (fake texting partner) texting conversation was a neutral conversation about living in Kent, OH. Thirty-two pseudo-confederate texting response bubbles were created and paired with 5 alternative forced choice participant response bubbles. The participant response bubbles ranged from positive to neutral to negative (similar to a Likert scale), with the top most response option representing positive, the middle being neutral, and the bottom most option being most negative (e.g., Fig. 1). More specifically, the participant response bubbles contained one of the punctuation types, with the exclamation being most positive, no punctuation, ellipsis, and question mark being neutral, and the period being most negative (see Fig. 1).

These five types of punctuation were also used in the pseudo-confederate text messages: question mark, ellipsis, period, no punctuation, and exclamation. No punctuation, question marks, and ellipses acted as fillers and reflected typical uses of typographical markers in texting behavior (two-thirds of the trials; see Riordin \& Kreuz, 2010). The rest of the trials were primarily made up of exclamations (positive condition) or periods (negative condition).

## Design \& Procedures

At the beginning of the task, participants were told they would be having a texting conversation with another person, but instead of being able to freely type their responses, they would be given five response options to choose from (see Fig. 1). The participant was also asked to imagine that the conversation he or she was having was with a person he or she knew well, to promote ecological validity.

Figure 1: This is an example of a negative (left) and positive (right) pseudo-confederate text bubble, with the participant 5 alternative forced-choice response bubbles.

During the course of the interaction, the participant was presented with an image of an iPhone (Apple, Inc.), with a pseudo-confederate text bubble. They were then asked to read the text message, then to click the "next" button to transition into the participant response screen. On this
screen, they were able to see the pseudo-confederate text message bubble, with the 5 forced choice response options to the right of the iPhone (Fig. 1). After the response was made, the participant was brought to another screen that displayed a continuous rating scale, that required the participant to rate his or her perception of the conversation's sincerity (Fig. 2). Participants were randomly assigned to one of two between subjects conditions: Pseudo-confederate Valence Condition (positive: $\mathrm{n}=9$ or negative: $\mathrm{n}=10$ ).

Figure 2: The continuous rating scale participants used to rate the sincerity of the conversation, after each trial ("Please rate how sincerity of the conversation.")

## Measures

Participant Valence Selection Participants had five responses to choose from, that were ordered from positive (exclamation), to neutral (no punctuation, ellipsis, question mark), to negative (period). The response option chosen corresponded with an ordinal scale (exclamation (1) = most positive to period (5) $=$ most negative). Though the difference was not large, the participants in the positive condition chose response options on the more positive side of the Likert scale (mean: 1.99), relative to the negative conversation (mean: 2.23; $\mathfrak{t}=2.212, p<.05$ - independent samples t -test), with a larger number indicating a more negative valence. In order to reflect a more continuous measure of emotional contagion, a running average of the Likert scale ratings was calculated to reflect fluctuations in valence over the course of the interaction.

Intonational Punctuation Alignment Each pseudoconfederate response had one form of punctuation -- with each participant response bubble containing one of the five punctuation types. Depending on the response option chosen, the response was recoded as matching or mismatching the pseudo-confederate's use of punctuation. That is, if the pseudo-confederate used a period, what was the likelihood of the participant selecting a response option containing a period, too? Participants in the positive condition matched the pseudo-confederates choice of punctuation approximately $48 \%$ of the time, but only $28 \%$ of the time in the negative condition $(\mathrm{t}=2.913, p<.001-$ independent samples $t$-test).

Conversation Sincerity Participants were also asked to rate the sincerity of the conversation. This was done by clicking along a continuous rating scale (see Fig 2), and was measured based on pixels. The pixel rating scale ranged
from approximately $400-1200 \mathrm{px}$, with smaller numbers being related to more sincerity, and higher numbers related to lack of sincerity. Overall, positive conversations were rated as significantly more sincere (mean: 613.22px) than negative conversations (mean: 778.13px; $\mathrm{t}=3.848, p<$ .001- independent samples t-test).

## Results

Outcomes are reported from linear mixed-effects models built using lme4 package in R (R Core Development Team, 2008). A mixed effects regression was used to predict receiver perceived sincerity by Pseudo-confederate Valence Condition (positive or negative), Participant Valence Selection (Likert-like response options), and punctuation alignment (match or mismatch). The models implemented maximal random effect structures to achieve model convergence, with participants and trial set as random intercepts. All categorical variables were dummy coded.

Pseudo-Confederate Valence (Manipulation Check) As a manipulation check, to determine if the conversations would be perceived as positive or negative by our participants, the pseudo-confederate responses were presented to four female participants (mean age $=20.5$ ) who did not participate in the pseudo-texting conversation. These participants were asked to rate each pseudo-confederate response bubble on a continuous rating scale for positive/negative valence. The rating scale spanned 400-1200 pixels, with lower numbers representing more positive valence, and higher numbers representing negative valence. The positive pseudo-confederate messages received an average pixel rating of 642.11 px , while the negative pseudo-confederate messages were rated at approximately 850.77 px ( $\beta=$ -208.66, $\mathrm{se}=28.03, \mathrm{t}=-7.37, p<.001$; similar to Fig 2.).

Intonational Punctuation Replication To determine if pseudo-confederate punctuation was interpreted as affective in nature (question 1), conversational sincerity was assessed between the conversational valence conditions (dummy codes: positive $=0$, negative $=1$ ). Results revealed that the negative condition was rated as significantly more insincere than the positive condition $(\beta=208.66$, $\mathrm{se}=25.53, \mathrm{t}=8.17$, $p<.001$ ), replicating Gunraj et al. (2016).

Intonational Punctuation Style Matching To determine if participants aligned with the pseudo-confederate's use of punctuation (question 2), intonational punctuation was evaluated between the two conversational conditions (dummy codes: positive $=0$, negative $=1$ ). Results from this mixed effects model revealed that the negative condition was rated as significantly more insincere than the positive condition ( $B=-1.05$, se $=0.20, \mathrm{t}=-5.22, p<.001$; logistic model, family set as binomial; Jaeger, 2008). This suggests
that interlocutors might be more likely to align under positive, than negative contexts.

Conversational Appraisal In the above analyses, we show that intonational punctuation and style matching occurs differently depending on the conversational valence. The last analyses (question 3) intended to determine whether or not the appraisal of the interaction (sincerity) should be affected by the pseudo-confederate's tone, similarity (to the pseudo-confederate) of their intonational punctuation, and the valence of the response selection.

The results indicated a number of main effects and an interaction. Specifically, there was a main effect of Pseudo-confederate Valence Condition, indicating that participants in the positive condition rated the conversation as significantly more sincere than participants in the negative condition ( $\beta=124.675$, $\mathrm{se}=52.747, \mathrm{t}=2.364, p<$ .05). This suggests that participants were sensitive to pseudo-confederate affective tone.

Figure 3: This figure represents the relationship between punctuation alignment and sincerity, as a function of pseudo-confederate valence.

There was also main effect of Participant Valence Selection (i.e., Likert-like responses; $\beta=97.348$, se $=$ 43.442, $\mathrm{t}=2.241, p<.05$ ) but no interaction between Pseudo-confederate Valence Condition x Participant Valence Selection. This suggests that as participants rated the interaction as less sincere, they chose more negative response options (e.g, emotional contagion).

Lastly, though there was no main effect of intonational punctuation style matching ( $p=.352$ ), there was a significant Pseudo-confederate Valence Condition $x$ punctuation alignment interaction $(\beta=49.841$, $\mathrm{se}=18.424$, $\mathrm{t}=2.705, \mathrm{p}<.01$; see Fig. 3). This indicated that as participants assessed the sincerity of each turn, the more sincere the turn seemed, the more likely the participant would match the pseudo-confederate's punctuation.

Alternatively, the more insincere the conversation, participants were less likely to align their punctuation, with the caveat that highly insincere ratings increased negative punctuation alignment.

## Discussion

Texting provides a wealth of communicative benefits. However, texting necessarily requires a fast, reduced, and often ambiguous delivery of information (Ling \& Baron, 2007). In the face of ambiguity, the receiver of these messages must use their own representations of the world to interpret tone correctly, especially when the tone is not as explicit as vocal tone because of its dual meaning (i.e., grammatical and adapted pragmatic cues; Byron \& Baldridge, 2005; Derks et al., 2008; Harris \& Paradice, 2007; Lo, 2008; Riordan et al., 2014; Walther \& D'Addario, 2001). Therefore, it is not always easy for a receiver of an emotionally valenced text message to correctly interpret tone. In the current study, we specifically evaluate the role of positive and negatively valenced punctuation and its effect on a receiver's ability to interpret tone.

Consistent with Gunraj et al. (2016), the results indicate that participants are in fact sensitive to punctuation as an effective cue to conversational tone. Additionally, the participants perception of the pseudo-confederate's sincerity shaped the participants' responses -- with a more insincere pseudo-confederate receiving responses that were more negatively valenced, though dampened. And finally, we see the convergence and divergence of punctuation use by the participant for pragmatic effect.

Though the current results provide interesting insight into the pragmatic nature of intonational punctuation, the current study is not without limitation. The main limitation of the current study is the lack of ecological validity, which may have affected patterns of responding. For example, participants in the positive condition may have attempted to decrease social distance by using the same communicative mechanisms engaged in FFC (behavioral entrainment; Byrne, 1971; Bernieri \& Rosenthal, 1991; Chartrand \& Bargh, 1999; Niederhoffer \& Pennebaker, 2002). Specifically, participants in the positive condition exhibited emotional contagion and intonational punctuation alignment, which in other domains has been suggested to promote interpersonal liking and communicative smoothness (Chartrand \& Bargh, 1999). Even though the participants were instructed to imagine they were texting with someone they knew well, our participants may have aligned less and been unsure of how to interpret the one word responses ending with a period (negative), because they lacked relevant history with their texting partner (Bernieri \& Rosenthal, 1991).

Alternatively, participants may have defaulted to rules of social engagement, in that it is typically socially
unacceptable to have contentious interactions with strangers (Morand et al., 2003). Therefore, participants may have been more likely to disengage synchronous mechanisms to defuse the negative interaction. However, the more contentious (i.e., more insincere the conversation seemed) the more likely the participant converged their text response with the pseudo-confederate. One should approach this interpretation with caution, because it is difficult to claim intentionality because the interaction was with an assumed stranger, and behavioral frequencies were assessed, and not via time course analysis. These results, nonetheless, are consistent with negative FFC interactions, in which decreases in convergence have been found (Abney, Paxton, Kello, \& Dale, 2014; Paxton \& Dale, 2013).

Finally, we did not look specifically at the time course of synchrony across the interaction. This was mostly due to the low sample size and the preliminary nature of the current study. We first wanted to show that emotional valence has the potential to differentially impact communication in a texting context. Punctuation matters just as much as vocal prosody, because of the pragmatic implications of the cue. Therefore, the next step of this project will be to expand this paradigm, by collecting more data so we might be able to explore the temporal dynamics of emotional valence during text based communication.

## Conclusions

We are relying more and more on digital forms of communication, with even the most prominent political leaders communicating through short, fast text-based responses via social media. In the current study, we provide preliminary insight into the cognitive mechanisms (e.g., emotional contagion) that drive the interpretation of intentionality. Texters (college-aged) not only use typographic variation to indicate pragmatic meaning, but also use it to infer intentions. Additionally, the choice to use certain typographical cues may push the valence of a conversation in a more positive or negative direction. Therefore, one should be aware that one's use of punctuation has pragmatic implications over and above grammatical form, in texting. We see that texting follows similar rules as FFC. In that, language is naturally ambiguous, but in a texting context ambiguity is a critical feature of communicating. Additionally, the texter will follow the valence of their communicative partner as a means to increase and decrease social distance. Therefore, failure to use the appropriate (texting) affective cues could lead to higher rates of miscommunication, misunderstandings, and generally hard feelings.

## Acknowledgments

A special thanks goes to the MADI lab research assistants that worked so hard to collect data.

#### Abstract

Social network graphs are often used to help inform judgments in a variety of domains, such as public health, law enforcement, and political science. Across two studies, we examined how graph features influenced probabilistic judgments in graph-based social network analysis and identified multiple heuristics that participants used to inform these judgments. Study 1 demonstrated that participants' judgments were influenced by information about direct connections, base rates, and layout proximity, and participants' self-reported strategies also reflected use of this information. Study 2 replicated findings from Study 1 and provided additional insight into the hierarchical ordering of these strategies and the decision process underlying judgments from social network graphs.

Keywords: social network analysis; graph comprehension; data visualization; judgment and decision making

## Introduction

## Social Network Analysis

Social network analysis is an analytical method for understanding data that depicts relationships between entities, such as communications between people or the flow of information through a community. Social network analysis (SNA) can be used to inform judgments such as who the most connected or influential person is in a community. The applications for SNA are widespread. The CDC has used social networks to map the spread of infectious diseases (Cook, 2007), and intelligence professionals have used SNA to map potential terrorist suspects. For example, Krebs (2002) was able to map a network of suspected $9 / 11$ terrorists after the attacks based on publicly available information in the news and provide insight into the terrorist organization.

Social networks are typically depicted using node-link diagrams, in which nodes (depicted with circles) represent objects, such as people, and edges between the nodes (depicted with lines) represent a connection, such as a friendship or a recent communication. Although there are quantitative measures of graph structures, such as network centrality, SNA often involves some degree of visual interpretation. In many applications of SNA, such as tactical decision making in military organizations, users of network graphs have limited time to make their decisions and may not have the background to supplement their visual
interpretation with more objective, quantitative measures. Thus, clearly communicating the important information in network graphs is essential. In practice, however, these network visualizations are often complex with hundreds or thousands of nodes, and relatively little is known about the cognitive strategies people use to make probabilistic judgments from these graphs. In the present study, we aimed to identify graph features and heuristics that influenced probabilistic judgments in scenarios that mirrored real-world SNA tasks.

## Graph Perception

Much research has applied perceptual and cognitive theories to improve graph comprehension and readability. Purchase, Cohen, and James (1997) first demonstrated that several aesthetic qualities could improve comprehension, such as maximizing the symmetry of the graph, minimizing the number of intersecting edges, and minimizing the number of bends in a series of segments. Purchase (2000) found that graph layouts that minimized intersecting edges significantly improved participants' abilities to answer questions about the relationships in the graph. Similarly, Ware, Purchase, Colpoys, and McGill (2002) found that cutting unnecessary edges significantly improved cognitive performance.

Other perceptual features in graphs have been studied as well. For example, McGrath, Blythe, \& Krackhardt (1997) found that nodes that were positioned closer to the center of the graph were perceived as more prominent, suggesting a bias towards layout centrality. Additionally, nodes were more likely to be considered to be in the same group if they were positioned closer to each other, and nodes positioned directly between two nodes (as opposed to at an angle) made them more likely to be considered a "bridge" between the two nodes.

Gestalt principles may help explain why some aesthetic features can influence graph interpretation by exploiting people's tendency to identify patterns (Novick \& Bassok, 2005). The Gestalt principle of good continuation suggests that paths are more easily recognized when they contain less jaggedness, suggesting that the fewer the bends between two nodes, the more readily the path connecting them will be observed. The principle of proximity suggests that spatial proximity between objects implies logical groupings. Other cognitive heuristics may also influence graph interpretation.

For example, people sometimes ignore base rates when making probabilistic judgments. The extent to which this occurs when making judgments from network graphs, which may depict base rate information in a visual way, is unclear (but see Micallef, Dragicevic, \& Fekete, 2012).

## Pilot Study

We conducted a pilot study with 30 participants recruited from Amazon Mechanical Turk (AMT) to identify graph features people attend to when making judgments about the likelihood that a particular node belonged to a defined category. We planned to use the results of the pilot study to inform our decision about graph features to manipulate in our experiments ${ }^{1}$. Participants were asked to play the role of a data analyst at a law enforcement agency and use nodelink graphs to estimate the likelihood that they would further investigate a person of interest (POI) in a community that has known drug users (Figure 1). They were also asked to describe the strategies they used to make their judgments. The POI was indicated as a black node, known drug users as blue nodes, and everyone else as yellow nodes. Lines were drawn between nodes to indicate recent communications. Two graph features were varied, 1) the number of direct connections the POI had, and 2) the number of drug users in the whole graph (base rate). The graph visual was generated using a force-directed layout, a popular way of visualizing graph data. Participant responses revealed two common strategies. The first was based on the number of drug users within the POI's direct connections (what we call the "ratio" strategy, $N=10$ ). The second strategy was based on the spatial proximity of drug user nodes to the POI node in the visual layout, regardless of whether they were actually closely connected to the POI ("proximity" strategy, $N=8$ ). We expected to see instances of the ratio strategy, but not necessarily the proximity strategy, since the position of nodes in a force-directed layout is a function of connections rather than nodes. In general, layout position in a graph can be misleading, and two nodes visually close to each other but not connected may not necessarily have a strong relationship. Three participants in the pilot study also mentioned relying on the total number of drug users in the graph. This strategy was expected to be more frequent considering that base rates were explicitly manipulated across graphs. However, participants apparently found base rates less informative than ratio and proximity features for the pilot set of graphs.

## Overview of Experiments

We conducted two experiments to understand how the graph features identified in the pilot study influence probabilistic judgments. In each study, we manipulated the three features identified during our pilot study: 1) ratio, or the number of connections the POI has to salient nodes, 2)

[^458]base rate of salient nodes, and 3) proximity of salient nodes to the POI.

Figure 1: Example network graph provided in pilot study.

## Study 1

## Participants and Procedure

Participants. We recruited 30 participants from AMT. Participants were required to have a "Masters" qualification, indicating that they had repeatedly demonstrated good performance in the AMT marketplace. Most participants reported having no experience ( $72.41 \%$ ) or only slight experience ( $17.24 \%$ ) with SNA. One participant was excluded from analysis for failing an attention check.

Scenario. Similar to the pilot study, participants were asked to take on the role of a data analyst at a law enforcement agency and use graphs to identify potential drug users in a community. They were provided a set of 36 graphs that described communications in a small community over the past month. Participants were told that links between nodes represented non-family relationships with others, such as friends and coworkers. No information was provided on how the graphs were constructed. For each graph, participants made a judgment of how likely they would be to investigate the POI and described how they used the graph to make their judgment.

Materials. The graphs were small real-world graphs generated from the Polbooks dataset of co-purchased political books (V. Krebs, unpublished, http://www.orgnet.com/). Graphs were rendered with the default graph plotting parameters in the R iGraph package, which uses the Fruchterman-Rheingold force-directed algorithm. Each graph consisted of 104 nodes. As in the pilot study, the POI was indicated as a black node, known drug users as blue nodes, and everyone else as yellow nodes. Direct connections to the POI were highlighted in the graphs to aid interpretation. Emphasizing direct connections in this way may have led to more emphasis on the ratio strategy, but highlighting connections was deemed important to help participants distinguish between graph connectedness from layout proximity (i.e. visual closeness).

Conditions. Three graph conditions were manipulated within-subjects: 1) number of drug users in the POI's N direct neighbors ( $0 / \mathrm{N}, 1 / \mathrm{N}$, Half/N); 2) overall base rate of known drug users in entire graph ( $5 \%$ or $50 \%$ of all nodes); and 3 ) proximity placement of known drug user nodes (near or far from POI). Note that proximity was the physical location of drug user nodes within the visual graph layout and not the graph connectedness. Graph connectedness was controlled by removing edges that connected proximal drug user nodes to the POI's direct neighbors (Figure 2).

Figure 2: Graph feature conditions. Note that in the Proximity: Near graph, the proximal blue nodes are not connected to the POI or the POI's direct neighbors.

Likelihood Judgments. For each graph, participants were asked to rate how likely they would be to investigate the POI on a scale of 1 to 7 ( $1=$ Extremely Unlikely, $7=$ Extremely Likely).

Strategy Use. After giving their likelihood rating, participants were also asked to describe any specific graph information they used in making their rating. Responses were open-ended text responses and were analyzed using a structured coding approach, described in Table 1, with three coders who coded $75 \%$ of the responses independently and $25 \%$ overlapping. Inter-rater reliability on the $25 \%$ co-coded responses was high (Cohen's Kappa > .75).

Table 1: Coding scheme for open-ended responses.

| Strategy | Description |
| :---: | :---: |
| Ratio | Mentions number of users in POI |
| connections |  |
| Base Rate | Mentions number of users in graph |
| Proximity | Mentions visual closeness of POI to users |

## Results and Discussion

Likelihood Judgments. We modeled likelihood judgments with a linear multilevel model with base rate, proximity, and ratio conditions treated as random effects. Graph feature conditions were nested within participant. Multilevel models are able to estimate the variance associated with each random effect; thus, the model can account for the within-individual variability for different graph feature conditions. In addition to modeling random effects, multilevel models can also simultaneously estimate fixed effects, which in this case represent the average effect for the whole sample.

We sequentially entered each graph feature into the model as a fixed effect to examine its effect on likelihood ratings. Base rate, ratio, and proximity each significantly improved the fit of the model $\left(\chi^{2}(1)=34.51, p<.001, \chi^{2}(2)=148.62\right.$, $p<.001$, and $\chi^{2}(1)=45.07, p<.001$, respectively). Specifically, higher base rates increased the likelihood of investigating the POI $(b=0.97, t(1011)=7.54, p<.001)$, higher ratios increased the likelihood of investigating ( $b=$ $1.24, t(1011)=7.18, p<.001$ for $1 / \mathrm{N}$ vs. $0 / \mathrm{N}$ and $b=3.86$, $t(1011)=22.34, p<.001$ for Half/N vs. $1 / \mathrm{N})$, and closer proximities also increased the likelihood of investigating ( $b$ $=1.02, t(1011)=9.58, p<.001)$. These results suggest that participants considered all three graph features when making their judgments. The observation that participants' suspicion levels of the POI increased with proximity to known drug users was significant, because it suggests that participants believed proximity to be a meaningful indicator.

We also found a significant interaction between base rate and proximity $\left(\chi^{2}(1)=146.00, p<.001\right)$. When proximity was far, there was no difference between the base rate conditions, but when proximity was near, higher base rates significantly increased the likelihood of investigating ( $b=$ $1.70, t(1006)=13.96, p<.001$; Figure 3). In other words, base rate information only affected judgments to the extent that it placed more users near the POI.

There were also interactions between the base rate and ratio conditions $\left(\chi^{2}(2)=112.90, p<.001\right)$ as well as between the ratio and proximity conditions $\left(\chi^{2}(2)=81.89, p\right.$ $<.001$ ), as depicted in Figure 3. Increasing the base rate had a stronger effect in the $0 / \mathrm{N}$ and $1 / \mathrm{N}$ conditions compared to the Half/ N condition $(b=1.70, t(1006)=11.40, p<.001$ and $b=0.94, t(1006)=6.32, p<.001$ for $0 / \mathrm{N}$ vs. Half/N and $1 / \mathrm{N}$ vs. Half/ N , respectively). Likewise, proximity had a stronger effect in the $0 / \mathrm{N}$ and $1 / \mathrm{N}$ conditions as well $(b=$ $1.36, t(1006)=9.09, p<.001$ and $b=0.87, t(1006)=5.85$, $p<.001$, respectively). These interactions reveal that, in the highest ratio condition, base rate and proximity information had little effect. One interpretation of this result is that when ratio was high, participants did not feel a need to look at other information in the graph. In contrast, when the ratio was $0 / \mathrm{N}$ or $1 / \mathrm{N}$, base rate and proximity information both influenced judgments, such that higher base rates and closer proximity increased likelihoods of investigating.

Strategy Use. Analysis of participants' self-reported strategies validated our findings from the pilot study. Participants mentioned using the ratio strategy for the majority of graphs (85.34\%). Proximity was the next most frequently mentioned strategy ( $22.41 \%$ ), followed by base rate a small percentage of the time (12.64\%).

Figure 3: Interactions between graph feature conditions.

## Study 2

Study 2 sought to replicate the findings of Study 1 with a broader range of stimuli. We introduced two additional scenarios, public opinion and disease propagation. Network graphs can be used to represent relational data from a variety of domains, and assumptions about the data may change interpretations of the graph. For example, base rates may be utilized more when the activities represented in the graphs are perceived to be more mobile or contagious. We speculated that a network graph representing the spread of an infectious disease could lead people to use base rate strategies more often than a network graph representing the spread of drug use. Study 2 also sought to better understand the hierarchical ordering of cognitive strategies identified in the previous studies by constructing a decision tree that could predict the conditions under which particular strategies will be used.

## Participants and Procedure

Participants. We recruited 196 participants from AMT. Participants were limited to U.S. residents and had at least a $90 \%$ approval rating for previous HITs. We excluded 11 participants who either failed attention checks or had participated in a previous study. Most participants said they had no prior experience ( $64.86 \%$ ) or only slight prior experience ( $28.65 \%$ ) with SNA.

Scenario and Materials. Participants were provided the same set of 36 graphs from Study 1 and were asked to make
likelihood judgments about the POI in each graph.
Conditions. The same three graph conditions from Study 1 were manipulated within-subjects. We also introduced different scenarios as a between-subjects manipulation for the source of the graph data. Participants were randomly assigned to one of three data scenarios: drug use, political opinion, and infectious disease (Table 2).

Table 2: Description of data scenarios.

| Scenario | Brief Description |
| :--- | :--- |
| Drug | In a community in which some percentage of <br> people are known users, how likely will the <br> POI become a drug user in the next six <br> months? |
| Opinion | In a community in which some percentage of <br> people are known proponents of a new <br> proposal, how likely will the POI become a <br> proponent in the next six months? |
| DiseaseIn a community in which some percentage of <br> people are infected with a new disease <br> transmitted through social contact, how likely <br> will the POI become infected in the next six <br> months? |  |

Strategy Use. In contrast to Study 1, in which participants described their analysis strategy in an open-text form, participants in Study 2 rated the strategies from Study 1 (ratio, base rate, and proximity) as well as distractors (e.g., central or peripheral location of POI, presence of a cluster of nodes) as to how important they were to their likelihood judgment. Ratings were on a scale of 1 (Not at all important) to 5 (Extremely important). The list order of strategies was randomized at each presentation.

## Results and Discussion

Likelihood Judgments. We used the same model from Study 1 but added scenario to the model as a fixed effect. There was a significant main effect of scenario on likelihood judgments ( $\chi^{2}(2)=26.40, p<.001$ ); specifically, participants in the disease condition gave higher likelihood ratings on average than participants in the drugs or opinion conditions $(b=0.58, t(182)=4.65, p<.001$ and $b=0.63, t(182)=$ $4.71, p<.001$ for disease vs. drugs and disease vs. opinion, respectively). As in Study 1, there were also main effects of base rate $\left(\chi^{2}(1)=288.97, p<.001\right)$, proximity $\left(\chi^{2}(1)=\right.$ 291.26, $p<.001$ ), and ratio $\left(\chi^{2}(2)=671.77, p<.001\right)$. As depicted in Figure 4, higher base rates led to higher likelihood ratings $(b=1.21, t(6471)=24.06, p<.001)$, higher ratios led to higher ratings $(b=0.62, t(6471)=8.92$, $p<.001$ for $1 / \mathrm{N}$ vs. $0 / \mathrm{N}$, and $b=2.16, t(6471)=31.39, p<$ .001 for Half/N vs. $1 / \mathrm{N}$ ), and closer proximities also led to higher ratings $(b=0.99, t(6471)=25.00, p<.001)$.

We again found two-way interactions between base rate and proximity $\left(\chi^{2}(1)=645.45, p<.001\right)$, base rate and ratio $\left(\chi^{2}(2)=424.43, p<.001\right)$, and proximity and ratio $\left(\chi^{2}(2)=\right.$
501.50, $p<.001$ ). Consistent with Study 1, increasing the base rate only mattered when proximity was high ( $b=1.36$, $t(6466)=28.31, p<.001)$; increasing the base rate had stronger effects when ratios were $0 / \mathrm{N}$ or $1 / \mathrm{N}$ compared to Half/N $(b=1.28, t(6466)=21.70, p<.001$ for $0 / \mathrm{N}$ vs. Half $/ \mathrm{N}$, and $b=0.79, t(6466)=13.43$ for $1 / \mathrm{N}$ vs. Half/N); and closer proximity also had stronger effects when ratios were $0 / \mathrm{N}$ or $1 / \mathrm{N}(b=1.30, t(6466)=22.16, p<.001$ for $0 / \mathrm{N}$ vs. Half $/ \mathrm{N}$, and $b=0.36, t(6466)=6.19, p<.001$ for $1 / \mathrm{N}$ vs. Half/N). In other words, when the ratio of users in the POI's connections was very high (Half/N), other graph features had less influence on judgments.

Figure 4: Main effects of data scenario and graph features.
As depicted in Figure 4, main effects of graph features were found for each scenario we tested. The main interaction we were interested in was between scenario and base rate, since we expected that base rates would be utilized more when the scenario described more contagious activities, such as the spread of disease. There was not a significant interaction between scenario and base rate, although significant interactions did emerge between scenario and the proximity and ratio graph features $\left(\chi^{2}(2)=\right.$ $6.31, p=.04$ and $\chi^{2}(4)=40.21, p<.001$, respectively $)$. However, Figure 4 suggests that differences were small and, overall, graph features affected judgments in a consistent way across scenarios.

Strategy Use. Consistent with Study 1, participants' ratings of strategy importance reflected a tendency to rely on the ratio strategy more than other strategies. A multilevel model with strategy treated as a random effect and nested within participant revealed that participants rated proximity and ratio information as more important to their judgment than base rate information $(b=0.24, t(368)=3.43, p<.001$ and $b=0.78, t(368)=11.32, p<.001$, respectively). Participants
rated ratio information as more important than proximity information, $b=0.54, t(368)=7.89, p<.001$.

Decision Tree. Given the multiple interactions between graph features, we modeled the influence of graph features on likelihood judgments with a decision tree using the rpart package in R. Human judgment is often based on 'fast and frugal' heuristics (Gigerenzer, \& Goldstein, 1996), which can be modeled by decision trees. Decision trees identify a series of binary decisions to maximize prediction accuracy of an outcome variable.

The model in Figure 5 shows the decision tree for the Study 2 data. The first decision point splits the data based on ratio. If the ratio was high (many salient nodes in the POI's direct connections), the model estimated that the likelihood rating was high (5.8), and no other variables were considered (far right side of Figure 5).

Figure 5: Decision tree predicting likelihood of investigating the POI. $n$ represents number of judgments collected from participants.

The left side of the first decision point indicates that when there were zero or one salient node(s) in the POI's direct connections, the model next split the data based on the base rate. If the base rate was low (left side of Figure 5), the model then made another split based on ratio, and proximity was not used. If the base rate was high, the model then used proximity. If proximity was far, the model used ratio information again to make the final classification.

## General Discussion

In this research we identified three graph features that influenced judgments about a specific person of interest (POI) in a social network graph: 1) number of salient nodes within the POI's direct connections, 2) base rate of salient nodes in the graph, and 3) proximity of salient nodes to the POI. Across two experiments, we demonstrated the influence of these features on probabilistic graph-based
judgments by manipulating their presence in a series of graphs. Additionally, through our analysis of participants' self-reported strategies and strategy importance ratings, we demonstrated that participants consciously use these graph features in their judgments. Participants reported primarily using the ratio strategy to make their judgments, followed by the proximity and base rate strategies. No matter which data scenario was used (e.g., drug use, disease, public opinion), base rate, proximity, and ratio manipulations influenced judgments in similar ways, with only slight differences across scenarios.

## Strategy Use

Participants consistently used the ratio strategy to make likelihood judgments. The three-level manipulation of this variable $(0 / \mathrm{N}, 1 / \mathrm{N}, \mathrm{Half} / \mathrm{N})$ was the strongest determinant of likelihood judgments and the ratio strategy was the most frequently self-reported strategy. Furthermore, a decision tree analysis suggests that when the number of connections was high, participants made 'fast and frugal' decisions without using the other strategies.

In other cases, participants made use of base rate and layout proximity. The decision tree analysis suggests that each of these graph features was considered by participants when making likelihood judgments, and manipulating each of these variables led to significant main effects on judgments. However, the relative importance of these two strategies is less clear. Participants were more likely to mention using the proximity strategy than the base rate strategy in Study 1, and in Study 2 participants rated the proximity strategy as more important than the base rate strategy. Yet the decision tree analysis revealed that base rate was a decision point before proximity was considered, suggesting that base rate may be more important than proximity to participants' judgments. These results suggest that there may be a disconnect between participants' selfreported strategies and the strategies revealed by their actual judgments. One interpretation of this finding could be that participants were mistaken in how much they considered each graph feature. Future research could further explore the relative importance of these strategies by testing different response formats, scenarios, and graphs.

## Is Use of Proximity an Error?

An important question about these results is whether the use of proximity should be considered a reasoning error. It is true that in force-directed layouts, which was the layout algorithm used to generate the graphs in these studies, layout distance does often have a relationship with graph distance. In other words, the physical distance between two nodes is somewhat related to the number of edges that separate those nodes. However, it could be misleading to rely only on layout proximity to make the kinds of judgments in these studies for two reasons. First, the extent to which proximity provides meaningful information about the relationship between two nodes depends critically on the layout algorithm used for graph construction. Second, in
many cases, users viewing a graph will not have knowledge of the algorithm used to construct the graph (as was the case in this study), leaving the meaningfulness of proximity unclear. Thus, although use of spatial proximity as a factor in judgment is not necessarily wrong in itself, overuse of this heuristic could lead to misinterpretation in some cases. Understanding how novice audiences interpret proximity could help inform the design of layouts and the use of graphs by analysts, particularly for graphs whose layout algorithms are independent of spatial distance.

