The fact that 'knowledge' has a verb form, as well as approximate near-synonyms such as 'thought' and 'believed', allowed us to model our investigations of knowledge directly on Gentner's (1981) research on the semantic integration of verb meanings. Of course, not all concepts of interest to psychologists and philosophers will necessarily exhibit these desirable traits. Where this is not the case, other semantic integration tasks may be more appropriate. For example, these constraints would not apply to semantic integration tasks measuring recognition for sentences or phrases (e.g., Bransford \& Franks, 1971; Owens, Bower \& Black, 1979). As described earlier, this type of task presents some disadvantages (e.g., increased ambiguity from the assessment of recognition memory over larger semantic units). However, these disadvantages are not insurmountable. In particular, employing a remember-know procedure (Tulving, 1985) could help distinguish between genuine recollection and familiarity. With sufficient care, it should be possible to craft phrases or sentences that unambiguously express whatever concept may be of interest to researchers.

The present investigation demonstrates the need for empirical research on knowledge attribution and knowledge concepts, and also illustrates a powerful method that may be applicable in future investigations. Further research is needed to explore both the implications of these early findings on Gettier cases, as well as other factors that are potentially relevant to knowledge, such as the salience of error (e.g., Schaffer \& Knobe, 2012) and agents' practical interests (e.g., Pinillos, 2012). Moreover, semantic integration tasks may prove useful for the study of other
philosophical concepts, including intention (Knobe et al., 2012) and causation (Livengood \& Machery, 2007).

#### Abstract

Recent work on causal learning has investigated the possible role of generic priors in guiding human judgments of causal strength. One proposal has been that people have a preference for causes that are sparse and strong-i.e., few in number and individually strong (Lu et al., 2008). Evidence for the use of sparse-and-strong priors has been obtained using a maximally simple causal set-up (a single candidate cause plus unobserved background causes). Here we examine the possible impact of generic priors in more complex, multicausal set-ups. Sparse-and-strong priors predict that competition can be observed between candidate causes even if they occur independently (i.e., the estimated strength of cause A will be lower if the strength of uncorrelated cause B is high rather than low). Experiment 1 revealed such a cue competition effect in judgments of causal strength. Experiment 2 showed that, as predicted by a Bayesian learning model with sparse-and-strong priors, the impact of the prior diminishes as sample size increases. These findings support the importance of a preference for parsimony as a constraint on causal learning.

Keywords: causal learning; generic priors; causal strength; parsimony; Bayesian modeling

## Introduction

## Prior Beliefs in Causal Learning

Humans (and other intelligent organisms) are able to extract causal knowledge from patterns of covariation among cues and outcomes. Viewed from a Bayesian perspective, causal inferences are expected to be a joint function of likelihoods (the probability of observing the data given potential causal links of various possible strengths) and priors (expectations about causal links that the learner brings to the task). For relatively simple causal set-ups involving binary variables, human causal judgments can be described quite accurately by the power PC theory (Cheng, 1997), which uses a noisyOR likelihood function to integrate the influences of multiple generative causes (Griffiths \& Tenenbaum, 2005; Lu et al., 2008; see Holyoak \& Cheng, 2011, for a review).

Prior beliefs about causal relationships can also be formulated within a Bayesian framework for causal learning. Generic causal priors can be thought of as preferences for certain types of causal explanations, without
relying on domain-specific knowledge. Some Bayesian models have assumed uninformative priors (e.g., Griffiths \& Tenenbaum, 2005); however, other models have incorporated substantive generic priors about the nature of causes. In particular, Lu et al. (2008) proposed that people have a preference for causes that are sparse and strong: i.e. a preference for causal models that include a relatively small number of strong causes (rather than a larger number of weak causes). Such priors can be viewed as a special case of a more general pressure to encourage parsimony (Chater \& Vitanyi, 2003), which implies a combination of simplicity and explanatory power. The preference for parsimony has a number of expressions elsewhere in causal learning phenomena and theory. For instance, causal learners appear to make the default assumption that causes act independently in producing an effect, rather than interacting (Cheng, 1997; Novick \& Cheng, 2004). Moreover, people generally prefer simpler explanations to equally accurate but more complex explanations (Lombrozo, 2007).

## Generic Prior: Sparse-and-Strong (SS) Causes

Lu et al. (2008) formalized the "SS power" model with sparse-and-strong (SS) priors for simple causal models with a single candidate cue and a constantly-present background cause. When the candidate cause generates (rather than prevents) the effect, there is an expectation that the candidate cause is strong (strength close to 1) and the background is weak (strength close to 0 ), or vice versa. A single free parameter, $\alpha$, controls the strength of the prior (when $\alpha=0$, the distribution is uniform).

The possible role of generic priors in causal strength
Table 1. Contingency learning data for one experimental block (44 trials) by trial type

| Conditions |  | C | AC | BC | ABC |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Weak-B | E absent | 1 | 6 | 3 | 7 |
|  | E present | 10 | 5 | 8 | 4 |
| Strong-B | E absent | 1 | 6 | 9 | 10 |
|  | E present | 10 | 5 | 2 | 1 |

Figure 1: Sparse-and-strong prior distribution over causal strengths of three causes. Colors indicate the values of prior probability (red corresponds to highest probability).
judgments has so far only been examined for very simple causal graphs (e.g., one generative candidate cause and a constantly-present background cause). Lu et al. (2008) fit several causal learning models to parametric data for human strength judgments. They found the best fit was provided by a Bayesian implementation of the power PC theory that incorporated SS priors with an $\alpha$ value of 5 (not 0 ), implying a human preference for sparse-and-strong causes. When $\alpha$ value is set to zero, the prior distribution would be equivalent to a uniform distribution.

The generalization of the sparse-and-strong prior for more than two causes is straightforward. For the experiments reported here, the SS prior is constructed on the basis of three candidate causes, $A, B$, and $C$, which are all generative. The SS prior can be defined as,

$$
\begin{align*}
& P\left(w_{A}, w_{B}, w_{C}\right) \propto \\
& \quad e^{-\alpha\left(1-w_{A}\right)-\alpha w_{B}-\alpha w_{C}}+e^{-\alpha w_{A}-\alpha\left(1-w_{B}\right)-\alpha w_{C}}+e^{-\alpha w_{A}-\alpha w_{B}-\alpha\left(1-w_{C}\right)} \tag{1}
\end{align*}
$$

in which $w$ denotes causal strength for different causes.
Figure 1 illustrates the sparse-and-strong prior in the three-cause situation. A signature of SS priors is the preference for one strong cause coupled with other weak causes, i.e., a set of "ideal" causal strengths for the three causes might be $w_{\mathrm{A}}=1, w_{\mathrm{B}}=0$ and $w_{\mathrm{C}}=0$. This preference instantiated in SS priors implies a key empirical prediction: competition effects in judgments of causal strength when multiple causes co-occur. Strength competition implies that if a candidate cause appears along with another cause of greater strength (as defined by likelihoods), then the strength of the weaker candidate cause will be underestimated. This prediction goes beyond competition effects predicted by the likelihood function alone (i.e., a model assuming uninformative priors). The goal of the present paper is to test this key empirical prediction in a situation requiring inference based on multiple causes.

## Competition Between Causes

Various competitive dynamics are commonly observed in causal learning paradigms, including blocking (e.g., Shanks, 1985), overshadowing (e.g., Waldmann, 2001) and unovershadowing (De Houwer \& Becker, 2002). However, in all these paradigms the competition is between cues that cooccur in a systematic way. For example, blocking is typically obtained when cue A is first shown to produce the effect by itself, and then the compound cue $A B$ is introduced and also followed by the effect. From a Bayesian perspective, a lower causal strength judgment for the blocked cue, B , is entirely rational, as the learner has no opportunity to observe what happens when $B$ is presented without A (i.e., there will be greater uncertainty about the strength of B than of A). More generally, Bayesian models with uniform priors can readily account for a wide range of competition effects that involve cues occurring in a correlated fashion (Carroll, Cheng \& Lu, in press).

However, sparse-and-strong priors are unique in predicting competition between independently-occurring causes (e.g., the occurrence of cue A is uncorrelated with the occurrence of cue B). We will show simulation results confirming that when alternative causes A and B occur independently, a Bayesian model with uniform priors predicts that judgments of the strength of $A$ will not be influenced by the strength of $B$, or vice versa (also see Busemeyer, Myung \& McDaniel, 1993a). In contrast, an otherwise-identical model incorporating sparse-and-strong priors predicts that early in learning (when the impact of priors is maximal), independently-occurring causes will compete for strength (e.g., the strength of A will be judged to be lower if $B$ is strong rather than weak).

The present experiments include two conditions based on a set of contingency data, $D$, shown in Table 1. The occurrences of causes A and B are independent in both conditions. The causal power of A is held constant across the two conditions ( 0.5 ), but the causal power of B varies from one condition ( 0.2 , weak- $B$ condition) to the other ( 0.8 , strong-B condition).

For this set of contingency data the model computes the mean of estimated causal strength derived from the posterior distribution:

$$
\begin{equation*}
\bar{w}_{A}=\int_{0}^{1} w_{A} P\left(w_{A} \mid D\right) \tag{2}
\end{equation*}
$$

The posterior distribution $P\left(w_{A} \mid D\right)$ is obtained by applying Bayes rule to combine likelihood function and priors as

$$
\begin{equation*}
P\left(w_{A} \mid D\right)=\iint \frac{P\left(D \mid w_{A}, w_{B}, w_{C}\right) P\left(w_{A}, w_{B}, w_{C}\right)}{P(D)} d w_{B} d w_{C} . \tag{3}
\end{equation*}
$$

In our simulations, we employed the noisy-OR likelihood function (Cheng, 1997), since binary causes and effects were used in the experiments:

$$
\begin{aligned}
& P\left(E=1 \mid C_{A}, C_{B}, C_{C} ; w_{A}, w_{\boldsymbol{B}}, w_{C}\right) \\
& \quad=1-\left(1-w_{A} C_{A}\right)\left(1-w_{\boldsymbol{B}} C_{B}\right)\left(1-w_{C} C_{C}\right)(4)
\end{aligned}
$$

where $E$ and $C$ indicate the presence or absence of effect and causes, respectively.

Figure 2 shows the model predictions for causal strength of A in the two conditions. The Bayesian model with SS prior (center bards in Figure 3) predicts different estimates of $w_{\mathrm{A}}$ across conditions due to competition between causes A and B, even though the two cues occur independently. In contrast, a model with uniform prior (right bars in Figure 3) predicts that $w_{\mathrm{A}}$ will not vary across the two conditions. The latter simulation result confirms that a Bayesian model with uniform priors does not predict competition between independently-occurring causes when the likelihood function is a noisy-OR, extending the similar negative conclusion for the case in which the likelihood function is linear (Busemeyer et al., 1993a).

Testing these opposing predictions provides a means to discriminate between alternative possible priors for causal inference with multiple cues. The prediction of competition between independently-occurring causes has never been clearly tested. Busemeyer et al. (1993b) reported an experiment that obtained competition between uncorrelated cues, in a paradigm that may have drawn on causal learning mechanisms. However, this competition effect was observed only when participants were informed that the two cues would be of different strengths, one strong and one weak (see their Footnote 5, p. 194). It is possible that this instruction suggested to subjects that the cues were expected to be competitive. In general, relatively few studies of causal learning have used complex causal set-ups involving more than one or two candidate causes. The present experiments were designed to determine whether multiple candidate causes would compete for causal strength, and whether such effects can be modeled by assuming people have priors that causes will be sparse and strong.

## Experiment 1

## Method

Participants Participants were 90 undergraduate students at the University of California at Los Angeles (UCLA) who participated for class credit ( $80 \%$ female, mean age $=20$ years). Half were assigned to the strong- $B$ condition and half to the weak-B condition.

Procedure Participants read a cover story, as follows: "Imagine that you are assisting a doctor at a new island resort. Many of the guests at this new resort have become ill, and you are charged with helping to determine the cause
of the illnesses. Every day, at dinner, the resort provides a complimentary salad for its guests. The salads can be made with different exotic vegetables. The salads always have at least one exotic vegetable, and can be ordered with up to three different exotic vegetables. The resort's doctor thinks one or perhaps several of these exotic vegetables may be causing the illness <pictures of three vegetables are shown>. You will be reviewing a number of case files that describe what a guest ate and whether they became sick. After viewing these files you will be asked to give your assessment of which vegetable or vegetables are the culprits. Please pay attention to each case.... When you are done reviewing the cases you will be asked to estimate how many people each vegetable is likely to affect negatively."
These vegetables were labeled $\mathrm{A}, \mathrm{B}$, and C , and were shown as photographs of exotic vegetables (see Figure 2, top). These photographs depicted the actual vegetables radicchio, bitter melon, and black garlic. The assignment of vegetables to the labels $\mathrm{A}, \mathrm{B}$ and C was randomized across participants. During the learning phase, participants viewed "case files" for individual guests, showing which combination of vegetables they had eaten, and whether or not they had fallen ill.

There were four possible combinations of fruits: each guest had either eaten vegetable $C$ alone, vegetables $A$ and $C$, vegetables $B$ and $C$, or all three vegetables $A, B$, and $C$. These four combinations were presented in equal number, such that A and B both occurred 50 percent of the time, and the correlation between the occurrence of A and B was 0 . A total of 44 cases ( 11 of each type) was the minimum number required to reflect the underlying causal powers in the presented distribution of cause combinations and their associated outcomes.

The numbers of guests who became sick after eating each combination were determined by the causal powers assigned to each vegetable, calculated according to the noisy-OR likelihood function under the default assumption that each cause acts independently to produce the effect (Cheng, 1997). In both conditions, vegetable $A$ was assigned a causal strength of .50 , and vegetable $C$ was assigned a causal strength of .10. In the strong-B condition, vegetable B was assigned a causal strength of .80 , whereas in the weak-B condition, vegetable $B$ was assigned a causal strength of .20 . Cause A was the focus of the study, as we were interested in whether its judged strength would be influenced by the variation in the strength of cause B. Cause C served as an observable "background" cause, as it was shown to be present on every trial. The resulting contingency data is summarized in Table 1.