## Future Directions

The present studies were carried out with participants who lacked a background in SNA. Future studies plan to examine how novices and experts differ in their use of graph information. We also plan to further assess the validity of proximity information by testing different graph layouts and examining correlations between path and spatial distance.

# Explicit Predictions for IIIness Statistics 

Talia Robbins (talia.robbins@rutgers.edu) Pernille Hemmer (pernille.hemmer@rutgers.edu)<br>Department of Psychology, 152 Frelinghuysen Road<br>Piscataway NJ, 08901 USA

#### Abstract

People's predictions for real-world events have been shown to be well-calibrated to the true environmental statistics (e.g. Griffiths and Tenenbaum 2006). Previous work, however, has focused on predictions for these events by aggregating across observers, making a single estimate for the total duration given a current duration. Here, we focus on assessing predictions for both the mean and form of distributions in the domain of illness duration prediction at the individual level. We assess understanding for both acute illnesses for which people might have experience, as well as chronic conditions for which people are less likely to have knowledge. Our data suggests that for common acute illnesses people can accurately estimate both the mean and form of the distribution. For less common acute illnesses and chronic illnesses, people have a tendency to overestimate the mean duration, but still accurately predict the distribution form.

Keywords: Prediction; Judgment; Health; Cognition

## Introduction

Imagine that you have the flu and need to decide whether you will be better in time to travel to a conference this weekend. You are now faced with predicting how long you will be sick. For this inference, you will need to use your knowledge of real-world statistics, including both the mean duration and most likely form of the duration distribution.

People have been shown to make optimal predictions for the duration of many real-world events (Griffiths \& Tenenbaum, 2006). In these domains, people's beliefs about the underlying distribution of quantities (e.g. cake baking times are captured by a bimodal distribution) have been shown to be accurate in the aggregate. These findings have been extended to people's ability to make predictions for illness duration (Robbins and Hemmer, in revision). People were able to make predictions that were consistent with both the mean and form of illness distributions for common acute illnesses (e.g. common cold and seasonal flu), but systematically overestimated the duration of chronic illnesses (illnesses with which they had significantly less experience). This suggests they had knowledge of the correct form of the underlying illness duration distributions.

One limitation of the procedures used in previous experiments (e.g. Griffiths \& Tenenbaum, 2006) is that each participant made only one prediction about a total duration given its current duration. As such, data was aggregated over participants to assess the fit of participant data to the true duration distributions. As Griffiths and Tenenbaum (2006) explain, this gives a guide to peoples' implicit beliefs about the distributions. As such, these experiments do not allow for an assessment of whether people have knowledge of the correct form of the underlying illness distribution at
the individual level. Accordingly, these studies could be illustrating the wisdom of the crowds effect, whereby aggregating over many individual judgments from a group of people leads to a response that is closer to the ground truth than that of a smaller group (Surowiecki, 2004).

To our knowledge, no previous work has assessed the correspondence between people's beliefs and the statistics of the environment-specifically illness statistics-at the individual level. Therefore, in the current study, we assessed whether people understood the true statistics for the durations of different illnesses by asking them directly what they thought the mean and correct form of illness duration distributions were. This allowed us to evaluate whether people have an internal model for real-world statistics that they can consciously access and use to make predictions.

Understanding illness duration is critical for illness identification. For instance, imagine you have a cough and high fever, and thinking you have the flu you try to estimate how long you will be sick. One thing you will draw on is your understanding of the real-world distribution of durations for different illnesses. If your symptoms begin to fade after three days, this may confirm your suspicion that you have the flu, since this is within the normal distribution for the flu. However, if you are still sick after 10 days, you might begin to believe you have a different illness such as the common cold, because you know that 10 days is reasonable within the distribution of duration for the common cold. This estimation requires an understanding of the entire distribution of illness duration, rather than just the mean or some conditional duration. With only the mean of the distribution, you would not know how much variation in duration is normal, or at which point a particular illness is unlikely given the duration of your symptoms.

Illness further provides an interesting example for prediction because people have different levels of experience for different illnesses-e.g. common illnesses such as the cold, or less common illnesses such as bacterial meningitis. Experience may also differ between acute (e.g. cold) and chronic (e.g. asthma) illnesses. An acute illness is defined as one which can be cured with treatment, while a chronic illness is defined as one that can be managed but not cured. Differing levels of experience between chronic and acute illnesses may influence the accuracy of a person's prior beliefs, and different priors might be appropriate for different illnesses, given personal experience.

The observer's prior beliefs play an important role, as optimal predictions are assumed to follow Bayesian principles. Bayes rule gives a principled account of how people should update their prior beliefs given evidence from the world. Each time a person experiences an illness, they
should update their prior probability distributions for the duration of that illness. This would result in illnesses that are experienced more often having very accurate prior distributions. For illnesses that are less commonly experienced, people might adjust their prior beliefs to those of illnesses for which they have more knowledge of the correct form of the distribution, when making inferences. While people might use evidence from other sources when updating their priors, evidence that is personally experienced is better integrated than information acquired in other ways (Sallnas, Rassmus-Grohn, \& Sjostrom, 2000).

In this paper, we sought to assess whether the correspondence of people's beliefs to Bayesian optimal predictions in the aggregate (e.g. Griffiths \& Tenenbaum, 2006; Robbins \& Hemmer, in revision) extended to estimations for the mean and correct form of illness duration distributions at the individual level. We further sought to apply this approach to a domain with direct implications for real world problems-specifically patient health. In Experiment 1, we simply asked participants to predict the mean duration of each of nine illnesses.

In Experiment 2, we sought to assess whether people could make estimations of the correct form of illness distributions. To do this, we gave participants four distribution options-each fit to the true clinical data for that illness-and asked them to select the distribution form that best described that illness. Because each of the distribution options was fit to the clinical data, consistent selection of the correct distribution would clearly illustrate that there is a correspondence between people's internal model and the true statistics of the environment. This suggests that they have a cognitive representation of the form of the distribution of durations that they can consciously access.

## Experiment 1: Mean Estimation

## Methods

Participants Ninety-Nine Mechanical-Turk workers from the United States participated in exchange for $\$ 1$.
Materials We selected nine illnesses-five acute and four chronic (see Table 1) -intended to span a range of durations and familiarity. Familiarity was determined based on prevalence statistics for the number of people diagnosed with that illness each year (see Table 1). Table 1 also includes the source of the clinical data used for the illness duration distributions.

We first needed to determine the mean and correct form of the nine illness distributions. Illness durations have been found to be well modeled by a type of distribution known as a survival function, which includes Gamma, Exponential, and Weibull. The Erlang distribution is a special case of the Gamma distribution, where $\alpha$ must be an integer, which is often used to model illness duration and illness stages in transmission models of infectious disease, and to infer parameters from clinical data (Krylova \& Earn, 2013). For this reason, we assume Erlang is the correct distribution for the nine illnesses. See Figure 1 for the clinical duration

Figure 1: Histograms of clinical data for nine illnesses with best fitting Erlang distributions. Grey bars show the frequency of each illness duration, black lines show the Erlang fit to clinical data. $\mu$ gives the distribution mean.
distributions for the nine illnesses used in this experiment, with corresponding Erlang distribution fits. The clinical data provides a ground truth for both the mean and form of distributions to compare to participant responses (see Table 1 for clinical data sources).
Procedure The procedure was identical to that of Griffiths and Tenenbaum (2006), with the important difference that we did not condition on the current unit of time. As a consequence of the units of time available in the experiment, there may have been an anchoring effect, which is when people are systematically influenced by starting points regardless of whether they are informative (e.g. Chapman \& Johnson, 1999). By not providing the units of measure, we eliminate any possible anchoring effect. Our current procedure provides a truer picture of people's ability to estimate the mean because they are not given a frame of reference. Participants simply made a prediction about the total duration of each of the nine illnesses. The question read: "Given that you meet someone with illness $X$, what do you think will be the total duration of their illness?" Participants responded by typing in a number and selecting a unit of time from a dropdown menu presented on the computer screen. The experiment was performed using the Qualtrics interface. The order of presentation was randomized.

Participants were also asked to categorize each illness

using one of five labels: "Lasts a short time, will go away completely even without treatment", "Can vary in length, requires immediate treatment, but can be cured", "Is long term, requires treatment, but can eventually be cured", "Lasts the rest of a person's lifetime, treatment can only manage symptoms, it cannot be cured, but does not necessarily cause death", "Varies in length, treatment can only manage symptoms, cannot be cured, eventually causes death". Participants were also asked several basic demographic questions (e.g. age and experience with the nine illnesses) which are not analyzed here.

## Results

Given that participants could respond with any unit of time, we first normalized participant responses to the unit of time for the clinical distributions. Responses were then filtered for outliers. Data was excluded in the following way: unreasonably large responses (defined as those 3 standard deviations greater than the mean response for a given illness) and participants who had more than two data points excluded based on the above criteria. The responses analyzed were 85 for appendicitis, 90 for the seasonal flu, 90 for the common cold, 87 for bacterial meningitis, 77 for mononucleosis, 90 for COPD, 90 for chronic heart disease, 90 for type II diabetes, and 90 for asthma.

First, we examined people's ability to characterize the durations of acute and chronic illnesses. Chronic illnesses are lifelong, which is a critical difference from acute illnesses which are curable. To determine whether participants had basic knowledge of the illnesses they were making estimations about, we examined their responses to questions asking to characterize each illness. For the common acute illnesses-common cold and seasonal flu$92 \%$ of participants correctly responded that the illnesses were short term and curable. For the less common acute illnesses-appendicitis and bacterial meningitis- $81 \%$ and $66 \%$ of participants respectively labeled these illnesses as short term. For the four chronic illnesses $74 \%-84 \%$ of participants correctly responded that these illnesses were lifelong. This clearly shows that people understand the chronicity of the chronic and common acute illnesses.

We first evaluated the accuracy of participant's mean

Figure 2: Red bars show the percentage of participants that were X number of standard deviations from the mean. Positive numbers indicate estimations above the mean, and negative numbers indicate estimations below the mean.
responses (see Table 2). A qualitative evaluation of the data illustrates that participant responses were close to the true mean for more prevalent acute illnesses (i.e. common cold and seasonal flu), and that participants overestimated the duration of chronic illnesses, similar to the pattern found by Robbins \& Hemmer (in revision).

In order to evaluate whether participant responses were accurate relative to the true mean of the empirical illness distributions, we used a two one-sided t-test approach (e.g. Limentani et al., 2005). We used this approach as it allows us to test for practical equivalence (e.g. Rogers, Howard, \& Vessey, 1993). A one-sample t-test might find a significant difference between a population mean of seven days and a participant response mean of eight days. While this difference is significant, it places too rigid a standard for our purposes, leading to an inaccurate conclusion that participants do not understand the mean of that illness. For this reason, we set a criterion considering accuracy to be within one standard deviation of the mean of the empirical illness distributions (standard deviations for each illness are displayed in Figure 2). We then conducted a t-test on either end of this threshold to determine if participant responses were significantly greater than the lower threshold, and significantly less than the upper threshold.

We found that for mononucleosis and the common cold,

Table 2: True and estimated illness durations

| Illness | True Duration | Participant Response | \% using unit of time (correct unit is bolded) |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
|  |  |  | Hours | Days | Weeks | Months |
| Years |  |  |  |  |  |  |
| Acute |  |  |  |  |  |  |
| Appendicitis | 39 hours | $471.6(\mathrm{SD}=969.5)$ hours | $\mathbf{8 . 4}$ | 32.6 | 39.0 | 12.6 |
| Seasonal Flu | 3.9 days | $8.9(\mathrm{SD}=4.5)$ days | 2.1 | $\mathbf{3 7 . 9}$ | 56.8 | 3.2 |
| Common Cold | 5.1 days | $6.3(\mathrm{SD}=3.2)$ days | 1 | $\mathbf{6 5 . 3}$ | 33.6 | 0 |
| Bacterial Meningitis | 5.5 days | $37.3(\mathrm{SD}=44.0)$ days | 2 | $\mathbf{1 0 . 5}$ | 45.3 | 36.8 |
| Mononucleosis | 10 weeks | $9.3(\mathrm{SD}=13.0)$ weeks | 1 | 9.5 | $\mathbf{3 5 . 8}$ | 32.6 |
| Chronic |  |  |  |  |  | 21.1 |
| COPD* | 6 years | $36.6(\mathrm{SD}=22.0)$ years | 0 | 1 | 0 | 5.3 |
| Type II Diabetes | 12 years | $36.0(\mathrm{SD}=22.5)$ years | 0 | 1 | 0 | 5.3 |
| Chronic Heart Disease | 13 years | $26.4(\mathrm{SD}=20.0)$ years | 0 | 1 | 2.1 | 2.1 |
| Asthma | 15 years | $42.5(\mathrm{SD}=25.7)$ years | 4.2 | 1.1 | 0 | 2.1 |

[^459]responses were within the one standard deviation of the true mean-meaning the estimates were practically equivalent to the true mean (upper threshold: Mononucleosis: $t(76)=-6.1$ $p<.01$, Common cold: $t(89)=-6.9$. $p<.0$; lower threshold: Mononucleosis: $t(76)=5.1$. $p<.01$, Common cold: $t(89)=13.4 . p<.01)$. For the other seven illnesses, responses were found to be greater than the lower end of the threshold, but not less than the higher end of the threshold, suggesting a pattern of overestimation, (Appendicitis: $t(84)=4.3 . p<.01$, Seasonal flu: $t(89)=13.0, p<.01$, Bacterial meningitis: $t(86)=7.1, \quad p<.01$, COPD: $t(89)=14.9, p<.01$, Type II diabetes: $t(89)=20.4, \quad p<.01$, Chronic heart disease: $t(89)=20.0 . p<.01$, Asthma: $t(89)=13.2 . p<.01)$.

Given that participants were not within the one standard deviation threshold for seven illnesses, we wanted to further examine how misaligned they were for each illness. Therefore, we calculated the percentage of participants at each standard deviation from the mean (see Figure 2). For the common cold and mononucleosis, the majority of participants (approx. 80\%) were within one standard deviation, as illustrated in the TOST. For the seasonal flu more than $70 \%$ of participants were within four standard deviations of the mean, which may seem like a large deviation from the correct response, however it is also important to note that the standard deviations varied greatly between illnesses. For the seasonal flu, the standard deviation was only 1.73 days, meaning that more than $70 \%$ of participants responded within 6.8 days of the true mean. Conversely, for the least prevalent acute illnesses, appendicitis and bacterial meningitis, only $34 \%$ and $38 \%$ of participants respectively were within four standard deviations of the true mean, with some participants being up to 80 standard deviations away (for appendicitis this corresponded to 1416 hours or 59 days). This illustrates that participants had lower agreement, and less accurate mean estimations for these illnesses.

For the chronic conditions, fewer participants were within four standard deviations of the mean, with $31 \%$ for COPD, $100 \%$ for type II diabetes, $61 \%$ for chronic heart disease, and $47 \%$ for asthma. Participant responses were all within four standard deviations of the mean for type II diabetes because the standard deviation is 24 years.

We then examined whether the absence of a time anchor influenced the unit of time participants used to respond (see Table 2). For the acute illnesses, multiple units of time can be used to express the same value; i.e., a one week long illness can be characterized as seven days or one week. For seasonal flu and common cold, more than $80 \%$ of participants responded with either the clinical (days) or the adjacent and reasonable (weeks) unit of time. For mononucleosis, approximately $66 \%$ of participants used the clinical or adjacent unit of time. For the least prevalent acute illnesses-appendicitis and bacterial meningitisparticipants used the clinical or adjacent unit of time only $40 \%$ and $55 \%$ of the time. For the four chronic illnesses, $92 \%$ to $95 \%$ of participants chose the clinical unit of time. The results suggest that participants could reliably use the
clinical unit of time when estimating durations of prevalent acute illnesses and chronic illnesses.

## Experiment 2: Distribution Form Estimation

## Methods

Participants Forty Mechanical-Turk workers from the United States participated in exchange for \$2. The participants had not participated in Experiment 1.
Materials The same nine illnesses from Experiment 1 were used. We selected four distributions as response options in the distributional form task: Erlang, Gaussian (a.k.a. Normal), Uniform, and Bimodal. These distributions were chosen as they can reasonably describe illness durations. The Erlang, which was always the correct answer, was chosen because illness distributions have been found to be well modeled by this distribution and provide a good fit for all the clinical distributions. Normal was chosen because the bell-curve is ubiquitous, and in some cases is very close to the Erlang distribution. This allows us to evaluate how well participants can discriminate very similar distributions. Bimodal was chosen because for chronic illnesses it might be reasonable to assume that there is one group of people who die immediately, and another group that lives with the illness for a longer time. Lastly, uniform was chosen because simple Bayesian prediction models assume a single uninformative (or uniform) prior (e.g. Gott, 1993). Selecting the uniform form of the distribution might suggest observers using a heuristic insensitive to prior beliefs.

Distributions were presented to participants as histograms of the average total duration of an illness. For each illness, the presented histograms were created by producing the best fit to the true clinical data for that illness for each of the four distributions. In this way, participants' choice of distribution

Figure 3: Screenshot of experimental interface for sample question (seasonal flu). Distribution types, top left to bottom right, are: Uniform, Normal, Erlang, and Bimodal.
would be based solely on distribution form. The histograms were presented with descriptive captions. The captions for each distribution form were consistent for all illnesses. Captions described several critical points on the graph using frequencies out of 100 (see Figure 3). The descriptions for each distribution form were matched to illustrate the same number of points on the histogram. Four naïve raters evaluated the relationship between the descriptors and the histograms and in all cases found them to be well-matched and easily understood. The experiment was presented using the Qualtrics interface.
Procedure Participants were first shown instructions on how to read graphs in our task. They then completed a training task, with two training sessions of four trials each. For each trial, participants were shown one histogram (illustrating one of the four distributions types used throughout this experiment) and asked to match it to one of four captions. The training trials were designed to illustrate duration without referencing illnesses. One set depicted the amount of time it takes for a person to turn into a zombie after being bitten, and the second set depicted the number of licks it takes to get to the center of a tootsie pop.

After the training task, participants were asked to choose the appropriate histogram from the four distribution options for each of the nine illnesses (presented one at a time) by selecting it with a radio button. Both question and choice order were randomized.

## Results

Data were excluded if participants answered two or more questions incorrectly in each of the two four trial trainingsets. This removed two participants' data from analysis.

First, we assessed the proportion of trials for which participants chose the clinical distribution (Erlang). Participants chose Erlang $42 \%$ of the time, which was significantly greater than chance ( $25 \%$ ), based on a onesided Binomial test ( $p<.01$ ). It was also chosen significantly more often than any of the other distributions: Normal $X^{2}(1, \mathrm{~N}=342)=11.8, \quad p<.01$, Uniform $\quad X^{2}(1, \mathrm{~N}=342)=93.9$, $p<.01$, and Bimodal $X^{2}(1, \mathrm{~N}=342)=48.0, p<.01$.

While participants selected Erlang with the greatest frequency overall, we were further interested in how frequently they chose the correct response for each individual illness. We performed a one-sided Binomial test and found that for six of nine illnesses, participants performed better than chance (i.e. significantly more than $25 \%$ of participants chose the Erlang distribution): seasonal flu ( $53 \%, p<.01$ ), common cold ( $50 \%, p<.01$ ), bacterial meningitis ( $42 \%, p=.016$ ), mononucleosis ( $42 \%$, $p=.016$ ), COPD ( $45 \%, p<.01$ ), type II diabetes ( $47 \%$, $p<.01$ ). Participants did not select any of the other distributions at a level higher than chance. See Figure 4 for the proportion of participants that chose each distribution option for the nine illnesses.

Lastly, we performed a chi squared test to determine whether participants selected the Erlang distribution significantly more often than the other distribution choices.

Participants chose Erlang more often than Uniform for eight out of nine illnesses: seasonal flu $X^{2}(1, \mathrm{~N}=38)=18.0, p<.01$, common cold $\left.X^{2}(1, \mathrm{~N}=38)=19.0, p<.01\right)$, bacterial meningitis $X^{2}(1, \mathrm{~N}=38)=9.8, p<.01$, mononucleosis $X^{2}(1, \mathrm{~N}=38)=17.0$, $p<.01, \operatorname{COPD} X^{2}(1, \mathrm{~N}=38)=13.3, p<.01$, chronic heart disease $\quad X^{2}(1, \mathrm{~N}=38)=7.9, \quad p<.01$, type II diabetes $X^{2}(1, \mathrm{~N}=38)=8.8, p<.01$, and asthma $X^{2}(1, \mathrm{~N}=38)=4.7, p=.03$.

Erlang was chosen significantly more than Bimodal for five of nine illnesses: seasonal flu $X^{2}(1, \mathrm{~N}=38)=9.7, p<.01$, common cold $X^{2}(1, \mathrm{~N}=38)=4.5, p=.03$, bacterial meningitis $X^{2}(1, \mathrm{~N}=38)=8.0, p<.01, \operatorname{COPD} X^{2}(1, \mathrm{~N}=38)=9.2, p<.01$, and type II diabetes $X^{2}(1, \mathrm{~N}=38)=23.6, p<.01$.

Participants chose Erlang significantly more than Normal for two out of nine illnesses: seasonal flu $X^{2}(1, \mathrm{~N}=38)=8.1$, $p<.01$, and common cold $X^{2}(1, \mathrm{~N}=38)=8.4, p<.01$. As shown above, Erlang was chosen significantly more often than any other distribution for both seasonal flu and common cold.

Figure 4: Red bars show the percentage of participants that chose a distribution choice.

## General Discussion

We evaluated people's ability to estimate the mean and correct form of duration distributions at the individual level within the domain of health. Examining people's representations of illness duration statistics is important, because it allows us to understand the correspondence between people's beliefs and the statistics of the environment-in this case-illness statistics. In addition, these experiments shed light on people's internal representations of real world statistics.

Our most interesting finding is that participants appeared to have knowledge of the correct form of the underlying illness distribution, choosing the assumed clinical distribution (Erlang) more frequently than any other distribution. When broken down by illness, they chose the clinical distribution more frequently for the most prevalent acute illnesses: seasonal flu and common cold.

While participants often inferred the form to be the normal distribution, this may be explained by the similarity of many of the normal fits to the Erlang fits. This occurred because the normal distributions were truncated by a lower duration bound of zero. We deliberately included the Normal distribution because of the potential confusability with the clinical distribution. As such, the fact that participants still chose the clinical distribution as the correct form overall, suggests they have strong beliefs about the
form of illness duration distributions and that these correspond to the environmental statistics. It is important to note that research has illustrated that people often fail at graphical interpretation (e.g. Gerteis et al., 2007), which makes participant performance in this task impressive.

When examining participants' estimates for the mean, we found that for more prevalent acute illnesses (i.e., common cold and seasonal flu), they were able to accurately estimate the mean duration. We also found a pattern of overestimation for chronic illnesses and less-prevalent acute illnesses which was similar to the pattern of overestimation found by Robbins and Hemmer (in revision).

The pattern of overestimation for chronic illnesses might be explained by people applying a probabilistic model of life expectancy to their understanding of the distribution form for illness durations. Because they have little experience with chronic illnesses, and they understand that chronic illnesses are life-long, their overestimation might be due to a strategy of applying parameters from the true distribution of lifespans (adjusted slightly to account for decreased life-expectancy with a chronic illness) to their knowledge that illnesses follow the form of an Erlang distribution. Their ability to select the appropriate distribution form for these illnesses suggests that they can use knowledge of the form of other illness distributions even if they do not have enough experience to set the parameters accurately. This overestimation might also be adaptive in terms of planning for the future. For chronic illnesses, it may be safer to assume a longer duration to plan sufficiently for the future, i.e., retirement savings.

A logical next step for this work would be to ask participants to independently generate distributions, rather than asking them to select from a limited number of options. Goldstein \& Rothschild (2014) have shown that participants can generate these distributions when presented with data, which suggests that this method could be used to evaluate peoples' internal representations of real-world statistics.

Our results illustrate that people hold accurate representations for both the form and mean of duration distributions of prevalent acute illnesses. Significantly, the most prevalent acute illnesses-the com mon cold and seasonal flu-are also the ones for which participants consistently demonstrate knowledge of the correct distribution form, and accurately predict the mean at the individual level. This suggests a prior belief that is better calibrated to the true environmental statistics for illnesses participants have experience with. Taken together, the data suggests that people have an internal representation of illness statistics that they can consciously accessindicating that people can not only combine illness experiences with rational statistical updating, but also have accurate knowledge of these prior distributions.

#### Abstract

We present an experimental study investigating the role of information-theoretic factors in determining patterns of redundancy and focus in language and other communication systems. Pairs of participants played a simple communication game using a non-linguistic visual medium to send messages to each other. We manipulated noise, effort, and time pressures and measured message length, redundancy, and accuracy. Participants behaved as predicted based on an informationtheoretic model, with message length and redundancy varying according to circumstance, but accuracy remaining constant.

Keywords: communication; focus; information theory; language; redundancy; signaling game

## Introduction

Questions invite answers. However, the invitation is not entirely open: There are important constraints on the form that an answer can take. Most obviously, it must be relevant (Grice, 1975; Wilson \& Sperber, 2004). In response to the question of who invented the printing press, for instance, "Мy sister loves cheesesteak" is not an acceptable answer unless some double meaning is understood. Perhaps less obviously, the length and syntactic completeness of an answer are also constrained. Fragment answers-that is, answers that are not whole sentences-are permitted and may even be preferred in some circumstances. At the same time, prosodic and morphosyntactic mechanisms (e.g., pitch fluctuations; cleft constructions such as "it was ... who") may be employed to add redundancy to certain elements in the sentence. Patterns of message length and redundancy should not be assumed to be random. In this paper we present a set of communication game experiments investigating how they vary according to information-theoretic factors.

As an example of how such patterns vary in English, consider the three answers to the printing press question that are given in (1). While (1a) is an acceptable answer, (1b) and (1c) are just as good, and would even be preferable in many contexts.
(1) Who invented the printing press?
a. Gutenberg invented the printing press.
b. Gutenberg did.
c. Gutenberg.

As evidenced by the acceptability of (1a), fragment answers are not obligatory. Indeed, whole-sentence answers
may help establish that the respondent heard and understood the question correctly; in some cases they may also serve to aid parsing of the what Schmitz (2008) calls the "critical" element (in this case Gutenberg). An answer like "The printing press was invented by Gutenberg", for instance, makes very clear through syntactic and prosodic means when precisely the listener should expect to get the answer. An utterance that does contain such unnecessary material is constrained in important ways; in particular, focus must be marked on the critical element. This is realized in English and many other languages by a pitch accent on that element (i.e., the element is distinguished from other parts of the sentence through variation in pitch, length and intensity; for discussion of this welldocumented phenomenon, see Ladd, 1996; Rooth, 1992). It is important to note that this focus is constrained by the grammar of the language and is more or less obligatorydistinguishing the wrong element, distinguishing the right element by the wrong means, or distinguishing no element at all, is likely to be perceived as odd. Example (2) illustrates this pattern, with small caps denoting pitch accent.
(2) Who invented the printing press?
a. $\checkmark$ Gutenberg invented the printing press.
b. $\checkmark$ Gutenberg did.
c. $X$ Gutenberg invented the PRINTING PRESS
d. $X$ GUTENBERG invented the PRINTING PRESS
e. $X$ Gutenberg invented the printing press

It should be noted that similar patterns pertain even when no explicit question has been asked. For example, a restaurant worker who notices a patron wandering around might say to them something like "Over there", "They're OVER THERE", or "The toilets are OVER THERE", even if the patron does not actually ask for directions.

Stevens (2016), following Schmitz (2008) and Bergen and Goodman (2015), argues for a theory of focus based partly in information theory (Shannon \& Weaver, 1949), whereby focus and redundancy are presented as a solution to noise, the random deletion/alteration of parts of a signal. Given that elements in messages may be lost as a result of mishearings, attention failures, and the like, focus is a means of emphasizing those elements that the speaker considers most important to transmit accurately. This can be seen as a process of adding
redundancy to important parts of the linguistic signal, compensating for the effects of noise. At the same time, depending on pressures of time and effort, non-focused elements (the parts of the signal that are easily inferred from context) can be reduced or even elided.

Stevens (2016) followed Rooth (1992) and many others in arguing that the inferrabillity of semantic material from the discourse context follows from the set of alternatives that is evoked by that context. For example, "Who invented the printing press?" evokes a set of possible answers \{x invented the printing press $\}$ which contains propositions like "Gutenberg invented the printing press", "Edison invented the printing press", etc. These alternatives all share overlapping semantic material, namely "invented the printing press" which is inferrable and thus less important in terms of information transmission. The material in need of protection from noise, in other words, is the material that does not overlap among all contextually available alternatives. We will therefore refer to redundancy on this material as non-overlapping redundancy, and redundancy on inferrable material as overlapping redundancy.

## Predictions of an information-theoretic model

If patterns of focus and redundancy in language are indeed a reflex of general information-theoretic concerns, then we expect that analogs to it will arise in any communication system that shares the goal of signaling the selection of one object from among a set of alternatives. For such systems we can thus make the following predictions. First, overall message length should vary according to time and effort costs: Messages should be longer if effort costs are low and time is not pressing. This might seem trivial, but the key point is that messages will not simply be minimally short in all cases. Because redundancy can be useful, messages will in fact be longer than they strictly need to be if time and effort constraints allow. Second, longer messages should differ from shorter messages not only with respect to length, but also with respect to the proportion of overlapping redundancy; that is, overlapping redundancy is a greater luxury than nonoverlapping redundancy, and should be dispensed with more readily. Third, the distribution of effort in a message should take noise into account. In particular, non-overlapping redundancy should be higher when noise is higher, both in an absolute sense (more redundancy overall) and in a relative sense (more non-overlapping redundancy than overlapping redundancy). Fourth, unless noise and time pressures become so great that they simply prevent accurate communication, we should expect communicative accuracy to remain relatively constant, regardless of the variation between messages predicted above. This is because that variation is (according to this account) designed to help maintain accuracy under different conditions.

There is evidence from natural language that speakers are sensitive to time and effort pressures. Corpus analysis suggests, for instance, that syntactic reduction is used to optimize information density (Jaeger, 2010), while work in experimen-
tal pragmatics demonstrates that referring expressions get shorter over time as interlocutors establish common ground (Krauss \& Weinheimer, 1964, Clark, 1996).

In general, however, it is hard to fully test the informationtheoretic basis of focus using natural-language data alone. There is more than one reason for this. A common difficulty in testing predictions in natural language is that the relevant explanatory factors are hard to manipulate (cf. Roberts, in press). To a small extent this is true here: While it is relatively straightforward to introduce noise and time pressures, for example, it is harder to make the act of producing natural-language utterances more effortful without imposing awkward physical constraints on participants. However, this is not the most serious obstacle in this case-in fact there is a history of research in phonetics in which awkward physical constraints are put on participants (e.g., Lindblom, 1990). The more serious problem is that, in established natural languages, there are constraints on such phenomena as pitch accent, focus, and utterance length that are encoded in the grammar. This means that while the patterns of interest might have arisen initially as a result of the information-theoretic factors discussed, we should expect them to an important extent to be "fossilized" as part of the language, incorporated into relatively constrained grammatical constructions, and less sensitive to contingent factors. Even if the information-theoretic account is right, therefore, behavior in established languages may be somewhat weak evidence for it; better evidence would be furnished by observing the establishment of a novel communication system. Furthermore, as stated above, we should expect our claims and predictions to apply across communication systems, linguistic or otherwise. It would therefore be advantageous for our purposes to test predictions in some non-linguistic communicative medium. Fortunately, the last decade or so has seen the development of a line of research in which participants communicate in the lab using "laboratory languages"-either artificial languages taught to the participants, or novel communication systems developed collaboratively over the course of the experiment (Galantucci, Garrod, \& Roberts, 2012, Roberts, in press). This approach allows researchers to investigate principles of communicative behavior while abstracting away as far as possible from the established natural languages that the participants bring with them into the lab. A common kind of study involves the use of visual communication systems. For instance, Garrod, Fay, Lee, Oberlander, and MacLeod (2007) had participants play a Pictionary-like game, while Galantucci (2005) made participants communicate by drawing on a pad that simulated continuous vertical motion, preventing the use of most established conventions. This kind of approach is particularly useful for investigating the challenges involved in establishing reference and constructing a new system from scratch. However, we were interested in the pressures acting on a system in which reference is in principle relatively straightforward, as is the case for a native speaker of a natural language, but where there are no established grammatical conventions as
in language. For this reason we had participants play a very simple communication game in which they had to fill in cells in a grid to convey a line that was drawn over the grid (Figure 1). Under ideal conditions, this task is rather trivial. We made conditions less ideal by manipulating noise, time pressure, and the effort required to produce a signal. We then measured the redundancy in the signals that were produced and the success rate in interpreting them.

## Method

## Participants

One hundred and twenty University of Pennsylvania undergraduate students participated in pairs for course credit or $\$ 5$.

## Procedure

In each trial a pair of participants played a simple cooperative signaling game. Each sat in a separate cubicle with a computer; neither participant could see or hear the other. The game consisted of a series of turns in each of which one player was nominated as Sender and the other as Receiver; players alternated roles, with the Sender in the first turn being selected at random. At the start of a turn the Receiver saw a white screen with the message "You are waiting on a message transmission from the other player". The Sender saw a screen as in Figure 1 On the left were two $7 \times 7$ grids, over each of which a different line figure was drawn. Every line figure consisted of a continuous line drawn between the center points of eleven contiguous grid cells. One of the two line figures was selected in green, while the other was white $?^{1}$

On the right of the screen was an empty $7 \times 7$ grid, slightly larger than the other two. Beneath the two leftmost grids there was also a button marked Send. The Sender's task was to communicate to the Receiver which of the two grids was selected in green by clicking on cells in the rightmost grid. At the moment of the Sender's first click a timer would start. Once the timer stopped (after either 5 or 30 seconds, depending on condition; see Section Experimental conditions) the grids would disappear and be replaced by the message "You are waiting on a guess from the other player." Clicking the Send button would have the same result. Once the Sender's turn had come to an end in one of those two ways, the Receiver's screen would change to display the two line figures that had been displayed to the Sender (in a random order, but each in the same orientation as for the Sender) as well as a third $7 \times 7$ grid in which certain cells might be colored black, and a button marked $O K$ (Figure 22. The black cells would always be cells that the Sender had clicked; however, not all cells that the Sender had clicked would necessarily be sent. The means of deciding which cells would be sent depended on the condition (Section Experimental conditions). The Receiver's task was to select which of the two line figures they

[^460]thought the Sender was trying to communicate. Both players were then told whether the Receiver chose correctly. Then a new turn began. There were 48 turns in total, which were preceded by two practice turns. In half the turns (the Overlap turns) the two line figures overlapped by five squares (as in Figures 1 and (2). In the other half (the Filler turns) there was no such overlap, such that any cell through which a line figure passed would serve to distinguish it from its competitor.

The only differences between the practice turns and the other turns were that the players' success in the practice turns did not count toward their final score, and that, following the practice turns, they were told to ask questions if they had any. If players scored over $80 \%$ in the non-practice turns, they were rewarded with $\$ 2$ each.

Figure 1: Sender's screen.

Figure 2: Receiver's screen.

## Experimental conditions

There were six between-subjects conditions in total (Table 1 ). Conditions differed from each other with respect to the time available to the sender (either 5 seconds or 30 seconds) and with respect to the means with which the sender could ensure that a message be sent. In the Effort conditions clicking a cell a specific number of times would guarantee that it was sent

Table 1: Experimental conditions

| Time limit | Effort | Noise |
| :---: | :--- | :--- |
| 30 seconds | High effort | High noise |
| 30 seconds | Low effort | Low noise |
| 5 seconds | Low effort (5s) | Low noise (5s) |

to the Receiver. The Sender had to click fifteen times on each cell in the High effort condition and five times in the Low effort conditions. Once a cell had been clicked the requisite number of times, it turned black. In the Effort conditions, a cell that turned black for the Sender was sure of being seen by the Receiver, but a cell that had not been clicked enough remained white and was sure not to be sent. The same was not true in the Noise conditions. In these conditions, each click on a cell would make it appear darker. Any cell that had been clicked once had a chance of being sent. Clicking more on the cell not only made the cell darker, but increased that chance (and the darkness of the cell increased proportionally to the probability that the cell would be sent). The probability of a given cell being sent was calculated as $1-(1-d)^{n}$, where $d$ is a decay parameter between 0 and 1 , and $n$ equals the number of times the Sender clicked on the cell in question. Two values were used for the decay parameter. In the High noise condition, it was set at 0.1 . In the Low noise conditions it was set at 0.4 . This meant that it would take many more clicks in the High noise condition than in the Low noise conditions to feel confident that the cell would be sent. For instance, 4 clicks in the latter condition would result in an $87 \%$ chance of the cell being sent, but a $34 \%$ chance in the former. In all conditions the number of cells clicked on can be taken to correspond roughly to utterance length, while in the Noise conditions, cell darkness can be taken to be analogous to greater effort in marking prominence.

The length of time available for the Sender to click on cells was varied, being set at either 5 or 30 seconds. For the Low effort and Low noise conditions, there was both a 5 -second condition and a 30 -second condition. For the High effort and High noise conditions, however, we ran only 30 -second conditions; this is because 5 seconds was not enough time for participants to send more than one cell in the High effort condition, or to have a good chance of doing so in the High noise condition, meaning that the results would be rather trivial and most of our measures could not be calculated.

## Measures

We measured the following variables.

Message length. This was calculated by counting how many squares had been clicked on (for Noise conditions) or turned black (for Effort conditions). Since one cell would be sufficient to distinguish between any two line figures (assuming it arrived), any message consisting of more than
one cell can be considered to contain redundancy.
Click effort. This was calculated by counting the number of clicks made by the Sender.

Overlapping redundancy. This was calculated by counting how many cells the Sender clicked on (for Noise conditions) or turned black (for Effort conditions) that overlapped with both line figures, and would therefore not differentiate the target figure from its competitor. (Note that this could be measured only for the Overlap turns, and not the Filler turns.).

Accuracy. This was calculated by counting the number of turns in which the Receiver chose the correct line figure.

## Results

Data reported in the following sections come from Overlap turns only, for the sake of consistency between the measures. Unless otherwise stated, all models reported are mixed effects linear regression models with random intercepts for both subject and item, using the Satterthwaite approximation of degrees of freedom to obtain a $p$-value from a t -value.

## Variation in message length

We predicted that overall message length should vary according to time and effort costs, with messages being longer than strictly necessary if time and effort constraints allowed. This was supported by the data. One cell would have been sufficient in every condition to signal which line figure to choose; however, messages were longer than this in every condition (Figures 3 and 4). In all but the High noise and High effort conditions, message length also remained relatively constant throughout a game, though it was lower in the Low noise (5s) than in the Low noise condition ( $\beta=-4.83$, $S E=$ $0.75, t=-6.48, p<0.001$ ) and in the Low effort ( 5 s ) condition than in the Low effort condition ( $\beta=-7.64, S E=$ $0.65, t=-11.83, p<0.001$ ), suggesting that the shorter message lengths in the 5 s conditions were due to time constraints. In both the High noise condition and the High effort condition, message length began high and fell over the course of the game in a rather linear fashion, converging in the High effort condition with the Low effort (5s) condition. This suggests that effort came to exercise increasing pressure as time went on. It is likely also the case that it partly reflects participants' growing familiarity with the game, although if this were the main explanation, one would expect a sharper fall by the middle of the game rather than a linear decline. Message length in the noise conditions did not quite converge (i.e., the slope was less steep), likely because less effort was necessary in this condition.

## Message length and overlapping redundancy

We predicted that shorter messages should differ from longer messages with respect to the proportion of overlapping redundancy. This was confirmed. The proportion of clicks devoted

Figure 3: Message length in effort conditions.

Figure 4: Message length in noise conditions.
to overlapping redundancy (as opposed to non-overlapping redundancy) correlated with click rate ; $r=0.29, p<0.001$ ), but the correlation was stronger $(r=0.56)$ in the High effort and High noise conditions alone, where there was greater pressure on participants (Figure 5).

## Distribution of effort

We predicted that the distribution of effort would take noise into account and that non-overlapping redundancy would be higher when noise is higher, both in an absolute sense and relative to overlapping redundancy. This was confirmed by results. First, click effort was lowest in the Low noise (5s) condition, but higher in the High noise condition than in the Low noise condition ( $\beta=58.57, S E=7.56, t=7.75, p<0.001$ ), in both of which rounds lasted 30 seconds (Figure 6. Sec-

Figure 5: Correlation between click effort and overlapping redundancy (High effort and High noise conditions only).

Figure 6: Click effort in noise conditions.

Figure 7: Proportion of clicks on overlapping redundant cells in Noise conditions.
ond, for the proportion of overlapping redundancy, there was a significant interaction of turn and condition for the High noise and Low noise conditions ( $\beta=0.006, S E=0.002, t=$ 3.07, $p<0.01$ ): Although all the noise conditions began at roughly the same place (Figure 7), the proportion of overlapping redundant cells clicked in the Low noise condition remained relatively constant, but decreased on the High noise condition. There is also a main effect of condition if the interaction terms are excluded from the model $(\beta=0.11, S E=$ $0.04, t=2.81, p<0.01)$. The proportion of clicks on overlapping redundant cells was significantly lower in the Low noise ( 5 s ) than in the High noise condition ( $\beta=-0.10, S E=$ $0.04, t=-2.44, p<0.05)$.

## Accuracy rates

We predicted that accuracy would remain similar between conditions, regardless of differences in message length, click effort, and redundancy. This was broadly true. Overall mean accuracy was very high ( $97 \%$ ), and did not differ significantly between conditions, with one exception (Figure 8): It was lower in the Low noise (5s) condition ( $\beta=-0.07, S E=$ $0.02, t=-2.81, p<0.01)$. This likely represents an underestimation of noise by participants; this was the only condition in which senders had little time to send a signal, but could not be sure before sending it how much the receiver would see.

## Discussion

We modeled the emergence of a system similar to linguistic focus by having participants play a simple non-linguistic

Figure 8: Accuracy rates by condition. Error bars show 95\% confidence intervals.
communication game, in which we manipulated noise, effort, and time pressures. We made four predictions consistent with an information-theoretic account of focus: that message length should vary according to time and effort costs, that longer messages should differ primarily with respect to redundant material that is shared with alternatives, that the distribution of effort in the message should take noise into account, and that accuracy should be stable in spite of variation in other measures. These predictions were confirmed. The patterns we observed also resemble patterns in natural language. While message length varied considerably between conditions, accuracy was maintained, largely due to distribution of effort being skewed toward protecting nonoverlapping material from noise. On the one hand this is consistent with the natural-language examples given in the introduction to this paper. On the other hand, it is also consistent with findings from experimental pragmatics studies in which participants repeatedly refer to a set of unfamiliar shapes; referring expressions are reliably shorter at later stages of such interactions (Krauss \& Weinheimer, 1964, Clark, 1996). This is typically explained in terms of the establishment of common ground-participants develop a shared perspective on the objects in question. On the surface, this does not obviously apply so well to our study, but the fundamental mechanism is the same. The point in both cases is that message length varies as a result of time and effort pressures on the one hand, and the sender (or speaker)'s confidence that the message will be understood by the receiver, on the other.

Overall, our results lend support to the view that linguistic focus may have emerged as a response to informationtheoretic pressures. We also consider that the experimental approach we have taken may prove fruitful for future work.

## Acknowledgments

We are grateful to Robin Clark for insightful comments on the development of this project, to Lisa Raithel for preparing the software, and to members of the Cultural Evolution of Language Lab for assistance in running the experiment. This work was funded in part by the American Council of Learned Societies (ACLS).

# Manual Response Dynamics Reflect Rapid Integration of Intonational Information during Reference Resolution 

Timo B. Roettger \& Mathias Stoeber<br>timo.roettger@uni-koeln.de, m.stoeber@uni-koeln.de<br>Department of Linguistics - Phonetics, University of Cologne, Herbert-Lewin-Straße 6<br>D-50931 Cologne, Germany

#### Abstract

Intonation plays an integral role in comprehending spoken language. It encodes post-lexical pragmatic functions such as sentence modality and discourse contexts. The present experiment investigates how and when listeners integrate intonational information to anticipate reference resolution. While most work on the real-time processes of intonation-based intention recognition has utilized eye tracking, the present study uses the mouse tracking paradigm, a valuable complementary method to investigate the time course of speech processing. Participants had to choose an interpretation based on pre-recorded instructions containing different intonation contours. Recordings of the $\mathrm{x}, \mathrm{y}$ coordinates of participants' computer mouse movements reveal that listeners integrate intonational information rapidly as soon as they become available and anticipate potential referential interpretations early on.

Keywords: intonation, reference resolution, mouse tracking

## Introduction

During the perception of an unfolding speech signal, listeners use acoustic information to guide their interpretation of what a speaker intends to communicate. This process can take place long before disambiguating lexical information becomes available, allowing the listener to make rapid inferences about what a speaker intends to say, even if these inferences are based on partial information.

Intonation plays an integral role in this interpretation process. Among other things, intonation is commonly used to express discourse relations such as givenness and contrastiveness (e.g. Ladd 2008). Intonational acoustic events such as pitch accents have been shown to consistently encode the discourse status of referents. For example, in German or English, a high rising pitch accent generally signals new information, while for example deaccentuation (i.e. the absence of a pitch accent) tends to signal given information (e.g. Fery \& Kügler 2008, Cangemi et al. 2015 inter alia).

While much work has been done on how intonational events encode discourse relations, there is only little work on how and when listeners integrate this acoustic information with the relevant discourse information.

To fully understand intonation-based intention recognition, it is necessary to use experimental techniques that measure the real-time integration of intonational information to resolve temporally ambiguous interpretations. While eye tracking experiments have advanced our knowledge about these processes tremendously (e.g. Dahan et al. 2002, Weber et al. 2006, Watson et al. 2006, Kurumada et al. 2014), it has been pointed out that the nature of oculomotor patterns constitutes a limitation of the eye-tracking paradigm (e.g. Spivey et al.

2005, Dale et al. 2007). Eye-movement data is characterised by ballistic "jumps" of the eye. Only by averaging over many trials can a pseudo-continuous trajectory be calculated, which is then interpretable as evidence for a continuous comprehension process.

This potential methodological shortcoming can be overcome by measuring another form of movement behaviour: the movements of hands. Over the last decade, it has been demonstrated that continuous nonlinear trajectories recorded from the streaming of $x, y$ coordinates of computer mouse movements can serve as an informative indicator of cognitive processes (e.g. Spivey et al. 2005, Magnuson 2005). Even though mouse tracking has been applied to diverse phenomena in cognitive science, its usefulness for speech processing research has been somewhat neglected. This paper provides evidence that mouse tracking is suitable to unravel real-time dynamics of speech processing beyond lexical and phonemic processing (see also Tomlinson \& Bott 2013 and Warren 2017).

## Real Time Integration of Intonation

Several studies have demonstrated that comprehenders can rapidly integrate intonational information to map an utterance containing referential expressions onto intended referents. These studies have focused on the discourse status of referents, i.e. whether an item has or has not already been mentioned or is explicitly contrasted to another referent.

Dahan et al. (2002) utilised the visual world paradigm in which specific items and geometrical shapes were distributed in a grid. Upon hearing specific auditory instructions listeners had to move the objects above or below the shapes. In one of their experiments, subjects heard a trigger sentence such as "Put the candle below the triangle." The object "candle" and the location "below the triangle" were thus introduced to the listener as given information. After the trigger sentence, listeners heard the critical instruction, either referring to the given object ("candle") or a lexical competitor which shares its word onset with the given object (here "candy"). When the target word was deaccented, listeners' eye movements revealed significantly more fixations to the already given object before the lexical disambiguation was available. Conversely, when the target word was accented, there were more fixations to the competitor.

Weber et al. (2006) extended these findings by showing that the presence or absence of a contrastive pitch accent on a modifying adjective allows listeners' anticipation of contrastivity of the noun (see also Watson et al. 2006).

Kurumada et al. (2014) examined the time course of the construction "It looks like an X" pronounced with either a high pitch accent on the final noun followed by a low boundary tone (e.g. it looks like a ZEBRA), or a contrastive high rising pitch accent on the verb and a rising boundary tone, a contour that can support contrastive inference, (e.g. it LOOKS like a zebra (but it is not)). They found that listeners integrate the pitch accent information on the verb to anticipate the status of the target referent.

These reported effects are consistent with the hypothesis that listeners integrate intonational information rapidly as soon as it becomes available and anticipate potential referential interpretations early on.

The contributions of the present paper to this literature are twofold: On the one hand, we aim to replicate previous findings showing that listeners take up intonational information rapidly to anticipate pragmatic interpretations using mouse tracking. On the other hand, we aim to proof that continuous response tracking can provide valuable insights into the realtime comprehension of utterance-long speech signals.

## The Present Study

The present study investigates intonation-based intention recognition in German using the mouse tracking paradigm. It is hypothesised that listeners integrate intonational information to anticipate referential ambiguity early on and that this anticipation is reflected in the dynamics of their mouse trajectories during response selection. In line with standards of reproducible research, all materials (including audio and visual stimuli), scripts, and raw data are available here: https://osf.io/n79x3

## Methodology

Participants had to choose visually presented response alternatives corresponding to pre-recorded speech files in a twoalternative forced choice design. Stimuli differed with respect to the available discourse context and the intonationally encoded information status of referents, enabling us to investigate the real-time integration of intonational information during reference resolution.
Experimental Set-up Participants were seated in front of a MacBook Pro 3.1 GHz Intel Core i7 with a display resolution of $1280 \times 800$. They controlled the experiment via a Logitech B100 corded USB Mouse. Cursor acceleration was made linear and cursor speed was slowed down using the CursorSense® application (version 1.32).

Participants and Procedure Ten native speakers of German (five male, five female) with an average age of 30.3 years $(\mathrm{SD}=4.9)$ participated in this experiment. All of them had normal or corrected-to-normal vision.

Participants were told about two different fantasy creatures which were introduced as 'wuggies'. These wuggies were displayed as having picked up certain real world objects such as a pear or a violin. The two wuggies differed in colour
("blau" 'blue' vs. "gelb" 'yellow’) and there were 10 different objects that the wuggies could pick up (bee, chicken, fork, marble, pants, pear, rose, saw, vase, violin).

On each trial, participants were exposed to a question screen that either did or did not provide a specific discourse context, followed by a response screen in which participants had to choose visually presented response alternatives depending on an auditorily presented sentence.

On the question screen, participants either heard nothing or they heard a question such as (1):
(1) "Hat der gelbe Wuggy die Geige aufgesammelt?" 'Did the yellow wuggy pick up the violin?'

The question provided a discourse context with certain elements being activated as given for the participant (here: the yellow wuggy and the violin). The question screen was visible for 2500 ms .

Following the question screen, participants saw two visually presented response alternatives, each depicting a wuggy carrying an object. After 1000 ms , a yellow circle appeared at the bottom centre of the screen. Participants were instructed to click on the yellow circle to initiate playback of an audio recording. The audio recording was a statement specifying which wuggy has picked up which object, e.g., "Der gelbe Wuggy hat die Geige aufgesammelt." 'The yellow wuggy has picked up the violin.' Participants were instructed to move their mouse immediately upwards after clicking the initiation button and choose the respective response alternative as soon as they could.

After each response selection, the screen was left blank for a 1000 ms inter-stimulus interval.

Prior to the beginning of the experimental trials, participants were given 36 practice trials to familiarise themselves with the paradigm.

Speech Material There were two sets of acoustic stimuli: questions providing a discourse context presented on the question screen and statements triggering participants' responses on the response screen. There were twenty different questions for all possible combinations of wuggies and objects (two wuggies $\times$ ten objects).

Likewise, there were twenty different statements, which were produced with four different intonation contours. Based on the question, i.e. the discourse context, and the visual scene at hand, statements differed with regard to the information status of the relevant constituents of the sentence: The question in (1) ("Hat der gelbe Wuggy die Geige aufgesammelt?") asks for confirmation that the proposition (including the identity of the subject and object) is true. Now consider the following answers (2-4):
(2) Der gelbe Wuggy hat die Geige aufgesammelt. 'The yellow wuggy has collected the violin.'
(3) Der gelbe Wuggy hat die Birne aufgesammelt. 'The yellow wuggy has collected the pear.'
(4) Der blaue Wuggy hat die Geige aufgesammelt. 'The blue wuggy has collected the violin.'

Figure 1: Representative waveform and f 0 contour for a statement produced with a rising accent on "Wuggy" and a falling accent on "Geige", a typical contour for broad focus. Accented words are highlighted with grey boxes.

Figure 2: Representative waveform and f0 contour for a statement produced with a rising accent on the auxiliary "hat", typically used to indicate verum focus. The accented word is highlighted with a grey box.

Dependent on the discourse context (here: whether there is question or not, and the question being asked), the answers in (2-4) are realised with different intonation contours (Fery \& Kügler 2008, Cangemi et al. 2015). If there is no discourse context available, both the subject and the object are new information in (2) (often referred to as broad focus) which can be prosodically encoded by specific pitch accents on both constituents. A common contour in these cases is a rising accent on the subject, followed by a high stretch of f 0 and a high or falling accent on the object (cf. Figure 1).

Alternatively, if there is a relevant discourse context such as the question in (1), the utterance in (2) can prosodically emphasise that the proposition of the question is true. This can be indicated, for example, by verum focus, which manifests itself here in the form of a high rising accent on the auxiliary ("hat", cf. Figure 2).

In contrast, the answers in (3) and (4) correct the proposition of the question. In (3), "Birne" is explicitly contrasted with "Geige", typically expressed by an intonation contour with a high rising accent on "Birne" (cf. Figure 3). In (4), "blaue Wuggy" contrasts with "gelbe Wuggy" in the question. In this context, a high rising accent on "blaue" and no

Figure 3: Representative waveform and f 0 contour for a statement produced with a rising accent on the referent "Birne", typically used to indicate contrastive focus. The accented word is highlighted with a grey box.

Figure 4: Representative waveform and f 0 contour for a statement produced with a rising accent on the subject modifier "blaue", typically used to indicate contrastive focus. The accented word is highlighted with a grey box.
accent on "Geige" is typically found (cf. Figure 4).
All acoustic stimuli were produced by a trained phonetician in a sound-attenuated booth at the Institute of Phonetics in Cologne with a headset microphone (AKG C420) using 48 $\mathrm{kHz} / 16$ bit sampling. The average stimulus duration of the trigger sentences was 1993 ms .

Visual Stimuli The pictures of the fantasy creatures were taken from a hand drawn set developed and used by van de Vijver \& Baer-Henney (2014). The pictures of objects were taken from the BOSS corpus (Brodeur et al. 2010).

Response alternatives of critical trials differed visually by the identity of the referent only (e.g. yellow wuggy carrying a pear vs. yellow wuggy carrying a violin). In addition to the critical trials, we included the same number of filler trials, in which response alternatives differed visually by the colour of the wuggy only (e.g. yellow wuggy carrying a pear vs. blue wuggy carrying a pear), or by both the colour of the wuggy and the identity of the object (e.g. yellow wuggy carrying a pear vs. blue wuggy carrying a violin). These visual contrasts were introduced to ensure that participants do not simply
learn to anticipate certain combinations of questions and visual contrasts, disregarding the acoustic information.

Stimuli Presentation and Predictions There were four different experimental conditions: In the broad focus condition, participants did not receive a question and had to respond to a broad focus statement (cf. Figure 1). Since participants had no discourse context available, they had to rely on lexical information only. It is expected that the mouse movements during reference resolution do not change until the lexical information becomes available (the onset of "Geige" in example 2).

In the other three conditions, participants received a question and were thus able to integrate the given discourse context with the intonational information encoding the information status of the referents. Participants saw a already mentioned, given object (here: "Geige") and a new object (here: "Birne").

In the object focus condition, the pitch accent on the object indicates the contrastive nature of the object. The available pitch accent information becomes available simultaneously with the lexical information, i.e. the rise in pitch starts at the onset of the word (cf. Figure 3). Assuming that the pitch accent information primarily cues contrastivity, we do not expect listeners to anticipate the referent, i.e. the broad and object condition should not differ.

In the verb focus condition, the pitch accent on the verb indicates verum focus, i.e. signalling that the proposition of the question is true implying that the statement contains the already mentioned object (here: "Geige"). As soon as the intonational information on "hat" becomes available, listeners are expected to integrate this information, enabling reference resolution before the lexical information becomes available.

In the subject focus condition, the pitch accent on the subject modifier indicates the contrastive nature of the subject. This information enables an early inference towards the given nature of the object which only occurs later in the utterance, making reference resolution possible very early on.

Left/right placement of target vs. distractor response alternatives was counterbalanced within participants.

Analysis The x, y screen coordinates of the computer mouse were sampled at 100 Hz using the mousetrap plugin (Kieslich \& Henninger 2016) implemented in the open source experimental software OpenSesame (Mathôt et al. 2012). Trajectories were processed with the package mousetrap (Kieslich et al. 2017) using the statistical software R (2016).

There was a total of 80 target trials, for a grand total of 800 trajectories across participants ( 200 per condition). Overall, $4.36 \%$ of trials with incorrect responses and $0.45 \%$ of trials with initiation times greater than 500 ms were discarded. Additionally, $1.67 \%$ of trials were excluded due to movement behaviour that violated instructions (loops, reaching the top of the screen before response selection).

For each of the remaining trials, we computed two measurements based on time- and space-normalised trajectories: First, we collected overall reaction times (RT) measured from
the initiation click up until reaching the target response. This serves as a latency baseline. Second, we measured the area under the curve (AUC) operationalised by the geometric area between the observed trajectory and an idealised straight-line trajectory drawn from the start and end points (Freeman \& Ambady 2010). A greater AUC is indicative of greater response competition between target and competitor during response selection.

We analysed data using hierarchical linear models using R and the package lme4 (Bates et al. 2015), afex (Singmann et al. 2016), and lmerTest (Kuznetsova, Brockhoff, \& Christensen 2016). Discourse condition (broad, object, verb, subject) was included as a fixed effect. Participants were specified as by-condition random slopes and referents were specified as random intercepts.

## Results and Discussion

Inspection of time- and space-normalised horizontal trajectories over time (cf. Figure 5) suggests that trajectories were characterised by initially gravitating toward the midpoint between response alternatives (horizontal cursor position $=0$ ) before eventually curving towards the target response (horizontal cursor position $=-1$ ).

Focus conditions elicited similarly-shaped trajectories that mainly differed with respect to their temporal characteristics. Not surprisingly, conditions differed in their overall response latency, measured from clicking the initiation circle to reaching the target response area $\left(\chi^{2}(3)=19.6, \mathrm{p}=0.0002\right)$ with the broad condition being the overall slowest ( $\beta=1578 \mathrm{~ms}$, $\mathrm{SE}=40.7$ ) followed by the object condition $(\beta=1457 \mathrm{~ms}$, $\mathrm{SE}=49.5$ ), the verb condition ( $\beta=1367 \mathrm{~ms}, \mathrm{SE}=51.9$ ), and the subject condition ( $\beta=1121 \mathrm{~ms}, \mathrm{SE}=93.8$ ) (cf. Figure 6, Table 1). Pairwise comparisons reveal significant differences between all four conditions. The earlier the relevant intonational cue in the acoustic signal, the faster listeners selected a response. Moreover, the difference between broad condition and object condition suggests that the integration of discourse context and intonation facilitated reference resolution (object) in contrast to cases without available discourse context (broad).

These overall response latencies were neatly reflected in early moments of direction change: The broad condition started curving towards the target response around 300 ms after lexical disambiguation (dashed line in Figure 5). This time-lag can be interpreted as the time it takes for listeners' movements to be affected by the relevant acoustic cue of the lexical item.

The subject condition elicited response trajectories that deviated towards the target response very early in the signal, after having heard the contrastive pitch accent on the subject modifier. As opposed to that, the verb condition started curving towards the target shortly after the acoustic onset of the referent suggesting that integrating intonational information of the verum focus led to an immediate anticipation of the target referent before lexical disambiguation has taken place.

Figure 5: Horizontal cursor position of mouse trajectories plotted over time for broad, object, verb, and subject condition. Dashed line indicates the averaged acoustic onset of the critical lexical item.

Figure 6: Violin plots of overall response latency (RT) of response selection.

Figure 7: Violin plots of area under the curve (AUC) values of response selection.

Crucially, the object condition started its curvature towards the target less than 200 ms after the point of lexical disambiguation. Taking the time lag of the broad condition into account, it becomes clear that even the object condition elicited trajectories that started curving towards the target response before lexical disambiguation had taken place. Listeners' anticipation in the object conditions seems puzzling. Both the lexical cue (onset of disambiguating phones) and the intonational cue (onset of the rising pitch movement) become available in the signal at the same time, i.e. the onset of the referential expression. The question arises as to how listeners anticipate the referent in the object condition. We propose two
possible answers to this question: On the one hand, linguistic functions are expressed by multiple acoustic cues distributed throughout the signal. Listeners might have picked up acoustic evidence indicating the contrastive nature of the referent before the pitch accent information had become available. On the other hand, within the microcosms of the experiment, listeners might have been able to anticipate the referent based on the absence of contradicting information. In other words, listeners did not hear a pitch accent on either the subject modifier nor the auxiliary, leading them to the conclusion that the object must be contrastive.

Overall, the observed patterns suggest that the integration of intonational information and discourse context facilitated reference resolution due to successful anticipation.

Table 1: Descriptive and inferential summary statistics for RT and AUC for each focus condition.

| Condition | RT |  |  | AUC |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | mean | est | SE | mean | est | SE |
| Broad | 1587 | 1578 | 40.7 | 0.39 | 0.39 | 0.02 |
| Object | 1466 | 1457 | 49.5 | 0.4 | 0.4 | 0.02 |
| Verb | 1367 | 1363 | 51.9 | 0.37 | 0.37 | 0.01 |
| Subjet | 1116 | 1121 | 93.8 | 0.31 | 0.31 | 0.03 |

Beyond these temporal operationalisations, results for area under the curve measurements (AUC) indicated that conditions differed in overall attraction of trajectories towards the competitor ( $\left.\chi^{2}(3)=12.4, \mathrm{p}=0.006\right)$ with the object condition exhibiting the greatest $\operatorname{AUC}(\beta=0.4, \mathrm{SE}=0.02)$, followed by the broad condition ( $\beta=0.39, \mathrm{SE}=0.02$ ), the verb condition ( $\beta=0.37, \mathrm{SE}=0.02$ ), and the subject condition ( $\beta=0.31$, $\mathrm{SE}=0.03$ ) (cf. Figure 7, Table 1). Not surprisingly, the earlier the relevant intonational cue in the acoustic signal, the less curvature towards the competitor was found. Importantly, albeit highly correlated, AUC and RT were not a direct mirror image of each other. While the broad condition is clearly the slowest, it was not the condition with the greatest AUC indicating that these measures reflect two different aspects of the response selection process: Overall latency and response competition.

## General discussion

The present study investigated intonation-based intention recognition in German using the mouse tracking paradigm. Listeners were exposed to different discourse contexts and different intonational patterns encoding the discourse status of referents. Analyses of continuous computer mouse movements during response selection suggest that listeners integrated intonational information rapidly as soon as it became available and anticipated potential referential interpretations early on. These insights are not new, of course. The present study merely replicates well-known results from studying oculomotor patterns with eye tracking (e.g. Dahan et al. 2002, Weber et al. 2006, Watson et al. 2006, Kurumada et al. 2014). Using the mouse tracking method, we showed that when listeners received discourse
relevant intonational information, their hand motions began to curve towards the target response before lexical disambiguation had taken place.

While the literature has mainly looked at intonational processing of rather clear mappings of intonational form and pragmatic interpretation, i.e. the presence vs. absence of a prominent pitch accent indicating contrastiveness, it remains to be seen, how these results generalise to scenarios in which listeners are exposed to more variable intonational information. Intonational categories have been shown to be characterised by a tremendous amount of variability (e.g. Grice et al., in press, inter alia), exhibiting no one-to-one mapping of form and function. Future research will need to answer the question as to how listeners accommodate to this degree of uncertainty in intonation-based intention recognition. The present study serves as a proof of concept that such questions can be conveniently studied using the mouse tracking paradigm (see also Tomlinson \& Bott 2013, and Warren 2017). We hope that our results spark more interest for this low-cost and pragmatically flexible experimental paradigm for research on speech perception within domains that go beyond phonemic and lexical processing. Mouse tracking proofs to be a fertile method to unravel the real-time dynamics of speech processing such as intonation-based intention recognition.

# Beyond candidate inferences: People treat analogies as probabilistic truths 

Brad Rogers (bwrogers@indiana.edu)<br>David Landy (dlandy@indiana.edu)<br>Department of Psychological and Brain Sciences, 1101 East 10th Street<br>Bloomington, IN 47405 USA

#### Abstract

People use analogies for many cognitive purposes such as building mental models, making inspired guesses, and extracting relational structure. Here we examine whether and how analogies may have more direct influence on knowledge: Do people treat analogies as probabilistically true explanations for uncertain propositions?

We report an experiment that explores how a suggested analogy can influence people's confidence in inferences. Participants made predictions while simultaneously evaluating a suggested analogy and observed evidence. In two conditions, the evidence is either consistent with or in conflict with propositions based on the suggested analogy. We analyze the responses statistically and in a psychologically plausible Bayesian network model. We find that analogies are used for more than just generating candidate inferences. They act as probabilistic truths that affect the integration of evidence and confidence in both the target and source domains. People readily treat analogies not as a one-way projection from source to target, but as a mutually informative connection.