The 44 cases were presented sequentially in a different random order for each participant. After viewing all 44 learning trials, participants were asked to give a causal strength rating for all three vegetables. Participants were shown a picture of each vegetable along with text that read, "Imagine 100 healthy people ate this vegetable; how many do you estimate would get sick?" Participants then made

Figure 2: Example trial showing a guest who ate A, B, and C vegetables and became sick (top). Example response trial (bottom).
their rating using a slider, inputting a value between 0 and 100 (see Figure 3, bottom). The order of the three questions was randomized for each participant. After making all three ratings, participants were shown a summary of their responses and were asked to confirm that they had correctly entered their ratings. Participants were randomly assigned to one of two experimental conditions (weak-B or strong-B).

## Results and Discussion

Data from two participants were excluded due to technical issues. Data from another eight were excluded because they entered responses of zero to both cause A and cause B, suggesting errors or a lack of engagement with the task. Figure 4 shows the data for the critical A cue, along with the predictions derived from the SS power model and an otherwise-identical model with uniform priors. Participants in the strong-B condition underestimated the strength of cause A relative to participants in the Weak-B condition (mean of 34.05 versus 46.95 ), $t(79)=2.17, p<05$. The data

Table 2. Observed human strength ratings ( $0-100$ scale) and predictions based on sparse-and-strong (SS) priors for three different cues in Experiment 1.

|  | $\mathrm{A}(.50)$ |  |  | $\mathrm{B}(.20, .80)$ |  | $\mathrm{C}(.10)$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
|  | Pred. | Obs. | Pred. | Obs. | Pred. | Obs. |
| Weak-B | 52 | 47 | 16 | 34 | 13 | 18 |
| Strong-B | 35 | 34 | 78 | 63 | 16 | 18 |

Figure 3: Observed human strength ratings ( $0-100$ scale) and predictions based on sparse-and-strong (SS) versus uniform priors for cause A (0-100 scale) in Experiment 1.
were fit using Lu et al.'s (2008) "SS power" model, which provides a Bayesian formalization of sparse-and-strong priors. For modeling purposes we simply set $\alpha=5$ (the value estimated for the data sets reported by Lu et al., 2008), thus avoiding any need to fit a free parameter to the present data. The SS power model predicts the observed difference in the judged strength of $A$ in the weak- $B$ versus strong-B conditions, whereas the model with uniform priors does not.

Table 2 presents the mean ratings of causal strength obtained for three different cues, and Figure 3 plots the human data with predictions from the two models assuming different priors. Across all cues and conditions, the SS power model provides a good overall fit to the human data ( $R=.95$, root mean square deviation, $\mathrm{RMSD}=9.1$ ).

Although the overall fit of the SS power model is quite good, it bears noting that the predictions of the SS power model for cue $B$ were more extreme than the estimates given by participants. That is, when B was weak participants overestimated its strength relative to the model with SS priors; when B was strong participants underestimated it relative to SS priors. The estimates of the model using uniform priors deviate from the observed data in a similar (though marginally smaller) fashion. We speculate that these discrepancies may be due to memory limitations. Whereas the models assume perfect memory for contingency data, participants are likely to forget presented instances on some proportion of the trials, and therefore to have greater uncertainty in their strength estimates than predicted by the models. The models' estimates are computed from the mean of the posterior distribution, so increased uncertainty would lead to less extreme strength estimates for cue B (i.e., estimates closer to 50). Uncertainty would be expected to have less impact on estimates for cue A, for which the veridical strength in fact corresponds to a rating of 50 .

## Experiment 2

It is a natural feature of Bayesian models that the influence of priors diminishes as learners gather more data. Thus, the SS power model (Lu et al., 2008) predicts that competition between causes should be strongest when participants have made few observations, and will diminish as participants are exposed to more data.

Experiment 2 examined competition between causes after varying amounts of experience. The design was identical to that of Experiment 1, but added a second independent variable: sample size. Participants in both strong- and weakB conditions were asked to make judgments of causal strength three times, after viewing 44, 88 and finally 132 total cases. This resulted in a $2 \times 3$ factorial design, with one between-subjects factor (causal strength of cue B) and one within-subjects factor (number of cases observed).

The cover story was the same as it in Experiment 1, except for one sentence: "The resort's doctor thinks one or perhaps several of these exotic vegetables may be causing the illness" (Experiment 1) was revised to read, "The resort's doctor thinks these exotic vegetables may be causing the illness."

## Method

Participants Participants were 114 UCLA undergraduate students who participated for class credit ( $76 \%$ female, mean age $=20$ years).

Procedure Experimental materials were identical to those used in Experiment 1. Participants in Experiment 2 went through three blocks of learning trials, making causal strength estimates after 44, 88 and 132 learning trials. The distribution of types of cases (combinations of causes and outcome) were identical within each block. Order of presentation was randomized for each participant.

## Results and Discussion

One participant gave the same response on every trial, and six responded with extreme ratings of 0 or 100 for cause A, or ratings of 100 for Cause C. Data from these seven participants were excluded from analyses.

Figure 4 shows mean causal strength ratings for each vegetable at the end of each of the three learning blocks. A factorial repeated-measures ANOVA found no overall effect of increasing sample size, $F(2,210)=2.31, p=.10$, or of condition, $F(1,105)=1.16, p=.28)$. However, the analysis revealed a significant interaction between condition and learning block, $F(2,210)=5.61, p<.01$. As shown in Figure 4, Experiment 2 replicated the competition effect observed in Experiment 1 after 44 trials. After the first block, participants underestimated the strength of A when it was paired with a strong B cause, relative to when it was paired with a weak B cause (means of 56 versus $46 ; t(105)=$ 2.26, $p<.05$ ). As predicted, this difference disappeared with

Figure 4. Observed human strength ratings ( $0-100$ scale, top) and predictions of SS power model (bottom) for cause A across blocks in Experiment 2.
an increase in sample size, supporting the hypothesis that the observed competition effect is due to people's priors. The effect of the strength of $B$ on ratings of $A$ was not significant after 88 or 132 trials, $t(105)=0.75, p=.46$, and $t(105)=-0.26, p=.79$, respectively. Assuming $\alpha=5$ as before, the SS power model ( Lu et al., 2008) provides a good fit to the human data across all cues and conditions ( $R$ $=.96, \mathrm{RMSD}=12.87$ ). For cause A , the human data for the weak-B and strong-B conditions converge on the veridical value (50) more quickly than does the model's predictions (see Figure 4), perhaps reflecting the additional uncertainty participants experienced due to their fallible memory for the observations.

Causal strength estimates for all three vegetables were somewhat higher in Experiment 2 than Experiment 1. This difference may be due to a small change in instructions, which in Experiment 2 emphasized the doctor's belief that the vegetables were indeed causing the illness.

## General Discussion

The experiments reported here provide evidence for competition between independently-occurring causes in causal strength judgments, as predicted by a Bayesian
model of causal learning that assumes sparse-and-strong priors. After participants had made a relatively small number of observations, a cause of moderate strength was judged to be weaker when a competing (but uncorrelated) cause was strong than when the competing cause was weak. After additional cases were presented, the two conditions converged. This competition dynamic cannot be explained by naïve Bayesian models that assume uninformative priors (Busemeyer et al., 1993a), nor can such models explain why the competition effect diminishes as data is accumulated. The present results support the hypothesis that causal learners have generic prior expectations about causal relationships, and that a sparse-and-strong prior accurately characterizes these expectations.

The experiments presented here go beyond most previous investigations on causal learning by examining a more complex causal situation, one that included three observed generative causes. Examining a causal situation with multiple causes enabled a novel test of predictions that discriminated between alternative possible priors. Moreover, the relatively complex situation examined here may be more representative of the actual situations that causal learners encounter in the real world.

Using an iterative-learning method, Yeung and Griffiths (2011) empirically derived a different (but non-uniform) prior that was suggestive of a preference for strong causes, but that lacked the competitive pattern associated with the sparse prior. However, since the iterative method did not fully converge for the background cause, their results are open to multiple interpretations. Our task with multiple cues may provide a good way to further evaluate the generalization of empirical priors derived from the iterativelearning paradigm.

Lu et al. (2008) formalized sparse-and-strong priors for both generative and preventive causes. However, the preference for "sparseness" only applies across causes of the same polarity. In the generative case, sparseness is an influential factor even for simple causal set-ups, in which a single observed cause competes with an unobserved background cause (assumed by default to be generative). However, in the preventive case of the sparse-and-strong prior, competition dynamics are not evident when there is only a single preventive cause, as the observed cause is preventive whereas the background cause remains generative. The influence of sparseness, and hence the possibility of competition, is also predicted to arise in complex causal situations involving multiple preventers. As previous investigations have only examined the simplest cases, further research with more complex causal set-ups is needed to examine the possible impact of sparse-and-strong priors for preventive causes.

#### Abstract

When two persons participate in a discussion, they not only exchange the concepts and ideas they are discussing, they also express attitudes, feelings and commitments regarding their partner: they express interpersonal stances. Endowed with backchannel model, several virtual agents are able to react to their partners' behaviour through their non-verbal behaviour. In this paper, we go beyond this approach, proposing and testing a model that enables agents to express a dyadic stance, marker of effective communication: agents will naturally coconstruct a shared dyadic stance if and only if their interpersonal stance is reciprocally positive. We focus on smile, which conveys interpersonal stance and is a particularly efficient signal for co-regulation of communication. With this model, a virtual agent, only capable to control its own individual parameters, can, in fact, modulate and control the dyadic stance appearing when it interacts with its partner. The evaluation of the model through a user perceptive study has enabled us to validate that the dyadic stance is significantly perceived as more positive (mutual understanding, attention, agreement, interest, pleasantness) when reinforcement of smile is reciprocal. Keywords: dyadic interaction; interactive behaviours; dynamical systems; dyadic stance; smile; virtual agent;

## Introduction

When we consider verbal communication, interlocutors not only exchange the concepts and ideas which constitute the subject of their discussion, they also express feelings, judgements or commitments regarding this subject. This "attitude which, for some time, is expressed and sustained interactively in communication, in a unimodal or multi-modal manner" corresponds to the stance: Chindamo, Allwood, and Ahlsén (2012) review the existing definitions and descriptions of stance; they show how these definitions have evolved from a focus on individual expression of stance to a more interactive and social description. Individual stance refers to two types of stance: epistemic and interpersonal stance (Kielsing, 2009). The epistemic stance is the expression of the relationship of a person to his/her own talk (for instance "certain"). The interpersonal stances convey the relationship of a person to the interlocutor (for example "warm" or "polite"). Moreover, during an interaction, "stances are constructed across turns rather than being the product of a single turn" (Chindamo et al., 2012). When interactants with individual epistemic and interpersonal stances are put in presence,
dyadic stances can be inferred (Prepin, Ochs, \& Pelachaud, 2012) from diachronic alignment between interactants. The effort of interlocutors to linguistically and non-verbally align through time is a marker of stance: it convey stance of mutual understanding, attention, agreement, interest and pleasantness (Louwerse, Dale, Bard, \& Jeuniaux, 2012).

The description of stance has not only evolved toward a distinction between individual and co-constructed stance. It has also evolved from a uniquely linguistic description (DuBois, 2007; Kielsing, 2009) to a description implying interactants’ Non-Verbal Behaviours (NVBs) (Scherer, 2005; Prepin et al., 2012). The non-verbal behaviours participate in maintaining contact between interactants and facilitate verbal exchange: they are an integral part of the communication process (Paradowski, 2011). NVBs actively convey stances through paralinguistic features (such as tone of voice, duration, loudness or prosody), facial expressions, and postures (Chindamo et al., 2012).

Models of interactive agents have mainly explored the automatic generation of virtual agent's behaviour aligned on the interlocutor's behaviour. Buschmeier, S., and Kopp (2010) combine a model of lexical alignment with a model generating behaviours based on linguistic information. Bailenson and Yee (2005) model the NVBs alignment of a speaking virtual agent to a listening human. They propose a Digital Chameleon (in reference to the Chameleon effect described by Chartrand and Bargh (1999)). Bevacqua, Hyniewska, and Pelachaud (2010) model the NVBs alignment of a listening agent to a speaking human: they propose a model of backchannels, i.e. NVBs aligned in time and nature, to facilitate human users to tell a story.

All these models focus on the adaptation of the virtual agent to its interlocutor, but do not take into account the reciprocal adaptation of this interlocutor: behaviours are computed in reaction to partner's behaviour, but not in interaction with partner's behaviour; the dynamical coupling associated to the mutual engagement of interactants is not modelled, and critical parameters of interaction such as synchrony and alignment which appear as side effects of this coupling (Paolo,

Rohde, \& Iizuka, 2008; Prepin \& Pelachaud, 2011, 2012a), are missed. In this paper, we aim at going further by proposing a model enabling virtual agents to co-construct their behaviours: agents will be enabled to adapt to each other behaviour on the fly (that is in the time scale of the coupling (Prepin \& Pelachaud, 2011)) and to perform a resulting behaviour which is a dynamically built mix of each other behaviour; agents will also be enabled to modulate how much their own behaviour is influenced by the behaviour of the other, and doing so, they can control the stance of the dyad.

In the present paper, we propose and test a model that enables virtual agents to co-construct a dyadic stance by taking advantage of the interactive loop existing between agents and the resulting conjugated effects of reciprocal alignments. Each virtual agent, only capable to control its own individual parameters, can, in fact, modulate and control the dyadic stance appearing when it interacts with its partner. We focus on smile behaviours for three reasons: (P1) a smile is one of the simplest and most easily recognized facial expressions (Ekman \& Friesen, 1982); (P2) recent works (Ochs, Niewiadmoski, \& Pelachaud, 2010) have shown that people are able to distinguish different types of smile when they are expressed by a virtual character; (P3) in multimodal communication, smile alignment appears in the form of synchronous smile expressions of interactants (Louwerse et al., 2012). These three properties of smile enable us to focus on the dynamical mechanisms of smiles alignment to model the co-construction of dyadic stances. For this purpose, based on the first property of smile (P1), we model the sensitivity to partner's smile as a motor resonance phenomenon. Considering the second property of smile (P2), we implement this model on a dyad of smiling virtual agents. Based on the third property of smile (P3), we enable the virtual agents' smiles occurring synchronously to reinforce each other depending on the two agents' individual stances.