## Introduction

A teacher proposes to her class that atmospheric carbon concentration is like the water level in a bathtub (Kunzig, 2009). This science classroom analogy suggests many possible inferences about the atmosphere (and maybe bathtubs) that students can test by collecting evidence. Perhaps the atmospheric carbon level rises or falls based on the difference between carbon "faucet" and "drain" rates. Or maybe once carbon levels hit the upper limit, carbon dioxide will spill over into outer space. These new inferences might be true, or not. But what about the analogy itself? Is it the sort of thing that can be true or false? Does it depend on the inference? If it can be true, what kind of evidence would support it?

Analogy is used in a wide range of uncertain contexts such as contentious negotiation (Loewenstein et al., 1999), ambiguous accounting determinations (Magro \& Nutter, 2012), scientific discovery (Gentner, 2002; Hesse, 1966), thinking about astronomical distances (Resnick et al., 2012), and war declaration decisions (Khong, 1992). We use analogies when knowledge is scarce. But does analogy act like other explanations? Can we combine analogy with observed evidence? Like explanations, do we believe in them more when they successfully predict or explain our observations? Currently there is no account for how we
integrate analogy and observed evidence when grappling to understand uncertain situations. Even more, there is no psychological account that explicitly affords epistemic value to analogy.

In this paper we examine and affirm the hypothesis that people treat analogies as probabilistic truths. Analogies can be treated as true or false, and people integrate analogies with evidence much like they do for causal explanations.

## Candidate Inferences Hypothesis

Analogy is often called "the weakest form of evidence." Indeed, one account is that an analogy does not provide any evidence at all to favor its suggested candidate inferences since the act of constructing an analogy does not involve collecting new observations. Proponents of this account suggest that an analogy might render propositions more plausible, but not more probable (Bartha, 2010). Popular theories of analogical inference (Doumas et al., 2008; Gentner, 1989; Hummel \& Holyoak, 1997; Lu et al., 2012) largely invoke this candidate inferences account: ${ }^{1}$

Analogical reasoning in uncertain contexts begins with a well-described source domain and a target domain that requires an inference. A speculative analogy is made from the source to the target, which establishes a structural map between the two situations. With some luck, the source domain might contain useful correspondences to unknown elements of the target, producing candidate inferences that can only be validated by observed evidence in the target domain.

Some computational models treat analogy as a weighted score (e.g., ACME, SME), but this score is typically taken to reflect coherence (Holyoak \& Thagard, 1989; Thagard, 1989) or structural consistency (Gentner, 1983) and has not been extended to estimate the truth or rationality of the analogy. The correspondence identified by the analogy is not something that could be true or false. Rather, it is considered an artifact of our thinking about possible target inferences that should only guide our pursuit of evidence.

[^461]
## Analogy as Evidence Hypothesis

In this paper, we explore a stronger account of analogy with an expanded epistemic role. On this account, analogies not only introduce plausible inferences; they create a probabilistic connection between source and target that establishes and conveys inferential confidence.

The basic intuition is suggested by Peirce's notion of abduction (1935) and Harman's notion of inference to the best explanation (1965). Inference to the best suggests that people have confidence in the explanations that make their observations the least surprising. When an analogy suggests an inference in the target domain, observed evidence for that inference should increase the likelihood of the analogy itself when the analogy is taken as an explanation for the target inference. Conversely, if the target inference turns out to be false, the analogy becomes suspect. Our account builds on this insight to propose that people treat analogies and source knowledge as raising the conditional probability of target inferences.

Some readers may find it easy to consider that analogies act as a kind of theory whose truth can be supported or refuted by evidence. Indeed, some philosophical investigations have proposed statistical bases for analogical rationality (Harrod, 1956; Mill, 1882), and a recent study has found that people are sensitive to these rational statistics (Rogers \& Landy, 2016). But this epistemological view of analogy has not been dominant in the literature. Still, we are only interested here in the psychological question of whether people treat analogies as a probabilistic truth, rather than the normative question of whether they ought to.

## Approach

We conducted an experiment that asked participants to rate their confidence in competing explanations in two domains that may or may not be related. We provided observed evidence in one domain whose coherence with competing explanations was manipulated across subjects. A statistical analysis estimates primary effects to determine whether observed evidence influences reported confidence in the analogy. A Bayesian network model was used to compare responses with a psychologically plausible instantiation of analogy that integrates with observed evidence.

## Experiment

Participants were presented a fictional narrative situation describing two novel scientific phenomena, including simple visual representations. ${ }^{2}$ Mutually exclusive

[^462]explanations are provided for the phenomena. A suggested correspondence between the phenomena is described as leading scientists to develop an explanation and experiment. After receiving the stimulus and a test condition statement, participants rate their confidence in each of the explanations and the analogy.

For 20 years, biological scientists have fought over the relation between FCS, exachrome, and nuwen in the human hippocampus. Some scientists believe that exachrome is produced in cell nuclei, and that exachrome drives up production of FCS. They think that nuwen doesn't matter for FCS production. The more exachrome, the more FCS. Other scientists argue that it is nuwen produced in the cell nuclei that drives production of FCS, and that exachrome is an irrelevant byproduct. Both of these production pathways (the exachrome pathway and the nuwen pathway) are chemically plausible; which is correct is a matter of current debate. It is quite unlikely that both are correct. The following image summarizes the debate:

Rat hippocampi are much less well understood than human hippocampi. Rat hippocampi do exhibit FCS, but they do not contain exachrome or nuwen. Recently, one scientist (who was not attached to either of the other groups mentioned before) has suggested that FCS might be produced in rats in a way similar to that of humans. She identified two chemicals--called endochrome and oowen--that are similar to exachrome and nuwen, and that are produced in the rat hippocampus.

In other non-biological contexts, nuwen is sometimes used to predict properties of oowen, and exachrome is sometimes used to predict properties of endochrome. The following image summarizes the possibilities suggested by this scientist:

Rat Hippocampus

Recently, on the basis of the suggested links between exachrome and FCS in humans, and between human and rat FCS production, the scientist and her colleagues tested a novel hypothesis using rat hippocampi. The scientists injected the rats with a hormone that stimulates the production of endochrome. Several days later, they examined the level of FCS in the rat brain, predicting that it would show an increase.

Figure 1. Stimulus narrative presented to all participants

## Participants

We recruited $\mathrm{N}=300$ adults living in the US from Amazon's Mechanical Turk where participants can volunteer to complete short studies and other tasks in return for 35 cents.

## Design

Each participant was presented the same narrative (Fig. 1). Additionally, they were presented a single statement regarding the outcome of the scientific experiment implemented on the rat brain. This statement varied between subjects for three balanced conditions:

- As it turned out, increasing endochrome led to a large increase in the level of FCS in the rat hippocampus. (Confirm)
- The experiment results haven't been released yet, so we don't know how it worked out. (Neutral)
- As it turned out, increasing endochrome did not increase the level of FCS in the rat hippocampus at all. (Disconfirm)

## Procedure

Following presentation of the narrative and conditional statement, participants were asked to indicate their confidence for each explanation using a 7-point Likert scale:

- Exachrome causes the production of FCS in human hippocampus.
- Nuwen causes the production of FCS in human hippocampus.
- Endochrome causes the production of FCS in rat hippocampus.
- Oowen causes the production of FCS in rat hippocampus.

They were also asked to indicate their confidence that the situations are analogous:

- The production of FCS in rat hippocampus works similarly to that of human hippocampus.

Two balanced question orders were used. No response differences were observed on the basis of question order, so the factor was removed from subsequent analysis. All conditions contained a simple attention check. About $1 / 4$ of participants failed the attention check and were removed from the analysis.

## Statistical Analysis \& Results

We analyzed the participant responses by regressing each response item against the between-subject condition statements with each condition coded as a dummy variable. Since the assumptions violated linearity, we used resampling with 10,000 replications to evaluate statistical significance. For comparison, we also calculated Cohen's d to corroborate the significance of the observed effect sizes.

As expected, participant confidence in this explanation increased for the confirmation condition and decreased for the disconfirmation condition ( $\mathrm{p}<0.0001, \mathrm{~d}=2.5$ ). Since the procedure asserted that the two explanations about the rat hippocampus were unlikely to be simultaneously true, we predicted that the competing explanation would follow the opposite pattern. Indeed, when Endochrome $\Rightarrow$ FCS was
supported, confidence ratings for the Oowen $\Rightarrow$ FCS explanation decreased ( $\mathrm{p}<0.0001, \mathrm{~d}=2.5$ ).

Participants confidence ratings in the source domain explanations were also influenced by the observed evidence in the target domain. Confidence in the corresponding source explanations about the human hippocampus changed in the direction consistent with the correspondence structure of the analogy. For the Endochrome $\Rightarrow$ FCS explanation confidence increased with positive evidence and decreased with negative predictions ( $\mathrm{p}<0.0001, \mathrm{~d}=0.75$ ). Confidence in the competing source explanation Nuwen $\Rightarrow$ FCS was inversely affected ( $p<0.0001, d=-0.80$ ). Finally, successful predictions made participants more confident in the idea that the two domains were analogous ( $\mathrm{p}<0.0001, \mathrm{~d}=0.50$ ).

Participant responses strongly supported our hypothesis people treat the analogy as evidence for the inferences is suggests. New successful predictions made on the basis of a mapping from the source to the target increased confidence in the commonality of the domains, as well as in the untested scientific explanation that generated them.

## Bayesian Network Model \& Results

We further analyzed the data using a Bayesian network model (Pearl, 2009) to estimate the influence of the suggested analogy on the response item confidence statements in a way constrained by a plausible causal structure. In the model, each causal explanation is represented as a single node and assigned a prior baseline probability. Since it was stated in the stimulus that the two explanations within a domain were unlikely to be simultaneously true, the model places a negative correlation between the explanations. Without an analogy, the source and target domains (i.e., human and rat hippocampus, respectively) have no causal linkage. On the other hand, if there is a known analogy that is taken as certain, strong causal linkages are present from the source to the target domain.

Figure 2. Bayesian network structure without analogy and with certain analogy

With an uncertain analogy, though, the structure itself becomes probabilistic. To capture this, we take the model a step further by representing the analogy itself as a single node. In this way, we can gauge the evidentiary influence of
the analogy and participants' confidence in it using their confidence ratings. If the domains were sufficiently complex that multiple mappings were possible, it might be necessary to include structural evaluations in the model such as rankings from a model of structural correspondence (Landy \& Hummel, 2010). But in this case, the mapping from source situation to target situation is plainly obvious and can be treated as a single node.

Although the distinction is often drawn between superficial and deep analogies, how people consider the truth of an analogy has not been investigated to the best of our knowledge. As a starting place, the analogy was modeled as a Boolean variable-true or false. Participant confidence in the analogy was estimated by a Beta-distribution..

Now the probability of a target domain explanation prior to observing the experimental results depends on both the probability of the truth of the source domain explanation and the probability of the truth of the analogy. If the analogy is true, then what is true or false in the source domain is also true or false in the target domain. However, if the analogy is false, the truth of the target explanation is independent of the source domain knowledge. In other words, an analogy guarantees correspondence, but a failed analogy does not guarantee non-correspondence. This approach effectively introduces a probabilistic switch between the no analogy and certain analogy network structures.

The prior probabilities of the Bayesian network were fit without including the evidence obtained by the experimental results (i.e., the test condition statement). So each individual is taken to have an estimate of the prior probability of each of the source explanations, the analogy, and the target explanations. The prior probabilities provide an associated estimate of participant confidence that the experimental results will be confirmed or disconfirmed.

Figure 3. Bayesian network structure with uncertain analogy and evidence from experimental results (i.e., test condition)

The participant data was fit using a hierarchical model. Participants were assumed to have been randomly selected from a population having a single distribution of subjective priors for each node. The priors were estimated using Dirichlet distributions for the domain explanation
probabilities ${ }^{3}$ and Beta distributions for the analogy and the evidence probabilities. The model had 14 population-level free parameters, fit to 1500 participant responses. Participants from the neutral condition were assumed to respond based on these prior parameter estimates without any additional evidence. Participants from the evidence condition were modeled by updating the Bayes net given the appropriate evidentiary outcome, and these posterior estimates were fit to the responses.

Figure 4. Posterior predictive distributions by condition for each explanation compared with response distributions

We solicited confidence ratings using a Likert scale rather than explicit probability estimates. So a final step in the model was to translate posterior probabilities from the

[^463]Bayesian network into Likert response values. We treated Likert values as ordered and evenly distributed from 0 to 1. Responses were then treated as beta-distributed among these values, with mean at the subjective probability. This allowed variance from the specific posterior subjective probabilities, minimized degrees of freedom in the model, and afforded a limited flexibility in translating posterior probabilities into Likert scale responses. The model was fit in Stan via R: 1,000 posterior samples proved sufficient for model convergence with population-level $\widehat{R}$ values all less than 1.1 (Bates et al., 2015).

Figure 4 indicates posterior predictions of each Bayesian network node overlay with the fit participant Likert responses for each condition. The major patterns in the data were generally well-captured by the model, suggesting that people were integrating evidence from the target prediction success into their confidence in the analogy, and were doing so in a manner that approaches rational behavior. Predictions matched the direction of the observed effects for all five model nodes. If the analogy were rejected by participants, we would expect no differences between conditions in the responses about the analogy and about the source explanations.

|  | Participant <br> (Likert fit) |  | Model Predicted 95\% HPI <br> Lower bound |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
|  |  | 0.14 |  | 0.13 |  |
| Upper bound |  |  |  |  |  |

Figure 5. Difference between confirm and disconfirm participant confidence ratings versus model predictions

The model fit can be evaluated by comparing differences between the distribution of participant responses and the simulated posterior predictions of the population (i.e., 1,000 samples of the posterior for each of 300 participants). Although the model matched the direction of the empirical results in every case, the outcome of this analysis revealed a systematic bias (discussed later) that could not be accounted for by this computational approach.

## Discussion

What does it mean to be confident in an analogy? What does it mean for an analogy to be assigned a probability value at all? This is an important open question. Analogies are rarely exact correspondences. Useful analogies are sometimes even known from the outset to be poor, such as "atoms are like solar systems." Alternatively, models and simulations in the social sciences are often presented as valid simplifications of complex phenomena. It seems, then, that we can be confident in an analogy's validity even when we do not believe the correspondence to be exact. This paper takes a first step toward answering these open questions by establishing a basic fact: people do treat analogies as probabilistic truths and integrate them with evidence.

## Implications for analogical inference

If analogies just generate candidate inferences, then people's confidence in explanations in one domain would be unaffected by observations in another. In contrast, we found that analogical mappings do raise posterior estimates of the likelihood of candidate inferences. Moreover, when uncertainty exists in the source domain knowledge, confirmed analogical inference in the target domain raises confidence in the corresponding source knowledge. This effect suggests that people treat analogies not as a one-way projection from source to target, but mutually informative.

Results show that the effective confidence of the analogy itself is influenced by the success of its inferences suggesting that people evaluate the analogy on more than its degree of structural correspondence. The analogy seems to have a causal property that can be integrated with and influenced by observed evidence. To that point, no evidence was ever presented in the source domain that could arbitrate between the proposed explanations, so evidence confirming a target domain inference could not possibly strengthen the structural correspondence between the domains. And yet, if the new information confirmed inferences made by the analogy, differences by condition in participant confidence ratings suggest they credited the analogy for the success.

It is worth noting that while the candidate inferences account is implied in many extant studies of analogy, the authors of those studies may not wish to explicitly commit to it. For the most part, we believe that the role of evidence in influencing the value of the analogy has been deferred rather than denied. We see these results as extending rather than negating extant approaches.

## Deviations from rationality

Although the observed confidence differences are quantitatively close to the model predictions, the observed differences are not completely compatible with rational allocation of probabilities under the assumption that analogies act as evidence for their inferences. Participants attributed success or failure of the analogy more to the veracity of the source explanations and less to the analogy than would be expected by the model structure. In other words, we expected confidence in the analogy to justify shifts in confidence in the source domain explanations. But the observed shifts in the source domain outpaced participant reported confidence in the analogy. One possible explanation is that participants may have interpreted the analogical statement more broadly than intended, so that the possibility of any related dissimilarity would reduce their confidence in the analogical statement. Another possibility is that people use different cognitive processes to rate confidence in analogical statements than they use to rate domain-specific statements. If true, then it may be necessary to apply a simple transformation to reported analogical confidence when modeling analogy in a Bayesian network.

## Limitations of the present study

One limitation of the experiment is that the relationship between mammal brains is not only a near analogy, it is also a biological homology. Rats and humans evolved from a common ancestor, so similarities between them may reflect properties of their ancestor rather than attribution of evidence to the analogy per se. Indeed, scientists regularly use animal models to predict properties of human beings on this basis. Because the inference of the experiment may have a biological explanation, shifts in confidence may reflect an alternate process of inference about the cause rather than about the analogy. In subsequent experiments using more distant domains-such as suggesting a link between ion behavior in "super-cooled glass" and macroeconomic decisions by nations-we find consistent, but less pronounced effects to those presented here.

## Future study

Even though we can conclude that people are willing to treat an uncertain analogy effectively as a probabilistic truth, it is not clear what cognitive processes underlie this effect. Two alternate hypotheses are:

1. People may treat the analogy as a kind of theory whose truth can only be supported by evidence in the source and target domains. This is the most straightforward interpretation of the experiment and the approach taken by the ERIC model of explanatory reasoning under uncertainty (Landy \& Hummel, 2010).
2. Success of an inference may imply a stronger structural correspondence than is actually observed. Confirming evidence for an inference in one domain may improve an implied estimate of unobserved, but still predictive, structural correspondence (Rogers \& Landy, 2016).

More investigation is needed to distinguish between these possibilities. We still await a fully integrated account of reasoning across correspondences among structures about which people have probabilistic beliefs.

#### Abstract

Biased attention is assumed to play an important role in the etiology and maintenance of depression and depressive symptoms. In this paper, we used data from a categorization task and an associated model to assess the attentional bias of people with varying levels of depressive symptoms. Attentional bias was operationalized as the parameter estimate in a prototype model of categorization. For estimation, we used a Bayesian hierarchical mixture approach. We expected to find a positive correlation between depressive symptoms and an $A B$ for negative material and a negative correlation between depressive symptoms and a bias toward positive material. Despite good model fit, Bayesian regression analyses revealed weak or moderate evidence in favor of the null model assuming no association between attentional preferences and depressive symptoms, both for negative and positive material.

Keywords: psychology; cognitive science ; attention; concepts and categories; Bayesian modeling; mood disorder

## Introduction

Biased attention takes an important position in cognitive theories explaining the etiology and maintenance of psychological disorders. In particular, depression has been theorized to be linked to biased attention for negative information (Beck, 1976). Multiple methods have been developed to assess attentional biases (AB). The most popular approaches include reaction time assessments, in which response latencies for negative, positive, and neutral material are compared, and translated into AB indices. Eye tracking techniques, comparing fixation durations on negative, positive, and neutral stimuli, are also a popular approach. Caution is recommended however, in both approaches. When relying on reaction time assessments, one has to consider the ambiguity and lack of reliability often associated with response latencies (Rodebaugh et al., 2016). Eye tracking techniques appear to yield good reliability estimates, but only if certain conditions are met (Rodebaugh
et al., 2016). Moreover, as these techniques focus exclusively on overt attentional processes, they are less informative with regard to attentional resources that are allocated covertly, without saccadic eye movements. Perhaps not surprisingly, results obtained with these existing approaches are not consistent (Peckham, McHugh, \& Otto, 2010).

The goal of this paper is to explore novel methodologies for assessing attentional biases associated with depressive symptoms. In particular, inspired by Viken, Treat, Nosofsky, McFall, and Palmeri (2002), we tested the applicability of a categorization approach to assess AB's in the context of depression (see also Kruschke \& Vanpaemel, 2015). Participants were presented pictures of human faces varying in emotional expression (emotional stimulus dimension) and hair color (neutral stimulus dimension). They were asked to classify these stimuli in two different categories, each represented by a prototype stimulus of that category. The two prototypes reflected extreme levels of the stimulus dimensions and were each other's opposites. For example, prototype A had a light hair color, and a very sad facial expression, versus prototype B with a dark hair color and a slightly sad facial expression. In this way, participants could either choose to focus on the hair color (or neutral) dimension or on the facial expression (or emotional) dimension to classify the pictures. These data, taking the form of classification counts of each category, per stimulus, were then used to estimate participant-specific parameters in a prototype model (e.g., Nosofsky, 1987). One of these parameters corresponds to the attentional weight (AW) for one stimulus dimension, reflecting the relative attentional preference for that stimulus dimensions compared to the other stimulus dimension.

We expected to find a positive correlation between depressive symptoms and an AB for negative material and a negative correlation between depressive symptoms and a bias toward positive material (Peckham et al., 2010). In addition
to depressive symptoms, we assessed anxiety symptoms, as depression and anxiety are known for their comorbidity, and our aim was to isolate the relation of $A B$ to depressive symptoms. Brooding or depressive rumination, and a negative mood, were also investigated in this study, since both variables have already been related to an attentional bias for negative material (Bradley, Mogg, \& Lee, 1997; Koster, De Lissnyder, Derakshan, \& De Raedt, 2011). Finally, the personality trait, neuroticism was assessed, in order to explore whether this important risk factor for depression, could be related to an AB for negative information.

## Method

Every participant received two versions of a classification task, each version was administered in two (withinparticipant) conditions. In all versions and conditions, participants were asked to classify facial stimuli according to two prototype stimuli. The stimuli were made up of only two different stimulus dimensions: brightness of hair color and intensity of emotional expression. In the happy condition, the emotional expression ranged from a slightly to a very happy facial expression, whereas in the sad condition, it ranged from slightly to very sad.

We report all data exclusions, all included questionnaires or measures, and all study conditions.

## Participants

A total of 309 first-year psychology students participated in this study in exchange for course credits ( 262 women, mean age $=18.53, \mathrm{SD}=1.90$, with a range from 17 to 39 ). The sample size was determined by the number of participants showing up during the two weeks of data collection, available for all first-year students of the Psychology department of the University of Leuven (Belgium).

## Materials

Self-report Measures The Center for Epidemiologic Studies - Depression Scale (CES-D; Radloff, 1977) was used to assess depressive symptoms (score: $0-60$ ). The Hospital Anxiety and Depression Scale (HADS; Spinhoven et al., 1997), was included to assess comorbid depression (score: 0 - 21) and anxiety symptoms (score: 0-21). We also included the Rumination Response Scale (RRS; Nolen-Hoeksema, \& Morrow, 1991) to assess brooding (score: 5-20), and the Ten Item Personality Inventory (TIPI; Gosling, Rentfrow, Swann, 2003) to assess neuroticism (score: 1-7). Finally, the current mood of participants was measured with a 5 -point Likert scale ("How do you feel at this moment? 1 (very unhappy) 2 (slightly unhappy) -3 (neutral) -4 (slightly happy) -5 (very happy"). Dutch versions of these questionnaires were administered.

Stimuli The stimuli were adopted from the Karolinska Directed Emotional Faces (KDEF; Lundqvist, Flykt, \&

Öhman, 1998). Applying Fotomorph 13.9 (Softland SRL) and GIMP (2008), the pictures were adjusted in such way they only systematically differed from each other on two dimensions: The intensity of facial expression and the brightness of the hair color. On the basis of the modified stimuli, a negative and positive stimulus set were created. In the sad condition, the intensity of the facial expression ranged between very sad and slightly sad, whereas in the happy condition, the intensity ranged from very happy to slightly happy. By creating five different levels of emotional expression (mild intensity - strong intensity) and five different levels of brightness of hair color (light - dark) and combining all possible levels, we obtained a stimulus set consisting of 25 different pictures for each condition. Prototypes were extreme on both dimensions (for example, a stimulus having a very sad emotional expression of level 5 , and very dark hair color of level 5). Figure 1 presents example stimuli.

Task In both conditions, participants were asked to classify all pictures of the condition-specific stimulus sets into category A or B. Category A was represented by one of the four prototypes, and category B by the inverse prototype, within the same emotional condition. For example, in the sad condition, if prototype A had level 5 of sadness (very sad) and level 5 of hair color (very dark), then prototype B had level 1 of sadness (slightly sad), and level 1 of hair color (very light). The prototypes stayed on participants' computer screen during the entire task. In each trial, participants had to classify one picture into one of the two categories. No feedback was provided, so participants could freely choose how to classify the stimuli. In making the classification decisions, participants thus could either base their classifications on the pictures' hair color or facial expression, reflecting their attentional focus on these dimensions.

Figure 1. The two upper pictures represent two possible prototypes. The stimuli at the bottom are random examples of the negative stimulus set, to be classified in category A or B. Adapted from "The Karolinska Directed Emotional Faces" - KDEF", by D. Lundqvist et al., 1998, CD ROM from Department of Clinical Neuroscience, Psychology section, Karolinska Institutet, ISBN 91-630-7164-9. Copyright 2015 by D. Lundqvist.

For each condition, there were two versions of the task, differing in the prototype pairs used. Version 1 consisted of prototype A1, with level 5 of sadness, and level 5 of hair color, and prototype B1, with level 1 of sadness, and level 1 of hair color. Version 2 consisted of prototype A2 with level 1 of sadness, and level 5 of hair color, and prototype B2 with level 5 of sadness and level 1 of hair color.

## Procedure

Each participant ran through both conditions, and in each condition, they performed two versions of the same task. The order of the conditions, and task versions within the conditions, was counterbalanced between participants.

In each task, participants categorized two blocks in which all 23 non-prototype stimuli were presented in a random order. Thus, within each task version, each stimulus was classified twice. After completing the categorization tasks, participants were asked to indicate their current mood state, and to fill out the CES-D, HADS, RRS, and TIPI.

## Model

The categorization data were analyzed using Nosofsky's (1987) weighted prototype classification model:

$$
\mathrm{P}(\mathrm{~A} \mid \mathrm{i})=\frac{\eta_{\mathrm{iA}}}{\eta_{\mathrm{iA}}+\eta_{\mathrm{iB}}}
$$

The model assumes that the probability of classifying stimulus $i$ in category $A, P(A \mid i)$, is driven by the perceived similarity between stimulus $i$ and prototype $A, \eta_{i A}$, divided by the overall perceived similarity between stimulus i and prototype A and prototype B. The perceived similarity between stimulus $i$ and prototype $A$ is assumed to be an exponential decay function determined by a sensitivity parameter $c$, and the weighted distance between the stimulus and the prototype, $d_{i A}$ :

$$
\eta_{i A}=e^{-c d_{i A}}
$$

The sensitivity parameter $c$ reflects how clearly the stimuli could be discriminated from each other. The weighted distance between the stimuli and prototype $A, d_{i A}$, was computed as follows:

$$
d_{i A}=w_{a}\left|x_{i a}-x_{A a}\right|+\left(1-w_{a}\right)\left|x_{i h}-x_{A h}\right|
$$

where $x_{i a}$ represents the coordinate of stimulus $i$ on dimension affect, and $x_{i n}$ the coordinate of stimulus $i$ on dimension hair, in psychological space. $x_{A a}$ is the coordinate of prototype $A$ on dimension affect, and $x_{A h}$ the coordinate of prototype $A$ on dimension hair. $w_{a}$ is the AW for the affect dimension, and $1-w_{a}$ is the AW for the hair dimension.

The coordinates of the stimuli and prototypes were obtained in a separate study in which a different group of 32 participants rated the two dimensions of all stimuli on a 10-
point Likert scale, ranging from 0 (light hair color/mild facial expression) to 9 (dark hair color/ intense facial expression). For both the sad and happy conditions, the split-half reliabilities of respectively the affect and hair color dimensions were .96 and .99 . The coordinates of the stimuli were calculated by taking the mean rating on each dimension for every stimulus.

The prototype model was extended hierarchically and with a mixture component in a Bayesian framework (see e.g., Bartlema, Lee, Wetzels, \& Vanpaemel, 2014). The hierarchical extension was used to accommodate continuous, qualitative individual differences, and to shrink extreme values, whereas the mixture component was included to accommodate discrete, quantitative individual differences. In particular, it allowed differentiating between three groups of participants: The first group consists of people whose behavior was captured better by a guessing model, which assumed that the response probability for each stimulus was .5. Identifying these participants avoids contamination of our parameter estimates by participants for whom the prototype model was not sufficiently appropriate, that is, participants who appeared to be guessing (see, e.g., Voorspoels, Rutten, Bartlema, Tuerlinckx \& Vanpaemel, in press, and Zeigenfuse \& Lee, 2010 for a similar approach).

Among the participants assigned to the prototype group, we allowed two subgroups: the 'affect group' and the 'neutral/hair group' with the 'affect group' having a higher group-level AW for the affect dimension, as compared to the 'hair group'. In particular, we restricted the mean AW for the affect dimension in the 'affect group' to be higher than the mean AW for affect in the 'hair group'.

## Results

## Model Analyses

The model was implemented in JAGS (Plummer, 2011). We ran 3 chains with 36000 iterations each, after discarding 4000 iterations for burn in. We performed separate analyses for the sad and happy conditions. The data from the two task versions (different prototypes) within each condition were jointly modelled in order to obtain a single AW in each condition. The model analyses identified two clearly distinguishable groups (a group focusing on affect and a group focusing on hair color) in both conditions.

In the sad condition, the 'affect group' contained 141 participants, whose AW was larger for the affect dimension (the group-level posterior had a mean $w_{-}$sadness $=.88$ ), compared to the 'neutral/hair group', containing 163 participants (mean $w_{-}$sadness $=.21$ ).

In the happy condition, the 'affect group' contained (again) 141 participants, whose AW was larger for the affect dimension (the group-level mean attention to happiness was: $w_{-}$happiness $=.87$ ), compared to the 'neutral/hair group' (mean $w \_$happiness $=.19$ ), consisting of 167 participants.

Also, a number of participants were not distinguishable from guessers. In the sad condition, we identified five guessers, with one of them being also, the only, guesser in the happy condition.

To evaluate the fit of the model, we inspected the grouplevel posterior predictive for all categorization tasks. To give an idea of how well the model performs, Figure 2 presents the posterior predictive for one of the two task versions in the sad condition. Each panel shows a schematic representation of the stimulus space (five by five stimuli, represented by the squares), with the corner stimuli being prototypes. The panels depict the latent groups. In each square, the background color provides an indication of the model's posterior prediction for the corresponding stimulus and group, as a gradient between the top left prototype (orange) and lower right prototype (blue). The stronger the color matches the prototype, the more firmly the model predicts classification in the corresponding category. In each square, the circle color is an indication of the average observed classification count of the corresponding stimulus, across all participants in the group. Thus, matching colors between background and circle provide insight in the match between the model's posterior predictions and the observed data.

Figure 2. Posterior predictive check, see text for details.

Inspection of Figure 2 reveals that the model successfully captures the patterns within each latent group. Also, the predicted and observed stimulus groupings are sensible considering the AWs applied in each group, with the affect group categorizing the stimuli according to the affect dimension, and the hair group according to the hair color dimension.

## Regression Analyses

After excluding five participants who were assigned to the guessing group, multiple regression analyses were performed to investigate the relationship between attentional preferences, as operationalized by the individual-level estimates of $w_{a}$, and depressive symptoms, anxiety symptoms, brooding, neuroticism, and current mood. All variables showed sufficient variability (see Table 1 for the descriptive statistics). Variance inflation factors (VIF; Hair, Anderson, Tatham, Black, 1995) indicated only a low degree of multicollinearity in our model (largest VIF was 3.22, well below the threshold of 10 ).

Table 1: Descriptive statistics.

|  | SD | mean | range |
| :--- | :---: | :---: | :---: |
| CES-D | 10.06 | 17.83 | $0-52$ |
| HADS_D | 3.63 | 4.41 | $0-18$ |
| HADS_A | 3.97 | 7.07 | $0-20$ |
| TIPI_E | 1.41 | 4.36 | $1-7$ |
| RRS | 3.52 | 10.47 | $5-20$ |
| Mood | 0.60 | 3.11 | $1-5$ |
| w_sadness | 0.37 | 0.51 | $0.04-0.99$ |
| w_happiness | 0.37 | 0.49 | $0.05-0.98$ |

Note. w_sadness is $w_{a}$ in the sad condition, whereas $\mathrm{w}_{-}$happiness is $w_{a}$ in the happy condition.

The regression analyses were performed using the BayesFactor package (Morey \& Rouder, 2013). A BF compares the evidence for the null model with the evidence for the alternative model. Given the null model in the numerator, a $\mathrm{BF}>1$ indicates evidence in favor of the null model, whereas a $\mathrm{BF}<1$ indicates evidence in favor of the alternative model.

To test the effect of each predictor (e.g., depressive symptoms), we compared a restricted model containing all predictors, except for the predictor of interest (null model), against a full model containing all predictors (alternative model). As a sensitivity analysis, both medium and ultrawide scale factors were used to calculate the Bayes factors. As can be seen in Table 2, the Bayes factors showed evidence in favor of the null model for all predictors in both conditions (with the exception of current mood in the sad condition when a medium scale factor was used). The strength of the evidence depends on the exact choice of scale factor. When the scale factor is medium, the evidence in favor of the null
model is weak, and thus these results are best interpreted as being inconclusive. With increasing scale factor, the evidence in favor of the null grows stronger, but it is never very strong. Overall, these analyses suggest that no strong evidence for meaningful associations could be found between the symptom and traits scores and the AWs. The near zero partial correlation coefficients (using the ppcor package; Seongho, 2015), confirm this picture, as can be found in Table 2.