## Model description

In order to create virtual agents able to co-construct a dyadic stance by taking advantage of the interactive loop they form with their partner, we focus on the agents capacity to mutually reinforce their smiles (see Introduction). The agents will be able to change the influence of their partner's smile on their own smile: the more their own actions are influenced by the perception of their partner's actions, the easier will be the coupling and the mutual reinforcement of the two agents smile; virtual agents will be able to control the dyadic stance they co-produce with their interlocutor.

## Smiles descriptions

In the proposed model, we focus on virtual agent's smiles. On one hand, smile is one of the simplest and most easily recognised facial expression (Ekman \& Friesen, 1982), and on the other hand it is one of the few behaviours often performed contingently by partners during interaction (Louwerse et al., 2012). The two muscles zygomatic major, on either side of

| Characteristics <br> of smile | Amused <br> smile | Polite smile | Embarrassed <br> smile |
| :--- | :---: | :---: | :---: |
| Cheek raising | + | - | - |
| Open mouth | + | - | - |
| Lips tension | - | - | + |
| Symmetry | + | + | - |
| Amplitude | + | - | - |

Table 1: Smiles characteristics depending on their type (table filled based on the results described in (Ochs et al., 2010)): + indicates significantly higher and - significantly lower values of the characteristic for a given type of smile than the others,
the face, have to be activated to create a smile, and are sufficient for an observer to recognize a facial expression as being a smile. However, subtle differences in dynamics and in muscular activations make smiles convey different messages (such as amusement and politeness). Ochs et al. (2010) have studied the characteristics of polite, amused, and embarrassed smiles of virtual agent's. Their results are summarized in Table 1 . The amused smiles are mainly characterized by large amplitude, open mouth, symmetry, and relaxed lips. Most of them also contain the activation of the cheek raising, and a long global duration. The polite smiles are mainly characterized by small amplitude, a closed mouth, symmetry, relaxed lips, and an absence of cheek raising. The embarrassed smiles often have small amplitude, a closed mouth, and tensed lips. They are also characterized by the absence of cheek raising and an asymmetry in the smile.

## Perception-Action mapping

In order to enable virtual agents to modify their facial expressions "on the fly" (that is dynamically and in real-time), as proposed in (Prepin \& Pelachaud, 2012b), facial expressions are updated frame by frame depending on both the speech expressed and the continuously incoming reactions of its partner. When an agent is performing an action (e.g. the display of a facial expression), it can have feedbacks concerning this action and can modify it "on the fly".
Several researches have shown that there is a natu$\mathrm{ral} /$ structural tendency to imitate the other and to better perceive the other when imitating back (Muir, 2005; Nadel, Prepin, \& Okanda, 2005). We model this property combining a mapping between the perceptive space and the motor space, and the self-activation of the motor space. Both the perceptive space and the motor space are defined by Action Units (AUs) in the Facial Action Coding System (Ekman \& Friesen, 1982) necessary to define smiles.

The self-activation of the motor space, with a weight $\alpha<$ 1 (see Figure.1), both simulates a short term memorisation of actions and facilitates the subsequent activation of similar actions (Schöner \& Thelen, 2006). The nearer $\alpha$ is to 1 , the longer the memorisation. We choose here $\alpha=0.95$ to ensure that this memorisation is "short term", i.e. that after 1 sec. (25 time steps), if there is no other stimulation, the activation of the AU is decreased by two thirds: $A U_{i}\left(t_{0}+25\right)<1 / 3$. $A U_{i}\left(t_{0}\right)$.

The mapping between perceptive and motor spaces corresponds to the links between perceived characteristics of smiles and generated characteristics of smiles. The mapping is based on the results on smiles reported in previous section. More precisely, the nodes in the perceptive and motor spaces correspond to the characteristics of the different types of smile ${ }^{1}$.

This mapping is represented in Figure 1 by links of different widths between the perceptive ( $A U_{p e r}$ ) and motor $\left(A U_{\text {prod }}\right)$ spaces. The dashed links ending with a circle represent inhibitory links.

Figure 1: Perceptive Space and Motor Space mapping.
The excitatory/inhibitory nature of links and their weight have been inferred from Table 1. We detail the modelled effects for each smile characteristic:

- Zygomatics: zygomatics appear in every smile and only their high amplitude indicates amused smile (Table 1); we assume that their perception will influence their production only if the perceived amplitude is over a threshold $t h_{\beta}$.
- Lips tension: amused and embarrassed smiles are incompatible (they have opposite characteristics, see Table 1); we assume that the specific AU of an embarrassed smile (i.e. lips tension) will inhibit and will be inhibited by the specific AUs of amused smile (i.e. cheeks raised and zygomatics over $t h_{\beta}$ ).
- Cheek raising: cheeks raising is an exclusive marker of amused smile (Table 1); we assume that its perception highly excites all the specific characteristics of amused smile (zygomatic above $t h_{\beta}$, cheeks raise and mouth opening).
- Mouth Opened: opening of mouth is not a specific characteristic of smiles. We assume that its perception only influence the opening of mouth production.
We stay at the level of a purely reactive model, only using muscular activations of produced and perceived signals. More cognitive modelling could infer emotions and intentions from these muscular activations.

## Interpersonal stance influence

Virtual agent's interpersonal stance (i.e. its stance regarding its interlocutor) influences the visuo-motor mapping (Fig.2).

[^190]For instance, a virtual agent with a cooperative attitude will be more sensitive to the interlocutor's perceived smile. Note that we do not model any cognitive model or strategy concerning the expression of stance, we just model how the interpersonal stance of the virtual agent modifies the way the agent is sensitive to its partner's behaviours: the agent will modify how much it is interactive, engaged and finally cooperative with its partner ${ }^{2}$

We assume here that interpersonal stance is represented as a single variable $\sigma$, in $[0,1]$, which multiplies all the influences between perceptive and motor spaces (see Fig.2). In the evaluation study, $\sigma$ only takes two values: $\sigma=0$ when the virtual agent is not cooperative, i.e. when its smiles are not reinforced by its partner's smiles; and $\sigma=0.45$ when the virtual agent is cooperative, i.e. when its smiles are reinforced by its partner's smiles. Note here that if $\sigma$ was higher than 0.45 , even without any communicative intention stimulating smiles, the reciprocal influence between agents would be too high to let smiles decrease.

## Virtual agents dyad

The last step in the design of our model is to put two virtual agents in presence, a speaker and a listener (Fig.2). For sake of simplicity and to focus on the dyadic effect of the smile expressions, the virtual listener has no access to the meaning of what the speaker says. The listener only perceives the speaker's non-verbal behaviour. On the other side, the speaker's speech directly influences its own actions in the motor space (see Fig.2).

Figure 2: Scheme of the interactive loop within the dyad.
We implement our model of virtual agents dyadic stance generation in the Leto/Prometheus Neural Network (NN) simulator (Gaussier \& Zrehen, 1994), interfaced with the virtual agent platform SEMAINE (Schröder, 2010). The NN simulator enables to design the architecture neuron by neuron and to control architecture dynamics in real-time (here frame by frame). The agent platform computes the communicative intention of the virtual character depending on its speech, and directly influences its actions in the motor space accordingly (see Fig.2). For instance, the utterance "I'm happy today" is automatically said with an amused smile.

[^191]In the context of face to face interaction, if both virtual agents have a cooperative interpersonal stance, they reciprocally reinforce their smiles (see Fig.3, (Prepin \& Pelachaud, 2012b)): a snowball effect on shared behaviours (when coupling occurs) and a decay/alignment of not-shared behaviours (when coupling is disrupted).

Figure 3: Dyadic dynamics of smiles. Solid and dotted lines are respectively for Agent1 and Agent2's intensity of smile.

The figure 4 shows the result of such an interaction on one agent: the virtual agent's smile is emphasized.

Figure 4: Snowball effect when smile reinforcement is reciprocal.

Finally, the proposed model enables one to simulate an interaction between two virtual agents with different smiling behaviour depending on the agents' interpersonal stance. The resulting interactions reflect different dyadic stances. In addition to cheeks raise and release of lips tension, the main side effect of mutual positive interpersonal stance is the snowball effect on smiles, i.e. the increase of smiles intensity and duration.

Indeed, considering that NVBs alignment and dynamical coupling are marker of the quality of the interaction (see Introduction), these side-effects (such as "snowball effect") are the cues that should give an impression of fruitful interaction. In order to validate that our model enables one to simulate interactions between virtual agents that convey different dyadic stances depending on the mutual reinforcement of their smiles, we have performed an evaluation presented in the next section.

## Evaluation of the model

To test that the proposed model enables one to simulate the co-construction of different stances, we have performed a user perceptive study. Our objective through this evaluation is to show that the smiles mutual reinforcement between two interacting virtual characters conveys specific stances. We have focused on the following dyadic stances: mutual understanding (the virtual characters seem to understand each other), mutual attention (the virtual characters seem to pay attention to each other), mutual agreement (the virtual characters seem
to be agreed with each other), mutual interest (the virtual characters seem to be interested to the discussion), mutual pleasantness (the virtual characters seem to spend a pleasant time to interact). These stances have been chosen since research (Louwerse et al., 2012) has shown that the mutual understanding, attention, agreement, interest and pleasantness are cues of the quality of an interaction between a speaker and a listener.
Hypothesis. The hypothesis we want to validate through the evaluation is the following:

The positive dyadic stance is significantly increased when reinforcement of smile is reciprocal.
More precisely, the evaluation aims to show that the mutual reinforcement of the smiles of the two interlocutors (i.e. the speaker and the listener) increases the impression of mutual understanding, attention, agreement, interest, pleasantness compared to an interaction in which only the listener's smiles are reinforced by the speaker's smiles (and not in the other way round).

A validation of this hypothesis will enable us to validate the proposed model which simulates virtual characters' dyadic stances through smiles mutual reinforcement and emerging snowball effect.
Procedure. In order to verify the hypothesis, we have performed the evaluation on the web. The evaluation was in French. Four video clips showing two virtual characters discussing were presented to participants. For each video clip, we asked the participants to answer 5 questions using a Likert scale of 5 points (from "strongly disagree" to "strongly agree"). The questions concerned their perception of the mutual understanding, attention, agreement, interest and pleasantness of the two virtual characters. An example of a question is "When you watch the two virtual characters discussing, according to you, do they understand each other?" (translated from French).
Video Clips. To evaluate the perception of the interaction between virtual characters in one way versus reciprocal conditions of smiles reinforcement, we have recorded the two conditions of interaction:

- reciprocal condition: both the speaker and the listener mutually reinforce their smiles depending on the smiles expressed by each other, "snowball effect" is enabled.
- control condition: only the listener reinforces its smiles according to the speaker's expressed smiles.
In the video clips, the virtual characters discuss using an unintelligible verbal language (corresponding to an acoustic deformation of French texts). By this way, we avoid an influence of what the virtual characters said on the user's perception. We have considered 6 different texts corresponding to the situation in which the virtual character tells a joke to its interlocutor. Given the text and the associated communicative intention, the virtual character expresses a polite smile at the beginning and an amused smile in the middle of the text. For each text, we have recorded video clips in the 2 conditions described above with a virtual character saying this text
with an acoustic deformation and another virtual character, in front, listening. In total, 12 video clips have been recorded. In order to visualize clearly the faces of the two virtual characters while keeping the impression that the virtual characters are face to face, we have used a film-making technique called split-screen (Fig.5). Before starting the evaluation on the web, to ensure that the instruction, the questions, and the video clips are understandable, the platform of test has been pre-tested with 7 participants.

Figure 5: Screen shot of a video clip of the two virtual characters interacting
Participants. Sixty-six individuals have participated in this evaluation on the web ( 34 females) with a mean age of $34(\mathrm{SD}=13)$. They were recruited via French mailing lists on line. The participants were predominantly from France ( $\mathrm{N}=63$ ). Each participant was shown and rated 4 video clips (two video clips selected randomly for each of the 2 conditions). The order of the presented video clips were counterbalanced to avoid any effect on the results.
Results (Fig.6). We have collected 264 video clips' ratings. Independent t-Test was conducted to compare the participants' ratings of the video clips in each condition. The analysis revealed statically significant effects of the condition on the participants' ratings of the mutual understanding ( $p<0.001$ ), the mutual attention ( $p<0.01$ ), the mutual agreement ( $p<0.001$ ), the mutual interest ( $p<0.001$ ), and the mutual pleasantness ( $p<0.001$ ).

Figure 6: Means and standard errors of the dyadic stances’ ratings for the two conditions. The significant differences between the condition are indicated by ${ }^{* *}$ for ( $p<0.001$ ), and * for $(p<0.01)$

Discussion of the results. The mutual understanding, attention, interest, agreement and pleasantness are perceived
significantly higher when the speaker and the listener mutually reinforce their smiles according to the other's smiles (reciprocal condition) than when only the listener reinforces its smiles depending on the speaker's expressed smiles (control condition). The impression of mutual understanding, attention, agreement, interest and pleasantness directly depends on the reciprocity of the interaction. These results are consistent with psychology studies which claim that the interaction effort must be shared and reciprocal to enable effective communication (Nadel et al., 2005; Paolo et al., 2008; Auvray, Lenay, \& Stewart, 2009; Fuchs \& DeJaegher, 2009). Finally, the results validate the hypothesis described above: The positive dyadic stance is significantly increased when reinforcement of smile is reciprocal and "snowball effect" is enabled.