Table 2: Overview of the BFs (> 1 indicates support for the null model), and the corresponding partial correlation coefficients.

|  |  | 3 | sad | happy |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
|  | BFm | BFu | PC | BFm | BFu | PC |
| CES-D | 1.89 | 3.23 | -.00 | 2.59 | 4.60 | .02 |
| HADS_D | 2.50 | 4.38 | .03 | 2.84 | 5.07 | .03 |
| HADS_A | 2.75 | 4.87 | .03 | 3.05 | 5.49 | .02 |
| TIPI_E | 2.82 | 4.99 | -.02 | 3.04 | 5.48 | -.02 |
| RRS | 2.32 | 4.05 | -.03 | 2.53 | 4.48 | .04 |
| mood | 0.87 | 1.39 | -.09 | 1.17 | 1.93 | -.08 |

Note. $\mathrm{BFm}=$ Bayes factor with medium r scale, $\mathrm{BFu}=$ Bayes factor with ultrawide r scale. $\mathrm{PC}=$ partial correlation coefficient.

## Discussion

Applying a categorization approach to the assessment of attentional biases in people with varying levels of depressive symptoms revealed weak to moderate evidence for the absence of an association between severity of depressive symptoms and an attentional bias to sadness or happiness. Similar BFs were observed for the other predictors of interest: anxiety symptoms, brooding, neuroticism, and current mood. In the light of the small Bayes factors, especially when using a medium scale factor, we cannot make strong statements about rejecting the alternative model, or accepting the null model.

These findings are in line with previous inconsistencies in results obtained with the frequentist approaches investigating attentional biases in the context of depression (Peckham et al., 2010). In some studies p values above .05, whereas in other studies, p values below .05 were found, without a clear explanation as to when to expect significant results and when not.

An important limitation of the current study that could explain the results, is the recruited sample. A high functioning student sample was recruited. Though we could observe a reasonable amount of variability in depression scores, the sample may have been too healthy to detect attentional biases related to depressive symptomatology. A next step is to apply this approach to data obtained in a sample of more severely depressed participants.

We believe the modelling approach demonstrated here, has a number of advantages that might prove useful in helping to
solve the elusiveness of attentional biases in the context of depression. First, attentional preferences were extracted from a model, that excluded people whose behavior could better be predicted by a guessing model, instead of the prototype model. This means that data resulting from random behavior were filtered out. Second, by considering a specific parameter in a model to conceptualize attentional biases, other processes that might influence participants' behavior in the task, such as people's discrimination abilities ( $c$ parameter), were factored out. Third, assessing attentional processes by considering their impact on categorization behavior could be quite insightful, given that classification decisions reflect the way in which people organize and structure their world. Attentional bias indices obtained by analyzing categorization behavior can give us an idea about how strongly attentional preferences influence the way in which people perceive and organize their environment.

# Is it fair? Textual effects on the salience of moral foundations 

Eyal Sagi (esagi@stfrancis.edu)<br>University of St. Francis<br>500 Wilcox St. Joliet, IL, 60435

#### Abstract

Many of the important decisions we make have moral implications. Moral Foundations Theory (Haidt \& Joseph, 2004) identifies 5 distinct styles of moral reasoning that may be applied to such decisions. This paper explores how reading text that emphasizes one of these styles might affect our reasoning. After participants read a series of tweets that emphasized the Fairness/Cheating foundation they exhibited an increased reliance on this style compared to when they read tweets emphasizing the Care/Harm foundation. This affected participants' answers to a questionnaire designed to measure the perceived importance of the different foundations, as well as in their rating of the foundations evident in other tweets. Interestingly, this effect was short lived and was not observed for the Care/Harm foundation. These results suggest that exposure to the moral reasoning of others might temporarily influence what moral arguments we are likely to accept and employ.

Keywords: Framing; Moral Foundation Theory; Moral Cognition; Priming; Text

## Introduction

Many of the important decisions we make have moral implications. But what factors might affect these decisions? In this paper, I examine the effect that encountering moral arguments might have on subsequent reasoning about moral issues. More specifically, I will argue that moral reasoning is subject to priming effects, where being confronted with a particular style of moral reasoning will result in increased salience for that style of reasoning.

## Moral Foundations Theory

While psychological research on morality encompasses a wide range of theoretical approaches (e.g., Gray, Young, \& Waytz, 2012; Malle, Guglielmo, \& Monroe, 2014; Rai \& Fiske, 2011; Young \& Saxe, 2011), in this paper I am interested in comparing different styles of moral reasoning and will therefore focus on Moral Foundations Theory (Graham et al., 2013; Haidt \& Joseph, 2004). Moral Foundations Theory identifies five different types of moral intuitions or concerns: Harm, Fairness, Loyalty, Authority, and Purity. Each of these moral concerns accounts for a different style of reasoning about moral dilemmas.

For instance, consider a person who believes that climate change is a problem because it endangers the lives of people and animals. This person is primarily concerned with the harm that climate change could cause to living beings. In contrast, another person might argue that climate change is problem because of its complexity and global reach, making it the obligation of nations to adhere to guidelines set by
international treaties. That person is using a type of argument that emerges from reasoning about authority. Critically, when analyzing any argument, it is important to remember that such moral concerns are not exclusive, and that a single argument can exhibit traits from several different concerns.

## Priming Moral Reasoning

Research based on Moral Foundations Theory has demonstrated that sensitivity to the different moral concerns varies across cultures (Graham, Haidt, \& Nosek, 2009), as well as based on ideological beliefs (Graham et al., 2009; Koleva, Graham, Iyer, Ditto, \& Haidt, 2012). Much of this research implicitly assumed that these styles of reasoning are stable and related to personality traits and beliefs. However, many stable traits in psychology provide a baseline for behavior that is affected by contextual and situational factors, such as priming.

The study presented here is designed to test whether such factors can also affect the salience of individual foundations. Specifically, I hypothesize that exposure to moral ideas and beliefs will result in temporary changes to the salience of the foundations that are at the core of these ideas.

For example, if an individual is presented with a text that relies on reasoning based on fairness, this individual might then become sensitized to the Fairness/Cheating foundation and be more likely to consider it as an important aspect of other, more ambiguous lines of reasoning. Likewise, reading a text about an individual that is harmed by a callous individual is likely to predispose the reader to identify harm as a more relevant consideration in subsequent texts that they otherwise would have.

To test this prediction, participants will be presented with a series of tweets that endorse either the Care/Harm foundation or the Fairness/Cheating foundation. Following this presentation, they will be asked to complete tasks that are designed to measure their sensitivity to these concerns. If moral reasoning is subject to priming effects, it is expected that participants who were presented with tweets endorsing the Fairness/Cheating foundation would find issues of fairness to be more relevant and important. In contrast, participants who read tweets that highlight Care/Harm should show heightened concern for that foundation.

## Method

## Participants

Thirty-six native English speakers from the University of St. Francis participated in the study in exchange for course credit.

Figure 1 - Mean scores on both parts of the MFQ30, by priming condition. The prime is administered after part 1 and before part 2. Error bars represent standard of error of the mean.

## Materials

## Moral Foundations Questionnaire

One of the frequently used tools for assessing an individual's level of concern for each of the 5 foundations is the 30 item Moral Foundations Questionnaire (MFQ30; Graham et al., 2011).

This questionnaire is composed of 2 parts: The first part asks participants to rate the relevance (on a 6-point scale) of various considerations to whether an act is right or wrong (e.g. "Whether someone suffered emotionally"). The second part asks participants to rate their agreement (on a 6-point scale) to various statements (e.g. "Chastity is an important and valuable virtue"). Each part is comprised of 16 items, 3 items corresponding to each of the foundations and 1 catch item.

It is important to note that while the two parts are measuring the same underlying concepts, they are using different approaches and therefore the scores on one part of the MFQ are not directly comparable to scores on the other. Nevertheless, a high score on a particular foundation in the first part can be taken as an indication of high concern for that foundation, and is therefore predictive of the score on the second part.

In this study, I used the first part of the MFQ30 to establish a baseline profile of the participants and the second part (administered after the care or fairness prime) to test for a priming effect.

## Tweets

In addition to the Moral Foundations Questionnaire, this study made use of several sets of tweets. These tweets were chosen from a corpus of over 700,000 tweets about the U.S.

Federal Shutdown of 2013 (cf. Dehghani et al., 2016; Sagi \& Dehghani, 2014b) ${ }^{1}$. Tweets were selected based on ratings of moral language computed statistically based on the Moral Foundations Dictionary (Graham et al., 2009) following the method described in Sagi and Dehghani (2014a).

The first set of primes, used as the prime in the Care condition, were uniformly high on the foundation of Care/Harm and low on the other 4 foundations. Likewise, a second set of primes served as the prime in the Fairness/Cheating condition. These primes were high on fairness and low on the other 4 foundations. Each of these lists comprised of 14 tweets, 7 tweets from liberal users and 7 from conservatives (see Appendix A).

In addition, a list of 25 tweets was selected such that each foundation was represented by 5 tweets. As before, for a foundation to be so represented, the tweet had to rate high on that foundation and low on all other foundations. This list of tweets was used for the rating task.

## Procedure

Participants first completed the first half of the 30 item Moral Foundations Questionnaire (MFQ30; Graham et al., 2011). Next, they rated their agreement, on a scale of 1 to 6 , to a series of 14 tweets that emphasized either the Fairness/Cheating foundation (Fairness condition) or the Care/Harm foundation (Care condition). After rating the primes, they completed the second half of the MFQ30.

Finally, each of the 5 moral foundations was described to the participants using the text from the website moralfoundations.org and they were asked to rate, on a scale of 1 to 6 , the relevance of each of the foundations to 25 tweets. Of the 25 tweets, 5 were primarily associated with each of the foundations. The tweets were presented in a

[^464]

Figure 2 - Mean ratings of tweets on the foundations of Care/Harm and Fairness/Cheating by experimental condition and order. Each block represents 5 tweets, in order of presentation. Error bars represent standard of error of the mean.
random order and its reverse, counterbalanced across participants. The ordering of the tweets (i.e., whether presented in the original random order or the reversed order) did not affect any of the analyses.

## Results

## Moral Foundations Questionnaire

Figure 1 presents the mean scores on both parts of the questionnaire. Since the prime is only presented after participants complete the first part, no differences are predicted in it. Agreement with the primes did not significantly differ based on condition (Care: $M=3.69, \mathrm{SD}=$ 0.68; Fairness: $M=3.61, S D=0.63 ; t(34)=-0.36$, n.s.)

Participants' responses to the second part of the MFQ30 were analyzed using a separate general linear model for each of the foundations, with the foundation score in the first part of the MFQ30 and the prime condition (Fairness vs. Care) as independent variables ${ }^{2}$. Participants' scores on the second part of the questionnaire were correlated to their scores on the first part, at least marginally (after correcting for multiple tests), for all but the Loyalty/Betrayal foundation $(F(1,32)=$ 1.87, $p=.18 ; F(1,32)>6, p<.05, r^{2}>.19$ for all other foundations). Only the Fairness foundation showed the predicted interaction between the score on the first part of the MFQ30 and condition $\left(F(1,32)=10.00, p<.01, r^{2}=.34\right.$; Fairness condition: $M=4.30, \mathrm{SD}=0.78$; Care condition: $M$ $=4.04, \mathrm{SD}=0.98 ; F<1$ for all other foundations).

[^465]Moreover, the scores on the fairness questions of the second part of the MFQ30 of participants in the Care condition correlated with their fairness score on the first part $(r(16)=.73, p<.001)$ while those of participants who read tweets evoking fairness did not $(r(16)=-0.11$, n.s.). This suggests that following the fairness primes participants concern for fairness was uniformly high - the prime essentially set all participants to the same level of concern on fairness. In contrast, similar correlations on the harm scores of the MFQ30 did not differ significantly (care condition: $r(16)=.42, p=.08$; fairness condition: $r(16)=.63, p<.01)$. These results suggest that the fairness prime successfully increased the salience of the Fairness/Cheating foundation, the care prime did not increase the salience of the Care/Harm foundation.

## Ratings of Tweets

To simplify the analysis of the ratings and avoid repeated tests, the analysis of the 25 rated tweets used a single model that contrasted the ratings of harm and fairness (although a similar, post-hoc, model using all 5 foundations yielded qualitatively similar results). This model included the participant and the tweet as random variables, and the condition as well as the foundation being rated as independent variables. To test for the possibility that this effect diminishes over time, the 25 tweets were divided into 5 blocks of 5 tweets based on order of presentation and this variable was included in the model (model $r^{2}=.37$ ). As
models that include this variable show no effect of agreement and are otherwise unchanged.
predicted, participants rated tweets as higher in fairness if they were previously exposed to tweets that exhibited fairness-based reasoning and vice versa $(F(1,1734)=5.46, p$ <.05). However, this effect quickly diminished as is evident by its interaction with the order of presentation $(F(1,1734)=$ $3.88, p<.05$; see Figure 2).

## Discussion

The results of the present study demonstrate that reading texts that evoke principles of moral reasoning can affect judgments and decisions made later. The effects observed in this paper are therefore best considered to be a type of priming effects. Since priming effects are, for the most part, short lived, the rapid decay of the effect in the second part of the study is also easily explained. However, it is likely that, because the second part of the study overtly asked participant to consider all five styles of moral reasoning, it accelerated this decay and that in a more natural setting the effect might last longer.

Perhaps more interesting is the fact that while reading tweets involving fairness and cheating resulted in a priming effect, reading tweets that favored the foundation of Care/Harm did not. One possible explanation is that while the federal shutdown readily appealed to the foundation of Fairness/Cheating, its appeal to Care/Harm is less direct and evident. This is reflected in the tweets - although Care/Harm was a dominant foundation in the corpus for liberals, considerations of fairness dominated the overall debate (cf. Sagi \& Dehghani, 2014b). It is possible that rather than simply evoking a moral foundation, a consistent and/or clear moral position might be required for a text to affect the moral reasoning of its reader.

More generally, there are numerous studies that demonstrate how the use of language can affect reasoning, both in the lab (e.g., Tversky \& Kahneman, 1981), and outside of it (e.g., Goodwin, 1994). Moreover, it is possible to use language to measure and trace the history of such frames (Sagi, Diermeier, \& Kaufmann, 2013).

In a similar vein, there is evidence that situational factors affect an individual's moral reasoning. The bystander effect, where individuals are less likely to render assistance when there are many other bystanders than when there are few, is a prominent example of such an effect (Darley \& Latane, 1968).

This study combines these two well-known effects and demonstrates that this type of framing can provide a context in which moral reasoning takes place. More interestingly, it is possible that repeated exposure to particular styles of reasoning might have a cumulative effect and eventually lead to the salience of the relevant foundation being permanently increased (or, perhaps, decreased, depending on the circumstances of exposure). This type of effect might be at the root of the development of moral beliefs and might provide insight into how and why such beliefs change.

Moreover, even temporary effects might have important implications. For example, the language used to draft jury instructions might influence the verdict one way if it highlights fairness and another if it highlights care. Likewise,
during negotiations, it is possible that a particular choice of language and reasoning by one side can serve to focus the negotiation in a particular direction, influencing all parties towards emphasizing the importance of a specific concern.

#### Abstract

Previous studies of causal learning heavily focused on binary outcomes; little is known about causal learning with continuous outcomes. The present paper proposes a qualitative extension of the causal power theory to the situation where a binary cause influences a continuous effect, and induces causal power under various ceiling situations with the continuous outcomes. To test the predictions, we systematically manipulated the type of outcome (continuous vs. percentage vs. binary) and the contingency information. The experiment shows that people estimate causal strength based on the linear-sum rule for continuous outcomes and the noisy-OR rule for binary outcomes. In the partial ceiling situation where causal power is partially inferred but not precisely estimated, the distribution of participants' judgments was bimodal with one mode at the minimum value and the other at the maximum value, suggesting some participants made conservative estimates while others made optimistic estimates. These results are generally consistent with the predictions of the causal power theory. Theoretical implications and future directions are discussed.

Keywords: causal reasoning; causal inference; causal power; continuous variable; integration rules.

## Introduction

The ability to learn causal relations is essential for explaining past events, controlling the present environment, and predicting future outcomes. Decision making based on causal knowledge enables us to achieve desired outcomes and to avoid undesired consequences. When there are two causes of a desired outcome, we should consider which cause has a high causal strength for producing the outcome. To estimate causal strength, we need to consider not only the states of the effect in the presence of the cause but also that in the absence of the cause (Rescorla, 1968). When a teacher thinks about the effect of active encouragement on students' homework performance, for example, he or she has to check whether the student finishes the homework both in the presence and absence of encouragement. It has been recognized that both children and adults readily form representations of causal networks (see Holyoak \& Cheng, 2011 for a review).

As causal relations are unobservable, they must be induced from observable events, and covariation among observable events serves as a fundamental cue to learn
causal relations (Hume, 1739/2000). For binary variables, covariation is represented as patterns of presence and absence. A measure of contingency is described by $\Delta P$ (Jenkins \& Ward, 1965):

$$
\begin{equation*}
\Delta P=P(E=1 \mid C=1)-P(E=1 \mid C=0) \tag{1}
\end{equation*}
$$

where $P(E=1 \mid C=1)$ is the probability of effect $E$ given the presence of candidate cause $C$, and $P(E=1 \mid C=0)$ is the probability of $E$ given the absence of $C$. Values of $\Delta P$ range from -1 to +1 . Positive $\Delta P$ values indicate a generative causal relation; negative $\Delta P$ values indicate a preventive causal relation.

Because $\Delta P$ is a measure of associative strength, it does not address issues in causation such as confounding and ceiling effects. For example, although it is impossible to judge the causal effect when the outcome always occurs regardless of the presence or absence of the cause (i.e., $P(E$ $=1 \mid C=1)=P(E=1 \mid C=0)=1)$, the $\Delta P$ model indicates that there is no causal relation (i.e., $\Delta P=0$ ). To model causal strength, Cheng (1997) proposed the power PC theory and derived generative causal power as an estimate:

$$
\begin{equation*}
w_{\mathrm{c}}=\Delta P /[1-P(E=1 \mid C=0)] \tag{2}
\end{equation*}
$$

Causal power $w_{c}$ is a function not only of contingency but also of the base rates of the effect. When the effect is always present, generative causal power is undefined, therefore explaining the (generative) ceiling effect. Buehner, Cheng, and Clifford (2003) systematically manipulated covariation information and demonstrated that judgments were well described by the causal power. Causal power is interpreted in the framework of causal Bayes nets by Glymour (2001) and of causal Bayesian models by Tenenbaum \& Griffiths (2001; Griffiths \& Tenenbaum, 2005).

Lu, Rojas, Beckers, and Yuille (2016) proposed a Bayesian theory of sequential causal learning. Their theory assumes that people select a different integration rule according to the type of outcome variable. On one hand, the noisy-OR rule is appropriate for a binary outcome and is consistent with Equation (2) in the causal power theory (Cheng, 1997). The rule assumes that two causes influence an outcome independently. It states that the effectiveness of two causes, both present, is the sum of the causal power of
each minus their product (i.e., $P(E=1 \mid A=1, B=1)=w_{\mathrm{A}}+$ $w_{\mathrm{B}}-w_{\mathrm{A}} \times w_{\mathrm{B}}$ ). On the other hand, the linear-sum rule is appropriate for a continuous outcome and is widely used in associative learning models such as the R-W model (Rescorla \& Wagner, 1972). This rule simply calculates the sum of the influence of each cause (i.e., $P(E=1 \mid A=1, B=$ 1) $=w_{\mathrm{A}}+w_{\mathrm{B}}$ ). Lu et al. (2016) presented a sequential Bayesian model that explains previous findings on outcomeadditivity in variations of the blocking paradigm.

Several empirical studies have provided supporting evidence for the use of the linear-sum rule for a continuous outcome. Rashid and Buehner (2013) systematically manipulated the quantity of continuous outcomes and tested which integration rules people use. The results appear inconsistent in that participants use the linear-sum rule for a generative cause and noisy-OR rule for a preventive cause. They suggested that the use of the linear-sum rule might be due to the absence of an upper limit for the quantity of the continuous outcome in their cover story. Prevention has a natural lower limit, the outcome quantity equal to 0 , sharing that property with binary outcomes. Saito (2015) manipulated means and standard deviations in causal learning with continuous outcomes and found that judgments are largely explained by difference in the means, but not by difference in the standard deviations. White (2015) examined causal judgments of interventions in temporal sequences of a continuous outcome variable in single individuals and reported that most of the results were explained by the difference between the mean outcome value for the pre-intervention time periods and that for the post-intervention time periods. These results suggest that people use the linear-sum rule for continuous outcomes. However, these studies do not reveal whether people use a different integration rule depending on the type of outcome variable since they did not compare judgments for continuous outcomes with those for the binary outcomes. In addition, it remains unknown how people estimate causal strength under various ceiling situation with the continuous outcomes. Since integration rules are core parts of the models of causal learning, it is important to investigate how people choose an integration rule.

In this paper, we extend the causal power theory qualitatively to address continuous outcomes and derive predictions under various ceiling effects. For our purposes, we treat cardinal outcomes as a special case of continuous outcomes. We also report a study investigating whether people choose the appropriate integration rules according to the type of outcome variables and whether their judgments correspond to causal-power predictions.

## Estimating causal power with continuous outcomes

The reasoner's goal is to induce the unobservable causal power of a candidate cause from observable events (Cheng, 1997). Consider a situation where a continuous effect $E$ may be produced by a binary background cause $B$ and/or a binary candidate cause C. Assume that:
(1) $B$ and $C$ influence $E$ independently,
(2) $B$ could increase $E$ but not reduce it,
(3) The causal powers of $B$ and $C$ are independent of the frequency of occurrences of $B$ and $C$, and
(4) $E$ does not change unless it is influenced.

These assumptions are similar to those with binary cause and effect (cf. Cheng, 1997; Pearl, 1998).

The joint influence of background cause $B$ and candidate cause $C$ on the continuous outcome $E$ is given by the linearsum rule (cf. Lu et al., 2016). According to this integration rule, the influences of multiple causes are integrated by simple addition. Since the outcome can take on different values, expected value and conditional expected value are used to describe its state. The expected value of the continuous outcome is calculated as follows:

$$
\begin{equation*}
E[e]=P(b) \cdot w_{\mathrm{b}}+P(c) \cdot w_{\mathrm{c}} \tag{3}
\end{equation*}
$$

In this equation, $P(b)$ and $P(c)$ denote the probabilities of occurrences of the background cause and candidate cause. Variables $w_{\mathrm{b}}$ and $w_{\mathrm{c}}$ are causal powers of the background cause and candidate cause. Although two different integration rules are used for a binary outcome (i.e., noisyOR rule for generative cause; noisy-AND-NOT rule for preventive cause), there is no distinction between generative and preventive causes in case of a continuous outcome.

When the cause is present (i.e., $P(c)=1$ ), the conditional expected value given the presence of the cause is

$$
\begin{equation*}
E[e \mid c]=P(b \mid c) \cdot w_{\mathrm{b}}+w_{\mathrm{c}} \tag{4}
\end{equation*}
$$

Similarly, the conditional expected value given the absence of the cause (i.e., $P(c)=0$ ) is

$$
\begin{equation*}
E[e \mid \neg c]=P(b \mid \neg c) \cdot w_{\mathrm{b}} \tag{5}
\end{equation*}
$$

Subtracting Equation 5 from Equation 4 yields the difference in conditional expected values (i.e., $\Delta E=E[e \mid c]$ $-E[e \mid \neg c]$ ). The difference in conditional expected values is:

$$
\begin{equation*}
\Delta E=P(b \mid c) \cdot w_{\mathrm{b}}+w_{\mathrm{c}}-P(b \mid \neg c) \cdot w_{\mathrm{b}} \tag{6}
\end{equation*}
$$

If we assume that the background cause and the candidate cause occur independently, two conditional probabilities equal to one another (i.e., $P(b \mid c)=P(b \mid \neg c)=P(b)$ ). Therefore, the causal power of the candidate cause $w_{c}$ is represented as follows:

$$
\begin{equation*}
w_{\mathrm{c}}=\Delta E-\{P(b \mid c)-P(b \mid \neg c)\} w_{\mathrm{b}}=\Delta E \tag{7}
\end{equation*}
$$

Within the range of outcome values greater than the minimum and less than the maximum, predicted values of the causal power are simply the differences in conditional expected values.

Predictions of the value of $w_{c}$ vary depending on the value of the continuous outcome. To illustrate these predictions,
consider a situation where a teacher investigates the effect of active encouragement on students' homework performance and gives 100 homework problems to each student. For example, a student had finished 25 out of 100 previous homework problems assigned; after the encouragement, the student finished 75 out of 100 new homework problems assigned. The causal power $w_{\mathrm{c}}$ is the difference in performance before and after the encouragement (i.e., $\Delta E=E[e \mid c]-E[e \mid \neg c]=75-25=50$ ).

However, this is not the case where one of the outcome values reaches the upper limit. We hypothesize that depending on the reasoner's assumption about the counterfactual value of the outcome if there were no upper limit, $w_{\mathrm{c}}$ has a range of possible values. We replace $E[e \mid c]$ in Equation (4) with the assumed counterfactual value $E^{\prime}[e \mid c]$. Suppose a student had finished 50 out of 100 previous homework problems assigned and then finished 100 out of 100 new homework problems assigned. It is inferred that the causal power is equal to or larger than 50 , but not precisely determined. Thus, the prediction of the causal power theory is an interval. Whereas some cautious reasoners might estimate the minimum value in the interval (50 in this case, resulting from $E^{\prime}[e \mid c]=100$ ), other reasoners might estimate a higher value in the interval (e.g., 100 , resulting from $E^{\prime}[e \mid c]=150$ ). When both outcomes are at the maximum value (e.g., a student finished 100 out of 100 homework problems regardless of the encouragement), the interval spans the entire range from 0 on and causal power becomes undefined. We call the former the partial ceiling situation and the latter the full ceiling situation. The difference between the partial and full ceiling situations is a unique feature in causal learning with continuous outcomes that have maximum values. The predictions of the causal power theory are shown in Table 1.

The purpose of the present study is to investigate whether people use proper integration rules according to the type of outcome variable and whether people differentiate between the partial and full ceiling situations. In addition to the conditions with continuous outcomes and binary outcomes, we added a condition with percentage outcomes. This is

Table 1: Design and predictions of the experiment.

| Continuous \& Percentage |  |  |  |  | Binary |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $E[e \mid c]$ | $E[e \mid c c]$ | $\Delta E$ | causal <br> power |  | $P(e \mid c)$ | $P(e \mid c c)$ | $\Delta P$ | causal <br> power |
| $100(0)$ | $0(0)$ | 100 | $\geq 100^{*}$ |  | $1.00(0)$ | $0.00(0)$ | 1.00 | 1.00 |
| $100(0)$ | $25(4.3)$ | 75 | $\geq 75$ |  | $1.00(0)$ | $0.25(0.4)$ | 0.75 | 1.00 |
| $75(4.3)$ | $0(0)$ | 75 | 75 |  | $0.75(0.4)$ | $0.00(0)$ | 0.75 | 0.75 |
| $100(0)$ | $50(5)$ | 50 | $\geq 50$ |  | $1.00(0)$ | $0.50(0.5)$ | 0.50 | 1.00 |
| $75(4.3)$ | $25(4.3)$ | 50 | 50 |  | $0.75(0.4)$ | $0.25(0.4)$ | 0.50 | 0.67 |
| $50(5)$ | $0(0)$ | 50 | 50 |  | $0.50(0.5)$ | $0.00(0)$ | 0.50 | 0.50 |
| $100(0)$ | $75(4.3)$ | 25 | $\geq 25$ |  | $1.00(0)$ | $0.75(0.4)$ | 0.25 | 1.00 |
| $75(4.3)$ | $50(5)$ | 25 | 25 |  | $0.75(0.4)$ | $0.50(0.5)$ | 0.25 | 0.50 |
| $50(5)$ | $25(4.3)$ | 25 | 25 |  | $0.50(0.5)$ | $0.25(0.4)$ | 0.25 | 0.33 |
| $25(4.3)$ | $0(0)$ | 25 | 25 |  | $0.25(0.4)$ | $0.00(0)$ | 0.25 | 0.25 |
| $100(0)$ | $100(0)$ | 0 | NA |  | $1.00(0)$ | $1.00(0)$ | 0.00 | NA |
| $75(4.3)$ | $75(4.3)$ | 0 | 0 |  | $0.75(0.4)$ | $0.75(0.4)$ | 0.00 | 0.00 |
| $50(5)$ | $50(5)$ | 0 | 0 |  | $0.50(0.5)$ | $0.50(0.5)$ | 0.00 | 0.00 |
| $25(4.3)$ | $25(4.3)$ | 0 | 0 |  | $0.25(0.4)$ | $0.25(0.4)$ | 0.00 | 0.00 |
| $0(0)$ | $0(0)$ | 0 | 0 |  | $0.00(0)$ | $0.00(0)$ | 0.00 | 0.00 |

Note. Numbers in parentheses are standard deviations. The causal power theory predicts " $\geq 100$ " for the continuous group and " 100 " for the percentage group.
because the upper limit for percentage outcomes has a clear maximum of 100 , unlike that for continuous outcomes.

## Method

## Participants

A total of 136 participants were recruited from Amazon Mechanical Turk (http://www.mturk.com/). An additional 35 participants were tested but excluded for failing to pass the comprehension question (see below for details). All were native English speakers and residing in the US.

## Experimental design

Participants were randomly assigned to one of three groups differing on the type of outcome (continuous, percentage, or binary). For all groups, the candidate cause was a binary variable (i.e., presence or absence of encouragement). Exclusion by the comprehension question resulted in unequal group sizes ( 56 participants in the continuous group, 43 in the percentage group, and 37 in the binary group). In addition to manipulating type of outcome, contingency information was manipulated within-subject (see Table 1). In the continuous and percentage groups, there were 15 contingency conditions resulting from the combination of five levels ( $100,75,50,25,0$ ) of conditional expected values in the presence and absence of the cause. The difference between $E[E \mid C=1]$ and $E[E \mid C=0]$ for each condition yielded five levels of nonnegative values in the outcome magnitude $(\Delta E=E[E \mid C=1]-E[E \mid C=0]=100$, $75,50,25,0)$. Similarly, the binary group had five levels of nonnegative values in the difference (i.e., $\Delta P=P(E=1 \mid C=$ 1) $-P(E=1 \mid C=0)=1.00, .75, .50, .25, .00)$. Participants in each group completed the causal learning task for all contingency conditions. The order of the contingency conditions was randomized across participants.

## Procedure

Instructions Participants were asked to read the instructions carefully and answer each question thoughtfully. The exact instructions in the continuous group were as follows (italicized sentences differed across groups):

A math teacher wants to investigate the effect of active encouragement on students' homework performance. Students are given 100 math homework problems of similar difficulty. The teacher randomly assigns some students to receive encouragement and assigns other students to receive no encouragement.

Imagine that you are a teaching assistant for the class. You are responsible for checking whether or not a student receives encouragement and how many out of the 100 homework problems the student finishes (0-100).

You will see several sets of student records. Each set contains the records of students from a school ordered in a random sequence. Each record describes
a student's homework performance before and after the experiment. After observing the records of sixteen students from a school, you will be asked to judge how much the encouragement increases performance at that school.

For the continuous group, the effect was a continuous variable (i.e., number of finished homework problems). The same instructions were used in the percentage group with one exception: the outcome observation was described as "what percentage of the homework problems the student finishes $(0-100 \%)$." In the binary group, both cause and effect were binary variables. Specifically, the instructions stated the outcome observation as "whether or not the student finishes the homework problems."

After reading the instructions, participants were asked to answer the comprehension question that checks the understanding of random assignment. The exact question was (italicized sentences differed across groups):

Before you begin viewing the records of the students' homework performance, consider the following situation. Suppose we conduct a study, and find that: the average number of the homework problems students in the experimental group (those who received encouragement) finish is 65 . Likewise, the average number of the homework problems students in the control group (those who did not receive encouragement) finish is 65 as well. Recall that the students are were randomly assigned to one or the other group. Can the homework performance in the experimental group be attributed to encouragement?

Participants were required to provide a "yes" or "no" answer and to justify their answer briefly. This question was intended to exclude participants who did not read the instructions properly and to encourage the assumption that the influence of background causes (i.e., causes other than encouragement) on homework performance was constant across the two groups (cf. Buehner et al., 2003). Similar questions were used in the percentage and binary groups with the corresponding modifications of the descriptions in terms of percentages. Participants received no feedback on their answers to this question.
Learning phase The learning phase consisted of 16 trials that presented information about the cause and effect in a pre-post design. For the continuous group, participants were requested to observe whether a student receives encouragement (present or absent) and how many out of the 100 homework problems the student finishes (0-100) before and after encouragement. On each trial, homework performance before the encouragement for a student was described with the illustration and text (e.g., "A student (ID: 12345) at this school finished 25 out of 100 previous homework problems assigned"). Student ID was a five-digit random number and designed to show that each trial described a different student. The states of the
encouragement were provided with the sentence (e.g., "The student received encouragement" or "The student did not receive encouragement"). The other two groups followed an identical procedure, except that the outcomes were expressed in percentage terms for the percentage group (e.g., "The student finished $75 \%$ of new homework problems") and as present or absent in the binary group (e.g., "The student finished the new homework problems"). The interstimulus interval was $1000-\mathrm{ms}$, and the button to proceed to next trial was presented $500-\mathrm{ms}$ after the presentation of all the information. Each trial was separated by a $500-\mathrm{ms}$ blank screen. Participants were required to learn causal strength of the encouragement on homework performance through trials.

There were 16 trials for each contingency condition in Table 1. Encouragement was present on 8 trials and was absent on 8 trials. For the continuous group, the outcomes were normally distributed with the variance set to be ten times that in the binary group (see standard deviations in parentheses in Table 1). The order of trials was randomized within-subject. To familiarize participants with the procedure, practice trials were presented prior to the learning phase.
Test phase After the 16 learning trials, participants were asked to estimate the causal strength of the candidate cause in a counterfactual question. In the continuous group, the question was "Suppose the next student (ID: 23456) at this school finished 0 out of 100 previous homework problems assigned. If the student now receives encouragement, how many out of 100 new homework problems will the student finish?" The responses were made on a rating scale ranging from 0 to 100 . Our scale limits the maximum strength to 100 so that responses can be compared across groups. Similar questions were used in the percentage and binary groups with modifications of the descriptions corresponding to the outcome type (e.g., for the binary group, "If these 100 students now receive encouragement, how many of them will finish their new homework problems?"). In addition, participants were also asked to report confidence in their judgment on a scale ranging from 0 (not confident at all) to 100 (extremely confident). After their judgments, participants completed the next contingency condition. To encourage the independence of judgments in each condition, participants received the following instructions: "Recall that the schools have students from very different socioeconomic backgrounds, and encouragement may have different effects on the students from school to school. Please evaluate each school separately."

## Results

Participants who failed to pass the comprehension question were excluded from our analysis below. This procedure reduced noise, but did not alter the general pattern of the results. Since the causal power theory makes different predictions for the non-ceiling and ceiling situations, separate analyses were conducted. Figure 1 shows the mean ratings of causal strength in non-ceiling situations. Overall, participants clearly differentiated between continuous and

Continuous

Percentage

## Binary

Figure 1: Mean ratings of causal strength in each contingency condition. Judgments with the same level of $\Delta E$ or $\Delta P$ in the non-ceiling situations are connected by lines. Judgments in the partial and full ceiling situations are represented by black symbols.
percentage outcomes on one hand and binary outcomes on the other. In the continuous group, judgments generally corresponded to the difference between the conditional expected values (i.e., $\Delta E=E[E \mid C=1]-E[E \mid C=0]$ ). Similar results were obtained in the percentage group, but the trend was much more evident. In contrast, judgments in the binary group were affected by both the difference between conditional probabilities $\Delta P$ and the base rates of the effect $P(E=1 \mid C=0)$. These descriptive analyses were confirmed by statistical analyses.

A two-way mixed ANOVA with the type of outcome (continuous vs. percentage vs. binary) as between-subjects factor and the contingency condition (11 contingency conditions except for the ceiling situations) as withinsubject factor resulted in a significant two-way interaction, $F(20,1330)=6.45, M S E=210.3, p<.001, \eta_{\mathrm{G}}^{2}=.069$. To explore the results in greater detail, we analyzed the effect of the type of outcome for each $\Delta E$ and $\Delta P$ condition. In the $\Delta E=50$ and $\Delta P=.50$ conditions, a two-way mixed ANOVA revealed a significant interaction between the type of outcome and contingency condition, $F(2,133)=5.54$, $M S E=116.1, p=.005, \eta_{\mathrm{G}}^{2}=.036$. As expected, judgments varied as a function of the base rate of the effect in the binary group, $F(1,36)=10.95, M S E=206.5, p=.002, \eta_{\mathrm{G}}^{2}$ $=.118$, but not in the continuous and percentage groups, $F \mathrm{~s}$ $<1$. The interaction was also significant in the $\Delta E=25$ and $\Delta P=.25$ conditions, $F(4,266)=7.76, M S E=153.6, p$ $<.001, \eta_{\mathrm{G}}^{2}=.057$, and in the $\Delta E=0$ and $\Delta P=.00$ conditions, $F(6,399)=2.33, M S E=242.7, p=.032, \eta_{\mathrm{G}}^{2}$ $=.015$. Although the incremental pattern of the results in the binary group in the $\Delta P=.00$ condition was inconsistent with the predictions of the causal power theory, it may be explained by misperception of contingency for sequential trials due to working memory limitations. This outcomedensity effect is consistent with causal-power predictions given the misperceptions (Cheng, 1997). It is worth noting that a similar but smaller trend was found in the continuous group, but not in the percentage group. This might be because the continuous group needs an assumption of equal
upper limits to compare outcomes whereas the percentage group does not.

Figure 2 depicts distributions of individual judgments in the partial and full ceiling situations. In the partial ceiling situation (i.e., $100-25,100-50,100-75$ conditions), a range of causal power is inferred (e.g., equal to or larger than 75 in the 100-25 condition). The distribution of participants' judgments appears bimodal with one mode at the minimum value of the interval and the other at the maximum value of the interval given our scale. These results indicate that some participants made conservative estimates while others made optimistic estimates. Dip tests confirmed the bimodality both in the continuous group ( $D=0.08, p=.013$ in the 100 25 condition, $D=0.13, p<.001$ in the 100-50 condition, $D$ $=0.14, p<.001$ in the $100-75$ condition) and percentage group ( $D=0.13, p<.001$ in the $100-25$ condition, $D=0.16$, $p<.001$ in the $100-50$ condition, $D=0.16, p<.001$ in the 100-75 condition). In contrast, the bimodality was not observed in the binary group, and the mode of the distribution corresponded to the point estimate of causal power (i.e., $w_{\mathrm{c}}=1$ ).

In the full ceiling situation where the causal power cannot be estimated (i.e., 100-100 condition), the distributions of the continuous and percentage groups appear bimodal while that of the binary group appear trimodal. This might be because participants had no option to answer "I don't know" in our materials.

## Discussion

The present study qualitatively extended the causal power theory to deal with the continuous outcomes and tested whether people differentiate between continuous and binary outcomes. The results showed that people estimate causal strength based on the linear-sum rule for continuous outcomes and the noisy-OR rule for binary outcomes. In the partial ceiling situation where the estimation of causal power has a range, the distribution of participants' ratings was bimodal with one mode at the minimum value and the other at the maximum value, suggesting some participants made conservative estimates while others made optimistic

Figure 2: Distributions of individual judgments in the partial and full ceiling situations.
estimates. These results are generally consistent with the predictions of the causal power theory.

The present study has theoretical implications for understanding how people estimate causal power. Whereas covariation models (e.g., $\Delta P$ model, Jenkins \& Ward, 1965) and associative models (e.g., R-W model, Rescorla \& Wagner, 1972) adopt one integration rule, Bayesian models generally assume multiple integration rules (Griffiths \& Tenenbaum, 2005, 2009; Lu et al., 2008, 2016). Our results demonstrate that people choose the proper integration rule according to the type of outcome, supporting the Bayesian models. Notably, this finding implies that people assume the invariance of causal power as a default, consistent with the proposal that causal invariance plays a key role in the construction of generalizable causal knowledge (Cheng \& Lu , in press). The two integration rules respectively represent the invariance of causal power for the two outcome variable types. Another theoretically important aspect is the bimodal distributions in the judgments in the partial ceiling situations. Computational models generally predict averaged results. The observed bimodality suggests that models incorporating different conservatism values and/or priors may explain individual differences in the partial ceiling situations. Further investigations will shed more light on the question of how people estimate causal power.

# Spatial Training and Mathematics: The Moderating Effect of Handedness 

Giovanni Sala (giovanni.sala@liv.ac.uk)<br>Department of Psychological Sciences, Bedford Street South, University of Liverpool, L69 7ZA, United Kingdom<br>Martina Bolognese (martina.bolognese@gmail.com)<br>Department of Life Sciences, Via Festa del Perdono, University of Milan, 20122, Italy<br>Fernand Gobet (fernand.gobet@liv.ac.uk)<br>Department of Psychological Sciences, Bedford Street South, University of Liverpool, L69 7ZA, United Kingdom

#### Abstract

The positive relationship between spatial ability and mathematical skills is a classical result in developmental and cognitive psychology. Given this correlational relationship, researchers have tried to establish whether spatial training can increase mathematical ability. Such research has provided mixed results. In this study, we analysed the effects of two types of spatial training and handedness on primary school children's arithmetical ability. The participants were pre-tested on a test of arithmetic and assigned to one of three groups: (a) one hour of mental rotation and translation training, (b) one hour of mental translation training only, or (c) a no-contact group. The results showed no significant difference between training groups and a significant interaction between training group and category of handedness. Interestingly, only extremely right-handed children in the mental rotation and translation group seemed to benefit from the training. These outcomes suggest that any spatial training needs to include mental rotation activities to be effective, and that the relationship between spatial training and achievement mathematics appears to be moderated by handedness.

Keywords: mathematics; mental rotation; spatial ability, handedness; STEM.

## Introduction

Concerns have been raised about young people's low achievements in mathematics, both in Europe (Greg, 2009) and the United States (Hanushek, Peterson, \& Woessmann, 2012; Richland, Stigler, \& Holyoak, 2012). Students' insufficient mathematical ability has serious implications, as the likelihood of graduating in Science, Technology, Engineering, and Mathematics (STEM) subjects is limited by one's mathematical ability. The job market increasingly demands workforce with STEM expertise and requires increasingly higher competencies, making competition fiercer worldwide (Halpern et al., 2007).
Students' attainment in mathematics is thus a matter of crucial practical importance. For this reason, an impressive amount of research has been devoted to pinpointing the cognitive correlates of mathematical ability (e.g., Deary, Strand, Smith, \& Fernandes, 2007; Lubinski, 2010; Peng, Namkung, Barnes, \& Sun, 2016; Rohde \& Thompson, 2007;

Wai, Lubinski, \& Benbow, 2009) and finding effective methods to improve students' mathematical skills.

These methods not only include traditional school interventions (for a review, see Hattie, 2009), but also cognitive-training based treatments. Examples of such treatments to foster students' attainment in mathematics and other academic and cognitive skills include working memory training (Sala \& Gobet, 2017a), chess instruction (Gobet \& Campitelli, 2006; Sala, Foley, \& Gobet, 2017; Sala \& Gobet, in press-a; Sala \& Gobet, 2016; Sala, Gobet, Trinchero, \& Ventura, 2016; Sala, Gorini, \& Pravettoni, 2015; Trinchero \& Sala, 2016), and music training (Sala \& Gobet, 2017b). The results show either minimal overall effects on academic achievement and overall cognitive ability (music and working memory training) or medium effects possibly due to placebo effects (chess). These results are in line with Thorndike and Woodworth's (1901) common element theory according to which far transfer - i.e., the generalization of a set of skills across domains only loosely related - rarely occurs (Gobet, 2016; Sala \& Gobet, 2017c; Sala \& Gobet, in press-b).

## Spatial Training

Another, relatively understudied, type of intervention to enhance mathematical ability is spatial training. Spatial training includes activities such as 2D and 3D mental rotation, spatial reasoning and visualizations (Sorby, 2011). However, given the difficulty of far transfer to take place, why should spatial training increase mathematical ability?

## The Relationship between Spatial and Mathematical Abilities

Problem solving in mathematics and STEM disciplines largely relies on spatial ability (Stieff \& Uttal, 2015). Mechanical physics and engineering deal with movement and interaction between elements in a geometrical space. Mathematicians work with functions represented in 2D and 3D space. More generally, several branches of mathematics - necessary to master disciplines such as physics and engineering - require the manipulation of spatial relationships (e.g. geometry, calculus, topology).

The tight relation between spatial ability and mathematical ability has been established empirically. These two separate constructs are highly correlated to each other (Mix et al., 2016). Spatial abilities - such as mental rotation ability (Mix et al., 2016; Wai, Lubinski, \& Benbow, 2009) - are thus strong predictors of achievement in mathematics, both in children (Lauer \& Lourenco, 2016) and in undergraduate and doctorate students (Wai et al., 2009). Thus, several researchers have suggested that training spatial ability causes improvement in mathematics achievement.

## Spatial Training to Train Spatial and STEM Abilities: The Empirical Evidence

Before asking whether spatial training leads to improving mathematical skills such as arithmetic or geometry, one has to verify whether spatial ability can be trained. A metaanalysis carried out by Uttal et al. (2013) suggests that this is the case. Spatial training appears to transfer both to the trained tasks and other spatial tasks not directly trained. ${ }^{1}$ Crucially, from a practical point of view, spatial ability seems to be malleable enough to be significantly boosted by a shortterm training (Uttal et al., 2013).

The evidence supporting the effectiveness of spatial training at improving performance on spatial tasks appears to be quite solid. Regrettably, it is not possible to reach the same conclusion for non-spatial tasks. The research on spatial training to improve STEM achievement has provided promising results, but the number of studies is still relatively limited.
In His, Linn, and Bell (1997), a group of undergraduates improved their attainment in an engineering course after attending a voluntary spatial training (3D orthographic projections). However, the fact that the sample was selfselected casts serious doubts upon the reliability of the outcome. More recently, Sorby (2009) reported that a group of undergraduates in engineering with low spatial ability improved their course grades after spatial training (Sorby, 2011), whereas a control group with no training did not show any amelioration. These positive findings were replicated two years later (Sorby, Casey, Veurink, \& Dulaney, 2013). Less clear were the results in Miller and Halpern's (2013) study. They did find a moderate positive effect after delivering spatial training, but only in items related to Newtonian mechanics. No benefits occurred in other courses.

The studies mentioned above dealt with university students. Cheng and Mix (2014) focused on the effects of short-term ( 40 minutes) spatial training on children's basic arithmetical ability. The training consisted of 40 minutes of mental rotation and mental translation exercises suitable for children (Ehrlich, Levine, \& Goldin-Meadow, 2006). The treatment group showed a small improvement (approximatively $d=0.20$ ) in the test of arithmetic, limited

[^466]to one particular type of items (missing-term problems). A study by Hawes, Moss, Caswell, and Poliszczuk (2015) found no significant effects of mental rotation training on a group of primary school children's arithmetical ability. Finally, Xu and LeFevre (2016) reported no transfer from spatial training to a number line task in a sample of kindergarten children.

## The Potential Moderating Role of Handedness

Several researchers have argued that the relation between mathematical and spatial ability may be moderated by handedness (Casey, Pezaris, \& Nuttall, 1992). Handedness is believed to affect achievement in mathematics because it represents the degree of dominance and development of the right hemisphere, which is involved in cognitive tasks such as spatial reasoning (Ganley \& Vasilyeva, 2011) and mental rotation ability (O'Boyle et al., 2005). Some non-righthanders (i.e., left-handed and ambidextrous people) have a more developed right hemisphere than right-handers (Gutwinski et al., 2011). Such a condition may explain why non-right-handers excel in domains where spatial ability is required. For example, non-right-handers are present among chess players in significantly greater ratio than the general population (Gobet \& Campitelli, 2007). The same pattern has been found in artists (Preti \& Vellante, 2007).

Whether non-right-handers are better than right-handers in mathematics is still a matter of debate (e.g., Benbow, 1986; Cheyne, Roberts, Crow, Leask, \& García-Fiñana, 2010; McManus, 2002). However, it appears that among righthanders, those who show a consistent preference for using the right hand (hereafter, extreme right-handers) underperform in mathematics (e.g., Annett \& Manning, 1989; Cheyne et al., 2010; Peters, 1991). The possible explanation relies again on the degree of development of the right hemisphere in comparison to the left hemisphere. According to Annett (2002), a strong dominance of the left hemisphere may lead to both being extremely right-handed and suffering from some deficits in spatial ability and, hence, in mathematics. In line with this idea, in a recent large study (total $N=2,314$ ), extreme right-handers obtained a poorer score on a variety of tests of mathematics compared to moderate right-handers (Sala, Signorelli, Barsuola, Bolognese, \& Gobet, submitted).

## The Present Study

In this study, we replicated and extended Cheng and Mix's (2014) study. There were two crucial additions. First, we tested whether the effects of training (if any) on mathematical ability interact with handedness. We expected extreme righthanders to perform more poorly on the pre-test of arithmetic than the moderate right-handers and non-right-handers. Most importantly, given that the extreme right-handers are believed to have a lower mathematical ability because of a
variety of tasks may stem from some general ability at performing spatial tasks (e.g., better strategies). In any case, this important theoretical issue is beyond the aims of this article.
spatial deficit, we also expected them to benefit most from the spatial training task. Second, along with the treatment and no-contact groups, another treatment group practicing only mental translation was included. The rationale was to understand whether mental translation training alone (i.e., no mental rotation) could positively influence attainment in mathematics (see below for details).

## Method

## Participants

A total of 159 first, second, and third graders in nine classes of a primary school in northern Italy took part in this experiment. The mean age of the participants was 7.61 years ( $\mathrm{SD}=0.89$ ). Parental consent was asked and obtained for all the participants.

## Materials

The participants were administered (a) the Edinburgh Handedness Inventory (EHI), ${ }^{2}$ (b) a spatial ability task (mental rotation and translation) suitable for children (score range $0-16$; Ehrlich et al., 2006), and (c) a test of arithmetic, designed by the experimenters (score range $0-27$; Cronbach Alpha = .96).

EHI is a multiple-item questionnaire that provides a continuous measure of handedness ( $h$ ), which is calculated using the formula $h=\frac{R-L}{R+L}$, where R and L indicate the number of preferences for the right and left hand, respectively. The range of values is between -1 , for extreme left-handedness, and +1 , for extreme right-handedness. The participants were categorized according to their $h$-values (Casey, 1995):
a) Extreme right-handers: $h \geq .90(N=48)$.
b) Moderate right-handers: $.40<h<.90(N=81)$.
c) Non-right-handers: $h \leq .40(N=30)$.

The test of mental rotation and translation ability consists of 16 items. The participant is shown four whole pictures and two parts of a flat shape. The participant has to mentally put the two pieces together and choose one of the four whole pictures (Figure 1).

In the test of arithmetic, finally, the participants solved simple mathematical equations (e.g., $3+4=$ ?) and missingterm problems (e.g., $3+$ ? $=7$ ).

## Design

All the nine classes were pre-tested in arithmetic, spatial ability (rotation/translation), and EHI. A week later, the nine classes were randomly assigned to three groups:
a) Three classes (one first-, one second-, one thirdgrade) attended 60 minutes of mental rotation and translation exercises. This training consisted of 16

[^467]rotation items and 16 translation items. Analogously to the testing session, the participants were asked to choose one of the pictures. Finally, children were given the two parts of the picture on separate pieces of cardstock and requested to confirm or change the choice after putting them together (Figure 2).
b) Three classes (one first-, one second-, one thirdgrade) attended 60 minutes of 32 translation exercises only (translation group; Figure 3). The training procedure was analogous to that in the previous group.
c) Three classes (one first-, one second-, one thirdgrade) did not carry any activity (no-contact group).

Figure 1. Two examples of the items used in the spatial test (translation and rotation).

Figure 2. An example of rotation item used in the fulltraining group.

Figure 3. An example of translation item used in both the training groups.

Finally, the three groups were post-tested in arithmetic and spatial ability immediately after the end of the training.

## Results

## Preliminary Analyses

The three groups did not differ in terms of age ( $p=.970$ ) or pre-test arithmetic test scores $(p=.391)$. As expected, the category of handedness had a significant effect on the pre-test scores in arithmetic $(F(2,156)=6.50, p=.002)$. Extreme right-handers were outperformed by both moderate righthanders ( $p<.001$ ) and non-right-handers ( $p=.048$ ).

The pre-post test correlations for arithmetical ability and spatial ability were $r=.94$ and $r=.60$, respectively (both $p \mathrm{~s}$ $<.001$ ).

Finally, an ANCOVA (pre-test scores as the covariate) confirmed that the spatial training had a significant effect on the score of spatial ability. In fact, the two training groups (full and translation) outperformed the no-contact group ( $p=$ .030 and $p=.004$, respectively).

## Main Analysis: Scores in Arithmetical Ability

The pre- test and post-test scores in arithmetical ability are summarized in Table 1.

Table 1. Scores in arithmetical ability the three groups.

| Group | $N$ | Pre-test | Post-test |
| :--- | ---: | ---: | ---: |
| Full-training | 56 | $16.73(9.20)$ | $18.04(7.98)$ |
| Translation | 53 | $18.81(7.02)$ | $18.79(6.79)$ |
| No-contact | 50 | $17.18(8.32)$ | $18.40(8.17)$ |

Note. Standard deviations are shown in brackets.
An ANCOVA (Table 2) was run to analyse the effects of the independent variables (group and category of handedness) on the results of the post-test of arithmetical ability, using pretest score and age as covariates. The results showed no
significant effect of age (in years, $p=.176$ ), category of handedness ( $h$-cat; $p=.846$ ), or group ( $p=.491$ ). As expected, a significant effect of the pre-test scores was found ( $p<.001$ ). Interestingly, a significant interaction between group and category of handedness was reported ( $p=.013$ ).

Table 2. The ANCOVA model of the scores in arithmetic

| Variable | $D f$ | $F$-value | $p$-value |
| :--- | ---: | ---: | ---: |
| Group | 2 | 0.72 | .491 |
| $h$-cat | 2 | 0.17 | .846 |
| Age | 1 | 1.85 | .176 |
| Pre-test scores | 1 | 333.69 | $\mathbf{. 0 0 0}$ |
| Group* $h$-cat | 4 | 3.27 | $\mathbf{. 0 1 3}$ |

The extreme right-handers in the full-training group showed the greatest mean improvement in the test of arithmetic compared to the other extreme right-handers. The pre- and post-test mean scores are summarized in Table 3.

Table 3. Extreme right-handers' scores in the three groups.

| Group | $N$ | Pre-test | Post-test |
| :--- | ---: | ---: | ---: |
| Full-training | 14 | $10.71(8.32)$ | $13.57(7.80)$ |
| Translation | 17 | $18.41(7.98)$ | $18.47(7.54)$ |
| No-contact | 17 | $12.88(8.35)$ | $14.76(8.88)$ |

Note. Standard deviations are shown in brackets.

## Discussion

The results of this experiment show no significant impact of the one-hour spatial training on children's arithmetical ability. In fact, most of the variance in the post-test of arithmetical ability is explained by pre-test scores $\left(r=.94 ; r^{2}\right.$ $\times 100=88 \%$ ). This outcome is in accordance with previous experimental studies (e.g., Cheng \& Mix, 2014; Hawes et al., 2015; Xu \& LeFevre, 2016) examining the effects of spatial training on arithmetical ability. In a wider perspective, our results are consistent with substantial research on far transfer (Burgoyne et al., 2016; Sala et al., 2017; Sala \& Gobet, 2016, 2017a, 2017b).

However, the significant role played by handedness, predicted by Annett (2002), sheds light on the potential benefits of spatial training on arithmetical ability. The extreme right-handers in the full-training group reported the best improvement in mathematical ability compared to both the whole groups and the sub-samples of extreme righthanders. This pattern of results suggests that short-term mental spatial training may be effective for a particular subsample of underachievers in arithmetic (i.e., extreme right-handers), as long as mental rotation activities are included.

## Recommendations for Future Research

This study highlights the possible benefits of mental rotation training for extreme right-handers' arithmetical ability. In order to confirm (or disconfirm) our results, future investigations should replicate and extend the design of the
current study. First, even if the total sample was large ( $N=$ 159), the subgroup of extreme right-handers consisted of only a few tens of individuals $(N=48)$ distributed across three groups. Given the importance of that subgroup for the main hypothesis of this study, future experiments should include more participants (e.g., as twice as many) to increase the statistical power, and hence the reliability, of the analysis and outcomes. Second, the future investigations should systematically manipulate the duration of training and administer both immediate and delayed post-test assessments. This way, it would be possible to evaluate whether the effects of spatial training on extreme righthanders' on mathematical ability increase with the duration of training and last after its end. Third, we collected only one measure of mathematical ability (i.e., arithmetic). The use of multivariate measures of mathematical ability and spatial ability would contribute to establishing whether spatial training benefits for extreme right-handers goes beyond basic arithmetic ability.

## Acknowledgments

The authors gratefully thank Yi-Ling Cheng and Kelly Mix for the assistance in designing the experiment, and the principal and all the teachers in the project for their support.

# Dissolving the Grounding Problem: How the Pen is Mightier than the Sword 

Nancy Salay<br>Queen's University

#### Abstract

The computational metaphor for mind is still the central guiding idea in cognitive science despite many insightful and well-founded rejections of it. There is good reason for its staying power: when we are at our cognitive best, we reason about our world with our concepts. But the challengers are right, I argue, in insisting that no reductive account of that capacity is forthcoming. Here I describe an externalist account that grounds representations in organism-level engagement with its environment, not in its neural activity.

# The Causal Frame Problem: An Algorithmic Perspective 

Ardavan S. Nobandegani ${ }^{1,2} \quad$ Ioannis N. Psaromiligkos ${ }^{1}$<br>\{ardavan.salehinobandegani@mail.mcgill.ca, yannis@ece.mcgill.ca\}<br>${ }^{1}$ Department of Electrical \& Computer Engineering, McGill University<br>${ }^{2}$ Department of Psychology, McGill University

#### Abstract

The Frame Problem (FP) is a puzzle in philosophy of mind and epistemology, articulated by the Stanford Encyclopedia of Philosophy as follows: "How do we account for our apparent ability to make decisions on the basis only of what is relevant to an ongoing situation without having explicitly to consider all that is not relevant?" In this work, we focus on the causal variant of the FP, the Causal Frame Problem (CFP). Assuming that a reasoner's mental causal model can be (implicitly) represented by a causal Bayes net, we first introduce a notion called Potential Level (PL). PL, in essence, encodes the relative position of a node with respect to its neighbors in a causal Bayes net. Drawing on the psychological literature on causal judgment, we substantiate the claim that PL may bear on how time is encoded in the mind. Using PL, we propose an inference framework, called the PL-based Inference Framework (PLIF), which permits a boundedly-rational approach to the CFP, formally articulated at Marr's algorithmic level of analysis. We show that our proposed framework, PLIF, is consistent with several findings in the causal judgment literature, and that PL and PLIF make a number of predictions, some of which are already supported by existing findings.

Keywords: Frame Problem; Time and Causality; Bounded Rationality; Algorithmic Level of Analysis; Rational Process Models

## 1 Introduction

At the core of any decision-making or reasoning task, resides an innocent-looking yet challenging question: Given an inconceivably large body of knowledge available to the reasoner, what constitutes the relevant for the task and what the irrelevant? The question, as it is posed, echoes the wellknown Frame Problem (FP) in epistemology and philosophy of mind, articulated by Glymour (1987) as follows: "Given an enormous amount of stuff, and some task to be done using some of the stuff, what is the relevant stuff for the task?" Fodor (1987) comments: "The frame problem goes very deep; it goes as deep as the analysis of rationality."

The question posed above perfectly captures what is really at the core of the FP, yet, it may suggest an unsatisfying approach to the FP at the algorithmic level of analysis (Marr, 1982). Indeed, the question may suggest the following twostep methodology: In the first step, out of all the body of knowledge available to the reasoner (termed, the model), she has to identify what is relevant to the task (termed, the relevant submodel); it is only then that she advances to the second step by performing reasoning or inference on the identified submodel. There is something fundamentally wrong with this methodology (which we term, sequential approach to reasoning) which bears on the following understanding: The relevant submodel, i.e., the portion of the reasoner's knowledge deemed relevant to the task, oftentimes is so enormous (or even infinitely large) that the reasoner-inevitably bounded
in time and computational resources-would never get to the second step, had she adhered to such a methodology. In other words, in line with the notion of bounded rationality (Simon, 1957), a boundedly-rational reasoner must have the option, if need be, to merely consult a fraction of the potentially largeif not infinitely so-relevant submodel.

Icard and Goodman (2015) elegantly promote this insight when they write: "Somehow the mind must focus in on some "submodel" of the "full" model (including all possibly relevant variables) that suffices for the task at hand and is not too costly to use." ${ }^{1}$ They then ask the following question: "what kind of simpler model should a reasoner consult for a given task?" This is an inspiring question hinting to an interesting line of inquiry as to how to formally articulate a boundedlyrational approach to the FP, at Marr's (1982) algorithmic level of analysis.

In this work, we focus on the causal variant of the FP, the Causal Frame Problem (CFP), stated as follows: Upon being presented with a causal query, how does the reasoner manage to attend to her causal knowledge relevant to the derivation of the query while rightfully dismissing the irrelevant? We adopt Causal Bayesian Networks (CBNs) (Pearl, 1988; Gopnik et al., 2004, inter alia) as a normative model to represent how the reasoner's internal causal model of the world is structured (i.e., reasoner's mental model). First, we introduce the notion of Potential Level (PL). PL, in essence, encodes the relative position of a node (representing a propositional variable or a concept) with respect to its neighbors in a CBN. Drawing on the psychological literature on causal judgment, we substantiate the claim that PL may bear on how time is encoded in the mind. Equipped with PL, we embark on investigating the CFP at Marr's algorithmic level of analysis. We propose an inference framework, termed PL-based Inference Framework (PLIF), which aims at empowering the boundedly-rational reasoner to consult (or retrieve ${ }^{2}$ ) parts of the underlying CBN deemed relevant for the derivation of the posed query (the relevant submodel) in a local, bottom$u p$ fashion until the submodel is fully retrieved. PLIF allows the reasoner to carry out inference at intermediate stages of the retrieval process over the thus-far retrieved parts, thereby obtaining lower and upper bounds on the posed causal query.

[^468]We show, in the Discussion section, that our proposed framework, PLIF, is consistent with several findings in the causal judgment literature, and that PL and PLIF make a number of predictions, some of which are already supported by the findings in the psychology literature.

In their work, Icard and Goodman (2015) articulate a boundedly-rational approach to the CFP at Marr's computational level of analysis, which, as they point out, is from a "god's eye" point of view. In sharp contrast, our proposed framework PLIF is not from a "god's eye" point of view and hence could be regarded, potentially, as a psychologically plausible proposal at Marr's algorithmic level of analysis as to how the mind both retrieves and, at the same time, carries out inference over the retrieved submodel to derive bounds on a causal query. We term this concurrent approach to reasoning, as opposed to the flawed sequential approach stated earlier. ${ }^{3}$ The retrieval process progresses in a local, bottomup fashion, hence the submodel is retrieved incrementally, in a nested manner. ${ }^{4}$ Our analysis (Sec. 4.1) confirms Icard and Goodman's (2015) insight that even in the extreme case of having an infinitely large relevant submodel, the portion of which the reasoner has to consult so as to obtain a "sufficiently good" answer to a query could indeed be very small.

## 2 Potential Level and Time

Before proceeding further, let us introduce some preliminary notations. Random Variables (RVs) are denoted by lowercase bold-faced letters, e.g., $\mathbf{x}$, and their realizations by nonbold lower-case letters, e.g., $x$. Likewise, sets of RVs are denoted by upper-case bold-faced letters, e.g., $\mathbf{X}$, and their corresponding realizations by upper-case non-bold letters, e.g., $X . \operatorname{Val}(\cdot)$ denotes the set of possible values a random quantity can take on. Random quantities are assumed to be discrete unless stated otherwise. The joint probability distribution over $\mathbf{x}_{1}, \cdots, \mathbf{x}_{n}$ is denoted by $\mathbb{P}\left(\mathbf{x}_{1}, \cdots, \mathbf{x}_{n}\right)$. We will use the notation $\mathbf{x}_{1: n}$ to denote the sequence of $n \operatorname{RVs} \mathbf{x}_{1}, \cdots, \mathbf{x}_{n}$, hence $\mathbb{P}\left(\mathbf{x}_{1}, \cdots, \mathbf{x}_{n}\right)=\mathbb{P}\left(\mathbf{x}_{1: n}\right)$. The terms "node" and "variable" will be used interchangeably. To simplify presentation, we adopt the following notation: We denote the probability $\mathbb{P}(\mathbf{x}=x)$ by $\mathbb{P}(x)$ for some $\mathrm{RV} \mathbf{x}$ and its realization $x \in \operatorname{Val}(\mathbf{x})$. For conditional probabilities, we will use the notation $\mathbb{P}(x \mid y)$ instead of $\mathbb{P}(\mathbf{x}=x \mid \mathbf{y}=y)$. Likewise, $\mathbb{P}(X \mid Y)=\mathbb{P}(\mathbf{X}=X \mid \mathbf{Y}=Y)$ for $X \in \operatorname{Val}(\mathbf{X})$ and $Y \in \operatorname{Val}(\mathbf{Y})$. A generic conditional independence relationship is denoted by $(\mathbf{A} \Perp \mathbf{B} \mid \mathbf{C})$ where $\mathbf{A}, \mathbf{B}$, and $\mathbf{C}$ represent three mutually disjoint sets of variables belonging to a CBN. Furthermore, throughout the paper, we assume that $\varepsilon$ is some negligibly small positive real-valued quantity. Whenever we subtract $\varepsilon$ from a quantity, we simply imply a quantity less than but arbitrarily close to the original quantity. The rationale behind adopting such a notation will become clearer in Sec. 4.