## Conclusion

In the present paper, we have proposed a model enabling virtual agents to co-create different dyadic stances. We have described this model entwining each agent's ability to control its cooperation to the interaction and the dyadic effects emerging from the resulting agents coupling.
Agents are able to produce a continuum of smiling behaviours. They can modulate their own smiles depending directly on their perceptions of their partner's smiles. They can control the level of this modulation and doing so control their interpersonal stance: a highly cooperative agent reinforces its smiles when its interlocutor smiles. Finally when a speaking agent (which produces smiles in relation to its speech) and a listening agent are put together, their behaviours modulate each other reciprocally and dynamically form a new behaviour. Performing a user perceptive study, we have shown that this dyadic behaviour is the expression of the two agents dyadic stance: the specific dyadic dynamics which appear depending on each agent interpersonal stance convey information on agents' mutual understanding, attention, agreement, interest and pleasantness. The evaluation highlights that the virtual agent's backchannels (one way reactions) are less effective than reciprocal reactivity to convey some dyadic stances such as mutual understanding, attention, agreement, interest and pleasantness: The agents' reactions must be reciprocal, as proposed in our model, to enable side effects of dynamical coupling such as emphasise of smiles, increase in intensity and duration.
Future works. One of the aspect of the virtual agents modelling we have proposed is the fact that each agent of the dyad, has a different dynamic depending on the other agent stance: the agent's own smile dynamic (for instance the smile slope) changes according to whether or not the other agent has co-operative interpersonal stance. As a consequence, each agent, knowing its own interpersonal stance and detecting its own smile slope variation, could infer the other agent's interpersonal stance. Finally each agent can use this signal for modulating its own stance, its model of the other, or the way it interacts.

One of the next steps is to apply such a model to human-
virtual agent interaction. For this purpose, we are currently integrating in the SEMAINE platform a system to detect in real-time user's smiles ${ }^{3}$. In this condition of direct interaction between user and virtual agent, the user perception of the dyadic stances could be different since the user is directly engaged in the interaction (compared to the studied conditions in which users have a third person point of view when they watch virtual characters interacting).

#### Abstract

We report a study of naming and lexical decision with 132 adult Greek speakers responding to 150 words and matched pseudowords with decorrelated frequency, length, neighborhood, syllable and bigram frequency, and transparency. This approach allowed us to individuate and accurately estimate the effects of each variable, and to assess their linearity and additivity. Significant effects of frequency, length, and syllable frequency were revealed, as well as several interactions. The results are informative for cognitive modeling of visual word recognition in more transparent orthographies.

Keywords: Visual word recognition; pseudowords; naming; lexical decision; mixed-effects models; Greek.

Models of visual word recognition posit distinct mechanisms and representations involved in the processing of orthographic stimuli. The implications of these hypotheses for response times (RT) to individual words and pseudowords are typically studied using naming and lexical decision tasks. A productive line of research concerns the effects of lexical and sublexical variables on RT distributions. In evaluating models and their properties, several variables have been examined in this light and have been found to be related to processing times, such as frequency, length, neighborhood, bigram and syllable frequency, and more (Balota, Yap, \& Cortese, 2006).

A common approach to such studies has been to form groups of stimuli differing in a parameter of interest, such as a low-frequency and a high-frequency group. Interactions are then examined by crossing levels of variables in subgroups. This has led to the identification of important effects but has recently been criticized for problems stemming from selection of atypical items and restricted parameter ranges (Balota, Yap, Hutchison, \& Cortese, 2012). More recent approaches have abandoned stimulus groupings in favor of regression approaches, in which wide value ranges of several variables are simultaneously entered in multivariate analyses (Yap \& Balota, 2009). Advances in statistical modeling have allowed more parameters to be examined (Baayen, 2008).

This approach has culminated in the "mega study" efforts, in which huge numbers of stimuli are presented to volunteer samples of unprecedented sizes. For example, the English Lexicon Project (Balota et al., 2007) includes about 40k words and pseudowords responded to by 1,260 participants. This allows examination of the full ranges of all parameters and their combinations. Special subsets may be selected for targeted analysis, so this method allows replication of previ-
ous studies and examination of potential biases or dependencies. Moreover, these data are available for future studies on as-yet unidentified parameters without further data collection. Thus mega-studies constitute a large step forward in our quest for understanding word processing.

The multiple regression approach is also vulnerable to criticism. Regression models typically include a linear effect for each variable, assuming that this effectively "partials out" all influence of the corresponding parameter, allowing the effects of other parameters to be accurately estimated. This is only the case when all effects are linear and independent. If not, the linear modeling removes only part of an effect, conflating the remainder with other correlated variables. The problems of linearity and additivity are compounded and cannot be addressed in stimulus sets with correlated effects because it cannot be known whether a variable has a true curvilinear effect or an interaction with a correlated variable. In both cases departures from linearity will be identified but the decision to "remove" one of the two will affect the other and may do so in a nonrepresentative or nonoptimal manner. Moreover, in the absence of curvilinearity and nonadditivity, correlated parameters necessarily lead to underestimated effects because shared variance is removed when one parameter is controlled.

Linearity is potentially informative as cognitive processing models can make specific predictions about the shape of the relationship between aspects of the stimuli and the time required to respond to them. Thus it is useful to establish the fitting functions on the actual RT distributions and incorporate them in modeling (cf. Balota \& Yap, 2011). Nonadditivity is also of great interest because it has implications for theoretical approaches insofar as the cause of each interaction must be understood within the context of relevant assumptions.

In the present study we begin to address these issues by examining RTs to a set of words and pseudowords in which variables typically examined in word recognition were uncorrelated. We work in Greek, a language with higher orthographic transparency and word length than English (Protopapas \& Vlahou, 2009), aiming to contribute to the cross-linguistic effort. We selected words from a corpus ensuring that there was no significant correlation among frequency, length, neighborhood, syllable and bigram frequency, and graphophonemic transparency. A set of pseudowords was then created, similarly uncorrelated, matching the word group in these vari-
ables. To the extent a reasonably wide range was sampled, this approach permits isolation of the effects of each variable and identification of individual interactions and nonlinearities. All items were presented in a naming and a lexical decision task. To maximize reliability and allow detection of small effects, we employed a relatively large sample, based on Rey, Courrieu, Schmidt-Weigand, and Jacobs (2009).

## Method

## Participants

The sample included 97 women and 35 men, native speakers of Greek, $18-36$ years old ( $M=23.3, S D=4.7$ ), mostly students (12-21 years of education, $M=15.4, S D=2.1$ ). Fourteen were left-handed.

## Stimuli

A set of 150 words were selected from the IPLR word list (Protopapas, Tzakosta, Chalamandaris, \& Tsiakoulis, 2012), $2-5$ syllables long (4-10 letters; 4-11 phonemes). In an iterative selection process, a set of properties were retrieved along with each word, including $\log$ frequency of occurrence; number of letters, phonemes, and syllables; orthographic and phonological neighborhood (Coltheart's N ); orthographic and phonological syllable frequency; letter and phoneme bigram frequency; and a nondirectional measure of graphophonemic transparency (log mean token "sonograph" probability; Spencer, 2009). A nonparametric index of association (Spearman's $\rho$ ) among all variables was calculated. The process terminated when groups of qualitatively distinct variables were not significantly correlated. The following variables were retained as most relevant for the analyses reported below: log frequency, number of letters, mean syllable and bigram frequency, and transparency. Figure 1 (top row) shows the distribution of each variable in the selected sets against the overall type and token distribution in the corpus.

A set of 150 pseudowords were constructed to resemble the words in basic phonological and orthographic structure and letter and phoneme distribution. The pseudowords were indistinguishable from the words in the target variables, as verified by the Kolmogorov-Smirnov test for equality of distributions. The results of these tests are listed in Table 1, along with the correlations among the variables for both sets.

A difficulty was encountered in pseudoword neighborhoods. Matching to the words required including items with many neighbors. Neighborhoods for long words are mainly due to grammatical inflection. Long words typically have few or no unrelated neighbors, but due to the rich inflectional system of Greek all content words have neighboring inflectional variants. Neighborhoods for pseudowords would therefore be limited to the inflectional families of word neighbors, so that some pseudowords would be strongly influenced by one lexical lemma. This was undesirable because pseudowords are known to activate lexical neighbors strongly (even assimilating their stress pattern; Protopapas, Gerakaki, \& Alexandri, 2007). Therefore, using pseudowords with neighbors would
result in a pseudoword set in which word activation might play a prominent role and suppress nonlexical effects. Thus we decided to minimize pseudoword neighborhoods and keep the pseudowords distinct from specific words, at the cost of matching and correlations involving neighborhoods.

## Procedure

A naming and a lexical decision task were implemented in DMDX (Forster \& Forster, 2003). In both tasks, each item was presented in Arial 36-pt white font at the center of a laptop $15.4^{\prime \prime}$ screen for 1.9 s . A few practice and warm-up items preceded the experimental stimuli. A short break was offered halfway through each block of 150 stimuli. For lexical decision, participants responded by pressing the left and right control keys. Words and pseudowords were intermixed randomly. The "word" response was set to the participant's preferred or nonpreferred hand, approximately counterbalanced. For naming, words and pseudowords were presented in separate blocks, in counterbalanced order between participants. Responses were recorded and onset times were subsequently verified using CheckVocal (Protopapas, 2007). The order of naming and lexical decision tasks was counterbalanced. In both tasks, items were presented in a different random order for each participant. A distractor task (digit span) was administered between the two tasks to minimize carryover effects.

## Results

Raw response times were logarithmically transformed and analyzed using mixed-effects models with crossed random effects for participants and items, separately for words and nonwords. Analyses were conducted using package lme4 (Bates, Maechler, \& Bolker, 2012) in R (R Core Team, 2012), mainly following Baayen (2008). All variables were centered. Models reported below included fixed effects and random slopes per participant for the linear effects of trial number and preceding RT, as well as random intercepts for participants and for items. These "baseline" effects are not discussed further.

For each task and stimulus type we examined the following: (a) A "full" model, with the complete set of variables, i.e., baseline effects plus all six experimental parameters (linear effects only, not interacting). This was used to estimate the "full" effects of each parameter. (b) For each parameter, a variant of the full model excluding that parameter. The item random intercepts of this model were used to estimate the "residual" effects of each parameter. (c) A baseline model with only the baseline effects. (d) For each parameter, a variant of the baseline model including only that parameter. This was used to estimate the "single" effects of each parameter. Comparison of this model to the baseline (via likelihood ratio) determined the significance of each parameter. (e) An "augmented" model, in which quadratic effects and interactions were added to the full model in a forward-backward procedure and retained when significant (determined via likelihood ratio at $p<.05$ ). The linear effects of all six parameters were retained whether or not they made significant contributions, and are listed in Table 1 (4 rightmost columns).

Table 1: Correlation coefficients (Spearman's $\rho$ ) among the 6 experimental parameters, for words (above the diagonal) and pseudowords (below the diagonal), and Kolmogorov-Smirnov tests for equality of distributions between words and pseudowords. The four rightmost columns show the estimated $\hat{\beta}$ for the corresponding linear effect in the augmented model (see text).

| Variable |  | Correlations |  |  |  |  | K-S test |  | Naming |  | Lexical decision |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | 2 | 3 | 4 | 5 | 6 | D | $p$ | Words | Pseudo | Words | Pseudo |
| 1 | frequency | -. 05 | . 00 | -. 02 | . 10 | . 00 |  |  | $-.0152^{*}$ |  | -.0311* |  |
| 2 | N letters |  | -. 01 | -. 05 | . 01 | -. 11 | . 06 | . 950 | +.0163* | +.0306* | +.0151* | +.0361* |
| 3 | neighborhood | $-.50^{\dagger}$ |  | -. 08 | . 07 | -. 02 | . 70 | . 000 | -. 0033 | $-.0668^{*}$ | -.0092* | +.0409* |
| 4 | syllable freq. | -. 08 | . 07 |  | . 09 | -. 09 | . 15 | . 079 | +.0032* | +.0022* | +.0044* | +. 0006 |
| 5 | bigram freq. | . 08 | -. 04 | . 06 |  | . 06 | . 09 | . 531 | -. 0039 | -.2131* | -. $2578 *$ | +. 1335 |
| 6 | transparency | . 00 | -. 03 | -. 12 | . 05 |  | . 05 | . 983 | +. 0000 | -. 0005 | +.0018* | -. 0010 |

Note: ${ }^{\dagger} p<.0005$; for all other correlations, $p>.1 ;{ }^{*}|t| \geq 2.0$

The variance of item random intercepts varied between tasks. In the baseline models, it was 4.98 for word naming, 16.03 for pseudoword naming, 9.99 for word lexical decision, and 7.90 for pseudoword lexical decision (all $\times 10^{-3}$ ). This sets an upper limit for the contributions of the experimental parameters, which are all item-related, indicating that there is more variance to be accounted for in pseudoword naming (the highest) than in word naming (the lowest). In comparison, the residual (error) variance of the baseline models were $13.1,19.3,37.9$, and 36.8 , respectively, suggesting that lexical decision tasks are "noisier" than naming tasks.

Linear individual effects The results for these analyses are summarized graphically in the four bottom rows of panels in Figure 1, in which the linear effect of each parameter is tested when all other parameters were in the model (residual vs. full model) and when no other parameters were in the model (single vs. baseline model). The two estimates were generally within one standard error of each other, indicating very close correspondence of the two types of analysis in estimating individual linear effects. The reduction in item variance (random intercept for items) by inclusion of each parameter was also very similar between the two approaches. There were some differences in significance but they concerned low variance proportions ( $1 \%$ ) or were associated with pseudoword orthographic neighborhood, which was not decorrelated.