[^469]Before formally introducing the notion of PL, we articulate in simple terms what the idea behind PL is. PL simply induces a chronological order on the nodes of a CBN, allowing the reasoner to encode the timing between cause and effect. ${ }^{5}$ As we will see, PL plays an important role in guiding the retrieval process used in our proposed framework. Next, PL is formally defined, followed by two clarifying examples.

Def. 1. (Potential Level (PL)) Let $\operatorname{par}(\mathbf{x})$ and $\operatorname{child}(\mathbf{x})$ denote, respectively, the sets of parents (i.e., immediate causes) and children (i.e., immediate effects) of $\mathbf{x}$. Also let $T_{0} \in \mathbb{R} \cup\{-\infty\}$. The PL of $\mathbf{x}$, denoted by $p_{l}(\mathbf{x})$, is defined as follows: (i) If $\operatorname{par}(\mathbf{x})=\varnothing, p_{l}(\mathbf{x})=T_{0}$, and (ii) If $\operatorname{par}(\mathbf{x}) \neq \varnothing, p_{l}(\mathbf{x})$ is a real-valued quantity selected from the interval $\left(\max _{\mathbf{y} \in \operatorname{par}(\mathbf{x})} p_{l}(\mathbf{y}), \min _{\mathbf{z} \in \operatorname{child}(\mathbf{x})} p_{l}(\mathbf{z})\right)$ such that $p_{l}(\mathbf{x})-\max _{\mathbf{y} \in \operatorname{par}(\mathbf{x})} p_{l}(\mathbf{y})$ indicates the amount of time which elapses between intervening simultaneously on all the RVs in $\operatorname{par}(\mathbf{x})$ (i.e., $\operatorname{do}\left(\operatorname{par}(\mathbf{x})=\operatorname{par}_{x}\right)$ ) and $\mathbf{x}$ taking its value $x$ in accord with the distribution $\mathbb{P}\left(x \mid \operatorname{par}_{x}\right)$. If $\operatorname{child}(\mathbf{x})=\varnothing$, substitute the upper bound of the given interval by $+\infty$.

Parameter $T_{0}$ symbolizes the origin of time, as perceived by the reasoner. $T_{0}=0$ is a natural choice, unless the reasoner believes that time continues unboundedly into the past, in which case $T_{0}=-\infty$. The next two examples further clarify the idea behind PL. In both examples we assume $T_{0}=0$.

(a)

(b)

Figure 1: Relation between PL and time. Three hollow dots signify that the depicted CBNs extend into the past and future.

For the first example, let us consider the CBN depicted in Fig. 1(a) containing the RVs $\mathbf{x}, \mathbf{y}$, and $\mathbf{z}$ with $p_{l}(\mathbf{x})=$ $4, p_{l}(\mathbf{y})=4.7$, and $p_{l}(\mathbf{z})=5$. According to Def. 1, the given PLs can be construed in terms of the relative time between the occurrence of cause and effect as articulated next. Upon intervening on $\mathbf{x}$ (i.e., $d o(\mathbf{x}=x)$ ), after the elapse of $p_{l}(\mathbf{y})-p_{l}(\mathbf{x})=0.7$ units of time, the RV $\mathbf{y}$ takes its value $y$ in accord with the distribution $\mathbb{P}(y \mid x)$. Likewise, upon intervening on $\mathbf{y}$ (i.e., $d o(\mathbf{y}=y)$ ), after the elapse of $p_{l}(\mathbf{z})-p_{l}(\mathbf{y})=$ 0.3 units of time, $\mathbf{z}$ takes its value $z$ according to $\mathbb{P}(z \mid y)$.

For the second example, consider the CBN depicted in Fig. 1(b) containing the RVs $\mathbf{x}, \mathbf{y}, \mathbf{z}$, and $\mathbf{t}$ with $p_{l}(\mathbf{x})=4, p_{l}(\mathbf{y})=$ 4.7, $p_{l}(\mathbf{z})=5$, and $p_{l}(\mathbf{t})=5.6$. Upon intervening on $\mathbf{x}$ (i.e., $d o(\mathbf{x}=x))$ the following happens: (i) after the elapse of $p_{l}(\mathbf{y})-p_{l}(\mathbf{x})=0.7$ units of time, $\mathbf{y}$ takes its value $y$ according to $\mathbb{P}(y \mid x)$, and (ii) after the elapse of $p_{l}(\mathbf{z})-p_{l}(\mathbf{x})=1$ unit of

[^470]time, $\mathbf{z}$ takes its value $z$ according to $\mathbb{P}(z \mid x)$. Also, upon intervening simultaneously on RVs $\mathbf{y}, \mathbf{z}$ (i.e., $d o(\mathbf{y}=y, \mathbf{z}=z)$ ), after the elapse of $p_{l}(\mathbf{t})-\max _{\mathbf{r} \in \operatorname{par}(\mathbf{t})} p_{l}(\mathbf{r})=0.6$ units of time, $\mathbf{t}$ takes its value $t$ according to $\mathbb{P}(t \mid y, z)$.

In sum, the notion of PL bears on the underlying time-grid upon which a CBN is constructed, and adheres to Hume's principle of temporal precedence of cause to effect (Hume, 1748/1975). A growing body of work in psychology literature corroborates Hume's centuries-old insight, suggesting that the timing and temporal order between events strongly influences how humans induce causal structure over them (Bramley, Gerstenberg, \& Lagnado, 2014; Lagnado \& Sloman, 2006). The introduced notion of PL is based on the following hypothesis: When learning the underlying causal structure of a domain, humans may as well encode the temporal patterns (or some estimates thereof) on which they rely to infer the causal structure. This hypothesis is supported by recent findings suggesting that people have expectations about the delay length between cause and effect (Greville \& Buehner, 2010; Buehner \& May, 2004; Schlottmann, 1999). It is worth noting that we could have defined PL in terms of relative expected time between cause and effect, rather than relative absolute time. Under such an interpretation, the time which elapses between the intervention on a cause and the occurrence of its effect would be modeled by a probability distribution, and PL would be defined in terms of the expected value of that distribution. Our proposed framework, PLIF, is indifferent as to whether PL should be construed in terms of absolute or expected time. Greville and Buehner (2010) show that causal relations with fixed temporal intervals are consistently judged as stronger compared to those with variable temporal intervals. This finding, therefore, seems to suggest that people expect, to a greater extent, fixed temporal intervals between cause and effect, rather than variable ones-an interpretation which, at least to a first approximation, favors construing PL in terms of relative absolute time (see Def. 1). ${ }^{6}$

## 3 Informative Example

To develop our intuition, and before formally articulating our proposed framework, let us present a simple yet informative example which demonstrates: (i) how the retrieval process can be carried out in a local, bottom-up fashion, allowing for retrieving the relevant submodel incrementally, and (ii) how adopting PL allows the reasoner to obtain bounds on a given causal query at intermediate stages of the retrieval process.

Let us assume that the posed causal query is $\mathbb{P}(x \mid y)$ where $\mathbf{x}, \mathbf{y}$ are two RVs in the CBN depicted in Fig. 2(a) with PLs $p_{l}(\mathbf{x}), p_{l}(\mathbf{y})$, and let $p_{l}(\mathbf{x})>p_{l}(\mathbf{y})$. The relevant information for the derivation of the posed query (i.e., the relevant submodel) is depicted in Fig. 2(e).

[^471]

Figure 2: Example. Query variables are shown in orange.

Starting from the target RV $\mathbf{x}$ in the original CBN (Fig. 2(a)) and moving one step backwards, ${ }^{7} \mathbf{t}_{1}$ is reached (Fig. 2(b)). Since $p_{l}(\mathbf{y})<p_{l}\left(\mathbf{t}_{1}\right)$, $\mathbf{y}$ must be a non-descendant of $\mathbf{t}_{1}$, and therefore, of $\mathbf{x}$. Hence, conditioning on $\mathbf{t}_{1} d$-separates $\mathbf{x}$ from $\mathbf{y}$ (Pearl, 1988), yielding $\left(\mathbf{x} \Perp \mathbf{y} \mid \mathbf{t}_{1}\right)$. Thus $\mathbb{P}(x \mid y)=$ $\sum_{t_{1} \in \mathbf{V a l}\left(t_{1}\right)} \mathbb{P}\left(x \mid y, t_{1}\right) \mathbb{P}\left(t_{1} \mid y\right)=\sum_{t_{1} \in \mathbf{V a l}\left(t_{1}\right)} \mathbb{P}\left(x \mid t_{1}\right) \mathbb{P}\left(t_{1} \mid y\right)$ implying: $\min _{t_{1} \in \operatorname{Val}\left(\mathbf{t}_{1}\right)} \mathbb{P}\left(x \mid t_{1}\right) \leq \mathbb{P}(x \mid y) \leq \max _{t_{1} \in \operatorname{Val}\left(\mathbf{t}_{1}\right)} \mathbb{P}\left(x \mid t_{1}\right)$. It is crucial to note that the given bounds can be computed using the information thus-far retrieved, i.e., the information encoded in the submodel shown in Fig. 2(b). Taking a step backwards from $\mathbf{t}_{1}, \mathbf{t}_{2}$ is reached (Fig. 2(c)). Using a similar line of reasoning to the one presented for $\mathbf{t}_{1}$, having $p_{l}(\mathbf{y})<p_{l}\left(\mathbf{t}_{2}\right)$ ensures $\left(\mathbf{x} \Perp \mathbf{y} \mid \mathbf{t}_{2}\right)$. Therefore, the following bounds on the posed query can be derived, which, crucially, can be computed using the information thus-far retrieved: $\min _{t_{2} \in \operatorname{Val}\left(\mathbf{t}_{2}\right)} \mathbb{P}\left(x \mid t_{2}\right) \leq \mathbb{P}(x \mid y) \leq \max _{t_{2} \in \operatorname{Val}\left(\mathbf{t}_{2}\right)} \mathbb{P}\left(x \mid t_{2}\right)$. It is straightforward to show that the bounds derived in terms of $\mathbf{t}_{2}$ are equally tight or tighter than the bounds derived in terms of $\mathbf{t}_{1}$. Finally, taking one step backward from $\mathbf{t}_{2}, \mathbf{y}$ is reached (Fig. 2(d)) and the exact value for $\mathbb{P}(x \mid y)$ can be derived, again using the submodel thus-far retrieved (Fig. 2(d)).

We are now ready to present our proposed framework.

## 4 PL-based Inference Framework (PLIF)

In this section, we intend to elaborate on how, equipped with the notion of PL, a generic causal query of the form ${ }^{8}$ $\mathbb{P}(\mathbf{O}=O \mid \mathbf{E}=E)$ can be derived where $\mathbf{O}$ and $\mathbf{E}$ denote, respectively, the disjoint sets of target (or objective) and observed (or evidence) variables. In other words, we intend to formalize how inference over a CBN whose nodes are endowed with PL as an attribute should be carried out. Before we present the main result, a few definitions are in order.

Def. 2. (Critical Potential Level (CPL)) The target variable with the least PL is denoted by $\mathbf{o}^{*}$ and its PL is referred to as the CPL. More formally, $p_{l}^{*}: \triangleq \min _{\mathbf{0} \in \mathbf{O}} p_{l}(\mathbf{0})$ and

[^472]$\mathbf{o}^{*}: \triangleq \arg \min _{\mathbf{0} \in \mathbf{O}} p_{l}(\mathbf{0})$. E.g., for the setting given in Fig. 2(a), $\mathbf{o}^{*}=\mathbf{x}$, and $p_{l}^{*}=p_{l}(\mathbf{x})$. Viewed through the lens of time, $\mathbf{o}^{*}$ is the furthest target variable into the past, with PL $p_{l}^{*}$.

There are two possibilities: (a) $p_{l}^{*}>T_{0}$, or (b) $p_{l}^{*}=T_{0}$, with $T_{0}$ denoting the origin of time; cf. Sec. 2. In the sequel, we assume that (a) holds. ${ }^{9}$

Def. 3. (Inference Threshold (IT) and IT Root Set (ITRS)) To any real-valued quantity, $\mathcal{T}$, corresponds a unique set, $\mathbf{R}_{\mathcal{T}}$, obtained as follows: Start at every variable $\mathbf{x} \in \mathbf{O} \cup \mathbf{E}$ with PL $\geq \mathcal{T}$ and backtrack along all paths terminating at $\mathbf{x}$. Backtracking along each path stops as soon as a node with PL less than $\mathcal{T}$ is encountered. Such nodes, together, compose the set $\mathbf{R}_{\mathcal{T}}$. It follows that: $\max _{\mathbf{t} \in \mathbf{R}_{\mathcal{T}}} p_{l}(\mathbf{t})<\mathcal{T}$. $\mathcal{T}$ and $\mathbf{R}_{\mathcal{T}}$ are termed, respectively, Inference Threshold (IT) and the IT Root Set (IT-RS) for $\mathcal{T}$.

For example, the set of variables circled at the stages depicted in Figs. 2(b-d) are the IT-RSs for $\mathcal{T}=p_{l}(\mathbf{x})-\varepsilon$, $\mathcal{T}=p_{l}\left(\mathbf{t}_{1}\right)-\varepsilon$, and $\mathcal{T}=p_{l}\left(\mathbf{t}_{2}\right)-\varepsilon$, respectively. Note that instead of saying $\mathcal{T}=p_{l}(\mathbf{x})-\varepsilon$ we could have said: for any $\mathcal{T} \in\left(p_{l}\left(\mathbf{t}_{1}\right), p_{l}(\mathbf{x})\right)$. However, expressing ITs in terms of $\varepsilon$ liberates us from having to express them in terms of intervals, thereby simplifying the exposition. We would like to emphasize that the adopted notation should not be construed as implying that the assignment of values to ITs is such a sensitive task that everything would have collapsed, had IT not been chosen in such a fine-tuned manner. To recap, in simple terms, $\mathcal{T}$ bears on how far into the past a reasoner is consulting her mental model in the process of answering a query, and $\mathbf{R}_{\mathcal{T}}$ characterizes the furthest-into-the-past concepts entertained by the reasoner in that process.

Next, we formally present the main idea behind PLIF, followed by its interpretation in simple terms.

Lemma 1. Let $\mathbb{P}(O \mid E)$ denote the posed causal query, with $\boldsymbol{O}$ and $\boldsymbol{E}$ denoting, respectively, the disjoint sets of target and observed variables. For any chosen IT $\mathcal{T}<$ $p_{l}^{*}$ and its corresponding $\boldsymbol{R}_{\mathcal{T}}$, define $\boldsymbol{S}: \triangleq \boldsymbol{R}_{\mathcal{T}} \backslash \boldsymbol{E}$. Then the following holds: $\quad \min _{S \in \operatorname{Val}(\boldsymbol{S})} \mathbb{P}(O \mid S, E) \leq \mathbb{P}(O \mid E) \leq$ $\max _{S \in \operatorname{Val}(\boldsymbol{S})} \mathbb{P}(O \mid S, E)$. Crucially, the provided bounds can be computed using the information encoded in the submodel retrieved in the very process of obtaining the $\boldsymbol{R}_{\mathcal{T}}$.

The message of Lemma 1 is quite simple: For any chosen inference threshold $\mathcal{T}$ which is further into the past than $\mathbf{0}^{*}$, Lemma 1 ensures that the reasoner can condition on $\mathbf{S}$ and obtain the reported lower and upper bounds on the query by using only the information encoded in the retrieved submodel.

It is natural to ask under what conditions the exact value to the posed query can be derived using the thus-far retrieved submodel, i.e., the submodel obtained during the identification of $\mathbf{R}_{\mathcal{T}}$. The following remark bears on that. ${ }^{10}$

Remark 1. If for IT $\mathcal{T}, \mathbf{R}_{\mathcal{T}}$ satisfies either: (i) $\mathbf{R}_{\mathcal{T}} \subseteq \mathbf{E}$, or (ii) for all $\mathbf{r} \in \mathbf{R}_{\mathcal{T}}, p_{l}(\mathbf{r})=T_{0}$, and $\min _{\mathbf{e} \in \mathbf{E}} p_{l}(\mathbf{e})>\mathcal{T}$, or

[^473](iii) the lower and upper bound given in Lemma 1 are identical, then the exact value of the posed query can be derived using the submodel retrieved in the process of obtaining $\mathbf{R}_{\mathcal{T}}$. Fig. 2(d) shows a setting wherein (i) and (iii) are both met.

### 4.1 Case Study

Next, we intend to cast the Hidden Markov Model (HMM) studied in (Icard \& Goodman, 2015, p. 2) into our framework. The setting is shown in Fig. 3(left). We adhere to the

Figure 3: Left: The infinite-sized HMM discussed in (Icard \& Goodman, 2015) with parameterization: $\mathbb{P}\left(x_{t+1} \mid x_{t}\right)=$ $\mathbb{P}\left(\bar{x}_{t+1} \mid \bar{x}_{t}\right)=0.9$, and $\mathbb{P}\left(y_{t} \mid x_{t}\right)=\mathbb{P}\left(\bar{y}_{t} \mid \bar{x}_{t}\right)=0.8$. Right: Applying PLIF on the HMM shown in left. Vertical and horizontal axes denote, respectively, the value of the posed query $\mathbb{P}\left(x_{t+1} \mid y_{-\infty: t}\right)$ and the adopted IT $\mathcal{T}$. The vertical bars depict the intervals within which the query lies due to Lemma 1. The dotted curves-which connect the lower and upper bounds of the intervals-show how the intervals shrink as IT $\mathcal{T}$ decreases.
same parameterization and query adopted therein. All RVs in this section are binary, taking on values from the set $\{0,1\}$; $\mathbf{x}=x$ indicates the event wherein $\mathbf{x}$ takes the value 1 , and $\mathbf{x}=\bar{x}$ implies the event wherein $\mathbf{x}$ takes the value 0 . We assume $p_{l}\left(\mathbf{x}_{t+i}\right)=i-2 .{ }^{11}$ We should note that the assignment of the PLs for the variables in $\left\{\mathbf{y}_{t-i}\right\}_{i=0}^{+\infty}$ does not affect the presented results in any way. The query of interest is $\mathbb{P}\left(x_{t+1} \mid y_{-\infty: t}\right)$. Notice that after performing three steps of the sort discussed in the example presented in Sec. 3 (for the IT $\mathcal{T}=-3-\varepsilon)$, the lower bound on the posed query exceeds 0.5 (shown by the red dashed line in Fig. 3(right)). This observation has the following intriguing implication. Assume, for the sake of argument, that we were presented with the following Maximum A-Posterior (MAP) inference problem: Upon observing all the variables in $\left\{\mathbf{y}_{t-i}\right\}_{i=0}^{+\infty}$ taking on the value 1, what would be the most likely state for the variable $\mathbf{x}_{t+1}$ ? Interestingly, we would be able to answer this MAP inference problem simply after three backward moves (corresponding to the IT $\mathcal{T}=-3-\varepsilon$ ). In Fig. 3(right), the intervals within

[^474]which the posed query falls (due to Lemma 1) in terms of the adopted IT $\mathcal{T}$ are depicted.

Our analysis confirms Icard and Goodman's (2015) insight that even in the extreme case of having infinite-sized relevant submodel (Fig. 3(left)), the portion of which the reasoner has to consult so as to obtain a "sufficiently good" answer to the posed query could happen to be very small (Fig. 3(right)).

## 5 Discussion

To our knowledge, PLIF is the first inference framework proposed that capitalizes on time to constrain the scope of causal reasoning over CBNs, where the term scope refers to the portion of a CBN on which inference is carried out. PLIF does not restrict itself to any particular inference scheme. The claim of PLIF is that inference should be confined within and carried out over retrieved submodels of the kind suggested by Lemma 1 so as to obtain the reported bounds therein. In this light, PLIF can accommodate any inference scheme, including Belief Propagation (BP), and sample-based inference methods using Markov Chain Monte Carlo (MCMC), as two prominent classes of inference schemes. MCMC-based methods have been successful in simulating important aspects of a wide range of cognitive phenomena and accounting for many cognitive biases; cf. (Sanborn \& Chater, 2016). Also, work in theoretical neuroscience has suggested mechanisms for how BP and MCMC-based methods could be realized in neural circuits; cf. (Gershman \& Beck, 2016; Lochmann \& Deneve, 2011). For example, to cast BP into PLIF amounts to restricting BP's message-passing within submodels of the kind suggested by Lemma 1. In other words, assuming that BP is to be adopted as the inference scheme, upon being presented with a causal query, an IT according to Lemma 1 will be selected-at the meta-level-by the reasoner and the corresponding submodel, as suggested by Lemma 1, will be retrieved, over which inference will be carried out using BP. This will lead to obtaining lower and upper bounds on the query, as reported in Lemma 1. If time permits, the reasoner builds up incrementally on the thus-far retrieved submodel so as to obtain tighter bounds on the query. ${ }^{12}$ MCMC-based inference methods can be cast into PLIF in a similar fashion.

The problem of what parts of a CBN are relevant and what are irrelevant for a given query, according to (Geiger, Verma, \& Pearl, 1989), was first addressed by Shachter (1988). The approaches proposed for identifying the relevant submodel for a given query fall into two broad categories (cf. Mahoney \& Laskey, 1998, and references therein): (i) top-down approaches, and (ii) bottom-up approaches. Top-down approaches start with the full knowledge of the underlying CBN and, depending on the posed query, gradually prune the irrelevant parts of the CBN. In this respect, top-down approaches are inevitably from "god's eye" point of view-a characteristic which undermines their cognitive-plausibility. Bottom-

[^475]up approaches, on the other hand, incrementally construct a submodel (by moving backwards from the query variables), using which the posed query can be computed. It is crucial to note that bottom-up approaches cannot stop at intermediate steps during the backward move and run inference on the thus-far constructed submodel without running the risk of compromising some of the (in)dependence relations structurally encoded in the CBN, which would yield erroneous inferences. This observation is due to the fact that there exists no local signal revealing how the thus-far retrieved nodes are positioned relative to each other and to the to-be-retrieved nodes-a shortcoming circumvented in the case of PLIF by introducing PL. It is worth reiterating again that PLIF subscribes to what we call the concurrent approach to reasoning (as opposed to the flawed sequential approach mentioned earlier), whereby retrieval and inference take place in tandem. The HMM example analyzed in Sec. 4.1, with infinitely large relevant submodel, stresses the importance and shows the efficacy of the concurrent approach.

Work on causal judgment provides support for the socalled alternative neglect, according to which subjects tend to neglect alternative causes to a much greater extent in predictive reasoning than in diagnostic reasoning (Fernbach \& Rehder, 2013; Fernbach, Darlow, \& Sloman, 2011). Alternative neglect, therefore, implies that subjects would tend to ignore parts of the relevant submodel while constructing it. Recent findings, however, seem to cast doubt on alternative neglect (Cummins, 2014; Meder, Mayrhofer, \& Waldmann, 2014). Meder et al. (2014), Experiment 1 demonstrates that subjects appropriately take into account alternative causes in predictive reasoning. Also, Cummins (2014) substantiates a two-part explanation of alternative neglect according to which: (i) subjects interpret predictive queries as requests to estimate the probability of the effect when only the focal cause is present, an interpretation which renders alternative causes irrelevant, and (ii) the influence of inhabitory causes (i.e., disablers) on predictive judgment is underestimated, and this underestimation is incorrectly interpreted as neglecting of alternative causes. Cummins (2014), Experiment 2 shows that when predictive inference is queried in a manner that more accurately expresses the meaning of noisyOR Bayes net (i.e., the normative model adopted by Fernbach et al. (2011)) likelihood estimates approached normative estimates. Cummins (2014), Experiment 4 shows that the impact of disablers on predictive judgments is far greater than that of alternative causes, while having little impact on diagnostic judgments. PLIF commits to the retrieval of enablers as well as disablers. As mentioned earlier, PLIF abstracts away from the inference scheme operating on the retrieved submodel, and, hence, leaves it to the inference scheme to decide how the retrieved enablers and disablers should be weighted and subsequently integrated. In this light, PLIF is consistent with the results of Experiment 4 in (Cummins, 2014).

In an attempt to explain violations of screening-off reported in the literature, Park and Sloman (2013) find strong
support for the contradiction hypothesis followed by the mediating mechanism hypothesis, and finally conclude that people do conform to screening-off once the causal structure they are using is correctly specified. PLIF is consistent with these accounts, as it adheres to the assumption that reasoners carry out inference on their internal causal model (including all possible mediating variables and disablers), not the potentially incomplete one presented in the cover story; see also (Rehder \& Waldmann, 2017; Sloman \& Lagnado, 2015).

Experiment 5 in (Cummins, 2014), consistent with (Fernbach \& Rehder, 2013), shows that causal judgments are strongly influenced by memory retrieval/activation processes, and that both number of disablers and order of disabler retrieval matter in causal judgments. These findings suggest that the CFP and memory retrieval/activation are intimately linked. In that light, next, we intend to elaborate on the rationale behind adopting the term "retrieve" and using it interchangeably with the term "consult" throughout the paper; this is where we relate PLIF to the concepts of Long Term Memory (LTM) and Working Memory (WM) in psychology and neurophysiology. Next, we elaborate on how PLIF could be interpreted through the lenses of two influential models of WM, namely, Baddeley and Hitch's (1974) Multi-component model of WM (M-WM) and Ericsson and Kintsch's (1995) Long-term Working Memory (LTWM) model. The M-WM postulates that "long-term information is downloaded into a separate temporary store, rather than simply activated in LTM," a mechanism which permits WM to "manipulate and create new representations, rather than simply activating old memories" (Baddeley, 2003). Interpreting PLIF through the lens of the M-WM model amounts to the value for IT being chosen (and, if time permits, updated so as to obtain tighter bounds) by the central executive in the M-WM and the submodel being incrementally "retrieved" from LTM into MWM's episodic buffer. Interpreting PLIF through the lens of the LTWM model amounts to having no retrieval from LTM into WM and the submodel suggested by Lemma 1 being merely "activated in LTM" and, in that sense, being simply "consulted" in LTM. In sum, PLIF is compatible with both of the narratives provided by the M-WM and LTWM models.

A number of predictions follow from PL and PLIF. For instance, PLIF makes the following prediction: Prompted with a predictive or a diagnostic query (i.e., $\mathbb{P}(\mathbf{e} \mid \mathbf{c})$ and $\mathbb{P}(\mathbf{c} \mid \mathbf{e})$, respectively), subjects should not retrieve any of the effects of e. Introspectively, this prediction seems plausible, and can be tested, using a similar approach to (Cummins, 2014; De Neys, Schaeken, \& d'Ydewalle, 2003), by asking subjects to "think aloud" while engaged in predictive or diagnostic reasoning. Also, PL yields the following prediction: Upon intervening on cause $\mathbf{c}$, subjects should be sensitive to when effect $\mathbf{e}$ will occur, even in settings where they are not particularly instructed to attend to such temporal patterns. Recent findings suggesting that people have expectations about the delay length between cause and effect already provide some supporting evidence for this prediction (Greville \& Buehner,

2010; Buehner \& May, 2004).
There is a growing acknowledgment in the literature that, not only time and causality are intimately linked, but that they mutually constrain each other in human cognition; cf. (Buehner, 2014). In line with this view, we see our work also as an attempt to formally articulate how time could guide and constrain causal reasoning. While many questions remain open, we hope to have made some progress towards better understanding of the CFP at the algorithmic level.

Acknowledgments. We are grateful to Thomas Icard for valuable discussions. We would also like to thank Marcel Montrey and Peter Helfer for helpful comments on an earlier draft of this work. This work was supported in part by the Natural Sciences and Engineering Research Council of Canada under grant RGPIN 262017.

#### Abstract

Perception of time is an active process that takes place continually. However, we are yet to learn its exact mechanisms conclusively. The temporal bisection task is ideal to investigate the circuitry underlying time perception. Caffeine, a commonly used stimulant, has been known to play a role in modulation of time perception. The objective of this article is to explore the role of caffeine, a neuromodulator, in the perception of time in human beings by conducting suitable experiments. The experiment shows that an expansion of time is perceived by subjects after caffeine ingestion and that caffeine has an accelerating effect on our time perception system. Additionally, we present a preliminary 2 -step decision model that fits the results of the experiment and potentially gives insights into the mechanisms of caffeine. We conclude by pointing out future directions towards a more biologically realistic computational model.

Keywords: Caffeine; Timing; Perception; Temporal bisection; Computational modeling; Decision making

## Introduction

Time perception is essential for human survival. It is a multilayered process which covers a wide range of timescales, from microsecond estimation to the maintaining of the circadian rhythm. However, there is still a lack of consensus on the mechanisms behind temporal perception.

Researchers have proposed several qualitative and quantitative models to explain the data obtained in various temporal judgement experiments (Jeffress, 1948; Machado, Malheiro, \& Erlhagen, 2009; Oprisan \& Buhusi, 2011), with Internal Clock Theory being one of the most widely accepted ones. It suggests that our perception of time highly relies on the clock speed. Akin to an internal clock, the theory of scalar expectancy postulates that a group of oscillating neurons would work as a pacemaker and help in the judgement of durations (Gibbon, 1977; Gibbon, Church, \& Meck, 1984; Wearden, 1991). As described in the information processing model in Figure 1, a pacemaker oscillates at a mean frequency and produces regular clock pulses, which are gated to an accumulator in working memory via a switch. The accumulator records and stores the number of pulses from the onset of the stimulus. A comparator decides if the current record in the working memory is close enough to the reference memory and responds accordingly. If the response is reinforced, the time value recorded in the working memory is stored in the permanent reference memory for reinforced values.

In the previous findings, it has been argued that the nuclei involved in the circadian rhythm in the brain partici-
pate in our perception of time (Cheng, Meck, \& Williams, 2006). Findings from psychopharmacological studies also suggest that caffeine and other psychoactive drugs affect these nuclei (Dunlap, 1999). Further, literature also shows that dopaminergic drugs influence the speed of internal pacemaker (Buhusi \& Meck, 2002). In general, caffeine has been known to have effects on other cognitive processes like vigilance, attention, memory and other cognitive functions (McLellan, Caldwell, \& Lieberman, 2016). There have been a wide range of studies that have investigated the role of caffeine in time perception. However, the findings are still largely inconclusive (Hussain \& Cole, 2015; Favila \& Kuhl, 2014; Borota et al., 2014).

Figure 1: Information-processing model for Scalar Expectancy Theory (adapted from SET, Gibbon (Gibbon et al., 1984)).

Given the above theoretical basis, we hypothesized that the administration of caffeine would cause a difference in perception of duration by influencing the speed of the internal pacemaker. The aim of the current experiment is to explore the role of caffeine, a neuromodulator, on time judgement via suitable experiments and to design a computational model, based on decision-making, to investigate the possible mechanisms underlying the perception of duration.

The temporal bisection task was initially used in 1977 to study temporal discrimination in rats (Church \& Deluty, 1977). As the task requires several time-dependent cognitive functions, such as the comparison of durations, it is
an ideal technique to study perception and processing of time (Wearden, 1991; Allan \& Gibbon, 1991). We have thus chosen the temporal bisection task as the paradigm to investigate the modulation of judgement of duration by caffeine.

## Experiment

## Participants

The study sample consisted of 24 adults ( 8 females and 16 males, mean age $=21$ years, $\mathrm{SD}=0.89$ ), who were students of the International Institute of Information Technology, Hyderabad, India. All participants gave informed consent prior to the experiment. A Python script was used to randomly assign each subject to either the control group (0mg caffeine) or the experimental group ( 200 mg caffeine). All participants were right-handed and had normal or corrected-to-normal vision.

## Materials and apparatus

Each participant was tested individually in a quiet room in the institute. The experiment was presented on a Macintosh laptop, which controlled the presentation of the experimental stimuli and recorded the participants' responses with Psychopy (Peirce, 2009). The participants were asked to convey their response using the ' $S$ ' and ' $L$ ' keys on the keyboard, for 'short' and 'long', respectively. The stimuli used for representation of duration in the bisection task were a white rectangle (during the training phase) and a white triangle (during the testing phase) on a black background, presented in the center of the screen. During the training phase, post-response feedback was presented as white text on a black background. The feedback was presented for 2 s in the center of the laptop screen (Droit-Volet, Brunot, \& Niedenthal, 2004).

The participants were administered plain or caffeinated milk orally, in the control or experimental group, respectively. The participants in the group were administered a moderate dose of 200 mg caffeine since it has been observed that caffeine enhances performance in several cognitive tasks with minimal side effects, in doses up to approximately 300 mg (Lieberman, Tharion, Shukitt-Hale, Speckman, \& Tulley, 2002).

Peak plasma levels of caffeine are found in the body about 30 minutes after ingestion (Blanchard \& Sawers, 1983), following which the effects are felt substantially for approximately 30 minutes (Barry, Clarke, Johnstone, \& Rushby, 2008). Hence, the experiment was conducted 20 to 25 minutes after the administration of plain or ceffeinated milk. One session of the experiment lasted for a duration of about 35 minutes.