Quadratic effects Examination of the raw and residual trends in Figure 1 indicated monotonic and largely linear effects of frequency, length, and syllabic frequency, especially for words. Some curvilinearity was apparent for other parameters, particularly for pseudowords. Nonlinearities were examined for every parameter in each case by testing quadratic terms added (centered) to the full model. The quadratic effect of bigram frequency was significant in pseudoword naming ( $\hat{\beta}=.1024, S E=.0435$ ), word lexical decision $(\hat{\beta}=.1720$, $S E=.0854$ ), and pseudoword lexical decision ( $\hat{\beta}=-.0778$, $S E=.0412$ ). The quadratic effect of orthographic neighborhood was significant in pseudoword lexical decision ( $\hat{\beta}=$ $-.0043, S E=.0021$ ) but seems spurious in light of the severely skewed distribution of this parameter. No other
quadratic terms were found to be significant. No higher-order terms or other nonlinear functions were tested.

Interactions Two-way interactions were examined by testing each pair of parameters. In word naming, there was an interaction between frequency and neighborhood ( $\hat{\beta}=.0054$, $S E=.0016$ ). In addition, there were interactions of transparency with frequency $(\hat{\beta}=.0007, S E=.0003)$, neighborhood ( $\hat{\beta}=-.0007, S E=.0003$ ), and syllabic frequency $(\hat{\beta}=.0002, S E=.0001)$. In pseudoword naming there was an interaction of length and neighborhood ( $\hat{\beta}=-.0201$, $S E=.0068$ ). In word lexical decision there were interactions of neighborhood with frequency $(\hat{\beta}=.0070, S E=.0023)$ and with transparency $(\hat{\beta}=-.0009, S E=.0005)$. Finally, in pseudoword lexical decision there was a marginal interaction of syllabic frequency with bigram frequency ( $\hat{\beta}=$ $.0050, S E=.0029$ ). There were no interactions involving the quadratic terms. No higher-order interactions were tested.

Following the addition of the aforementioned quadratic and interactive effects, the augmented models reduced the item variance (random intercepts) by half or more. Specifically, the proportion of item variance in the baseline model that was accounted for by the six experimental parameters was .48 for word naming, .71 for pseudoword naming, .48 for word lexical decision, and .50 for pseudoword lexical decision. Additional proportions in naming could be accounted for by modeling initial phoneme classes but there was no need for that in the present approach as the respective onset effects were adequately captured in the by-item random intercepts.

## Discussion

We employed a stimulus selection procedure to create a set of words and matched pseudowords with decorrelated parameters, aiming to examine curvilinear and interactive effects more accurately than with blind multiple regression. In this study we first confirmed that the linear effects are similar when estimated in full models vs. single-parameter models. Differences emerged for unmatched variables, as should be expected. Therefore this method achieves isolation of the effects of basic parameters, allowing further use in sit-

uations where complex modeling may be impractical or impossible, such as in fMRI. Use of decorrelated parameters to examine brain modulation in response to written stimuli has been previously reported for 465 monosyllabic English words (Graves, Desai, Humphries, Seidenberg, \& Binder, 2010). Our analysis supports this approach and extends it to multisyllabic words and a more transparent orthography.

Our results do not strongly challenge the common assumption of linearity, as most of the effects seem well approximated by a linear function. However, our analyses were based on $\log$ RT and not raw times. If linear fits on $\log$ RT can pass more stringent tests in comparison with a richer set of curvilinear alternatives, the implications for modeling are that models should predict logarithmic RT curves. The existing analysis techniques allow the field to progress from prediction of differences between conditions, or the mere existence of associations among parameters, toward more specific predictions of the relations between participants, items, and measures, as for example in the rate-amount (Faust, Balota, Spieler, \& Ferraro, 1999) and difference engine (Myerson, Hale, Zheng, Jenkins, \& Widaman, 2003) approaches. Simple correlation between predicted and measured times may become inadequate as more specific derivations and variance comparisons become increasingly feasible.

It remains to be established whether the effects uncovered in this analysis are properly accounted for in linear models of $\log$ RT. The effect of frequency, in particular, seems to level off somewhat towards lower frequencies. Although this may be an artifact of nonhomogeneous sampling affecting the lower end, it is consistent with a frequency effect less steep than logarithmic. Given that frequency has been log transformed, it may be fruitful to examine alternatives (e.g., power functions, ranks, or subjective estimates of familiarity) in accounting for the frequency effect (cf. Balota et al., 2012). It is reassuring that effect estimates and variance proportions in lexical decision were substantially greater (double) than in naming, consistent with the notion of frequency as a lexicalsemantic rather than surface variable.

The large effect of word length may seem surprising but it should be taken into account that multisyllabic words up to 10 letters long were involved. The Greek orthography is also rel-
atively transparent for reading (Protopapas \& Vlahou, 2009), conceivably supporting more serial approaches than English. This may explain why about half of the item variance in pseudowords was accounted for by length alone, almost as much in lexical decision as in naming. An interesting aspect of the data concerns the low-end shape of this relation, evident in pseudowords, although there may also be some flattening of the word curves. This may be related to the U-shape reported in other languages (see recent discussion in Yap \& Balota, 2009) and warrants further investigation.

No significant main effects of orthographic neighborhood were revealed in our analyses. This is surprising in light of consistent reports in the literature regarding neighborhood effects. However, there are issues with Greek word neighborhoods that warrant further scrutiny. Due to extensive inflection of nouns, verbs, and adjectives, many items counted as neighbors are inflectional variants, arguably linked to a single lexical lemma (contingent on one's theory of morphological representation in the lexicon). Moreover, the number of neighbors diminishes rapidly with word length, as there are fewer instances of words in longer letter-string space. This suggests that the emphasis on neighborhood effects may have resulted from an artifact of English being the most-studied language and allowing investigation restricted to short, single-syllable words. Alternatively, more flexible indices of orthographic distance may be required to express neighborhood density (e.g., Yarkoni, Balota, \& Yap, 2008).

In agreement with recent reports for other languages (Conrad, Tamm, Carreiras, \& Jacobs, 2010), inhibitory phonological syllabic frequency effects were found for words in both naming and lexical decision. A smaller but significant effect was found in pseudoword naming. No comparable effect was observed with orthographic syllable frequency (not reported above), consistent with the source of such effects lying within a phonological sublexical space. In contrast to syllables, orthographic bigram effects were minor, mainly restricted to pseudowords, and partly facilitatory, with a quadratic component resisting interpretation. There were no effects of phonological bigram frequency (i.e., phoneme pairs), consistent with an explanation for bigram effects related to orthographic familiarity with letter clusters.

Figure 1: (on previous page) The top row shows the distribution of parameter values for the stimulus set, separately for words (blue) and pseudowords (red), in comparison to all corpus types (light peach) and tokens (light blue). Bars display proportions of items, adding up to 1.0 . The other rows display the effects of each of the six experimental parameters on naming (Rows 2 and 3) and on lexical decision (Rows 4 and 5). Each box displays residual item effects (grey circles) in a model including baseline effects and all parameters except one. The red solid line plots a smoothed average (via function lowess) of these points. The dotted red line shows the effect estimate for this parameter when added to the predictor set, resulting in a full model. The teal solid line plots a smoothed average of the centered raw item means. The dotted green line shows the effect estimate of the parameter when included in a model with baseline and random effects only, absent all other parameters. The red and green numbers at the top of each panel are the corresponding effect estimates $(\hat{\beta})$ for the same-color dotted lines, whereas the numbers at the bottom of each panel are the proportions of item variance accounted for by this fixed effect; an asterisk denotes significant contribution (by likelihood ratio test). The vertical axis is scaled in $\log$ milliseconds (with respect to the grand mean intercept). Note different scaling of horizontal axes between parameters and also between distributions (top row) and effects panels.

There were no significant effects of consistency except in the augmented model for word lexical decision. This stands in contrast to large effects of regularity and consistency reported for English and may be attributed to the greater transparency of Greek. Nevertheless, there were consistent interactions involving transparency in word naming and lexical decision. Higher-probability grapheme-phoneme tokens were associated with increased RTs, an effect enhanced for higher-frequency words and diminished in larger neighborhoods. Instead of a pure consistency effect whereby more frequent mappings are decoded more rapidly, here we may have a situation in which systematic mappings permit greater confusion among lexical candidates. The fact that this only occurred for words-the (nonsignificant) trends for pseudowords being negative-suggests that it may be related to orthographic N being a poor index of neighborhood effects.

It should be kept in mind that our findings for pseudowords must be interpreted with caution as the stimulus set was not fully controlled and decorrelated due to the aforementioned neighborhood issue. This is not a major limitation of the study because most cognitive models typically focus on words and do not emphasize pseudoword processing.

Overall, the variance accounted for by our parameters was substantial but far from the $80 \%$ estimate Rey et al. (2009) gave for reproducible item variance in samples of this size. Although inclusion of initial phoneme class raised this proportion considerably, $80 \%$ was achieved only for pseudoword naming. Word naming lagged behind at $63 \%$, indicating that major sources of systematic item variance remain to be brought into the models (Adelman, Marquis, Sabatos-DeVito, \& Estes, in press). Morphological and semantic variables are obvious candidates to be examined in follow-up studies.

#### Abstract

Political scientists are increasingly turning to game-theoretic models to understand and predict the behavior of national leaders in wartime scenarios, where two sides have the options of seeking resolution at either the bargaining table or on the battlefield. While the theoretical analyses of these models is suggestive of their ability to capture these scenarios, it is not clear to what degree human behavior conforms to such equilibrium-based expectations. We present the results of a study that placed people within two of these game models, playing against an intelligent agent. We consider several testable hypotheses drawn from the theoretical analyses and evaluate the degree to which the observed human decisionmaking conforms to those hypotheses.

Keywords: Decision making; game theory; intelligent agents

## Introduction

Political scientists are increasingly turning to computational models to understand and predict nations' wartime behavior (Fearon, 1995). Many such models combine both military and political processes, where battlefield decisions occur within the context of an overall negotiation over a contentious resource (Filson \& Werner, 2002; Smith \& Stam, 2004). Game-theoretic models of these processes seek to capture possible outcomes on the battlefield and at the bargaining table (Powell, 2001, 2004; Slantchev, 2003). These models hypothesize equilibrium strategies that correspond to the behaviors of nations in real-world scenarios.

While the theoretical analyses of such game-theoretic models is suggestive of their representational power, it remains an open question as to how well they capture actual human behavior in wartime negotiation. These models focus on equilibrium behavior, where both sides optimize their outcomes in response to the others' behaviors. The computational challenges of such optimization often require the equilibrium analyses to make simplifying assumptions (e.g., to reduce uncertainty about the opponent). However, people are not constrained to adopt these same assumptions when making their decisions, so it is possible that human behavior in the face of this uncertainty may greatly deviate from the predictions generated by such theoretical models.

On the other hand, these computational models easily lend themselves to an experimental setting, where we can pit a human player against an intelligent agent playing according to the model of interest. In other words, we can place human players within the game hypothesized by a model and have them negotiate with an agent. We can then observe human behavior and quantify the degree to which that behavior conforms to the expectations generated by the model.

This paper presents a human subject study where we implemented games corresponding to two wartime negotiation models from the literature (Powell, 2004; Slantchev, 2003). We present behavior hypotheses extracted from the theoretical analyses of these models. We analyze the observed human behavior to see that it generally satisfies these hypotheses. However, there are also interesting deviations from these theoretical expectations that suggest possible extensions to the models to better capture human decision-making.

## Wartime Negotiation Models

A number of formal models in the literature represent war as a costly process embedded within a negotiation game. In these models, two sides are in a dispute over a desirable resource, such as territory claimed by both sides. The game begins with some initial split of the territory. The game progresses round by round, with each round consisting of one side proposing a split of the territory, the other side responding to that proposal, and a possible battle. The game ends with a final split achieved by either an agreement on the proposed split or a decisive military victory by one side on the battlefield.

To facilitate a game-theoretic analysis, these models make simplifying assumptions regarding military outcomes. In particular, the probabilities associated with the battlefield are fixed, so that one side's probability of winning does not change during the course of the game, regardless of previous military outcomes. The costs of a single battle are also fixed throughout the course of the game. In our study, we present these costs to the human players in terms of troops lost.

A critical property of these models is uncertainty about the likelihood of battlefield outcomes. If both sides had complete information about their probability of winning battles, they could do an exact cost-benefit analysis and immediately agree upon an acceptable territorial split. The models we consider instead have incomplete information, where one side is ignorant of the probability of battlefield outcomes. As the war progresses, this side will gain information by observing battle and bargaining outcomes, re-evaluate its prospects, and make different decisions on offers and battles. This asymmetry lends itself to our human subject study, as we can give the agent complete information about the game probabilities, but hide that information from the human player. Our experiments will then allow us to study how people update their beliefs based on the information that is revealed in the game.

We chose two models (Powell, 2004; Slantchev, 2003) for this investigation, based on their impact on the field and their appropriateness for a human-agent game interaction.

## Powell Model

The Powell model proceeds as follows (Powell, 2001, 2004):

1. Player 1 makes an offer of $x \%$ of the territory.
2. Player 2 decides to accept, reject, or go to war.
(a) If acceptance, Player 2 gets $x \%$ of the territory, Player 1 gets $(100-x) \%$, and the game is over.
(b) If war, both sides incur the battle costs. Player 1 collapses with probability $p_{1}$ and Player 2 collapses with probability $p_{2}$.
i. If only Player 1 collapses, Player 2 gets all of the territory, and the game is over.
ii. If only Player 2 collapses, Player 1 gets all of the territory, and the game is over.
iii. Otherwise, return to Step 1.
(c) If rejection, Player 1 decides whether or not to go to war.
i. If war, a battle occurs exactly as in Step 2b.
ii. If not, return to Step 1.

The following properties distinguish this model from the Slantchev model (described in the next subsection):

Battle: Attacking is a choice (if an offer is rejected).
War state: In each battle, there is a fixed probability that you win (lose) the overall war and gain (lose) all of the territory.

Counteroffers: There are no offers made by Player 2.
Player 1, the offering side, does not know the probabilities of collapse ( $p_{1}$ and $p_{2}$ ), but Player 2 does know these probabilities. Thus, Player 1 is uncertain about the two sides' relative military strength and, consequently, the feasible agreements. The equilibrium behavior can be described as screening, where Player 1 will make a series of increasingly attractive offers, expecting weaker opponents to accept early in the process, thus screening them out before making the higher offers necessary to appease stronger opponents (Powell, 2004).

## Slantchev Model

The Slantchev model includes an additional variable, military position (in $\{0,1,2, \ldots, N\}$ ), that represents the relative gains made by the two sides in the war so far (Slantchev, 2003). The game under this model proceeds as follows:

1. The initiating player makes an offer of $x \%$ of the territory.
2. The responding player decides to accept or reject the offer.
(a) If acceptance, the responding player gets $x \%$ of the territory, the initiating player gets $(100-x) \%$, and the game is over.
(b) If rejection, continue to Step 3.
3. Battle occurs, and both sides incur the fixed costs. Player 1 wins the battle with probability $p$, Player 2 with probability $1-p$.
(a) If Player 1 wins, military position increases by 1 . If it reaches $N$, then Player 1 receives all the territory and the game is over.
(b) If Player 2 wins, military position decreases by 1 . If it reaches 0 , then Player 2 receives all the territory and the game is over.
4. Return to Step 1 with initiating and responding players reversed.

This model deviates from Powell's as follows:
Battle: There is a battle every round.

War state: A single battle does not directly end the war, but affects the military position variable. Collapse occurs only if military position hits its maximum or minimum value.

Counteroffers: Both sides alternate in making offers.
Like the Powell model, Player 1 does not know the battle probability ( $p$ ), but Player 2 does, so the equilibrium behavior again exhibits some screening. However, the Slantchev model provides Player 1 with the additional information source of Player 2's counteroffers. Furthermore, the military position provides another variable for the sides to consider, in that their offering behavior will change depending on which side is in a stronger position in the overall war.

## PsychSim Agents

We implemented both the Powell and Slantchev games within PsychSim, a multiagent framework for social simulation (Marsella, Pynadath, \& Read, 2004; Pynadath \& Marsella, 2005). PsychSim agents have their own goals, private beliefs, and mental models about other agents. They generate their beliefs and behaviors by solving partially observable Markov decision problems (POMDPs) (Kaelbling, Littman, \& Cassandra, 1998), whose quantitative transition probabilities and reward functions are a natural fit for the game-theoretic dynamics of our chosen models of wartime negotiation.

PsychSim agents have a theory of mind that allows them to recursively model other agents (e.g., their beliefs, rewards, etc.), form expectations about their behavior, and choose optimal actions as a best response. With sufficient computation, the PsychSim agent's optimal action corresponds to the equilibrium strategy. However, we can also limit the agent's horizon when computing expected values and the depth of recursion in modeling others. By doing so, the agent can quickly compute approximate best-response actions even when a human opponent deviates from the equilibrium.

The behavior of the PsychSim agents in both the Powell and Slantchev models roughly corresponds to the informed side's equilibrium strategy. For example, when starting with less territory in the Powell model, the PsychSim agent chooses war until its opponent makes an offer that exceeds its threshold of acceptability, computed as a function of the probability of military collapse. Under the Slantchev model, the agent also rejects any offer below a threshold, but that threshold changes based on the current military position. In particular, if the military position favors the agent's side, the threshold is higher than it would be otherwise. The counteroffers made by the agent are similarly lower when the military position is in its favor than they would be otherwise.

While both Powell and Slantchev focused on the case where the uninformed side also started as the satisfied side, we can also model the case where the uninformed side starts as the dissatisfied side. We change the initial distribution of territory from having the human player start with $72 \%$ of the territory as the satisfied side, to having the human player start with only $28 \%$. The PsychSim agent computes its policy of
behavior using the same algorithm in both cases, although the resulting strategy is slightly different. Under Powell, the agent playing the satisfied side (with $72 \%$ of the territory) will no longer attack when receiving an unacceptable offer. Instead, it will simply reject the offer, hoping to avoid a battle that will risk collapse and loss of all its territory. Under Slantchev, the agent's thresholds as the satisfied side will be universally higher than those as the dissatisfied side.

## Wartime Negotiation Study

We used these agents in a study of how people make decisions in wartime negotiation games. The subjects played each model twice: once as the satisfied side (starting with $72 \%$ of the territory) and once as the dissatisfied side (starting with $28 \%$ ), leading to four experimental conditions: Powell72, Powell28, Slantchev72, and Slantchev28. For each condition, the subject played as Player 1 against a PsychSim agent until the two sides agreed on a split or one side achieved a military victory. If neither occurred within 15 rounds, the game terminated with the sides staying at the initial division of territory. In the two Powell conditions, both sides have the same probability of collapse ( $p_{1}=p_{2}=0.1$ ). In the two Slantchev conditions, we use the same probability of winning for Player $1(p=0.3)$ and the same initial military position, with Player 1 slightly closer to losing the war ( 3 on a range from 0 to 10 ).

## Hypotheses

The Powell and Slantchev models yield hypotheses about behavior that we might see in our human subject data:
Screening Behavior The uninformed side tries to find the minimal offer that is acceptable to its opponent. It does so by progressively increasing its offer until its opponent accepts, gradually screening out weaker opponents who are willing to accept lower offers. We expect to see players make these increasing offers under both Powell and Slantchev models.

Principle of Convergence Warfare ceases to be useful when there is no information to gain, at which point the sides can both agree on a settlement. Given the static battle probability and the lack of signaling moves in the Powell model, the potential information gain should be exhausted sooner than in the Slantchev model. As a result, we would expect settlement to be reached sooner under the Powell model, where the only information gain is through rejected offers.

Information Asymmetry Because of the screening behavior, Slantchev claimed, "as war progresses, the outcome becomes less advantageous for the worse informed party." We thus expect settlements that take more rounds to be less favorable to the human players. Furthermore, we expect this trend to be more pronounced under Powell, where the players receive less information than they do under Slantchev.

Total victory Total military victory (i.e., one side winning all of the territory on the battlefield) is rare, as war typically reveals information quickly enough for both sides to reach
settlements instead. The possibility of collapse in a single battle under the Powell model should make total victory much more common. We would thus expect that negotiated settlements (as opposed to total victories) to be less common under the Powell model than under Slantchev.

War avoidance Both models provide incentives for sides to sacrifice territory to avoid a costly battle. We would expect players who expressed a more positive attitude toward war (ATW) to exhibit more of a willingness to engage in war and give up less territory in the final settlement.

Military Asymmetry If the uninformed side is also at a military disadvantage (as is the case for our human players), then we expect it to overestimate its probability of winning the war, thus making lower offers than it would make in the complete-information case. Therefore, we would expect to see lower offers when the players receive less information about their relative military strength (i.e., under Powell) than when they receive more (i.e., under Slantchev).

Battle outcomes A battle in the Slantchev model will make the victor more optimistic and more willing to delay agreement. We would thus expect players to make lower offers after winning a battle than they would after losing a battle.

Starting Territory Our four experimental conditions could engender different reference points (Neale \& Bazerman, 1991) when people play as the satisfied or dissatisfied sides (starting with $72 \%$ or $28 \%$ of the territory, respectively). We hypothesize that satisfied sides will make fewer concessions, as the endowment effect makes players less willing to give up territory already owned (Kahneman, Knetsch, \& Thaler, 1991). Thus, we expect a player to offer less when starting with more territory than when starting with less territory. Similarly, we expect the dissatisfied side will end up with less territory, because any territory gain, however small, would be more likely considered as satisfactory. Furthermore, because the satisfied side has more to lose through a military outcome, we expect that the difference between initial and final territorial splits will be more favorable for the dissatisfied sides.

## Study Population

We recruited 240 participants, of an average age of 35 , via Amazon Mechanical Turk. $51 \%$ of the participants were female, and $49 \%$ were male. $65 \%$ of the participants were from the United States, $29 \%$ from India, and $6 \%$ from other countries. Regarding the participants' highest level of education, $12 \%$ of the participants had some high school or high school diploma, $63 \%$ had some college or college degree, and $25 \%$ had some graduate school or graduate degree. $13 \%$ of the participants used a computer for 1-4 hours a day, $43 \%$ for 5-8 hours a day, and $44 \%$ for more than 8 hours a day.

## Procedure

After being assigned an anonymous ID, each participant read an information sheet about the study and then filled out a background survey. Next, the participant played the negotia-
tion game four times, each time against a different agent from one of the conditions. The order of the four agents the player negotiated with was randomized. During the negotiation, the participant filled out an in-game survey. Following each negotiation game, the participant filled out an opinion survey. We designed the study to be completed within an hour, and the average duration of the study was 32 minutes.

## Measures

Background Survey The background survey asked about the participant's age, gender, nationality, education, computer experience, Attitude Towards War (Dupuis \& Cohn, 2006), Social Orientation (Van Lange, De Bruin, Otten, \& Joireman, 1997) and attitude towards Inappropriate Negotiation (SINS, from (Robinson, Lewicki, \& Donahue, 2000)).
Opinion Survey The opinion survey contained questions regarding the participant's goals during the game, and questions from the Subjective Value Index (SVI) survey on opinions about oneself, the negotiation outcome, the process and the opponent (Curhan, Elfenbein, \& Xu, 2006).

In-Game Survey The in-game survey asked participants to predict the opponent's responses. For example, after making an offer in the Powell game, participants said whether they expected their opponent to accept the offer, reject it or attack.
Game Logs The game logs captured the participant's actions, the PsychSim agent's actions and the world states (e.g. number of troops, military position, and territory).

## Results

We had 240 participants in the study. Each participant played four different games, one under each condition. Data from incomplete games were discarded. In the end, we had 238 games in the Powell72 condition and 239 games in the Powell28, Slantchev72 and Slantchev28 conditions.

## Hypothesis: Screening Behavior

This hypothesis states that the participants' behavior is most likely to be screening, by making incrementally higher offers to find out the lowest offer that satisfies the opponent. We analyzed the dynamics of the participants' offers to see whether they increased, decreased, or stayed the same from one round to the next. The results of Figure 1 show that, by and large, the human players exhibit screening behavior (i.e., more increases than the alternatives).

## Hypothesis: Principle of Convergence

The hypothesis states that under the Powell model, settlement should be reached sooner, compared to the Slantchev model. We compared the number of rounds it took for both sides to reach an agreement under these two models, excluding games that ended with one side winning the war (instead of reaching an agreement). Results show that, contrary to the hypothesis, it took participants significantly more rounds to reach an agreement when interacting with the Powell model

Figure 1: Distribution over participants' offer dynamics.
than when interacting with the Slantchev model ( $p<.0001$, Mean $_{\text {Powell }}=3.13$, Mean $_{\text {Slantchev }}=1.95$ ).

## Hypothesis: Information Asymmetry

This hypothesis predicted that settlements taking more rounds to reach agreement would be less favorable toward the human player, with the effect being more pronounced in the Powell model. Excluding games with no agreement, we analyzed the correlation between the territory participants ended up with and the total number of rounds needed to reach the settlement. In general, there is a weak yet significant negative correlation between the territory participants got in the settlement and the number of rounds needed to reach that settlement ( $r=-.1965, p<.0001$ ), providing evidence in favor of this hypothesis. The correlation is of medium strength both in the Slantchev ( $r=-.2372, p<.0001$ ) and Powell games ( $r=-.2309, p=.0004$ ), failing to demonstrate the hypothesized difference between the two models.

## Hypothesis: Total Victory

Under this hypothesis, we expect that negotiated settlements to be less common under Powell than under Slantchev because of the possibility of immediate collapse in the former. The data bore out this hypothesis, as fewer games in the Powell model ended in a settlement than in the Slantchev model ( $p<.0001$, Mean $_{\text {Powell }}=48.0 \%$, Mean Slantchev $=60.8 \%$ ). It is also interesting to observe that settlements were much rarer when the player started with $28 \%$ territory than when starting with $72 \%\left(p<.0001\right.$, Mean $_{28}=42.77 \%$, Mean ${ }_{72}=66.25 \%$ ).

## Hypothesis: War Avoidance

We hypothesized that players who are more pro-war would be less willing to give up territory, and more willing to go to war. We measured the participants' attitudes towards war (ATW) in the background survey, where higher ATW scores indicate more of a pro-war attitude, and lower ones indicate an antiwar attitude. We did not find significant correlations between ATW and the average offers participants made ( $r=-.0172$, $p=.5950$ ). We also did not find a correlation between ATW and the number of rounds played in the game ( $r=.0220, p=$ .4979). Battles were not a choice in the Slantchev model. In the Powell72 condition, the human player never initiated an attack, because the agent would always do so first. Therefore, we analyzed the correlation between ATW and the number of player-initiated attacks in only the Powell28 condition and

Figure 2: Change of offers made after battle outcomes.
found a marginally significant weak correlation ( $r=.1107$, $p=.0877$ ). Thus, there was only the slightest of evidence in favor of his hypothesis.

## Hypothesis: Military Asymmetry

This hypothesis states that in the Powell model, where less information is revealed to the players, the players will make lower offers than they would under Slantchev. However, when interacting with the Powell model, participants made slightly higher offers than when they interacted with the Slantchev model ( $p<.0001$, Mean ${ }_{\text {Powell }}=36.26$, Mean $_{\text {Slantchev }}=33.29$ ), exactly the opposite of our hypothesis.

## Hypothesis: Battle Outcomes

We expect players to make lower offers after winning a battle than they would after losing. We ignore the Powell model, which gives players no information about battle outcomes (beyond game-ending collapses). Under Slantchev, players lost $68 \%$ of the battles and won only $32 \%$. When players won a battle, the offers they made next were significantly lower than when they lost $\left(p=.0441\right.$, Mean $_{\text {Won }}=31.70$, Mean $_{\text {Lost }}=35.88$ ), thus bearing out the hypothesis.

## Hypothesis: Starting Territory

Initial Offer We compared the offers that participants made at the beginning of the negotiation. Participants made significantly higher offers when starting with $28 \%$ territory compared to $72 \%\left(p<.0001\right.$, Mean $_{28}=34.20$, Mean $_{72}=27.95$ ).
Average Offer We compared the average offers the participants made during the negotiation. When starting with $28 \%$ territory, participants made significantly higher offers than with $72 \% ~\left(p<.0001\right.$, Mean $_{28}=38.84$, Mean $_{72}=30.71$ ).