## Experimental Procedure

The temporal bisection task comprises duration judgement between two reference durations. The task involves subjects classifying various probe durations as either 'short' or 'long'. The conscious realm of time perception occurs in the range of seconds and minutes (Mauk \& Buonomano, 2004). Effects of emotion, age, etc. on time perception have been studied via
temporal bisection tasks in this time range (Droit-Volet et al., 2004). In order to see the effects of caffeine on this time range and to investigate conscious time estimation, we have chosen 400 ms (short standard) and 1600 ms (long standard), as the reference durations for our experiment.

The temporal bisection task consisted of two phases: training and testing. The training phase, in itself, was composed of three sections. In the first section, participants were presented with the short(S) and long(L) standard stimulus durations. Each standard was initially presented five times each and the subjects were asked to observe carefully. In section two of the training phase, the participants were presented with 5 trials each for $S$ and $L$, in randomised order. In each trial, after the presentation of stimulus, the participants were asked to decide if the given stimulus was short or long by pressing the ' $S$ ' or 'L' keys, respectively. On responding, they were presented with a feedback, informing them if their response was accurate or not. The feedback message lasted on the screen for a duration of 2 s . In section three of the training phase, the participants were again presented with 5 trials each of $S$ and $L$ in randomised order, similar to section 2 and asked to respond if they perceived the duration as short or long. However, this time, they were provided with no feedback. The inter-stimulus interval (ISI) in this phase was fixed at 1s. After the completion of section three, participants with a score higher than 7 correct trials out of 10 (in section three) were selected for the testing phase. The testing phase was conducted after a break of 1 minute.

Figure 2: Schematic diagram of the testing phase.

In the testing phase, as depicted in Figure 2, the participants were presented with 5 intermediate probe durations, $600 \mathrm{~ms}, 800 \mathrm{~ms}, 1000 \mathrm{~ms}, 1200 \mathrm{~ms}, 1400 \mathrm{~ms}$ in addition to the $400 \mathrm{~ms}(\mathrm{~S})$ and $1600 \mathrm{~ms}(\mathrm{~L})$ reference durations, in a randomised order and asked to respond if they perceived the given duration as short or long (Droit-Volet et al., 2004). The inter-stimulus interval was randomly chosen between 0.8 s and 1.2 s . No accuracy feedback was presented in the testing phase. Each block consisted of 35 trials, i.e. each probe duration occurred 5 times in a block in a random order. After each block, the participants were asked to take a 30s break. The participants were presented with 10 such blocks.

## Results and Analysis: Experiment

For each participant, the proportion of 'long' responses was calculated for each probe duration. In Figure 3, the proportion of 'long' responses from all participants in both groups has been plotted against the probe durations. The point of subjective equality (PSE) is the stimulus duration for which a subject recorded a response of 'long' with a $50 \%$ probability. The PSE was calculated for each participant by fitting a Weibull curve to the plot of proportion of 'long' responses vs probe duration. The PSEs for the 12 participants in the control group ( $M=1.137 s, S D=0.118$ ) was found to be generally higher than in the experimental group ( $M=0.929 s, S D=0.140$ ). An independent samples t-test revealed that there was a statistically significant difference between the two groups, $t(22)=3.76, p=0.001$.

Figure 3: Proportion of 'long' responses as a function of stimulus duration, by subjects from the control and experimental groups. Also, the PSEs of both groups are depicted (not to scale).

## Discussion: Experiment

An independent samples t-test showed that the PSE for the participants in the two groups remarkably varied from each other. This allows us to conclude that the administration of caffeine leads to a notable change in the perception of duration. The mean PSE of the 12 participants in the control group is higher than the mean PSE of the participants in the experimental group. Moreover, as shown in Figure 3, a clear shift in the PSE of the experimental group towards the shorter reference duration is observed. This shift in PSE implies that for a given stimulus duration, there is a higher probability that a participant responds 'long' in the experimental group than in the control group. In other words, a given probe duration is perceived as longer by participants under the influence of caffeine. These results lead us to conclude that caffeine produces a perception of expansion of time in humans.

The scalar expectancy theory postulates that a pacemaker
sends pulses at a mean frequency from the onset of stimulus, gated by a switch, to the accumulator. In the working memory, a comparator judges if the number of pulses accumulated is closer to a reference memory value of the short or the long standard and responds accordingly (Gibbon et al., 1984). In accordance with this information processing model, we can infer that caffeine could influence discrimination of temporal durations in one or more of the following ways.

- By increasing the frequency with which pulses are generated by the pacemaker. This would lead to a higher number of pulses getting accumulated for a given duration, due to which the comparator would associate it to be closer to the long reference duration.
- By causing distortion in the memory of the reference durations. Since the recall in the long-term memory has a higher variance, the interactions between these distorted representations of the reference durations would lead the working memory to make inaccurate comparisons, which could in turn result in increased 'long' responses.

## Computational Model

The dataset obtained from the above experiment was modeled using a simple decision model that fits the data, although biologically infeasible. This computational model is a twostep Gaussian model which has only two free parameters and is capable of reproducing the characteristics of the empirical data. The memories of the short and long reference durations in the temporal bisection task are modeled using scalar Gaussian distribution. The Gaussian helps depict the inherent noise in human memory (Kopec \& Brody, 2010).

## Description of the Model

The model proposed by us comprises of two steps. In step I, the model determines if the given stimulus is one of the reference durations, in which case, it responds accordingly, or is an intermediate duration, in which case it moves to the second step in order to make a decision. In step II, the model computes the difference between the stimulus and its memories of both the reference durations, and responds according to the one which is lesser in magnitude (Kopec \& Brody, 2010). Each of the two steps is explained in detail below.

## Model Step I

The memory of each of the two reference durations is modeled as a Gaussian distribution over durations, with a mean equal to the reference duration, and a standard deviation proportional to the reference duration. This proportion, referred to as the coefficient of variation, is randomly chosen from a suitable range of values (discussed in "Results and Analysis: Computational Model" section). The height of the Gaussian distribution of a particular reference duration at a given stimulus duration is taken as the probability of the stimulus being labelled as that reference duration( pL and pS ). As a participant can potentially classify the reference duration correctly
with $100 \%$ accuracy, discounting human error, the Gaussian distributions range from 0 to 1 (Kopec \& Brody, 2010). We take the probability of a stimulus duration being labeled as 'intermediate' ( pI ), to be the sum of the probabilities of the two reference memory distributions at that stimulus duration subtracted from 1, i.e. $p I=1-(p L+p S)$.

If the probabilities of the 2 reference memory density distributions at the stimulus duration are approximately equal, then the model responds either 'short' or 'long' with an equal probability. Otherwise, a choice is made if a given stimulus is long, short or intermediate depending upon the values of their respective probability distributions, $p L, p S$ and $p I$. If the stimulus is determined to be either the short or the long reference duration, then the model responds 'short' or 'long', respectively. If the stimulus is deemed to be 'intermediate', the model proceeds to step 2.

## Model Step II

The model computes if the stimulus duration ' $s$ ' is closer to either reference duration stored in memory and responds accordingly. The scalar Gaussian distributions for the short(TS) and long(TL) standards are used to model the reference duration values pulled from memory. One value ts is drawn from the TS distribution, and one value tl is drawn from the TL distribution. In order to model the shift in PSE brought about due to caffeine administration, the model is explicitly biased in this step towards responding 'short' or 'long', depending upon whether it's simulating the control group or the experimental group. The bias factor, B, is randomly picked from a certain optimal range (discussed below) depending upon the group. If $a b s(t s-s) * B<a b s(t l-s)$, then the subject responds 'short', and otherwise, the subject responds 'long'.

## Results and Analysis: Computational Model

The model contains only two free parameters, the coefficient of variation (CV) of the two probability distributions used to model the reference memories, and $B$, an intrinsic bias factor influencing the decision process. The values for these parameters were chosen by testing the parameter space over a range of values (CV range : $0.18-0.27$, resolution : 0.01 ; Brange : $0.6-1.4$, resolution : 0.1). The data generated by a certain value of CV and B was evaluated on the basis of an independent samples t -test between the data generated by the model and the empirical dataset collected from the control group. It can be observed from the Figure 4 that the following range of values are optimal for the 2 parameters:-

- For experimental group, $C V: 0.23-0.26$ and $B: 1.0-1.4$
- For control group, $C V: 0.17-0.22$ and $B: 0.6-1.0$

The lesser the p-value, the more significant the difference between the simulated data and the data collected from the control group. Thus, Figure 4 shows that for low values of CV and B , the data generated by the model is significantly similar to the empirical data for the control group.

Figure 4: Bubble chart of p-values of independent samples t -test between the empirical data of the control group and the simulated data at varying CV and B values.

The final model generates a dataset over 12 runs consisting of 350 trials each, simulating 12 subjects each for both the control and experimental groups. At the beginning of each run, the values for CV and B are randomly chosen from the optimal range for the concerned group.

To analyse the data generated by the model, the proportion of 'long' responses was calculated for each probe duration for every run. The point of subjective equality (PSE) was calculated for each run by fitting a Weibull curve to the plot of proportion of 'long' responses vs probe durations. The PSEs for the 200mg caffeine group ( $M=0.907, S D=0.022$ ), similar to the empirical data, was found to be lower than the PSEs for the control group ( $M=1.014, S D=0.047$ ). An independent samples t-test between the data showed a statistically significant difference between the two groups, $t(22)=6.736, p<0.001$.

## Discussion: Computational Model

From the statistics regarding the PSEs for the 2 groups, we can see that for corresponding groups, the simulated dataset as well as the human dataset gives similar mean PSE values. The standard deviation of the PSEs generated by the model is considerably lesser than the same in the human dataset. The higher variance in the human dataset might be due to human error, fatigue and slight inconsistencies in perception of time by different participants. The model tries to incorporate this variance between the PSEs for different subjects, by randomly picking a CV and B value, for each run, from the optimal range for the concerned group. Yet, this does not give rise to sufficient variation in the generated data as compared to the human dataset. However, the mean PSE is accurately simulated for both groups.

The independent samples t-test and the Weibull fit between the generated datasets for the experimental and control groups show that the model closely mimics human temporal judg-

Figure 5: Effect of setting the parameter CV on the size of decision regions $\mathbf{A}$. When CV is set to optimal values found for the 0mg group, the central region expands $\mathbf{B}$. When CV is set to optimal values found for the 200 mg group, the central region shrinks and there is more overlap of the Gaussians corresponding to the reference durations.
ment.
As mentioned in the previous section, high values of the parameters, $C V$ and $B$, were found to be suitable to model the experimental group, while low values of CV and B were suitable to simulate the control group. These parameter ranges might lend us some insight into the mechanism of caffeine action, as discussed below.

In the model, the value for B increases or decreases the distance of the stimulus from the short standard, depending upon whether it is high or low. If the distance of the stimulus from the short standard is higher than the distance from the long standard, the model would respond 'long'. This explains why a high value of B is suitable for modeling the experimental group and vice versa. We can, therefore, infer that this range of values for ' $B$ ' can be indicative of the frequency of the pacemaker. A rise in the rate at which pulses are generated would lead to more pulses being accumulated for a given duration and could lead to a perceived expansion of time.

In addition to the range of B-values, we also find that high values of CV are suited to modeling the experimental group. This can be explained as follows (see Figure 5). In step 1 of the model, the probability distribution for the 'long' reference duration has a larger standard deviation, as it has the same coefficient of variation as the 'short' reference duration, despite
having a larger mean. This implies that for a given stimulus, if the decision is made in step 1 itself, there is a higher probability that the response be 'long'.

The decision to proceed to step 2, is dependent on the value of pI , i.e., the probability that the stimulus is judged as 'intermediate' in step 1. In the experimental group, as the model uses higher CV values, for a given stimulus, the values of pS and pL would be higher than the values for the same in the control group, where the model uses lower CV values. This would cause a decrease in pI for a given stimulus in the experimental group's simulation. Therefore, the probability of the decision being made in step 1 increases, implying that there is a higher probability of the response being 'long' as compared to the control group, as explained in the previous paragraph.

A higher value of CV, while mean remains fixed, implies a larger standard deviation (SD). As the experimental group is being modeled accurately with a higher range of CV values as compared to the control group, the width of the Gaussian distributions used to model the reference durations is higher in the experimental group. This change in the width implies that caffeine might have the potential to cause distortion in the memory of durations. This leads us to infer that caffeine mechanism possibly works via the memory pathway rather than an attentional pathway, as the latter would require a leaner spread of the probability distribution. Despite investigative experiments, there is no general consensus on the nature of acute effects of caffeine on memory (McLellan et al., 2016). However, our model indicates an increase in uncertainty in the reference memory caused by caffeine.

## Limitations and Future Work

One major shortcoming of the model suggested by us is that it is purely a decision model and does not take into account the neural circuitry mediating time perception in humans. The model is pitched at an abstract level and in order to obtain biologically rooted insights, there is a need for a more realistic model.

Substantial evidence has been found that indicates that the basal ganglia and its dopaminergic pathways control time perception to an extent. For instance, it has been observed that PD patients, when administered medication that brings the dopamine concentration back to normal, are capable of performing time estimation accurately, unlike when offmedication (Jones, Malone, Dirnberger, Edwards, \& Jahanshahi, 2008). Furthermore, time perception studies can help in the early detection of such diseases that affect dopamine production and will also increase our understanding of the pathways and the brain areas that may be involved in such diseases.

The fundamental circuitry behind caffeine's action has been established to be the antagonism of adenosine receptors in the central nervous system which leads to interaction with dopamine receptors (Davis et al., 2003; Ferré, 2016). Caffeine blocks A2A receptors in the striatum and promotes a direct excitatory potentiation of D2 receptors. This leads
to an increase in the stimulation of psychomotor activity by dopamine (Ferré, 2016). Hence, we think that a model can be conceptualised which shows caffeine indirectly affecting time processing in the basal ganglia by modulating dopamine.

Alternatively, it has been observed that a cortical neuronal network, without the use of any kind of pacemaker, may have the potential to track duration by storing recent information (Mauk \& Buonomano, 2004). This can be used as inspiration for another biologically feasible model. Furthermore, there is indication in literature that a reinforcement learning based model of interval timing might be able to explain several behavioural as well as neural phenomena (Gershman, Moustafa, \& Ludvig, 2014). These are few methods that can be explored to further investigate the effect of caffeine on time perception.

# Peculiarity doesn't trump ordinarity: On recognition memory for exceptions to the category rule 

Olivera Savic (savic.7@osu.edu)<br>Department of Psychology, 1835 Neil Avenue, Columbus, OH 43210, United States

Vladimir Sloutsky (sloutsky.1@osu.edu)<br>Department of Psychology, 1835 Neil Avenue, Columbus, OH 43210, United States

#### Abstract

While exceptions to a regularity might be rare, categories that have exceptions are not. Previous studies on learning categories that have exceptions suggested special status of exceptional items in memory (e.g. Palmeri \& Nosofsky, 1995, Sakamoto and Love, 2004). However, this might be true only for a special kind of exceptions - those that call for forming complex binding structures, and could be learned only if they are fully memorized. In the two experiments in this study, we show that memory for exceptions is not better than memory for regular category members (Experiment 1). On the contrary, both children and adults had better memory for the features of regular items (Experiment 2). In addition, adults, but not 4-year-olds, showed better memory for the rule than for probabilistic features. The overall results challenge the idea of the special status of exceptions in memory.

Keywords: rule-plus-exception; differential memory; category structure

## Introduction

An exception is a case to which a rule or a general statement does not apply. Tomatoes are an exception to the category of vegetables, penguins are an exception to the category of birds, bats to the category of mammals, and the verb "cut" (since it does not change its form) is an exception to the rule of tense formation. While exceptions may be of various kinds, what is common for all of them is that they violate our expectations about how something (or someone) should behave, what it should look like, where it should belong, as well as other expectations that are based on our previous knowledge. Therefore, understanding of how we learn about and how we represent those rare, deviant cases is an interesting problem for the theories of category learning.

A common assumption underlying models that aimed to explain how we learn and represent exceptions, is that exceptions have a privileged memory status. Work in the schema literature contrasting memory for schema-consistent (i.e., in accord with expectations) and schema-inconsistent information, demonstrated that schema-inconsistent information is remembered better (for meta-analysis see, Rojahn \& Pettigrew, 1992). It has been argued that the schema-inconsistent memory advantage (i.e. tendency to false alarm to schema-consistent information) may be a specific case of a general advantage for distinctive
information. Similar to the "von Restorff effect", where there is a recall advantage for a single word in uppercase in a list of lowercase words (von Restorff, 1933), it is expected that once expectations about an event or category structure are formed, the deviant item should attract more attention and thus have stronger memory trace.

Another account that aimed to explain inconsistent information memory advantage focused on the difference in the depth of processing. Since deviant items may be more difficult to process than regular items (Fabiani \& Donchin, 1995; Graesser, 1981), they tend to receive more study time (Stern, Marrs, Millar, \& Cole, 1984), and this leads to better memory. When study time is limited, there should be no advantage, or the pattern may even be reversed (Metcalfe, 2002; Thiede \& Dunlosky, 1999).

Studies in category learning also support the claim of better memory for exceptions. In an old-new recognition task, Palmeri and Nosofsky (1995) tested participants' memory for two newly learned categories. In both categories, the majority of items could be categorized based on a simple (singledimension) rule, but there was one exception item which respected the rule of the contrasting category. The main result of their study was that participants showed superior recognition memory for those items that were exceptions to the rule. These findings were in accordance with the prediction of the RULEX (rule-plus-exception) model of classification learning (Nosofsky, Palmeri and McKinley, 1994). According to this model, people tend to form simple logical rules to define categories, and if not all the members of the category follow the formed rule, those occasional exceptions are stored in memory. Thus, regular members of the category and exceptions are supposed to be learned using two independent mechanisms. Based on RULEX, the role of memory processes in categorization of the regular category items should be minimal, which stands in high contrast with purely memory based representation of the exception.

Similar to RULEX, SUSTAIN (Love, Medin, Gureckis, 2004) model assumes formation of specialized representations (clusters) for exceptions that violate initially formed representation (cluster), and predicts that differential storage of exceptions makes them more distinctive in memory. The main difference between the two models lies in flexibility. SUSTAIN emphasizes the need for a flexible search of a given category structure, and allows for clusters
to be of different nature (e.g. rules, prototypes, attractors), all depending on the (sub)structure of the category and the task goals. That way, in addition to successfully predicting memory advantage for exceptions, SUSTAIN is sensitive to effects of structure saliency (e.g. frequency effects), familiarity effects (differentiating between old and new rulefollowing items) or unsupervised learning, which are all problematic for RULEX to account for (Sakamoto \& Love, 2004).

Despite described differences, both RULEX and SUSTAIN are in accord with the previous categorization and schema literature regarding (a) memory advantage for ruleviolating exceptions, (b) deeper (at a greater detail) processing of exceptions compared to regular category members (Loftus \& Mackworth, 1978) and (c) attribution of memory advantage for exceptions to differential attention during encoding (von Restorff, 1933).

## Nature of the exceptions

It is important to note here that previous studies (e.g. Palmeri \& Nosofsky, 1995, Sakamoto and Love, 2004; Davis, Love, \& Preston, 2012) focused primarily on a specific type of exceptions - exceptions that violate prior knowledge expectations by respecting the contrasting category rule. Those exceptions could not be learned by relying on a rule, nor by relying on the similarity with the other category members. In order to be successfully categorized they required forming complex binding structures. Thus, it is unclear whether the better memory for exceptions results from exceptions being rare and violating the prior knowledge expectation (in this case, the category rule), or because of their peculiar structure.

## Developmental differences

All hypothesized solutions for learning and representing exceptions were formulated with an adult in mind. Little is known about how exceptions may be learned and represented early in development.

Both RULEX and SUSTAIN assume engagement of selective attention and (to different extent) optimization of memory resources during category learning. However, previous studies suggest that in contrast to adults and older children, who optimize their attention to category and task relevant dimensions, young children tend to allocate attention to both relevant and irrelevant information (Sloutsky, 2010; Deng \& Sloutsky, 2016). The developmental differences in attention allocation during category learning (i.e., selective vs. distributed) have important consequences on what is remembered about categories. While selective attention results in better memory for information that is particularly useful for distinguishing the categories (e.g. rule features), distributed attention results in all information, relevant and relevant, being remembered equally well (Deng \& Sloutsky, 2016). Thus, if difference in recognition memory for regular category members and exceptions arise from optimization and selectivity, as previously suggested, no difference in memory for regular and exceptional items should be expected for young children.

## Current study

In the two experiments reported here, we tested the generalizability of the assumption of memory advantage for exceptions. In Experiment 1, we tested the claim of memory advantage for exceptions in situation of learning categories that have exceptions that violate previous expectation since they look more like the members of the other category and they also violate the category rule. However, in contrast to the exceptions used in the previous studies that respect contrasting category rule, they have a new rule on the deterministic dimension, which is on its own sufficient for successful categorization. In Experiment 2, the structure of the regular category members remained the same, but the nature of the exceptions was changed. In Experiment 2, exceptions were items that had all features new. Since exceptions in our study are individuals, for this latter kind of exceptions, different kinds of rules could be formed, since each feature is fully predictive.

Although the exceptions used here are very different from the ones used in the previous studies, they retain all the characteristics that are assumed to contribute to their special status in memory. They are rare, they may be studied for unlimited amount of time, and, most importantly, they violate the expectations based on the knowledge of regular items, both in terms of rule and appearance. On the other hand, they could be categorized equally successfully by employing different learning mechanisms and forming different representations, which makes them advantageous in comparison to the types of exceptions that could be learned by memorizing only.

Additionally, we examined developmental differences in learning and representing exceptions. Two age groups participated in the experiments: four-year-olds and adults. As previously described, a developmental study is particularly interesting since it will allow test of differences in the memory status of exceptions under regimes of distributed end selective attention category learning.

## Experiment 1

## Method

## Participants

Participants were 27 four-year-old children (Mage $=54.6$ months, range $48.5-59.9$ months, 14 girls) and 36 adults.

Data of one additional child and one adult participant were excluded due to the failure to discriminate between old (High-Match) items and items that had 5 of 6 features completely new (All-new-P) (A' not different from chance level of 0.5 , one sample $t$-test $p s>.05$ ).

All four-year-olds that took part in the experiments reported in this paper were recruited from preschools located in middle-class suburbs of Columbus. In order to take a part in the study they had to be between 48 and 60 months old. They were tested during their regular school hours in a quiet room in their preschool.

All adults that participated in the experiments reported here were The Ohio State University undergraduate students. They were tested in a quiet room in the laboratory located on campus and they received course credits for their participation.

## Stimuli

Stimuli were artificial dinosaur-like creatures created using Spore Creature Creator and Gimp (Figure 1). These creatures were accompanied by two novel category labels: Lulu and Momo.

Figure 1. Examples of stimuli used in the study where hands are the rule feature.

## The category structure

The categories of Lulus and Momos were dense 7dimensional categories with 1 non-diagnostic dimension, 5 probabilistic dimensions and 1 deterministic dimension (Table 1). Non-diagnostic dimension varied independently and gave no information about the category membership. Probabilistic dimensions varied between categories and within-category, with significantly higher between-category in comparison to within-category variance. Hence, probabilistic dimensions were predictive when taken together, since they reflected the overall similarity between category items. Deterministic dimension was fully predictive.

The neck length (short/long) was always the nondiagnostic dimension. The other 6 dimensions were: antennas, mouth, belly, wings, hands and feet. All dimensions were binary. The choice of deterministic feature (belly or hands) was balanced across the participants. Table 1 presents the structure of training and test items.

During the training, only High-Match and Exception items were presented. High-Match items always respected the category rule and had most of the probabilistic features of their own category (4 of 5). Exceptions were designed so they look more like the other category members (they had probabilistic features of the other category) but they also had a new rule feature.

In the test session, in addition to items presented during the training (High-Match and Exceptions), there were additional

4 types of items. Those new items were based on High-Match and Exception items, but either had one probabilistic feature new (One-new-P, E-One-new-P), or all probabilistic features new (All-new-P, E-All-new-P).

## Design and procedure

For adults, all instructions and questions were written on the screen and they responded by pressing designated keys on a computer keyboard. For four-year-olds, all instructions and questions were read by a trained experimenter who collected their verbal responses using a computer keyboard.

## Instructions

After the cover story about the two dinosaur families, Momos and Lulus, was read, participants were presented with the prototypes of Momos and Lulus. The prototypes were presented together, on the same screen. Participants were told that that is how Momos and Lulus usually look like and each of the six features of the two creatures was introduced, using the sentence frame: "Momos/Lulus usually have antennas like these" and pointing to the named feature (Figure 2). Training

During the training participants were presented with the exemplars of Lulus and Momos and they were asked to classify them. Items were presented individually in the center of a white background screen, accompanied by the question "Is this is a Momo or a Lulu?" Two buttons, labeled Momo and Lulu, were presented on the same screen. Participants responded by pressing one of the buttons if adults, or giving verbal answers if children. After they made a response, corrective feedback was provided. Feedback had two
elements. First, the button of the correct response was presented (that is, the correct answer button stayed on the screen) and second, feedback sentence was presented. If participant gave the correct answer, she received message "That's right! That's Momo (Lulu)!" If participant made a wrong choice, message "Oops! That's Momo (Lulu)!" was presented.

During the training session, 70 items were presented: 60 High Match items and 10 Exceptions. In the first block only High Match items were presented (20), while in the second and the third block participants saw both High Match (20) and Exception (4) items in random order. At the end of the third block, we presented additional 2 Exception items. The logic behind the dynamics described was that in order for Exceptions to be seen as Exceptions they should be presented after a representation of High-Match items was formed, and they needed to be less frequent. Order of presentation was randomized for each participant.
Memory test
Memory test was introduced immediately after the training session. Items were presented individually, followed by the question „Did you see exactly the same creature in the first part of the game?" and two buttons labeled „old" and „new". After participant gave a response, the next trial was presented. There was no feedback.

Memory test was given in one block. It had 64 trials in total, 8 trials of each item type, presented in random order.

## Results

## Training performance

For both age groups, average accuracy in categorizing HighMatch items was above the chance (one-sample t-tests against chance yield $t \mathrm{~s}>2.70$, both $\mathrm{ps}<.05$, two-tailed).

Both groups of participants misclassified Exceptions. The average proportion of accurately classified items was .41 for four-year-olds and .33 for adults, based on performance on all 10 items presented during the training session (both bellow the chance, $t \mathrm{~s}>2.38$, $p \mathrm{~s}<.05$ ). Since Exceptions had probabilistic features of the other category High-Match items, participants based their responses on the overall similarity of exceptions to High-Match items.

## Recognition memory

In order to estimate participants' recognition memory, we calculated A' scores (Snodgrass, Levy-Berger, \& Haydon, 1985). A' is a non-parametric analogue of the d' statistic (Brophy, 1986) and it is a measure of discriminability. No discrimination (chance performance) is indicated by value of 0.5 . With better discrimination the A' score increases.

Both age groups demonstrated high recognition accuracy (old - All-new-P). Average memory sensitivity scores were well above chance (both $p s<.001$ ).

To examine the hypothesized differences in memory for regular items and exceptions, A-prime scores were subjected to a two-way (Age by Type) ANOVA.

For the overall memory (old - All-new-P) the analysis indicated that there was no significant main effect of item type ( $p>.05$ ), whereas the main effect of age was significant,
$F(1,120)=8.87, p<.01, \eta=.07$ with 4-year-olds' performance being significantly lower than adults' performance (Figure 2).

The pattern was the same for the memory for probabilistic features. Again, adults have shown better memory than 4-year-olds $(F(1,120)=8.61, p<.01, \eta=.07)$ and there was no difference in memory for regular items and exceptions.

Note here that the lack of difference in memory for regular and exceptional items may be due to poor learning. This problem is resolved in Experiment 2.

Figure 2. Memory sensitivity scores (A-prime) for overall memory (OLD - All-new-P) across age groups and two item types in Experiment 1. The dashed line represents the point of no sensitivity. Error bars represent the standard errors of the mean.

## Experiment 2

## Method

## Participants

Thirty-three four-year-olds (Mage $=52.6$ months, range 44.0 - 53.6 months, 12 girls) and 39 adults took part in Experiment 3. Three additional 4-year-olds and one adult were excluded based on the same criteria used in Experiment 1(A' not different from chance level of 0.5 , one sample $t$-test, all $p s$ >.05). Participants were recruitment from the same participants' pool as in Experiment 1.

## Stimuli

The structure of the High-Match items and accompanying test items was the same as in the Experiment 1. The same stimuli set was used. Exceptions were different. They had all features new. Exceptions were individuals, thus there was one exception of Momo and one of Lulu category.

In addition to the stimuli types used in the Experiment 1, there were 2 additional item types: New-D and New-D Exceptions (See Table 1).
Design and procedure
Design and procedure of Experiment 2 respected the one described for Experiment 1 in every respect. Memory test had

88 trials. The experiment took approximately 15-20 minutes for adults and 25-30 minutes for children.

## Results

## Training performance

Performance on High-Match items was above chance for both age groups ( $t s>4.78$, both $p s<.001$, two-tailed). Both children and adults learned to categorize exceptions (ts (36, $23)=3.57,6.64, p s<.001)$.

## Recognition memory

Overall memory sensitivity was high for both age groups and well above chance (both $p s<.001$ ) (Figure 3). Differences in overall memory (old - All-new-P) were tested in a 2 (Age: 4-year-olds, adults) x 2 (Type: regular, exception) ANOVA. Participants had better memory for regular items (A' scores), regardless of their age $(F(1,140)=4.88, p<.05, \eta=.03)$.

Figure 3. Memory sensitivity scores (A-prime) for overall memory (OLD - All-new-P) across age groups and two item types in Experiment 2. The dashed line represents the point of no sensitivity. Error bars represent the standard errors of the mean.

In order to test for differences in memory for ( P and D ) features, 2 (Age: 4 -year-olds, adults) x 2 (Type: regular, exception) x 2 (Feature: P, D) ANOVA was conducted on A' scores. The analysis revealed significant main effects of age $(F(1,280)=5.13, p<.05, \eta=.02)$ and type $(F(1,280)=$ 13.26, $p<.001, \eta=.05$ ), and a significant age by feature interaction $(F(1,120)=6.05, p<.05, \eta=.02)$ on A' scores. As expected based on the previous studies (Deng \& Sloutsky, 2016), adults, but not 4 -year-olds, have shown differential memory - specifically better memory for rule than probabilistic feature. Both age groups had better memory for features of High-Match items, than those of exceptions (Figure 4).

## Discussion

Results presented in this paper challenge assumptions of the models of classification learning like RULEX and SUSTAIN. In two experiments reported here we have shown
that both children and adults have better memory for features of regular items than features of exception. These findings have at least two important implications. First, they show that regular category members are not processed minimally, as it is suggested by models which assume high level of optimization of attention. Secondly, they also show that exceptional items are not represented fully, that is, they are not necessarily memorized. Not only that RULEX model cannot account for these findings, but it predicts completely the opposite pattern. Although SUSTAIN would fit the data better (especially good memory for regular items), the finding of better memory for exceptions runs counter to its assumptions.

Figure 4. Memory sensitivity scores (A-prime) for probabilistic and deterministic features of two item types in Experiment 2 (Panel A: four-year-olds; Panel B: adults). The
dashed line represents the point of no sensitivity. Error bars represent the standard errors of the mean.

The representation of an exception depends on its nature. When exceptions violate categories defined by rules by respecting contrasting category rule and can be learned only if there is binding of features, there is better memory for exceptions than regular items, as shown in the previous studies (e.g. Palmeri \& Nosofsky, 1995, Sakamoto and Love, 2004). However, when the nature of exceptions, and the nature of a category they belong to, allows for more flexible approach, participants tend to optimize. In the case of the exceptions used in this study, they could be equally successfully categorized based on different representations, some of which could simply contain memory for one of the item's features. However, despite their easy-to-learn structure, if special status of exceptions is to be attributed to the fact they violate previous knowledge expectations, they are schema-inconsistent and rare, exceptions in our study would also be processed with more attention, more deeply and they would have stronger memory trace. However, this was not the case.

Contrary to the predictions based on schema literature, that participants are more prone to notice missing features or new features in schema-inconsistent items than schema-consistent items (Friedman, 1979; Goodman, 1980), our participants were more sensitive when we changed regular items' features.

In addition to the difference in memory for regular category members and exceptions, developmental differences in memory were also found. While adults had better memory for rule, than for probabilistic features, 4-yearolds didn't show differential memory. This pattern is in accordance with previous studies (Deng and Sloutsky, 2016). However, contrary to our predictions, there were no developmental differences in memory status of exceptions. Both age groups had better memory for regular category members, despite differences in attention allocation (selective vs. distributed).

Taken together, findings of this study suggest new directions for models of category learning and memory, by providing new evidence on attention and memory optimization during category learning.

## Acknowledgments

We would like to thank Sophia Deng for her comments on the design of the study. This research was supported by NIH grants R01HD078545 and P01HD080679 to VMS.