End Territory We compared the percentage of territory the participant had when the game ended. When starting with $28 \%$ territory, participants ended up with signifi-

Figure 3: Participant offers in response to opponent actions.
cantly less territory than when starting with $72 \%$ ( $p<.0001$, Mean $_{28}=22.31$, Mean $_{72}=45.55$ ).

Net Territory Gain Beyond the impact on absolute territory, we also hypothesized that the starting territory would affect the relative gain/loss in territory from the beginning to the end of the game. When starting with $28 \%$ territory, participants lost significantly less territory than when they starting with $72 \%$ territory ( $p<.0001$, Mean $28=-5.69$, Mean ${ }_{72}=-$ 26.45). Thus, the observed behavior conformed to all of our expectations about the effect of the initial division of territory.

## Offers In Reaction to Opponent Actions

We also compared the participants' offers under both models in reaction to their opponent's actions. In the Powell model, when not accepting the participant's offer, the opponent chose to either simply reject the offer or to attack the participant. In the Slantchev model, attacking was not a choice, but the opponent did make counteroffers when not accepting the participant's offer. The differences were significant when interacting with the Powell model ( $p<.0001$ ) and Slantchev model ( $p<.0001$ ). The results of Figure 3 show that attacking the participants prompted lower offers, while less aggressive actions (e.g. rejecting without attacking, or making a counteroffer) typically resulted in higher offers.

## Discussion

As we can see from the previous section, much of the observed behavior conformed to the expectations generated by the theoretical analyses of the Powell and Slantchev models. The information asymmetry that is critical to both models had the expected impact on the human players, as they clearly exhibited the hypothesized screening behavior. Furthermore, we also observed direct evidence of the claim that "as war progresses, the outcome becomes less advantageous for the worse informed party" (Slantchev, 2003). Our agent-based experimental setup also allowed us to try a variation of the game on the starting territory, and the data provided strong evidence for our hypotheses regarding that variation.

However, there were also some interesting deviations from our hypothesized behavior. Slantchev's Principle of Convergence hypothesized that warfare ceases to be useful when there is no information to gain. Our derived hypothesis
viewed the Powell game as more information-poor than the Slantchev one, leading us to expect that settlements would be reached sooner in the former. However, our data showed the opposite trend. We can at least partly attribute this deviation to people assessing the information gains differently than was prescribed in the two models' equilibrium analysis. Under the Powell model, players may try to gather more observations of their opponents' behavior, because they do not realize that the agent's threshold of acceptance does not change. Conversely, under the Slantchev model, the players may feel overly certain in their beliefs upon observing only a few (or even only one) counteroffers from their opponent.

We also saw little evidence to support our War Avoidance hypothesis. We did not find any link between a participant's attitude towards war and the offers they made, the duration of the war, nor the number of attacks. It is likely that some participants did not carry their attitudes toward war over into this abstract game setting. However, we also need to further differentiate within the ATW scale about why people are antiwar and what types of war they are against.

The deviation from the military asymmetry hypothesis is harder to explain. From the very beginning of a Slantchev game, the players can observe that their military position puts them closer to losing the war than winning the war. As the game progresses, they can potentially observe that the battle probability is not in their favor. We would thus expect players to be more pessimistic about their chances under the Slantchev model and, thus, to make higher offers to quickly appease their opponents. However, players made higher offers in the Powell model, where there was no feedback about the war outcomes, nor the other side's valuations.

Therefore, we need a more fine-grained analysis of when players in Slantchev made the unexpectedly low offers. For example, the data supported our Battle Outcomes hypothesis, where players made lower offers after winning a battle. By isolating such cases, we may see that the general military asymmetry hypothesis holds, but we can also understand the in-game contingencies that would override the general trend.

Furthermore, despite the general conformity over all of the data, not every player's behavior conformed to our hypotheses. We must therefore analyze the data to identify the more fine-grained contingencies and the individual differences among our participants. Such an analysis would give us a better understanding of how the participants viewed, for example, the potential information received in the game, their possible military outcomes, etc. This analysis will also guide future studies by suggesting further instrumentation that is needed to gather the required in-game data.

With these additional analyses and data, we can build upon the field's game-theoretic models to develop higher-fidelity models of human behavior in such wartime negotiation scenarios. Ideally, these models will help bridge the gap between the theoretical computational frameworks and the decisionmaking we see in the real world. By doing so, they will provide an invaluable computational tool for political scientists
to explore a richer set of contingencies and individual differences and hopefully provide better predictions and explanations of behavior in wartime negotiation.

#### Abstract

Although reasoning skills have been investigated in a number of different domains, very little is known about how children and adults use them in chemistry. Here, participants from 4 years to adults saw various mixtures presented using a standard property induction paradigm. The category and appearance of everyday materials were varied to assess the extent that participants use these features to inform their judgments about what happens when these materials are mixed with water. In general, the results followed similar patterns seen when this paradigm has been applied to other domains, with both category and appearance informing inductive generalizations. The findings contrast with interview-based measures of children's understanding of chemistry and offer an important addition to the field.

Keywords: property induction; chemistry; reasoning; cognitive development

## Background

There is a growing consensus that children learn and reason about novel situations by basing their generalizations on their previous experiences (e.g., Wellman \& Gelman, 1998). Children have extensive experience of chemistry in their everyday world, e.g., baking or rusting. However, there are few studies in cognitive science exploring children's reasoning about the chemical world. Here, we present a novel application of a property induction paradigm to investigate how primary school children (ages 4 to 11) reason about one basic chemical phenomenon - the mixing of different materials. ${ }^{1}$

[^193]The focus of this study is mixing because it is one of the earliest chemical phenomena children are deemed capable of grasping (e.g., Au, Sidle, \& Rollins, 1993; Johnson, 2000; Rosen \& Rozin, 1993) and because very little work exists in this area (Çalýk, Ayas, \& Ebenezer, 2005). Most of the few existing studies have used interviews. The results of these interviews suggest that young children attend almost exclusively to what they can see, i.e., the macroscopic properties of the materials (Arnold, Moye, \& Winer, 1986; Ebenezer \& Erikson, 1996; Haider \& Abraham, 1991) and have little or no conception of the particulate nature of matter (Liu \& Lesniak, 2006; Nakhleh \& Samarapungavan, 1999; Renström, Andersson, \& Marton, 1990). Briefly, the particulate nature of matter refers to the idea that materials are made up of invisible, sub-microscopic particles, with molecules being the smallest particles of most materials. Some knowledge of the particulate nature of matter is necessary to understand materials and how they interact with each other; naïve (incomplete or incorrect) understanding of particles likely leads to misconceptions of chemical phenomena. The assumption is that because young children are not able to explain the particulate nature of matter or the microscopic properties of materials that they lack the ability to reason adequately about materials

One issue with these findings is that the interview method relies on children having the appropriate language of chemistry to be able to explain the phenomena. As a result, it may be the case that children's abilities in this area have been greatly underestimated. Extensive studies of naïve physics and naïve biology indicate that children's reasoning abilities about these science phenomena surpass their abilities to explain them verbally. Tasks that are not reliant on verbal ability indicate that even infants have some understanding of physics (Wellman \& Gelman, 1998). For example, infants know that solid objects cannot just appear/disappear or move through physical barriers (Spelke, Breinlinger, Macomber, \& Jacobson, 1992), are distinct from one another (Xu \& Carey, 1996), and once put into motion travel over distances related to the force of that motion (Kotovsky \& Baillargeon, 1998). These tasks indicate young children do have some appreciation of the properties of materials; 3-year-olds know that wooden pillows are hard (Kalish \& Gelman, 1992) and 4-year-olds know that material is conserved if the object is broken up
(e.g., a plastic toy taken apart is still plastic even if it no longer operates as a toy; Smith, Carey, \& Wiser, 1985).

The success of these language-sparse experimental paradigms in uncovering the foundations of young children's emerging understanding in naïve physics and biology might suggest that young children can make sense of chemical phenomena. Here, we use a language-sparse property induction paradigm to study early chemistry reasoning. Briefly, the property induction paradigm investigates how children use category and appearance information in their generalizations of natural kinds, typically biological kinds (Gelman \& Markman, 1986; Gelman \& Markman, 1987). For example, Farrar, Raney, \& Boyer (1992) showed 5- to 10-year-old children a familiar target object with its familiar name (e.g., egg) and taught them a novel property about that object (e.g., 'has mitochondria inside'). Next, children were asked whether the four test items below also had that novel property:

1. Same category, same appearance (e.g., plain egg);
2. Same category, different appearance (e.g., spotted egg);
3. Different category, same appearance (e.g., snow ball);
4. Different category, different appearance (e.g., leaf).

At all ages, generalizations depended both on category and appearance, but how children relied on these cues changed with age. Pre-school children generalized more to objects in the same category with the same appearance than to the other items; in other words, they thought the typical cue correlation was necessary. Second graders generalized more to objects that matched in category and appearance than to objects matching in only one cue than to objects matching in neither cue; that is, they realize that category and appearance are separable predictors. Only fourth graders generalized more to same category, different appearance items than to different category, same appearance items, realizing that category was a better predictor than appearance. This mature pattern appeared even for second graders in a second study varying knowledge of the categories/properties in question, but only when children reasoned about known categories/properties. Generalization about materials may include more features than category and appearance. For example, 8-year-olds seem to generalize more often to items with matching causal information compared to perceptual features and 5 -year-olds seem to be able to make use of causal information when it is not in competition with physical features (Hayes \& Thompson, 2007). This distinction may be relevant for chemistry where the causal factors that determine mixing outcomes may not correspond to perceptual features. The results from these property induction studies have indicated that children as young as 2 years are not limited to appearance-based reasoning when categories/properties are well known (Gelman \& Coley, 1990), but variations in knowledge continue to play a vital role at older ages.

Given the success of this paradigm in furthering the understanding of young children's reasoning, it seems well suited as an application for the chemical phenomena investigated here - mixing. More specifically, do children
generalize from one mixture outcome to another if the substances involved are of the same category or of the same appearance? How does this depend on age and on children's knowledge of the substances involved?

In contrast to studies of biological properties, generalization of mixture properties does not depend on category only, but on appearance as well. Mapping the category and appearance properties onto chemistry, it might be useful to think of categories in chemistry as relating to materials and appearances in chemistry as relating to forms like powder, granule or larger chunks. Whether different materials dissolve in water or not depends on a variety of factors related to molecular structure. For instance, water is polar and can break other polar or ionic materials like salt ( NaCl ) apart, but not non-polar or covalent materials like sand (SiO2); roughly, like dissolves like. How different forms of a material mix with water might depend on factors related to surface area. For instance, table salt ( NaCl , in granular form) usually dissolves more quickly in water than rock salt ( NaCl , in a large chunk) because it has a greater surface area. As such, in addition to examining the role of language in children's reasoning about basic chemical phenomena, the current design allows for an investigation of whether children's generalizations about chemical properties are similar to those in other domains. Specifically, will reasoning about chemistry follow both material (category) and form (appearance) cues in the same way as for biology, will there be a different pattern for chemistry, reflecting domain differences in cue efficacy, or will young children remain appearance-bound, as predicted by the findings from interview studies?

## Method

## Participants

A total of 142 participants $\left(N_{\text {female }}=81\right)$ took part in this experiment. There were 122 children recruited from schools in eastern England, including 24 children from reception ( $M$ $=4.87$ years, $S D=0.35, N_{\text {female }}=11$ ), 32 children from year two ( $M=6.62$ years, $S D=0.46, N_{\text {female }}=19$ ), 33 from year four ( $M=8.60$ years, $S D=0.41 N_{\text {female }}=15$ ) and 35 from year $\operatorname{six}$ ( $M=10.74$ years, $S D=0.28, N_{\text {female }}=21$ ). In addition, 20 adult participants were recruited from the university and local community ( $M=26.45, S D=6.70$, $N_{\text {female }}=15$ ). For simplicity, these different age groups are referred to here as 5 -year-olds, 7 -year-olds, 9-year-olds, 11 -year-olds, and adults. Adults were paid $£ 10$ for their participation and represented a range of chemistry experience. Children were invited to dress up as scientists for the duration of the study and were given stickers and their schools given a special science presentation by a local science outreach program. The participating schools were typical schools in terms of their range of student abilities and backgrounds according to publically available government data (www.ofsted.gov.uk).

Figure 1. An example of a target. The picture on the left shows the water and the target (e.g., granulated brown sugar) before mixing. The picture on the right shows the water and target after they were mixed.

Figure 2. An example of a set of probes: (1) same material, same form (e.g., granulated brown sugar); (2) same material, different form (e.g., brown sugar cube); (3) different material, same form (e.g., sand); and (4) different material, different form (e.g., a pebble).

## Materials

Everyday items (e.g., sugars, salts, sand, etc.) were selected as stimuli because children may reason better about familiar content and for safety reasons. Twelve sets of items were chosen, with each set including a target and four probes (see Table 1). The probes followed the conditions mentioned above: (1) same material, same form; (2) same material, different form; (3) different material, same form; and (4) different material, different form.

Several constraints were imposed on the selection of the targets and probes based on pragmatics and the experimental design: (1) the target and probes were safe and appropriate for use with young children; (2) the target-probe pairs had similar appearances for their matching forms (solid, granule, or powder); and (3) the targets and probes were balanced in terms of their outcomes when mixed with water. When controlling for mixing outcomes it was noticed that long names, (e.g., antacid) were often associated with exciting outcomes such as fizzing. To avoid this possible confound
some items were given alternative names ${ }^{2}$. Finally, the relative mass and volume of the targets and probes were as similar as possible so that these perceptual features would not act as additional cues to the outcomes. Transparent 400 mL plastic beakers (see Figure 1) were used to show the mixing of each target with water. The beakers were filled with 250 mL of water and had lids to allow mixing of the targets with the water without risk of spillage. The probes were presented in transparent 140 mL plastic containers (see Figure 2), sealed with clear plastic lids for safety.

## Procedures

Participants sat opposite the experimenter at a table in a quiet area of their primary school or university. A clear plastic beaker with water was placed on the table and identified as water. A transparent plastic tub containing the target was displayed and identified for the participant, using the phrase "See this tub? This tub has [target name]. I'm going to mix the [target name] with the water.'

All items were named for the participants. In order to ensure no cues about the type of material could be implied from the instructions, mass/count words were not used (e.g., "This is a vitamin." or "This is some sugar."). Instead, only general names were given (e.g., "This is vitamin." or "This is sugar."). The form of the target and probe were not mentioned.

The target was added to the water, the beaker was sealed and it was turned upside down once to facilitate mixing. Participants were asked to describe what happened both to the target and to the water. This step ensured they were attending to the mixing.

Table 1: List of Target and Probe Materials

| Target <br> Form | Target Material | Probe <br> Material |
| :---: | :---: | :---: |
| Solid | Chalk | Lolly |
|  | Chocolate | Almond |
|  | Vitamin | Sweet |
|  | Paint | Incense |
| Granule | Peppercorns | Candy |
|  | Bath Bomb | Wax |
|  | Sugar | Stone |
|  | Coffee | Stock cube |
| Powder | Coconut | Soap |
|  | Antacid | Washing Soap |
|  | Salt | Rice |
|  | Kool-Aid | Play-Doh |

After mixing the target with water, the experimenter displayed and identified each of the four probes, one at a

[^194]time in a pre-established randomized ordering. For each probe participants were asked if it would do the same as the target using the phrase 'See this tub? This tub has [probe name] in it. Do you think this would do the same as [target name] if I put it in water?'

Participants were instructed to give "Yes" or "No" replies. Simplifying the required responses in this way was important in order to make the task accessible for the youngest participants. For the younger groups two sheets of paper were also available, green and red, with 'yes' and 'no' written on them respectively. Children could point to these if they did not give a verbal response. Only one child made use of these sheets. If participants did not give a specific 'yes' or 'no' response, the question was repeated to prompt a 'yes' or 'no' answer. Sessions were video recorded so that replies could be verified and confirmed off-line.

The target remained in view on the table mixed with the water while the participants saw the probes. After each of the four probes was presented, the target and water were cleared out of view before the next set of items was presented.

There were 12 sets of items each containing a target to be mixed with water and four probes for a total of 48 trials. Both the order of the 12 sets and the order four probes within each set were presented pseudo-randomly. The youngest group always completed the study in two separate sessions.

## Results

The proportion of "Yes" responses given by the participants to the probes were analyzed using a $5 \times 2 \times 2$ repeated measures ANOVA with the between-subjects factor of age group (5-year-olds, 7 -year-olds, 9 -year-olds, 11 -year-olds, and adults) and the within-subjects factors of material (same vs. different from the target) and form (same vs. different from the target). This ANOVA was conducted using the restricted maximum likelihood technique ( $R E M L$; Bagiella, Sloan, \& Heitjan, 2000). There were no overall significant differences among the three forms (powder, granule, or solid), making it feasible to combine them together and focus the analyses on same vs. different form only.

There was a significant effect of both material, $F(1$, $139.1)=445.44, p<.0001$, and form, $F(1,139.2)=418.56$, $p<.0001$, as well as a significant interaction between material and form, $F(1,139.3$ ) $=119.42, p<.0001$ (See Figure 3). More specifically, participants responded 'Yes" most often when the probe was the same material, and same form as the target ( $M=.96, S D=.21$ ), followed by probes that were the same material and different form ( $M=.59, S D$ $=.49$ ), probes that were a different material and same form ( $M=.49, S D=.50$ ), and probes that were a different material and different form ( $M=.30, S D=.46$ ). Post-hoc tests using Tukey's HSD indicated that each probe type was different from the others.

Figure 3. The mean proportion of "Yes" responses made to the same and different materials and forms across all age groups.

Figure 4. The mean proportion of "Yes" responses made to the same and different materials and forms by each age group.

The main effect of age group was not significant, $F$ (4, $139.1)=0.89, p=.47$. Similarly, age group did not interact significantly with material, $F(4,139.1)=2.03, p=.09$, form, $F(4,139.1)=1.15, p=.34$, or material and form combined, $F(4,139.2)=1.53, p=.20$ (see Figure 4).

## Discussion

This paper presents a novel adaptation of the property induction paradigm to explore how children reason about the chemical process of mixing. The design was created in order to use language-sparse methods as a way of further examining children's reasoning in this domain by addressing whether: (1) young children display a better understanding of mixing processes when assessed using a language-sparse method compared to interviews; and (2) whether children differentially attend to the category (material) or appearance (form) of materials when generalizing about mixing.

In terms of the first question, the results confirm that young children's reasoning about these materials does not differ from older children and adults in terms of mixing in
this context. These findings are consistent with other property induction studies, but are contrary to the results of interview studies (Gelman \& Markman, 1986; Gelman \& Markman, 1987; Liu \& Lesniak, 2006; Au, Sidle, \& Rollins, 1993). As such, there is some indication that this type of language-sparse methodology might be useful in further exploring how young children reason about other chemical phenomena.

In relation to the second question, participants of all age groups attend to category and appearance when making generalizations about mixing. The presence of this finding for the youngest age group suggests that even young children bring their everyday reasoning skills to understanding chemistry despite not yet being able to articulate sophisticated explanations. The findings presented here replicate the overall pattern found with property induction studies in other domains (e.g., Gelman \& Markman, 1987). Specifically, the category seems to have more influence than appearance on the generalizations that were made.

However, these findings are distinctive to property induction studies in other areas. Specifically, this study did not replicate the common finding of age related differences in the use of category and appearance. In a chemistry context like that presented here, both features seem to be influencing generalizations, whereas in other studies from the domain of biology the categorical information becomes more important for generalizations in older children than younger children (e.g., Farrar et al., 1992).

One explanation for the discrepancy between the results found here and other property induction studies might be that this task used naturalistic materials and actual mixing events, whereas most of the previous studies used pictures, words or text (Farrar et al., 1992; Gelman \& Coley, 1990; Gelman \& Markman, 1986; Gelman \& Markman, 1987; Hayes \& Thompson, 2007). More specifically, these previous studies mostly frequently used artificially selected stimuli with a constrained set of properties that allowed for a limited number of inductions, whereas the materials used here are more ecologically valid but they do include a wider variety of properties and more possible inductions.

Using real materials might have inadvertently allowed participants to attend to properties other than the category and appearance properties explicitly examined here (e.g., the density of objects could have been assumed by participants to have played a role in the outcome). In contrast, when experimental stimuli are created to vary only on a limited set of properties, then participants may base their generalizations more on the specific properties for which these artificial stimuli were designed to control. Thus, the inherent complexity of real-world materials might have prevented well-controlled and systematic studies of reasoning about chemistry. This language-sparse design provides a platform from which additional studies might be developed that control for the wide variety of features that may play a role when natural stimuli are used in property induction studies, while still being more ecologically valid.

It may be the case that children exploit multiple redundant cues in their natural environment, so the pattern found here may be indicative of their reasoning in their everyday lives.

Another reason for this finding in chemistry, but not biology might be due to domain-specific differences in the way chemistry information is processed. It could be the case that reasoning skills are applied differently in the biological and chemical contexts because the features that help in terms of generalization have different predictive validity.

In chemistry, appearance might be both an unreliable predictor and necessary for making a prediction. Firstly, appearance alone is generally an unreliable predictor of category. For example, white powder can be any number of different materials with a wide range of possible chemical properties. Secondly, it is difficult to make a prediction about the outcome based on the knowledge of the category without information about appearance. For example, aluminum is inert as a solid block, but easily combusts in powdered form. In contrast, in biology, appearance might be a reliable predictor of behavior when it predicts category membership (e.g., wings might predict bird and flying).

Most property induction studies introduce unreliable correlations amongst features like appearance and category and assuming that biology naturally includes more reliable correlations amongst these features, then it could be the case that property induction studies introduce unnatural reasoning settings. As such, the age difference apparent in biology generalizations may reflect children's growing understanding of what to do when the correlations they experience in their everyday lives are broken by our experimental designs in property induction. On the other hand, in chemistry, the correlations are naturally unreliable, matching the usual property induction design. Thus, the property induction paradigm might be more representative of naturalistic reasoning in chemistry but not biology. If that were the case, then the more mature reasoning seen in this chemistry context might be related to the match between the experimental design and children's everyday experiences rather than the differences inherent to reasoning about biology and chemistry.

This aspect of chemistry raises an intriguing perspective on development of categorization and reasoning skills. Cognitive science includes a large body of studies investigating the basic building blocks of cognition with which children learn about the world. In physics, biology, and psychology evidence has suggested that children generalize existing knowledge to extend their ability to reason about the world. A debate remains about the origins of these basic reasoning skills. Most areas of reasoning struggle to separate the question of how much of reasoning is dependent upon domain-specific experiences and how much is due to domain-general strategies. Chemistry may offer a unique perspective for this debate. Like physics, biology, and psychology, children are exposed to chemical phenomena throughout childhood, but the differences between these domains in terms of predictive validity of features might provide a new direction for further study.

If it is indeed the case that children are sensitive to the idea that different cues are meaningful in biology versus chemistry, then it could be the case that children are bringing very sophisticated reasoning skills to their attempts to understand chemistry. However, this is the first study in this area and other relevant cues (e.g., density, naming, etc.) should to be explored before firm conclusions can be made.

In sum, this novel application of the property induction paradigm to chemistry raises important questions about the development of reasoning skills in chemistry and further offers directions of research to address key questions of how children learn to reason about the world. The question of how abstract reasoning skills develop is a core issue for education. Previous research into young children's understanding of chemistry has relied upon language-based measures. This study offers a more sensitive measure of chemistry reasoning that is not constrained by a child's language development. The findings presented here might be useful in re-evaluating the assumptions that educators make about the reasoning skills children bring to chemistry learning and could be applied to develop more effective ways of learning for chemistry students of all ages.

# Does the Semantic Integration of Emotion Words Depend on Emotional Empathy? N400, P600 and Localization Effects for Intentional and Proprioceptive Emotion Words in Sentence Contexts 

Natalia Rak ${ }^{\mathbf{1}}$, Jarmo Kontinen ${ }^{2}$, Lars Kuchinke ${ }^{1}$, and Markus Werning ${ }^{2}$<br>(\{natalia.rak, jarmo.kontinen, lars.kuchinke, markus.werning\}@rub.de)<br>${ }^{1}$ Department of Psychology, Ruhr University Bochum<br>${ }^{2}$ Department of Philosophy, Ruhr University Bochum

#### Abstract

Empathy with other persons' emotions has been suggested to root in a simulation process involving brain regions that play a crucial role in the production of one's own emotions. The current ERP study combines this approach with an embodiedsimulative view of semantics. This view implies that those very brain regions should also be involved in the semantic memory and linguistic comprehension of intentional and proprioceptive emotion words. The relation between cognitive empathy measured by the MET test and the size of the N400 effect occurring when semantic emotions words violate semantic expectations is investigated.

Keywords: empathy, semantic memory, N400, P600, emulative semantics, embodied cognition, simulation theory, mirror neuron system, emotion, proprioception, multifaceted empathy test (MET)

## Introduction

The current debate about the neural realization of linguistic meaning and semantic memory can be characterized by two opposing views: According to the abstract-symbolic view, semantic memory is a modular and amodal system. Semantic representations are considered as rather stable, decontextualized mental symbols that are processed in a largely informationally encapsulated way and do not essentially recruit mechanisms from perceptual, motoric or emotional brain processes. Combining various neurolinguistic findings, Friederici (2002) e.g. argues that "semantic processes are mainly subserved by the left temporal region and that the frontal cortex is recruited when strategic and/or memory aspects come into play".
The embodied-simulative view, in contrast, assumes that the processing of linguistic meaning essentially involves perceptual, motoric and emotional brain regions corresponding to the contents of the words to be comprehended. Based on a review of neurobiological data, Pulvermüller (1999) suggests that neural assemblies that pertain to the sensory-motor cortices and are bound by neural synchronization play an important role in understanding the meanings of words and sentences. These cortical sensory-motor action and perception circuits are interdependent in language comprehension. According to Barsalou (2005) semantic representations can be regarded as simulators of sensory-motor and emotional contents. Werning (2012) has coined the notion of Emulative Semantics and proposes a compositional, but non-symbolic
recurrent neural network model that generates simulations for semantic representations.
Support for the embodied-simulative view comes from a number of neuro-linguistic studies especially in the domain of action words. Neuroimaging investigations have shown that the linguistic comprehension of verbal stimuli involve motor circuits, i.e. specific motor activations can be found when subjects understand speech sounds, word meanings, semantic categories and sentence structures (Pulvermüller \& Fadiga, 2010) involving action words or words associated with actions. FMRI studies (Pulvermüller, 2005) regarding the understanding of action verbs, e.g., hint at a differential top-down activation of motor and pre-motor areas. Martin (2007) reports that the understanding of concrete nouns like hammer, for which not only features, but also affordances are salient, results in an activity distributed over the premotor and the visual cortex. Brain areas involved in motor control contribute to neural networks in which verb representations are grounded. Studies on motor deficits such as Parkinson disease, e.g., reveal impairment of patients' action naming (Rodríguez-Ferreiro et al., 2009).

Embodied-simulative accounts of the semantics of action words have been linked to mirror neuron systems. Mirror systems have been reported in humans not only for actions (Rizzolatti et al., 1996), but also for intentional emotions (Bastiaansen et al., 2009; disgust - Wicker et al., 2003; facial expressions - Carr et al., 2003), and proprioceptive emotions (pain - Avenanti et al., 2005; touch - Blakemore et al., 2005). Mirror neuron systems map the perceptions of actions and intentional as well as proprioceptive emotions of an observed person onto the perceiver's own somatosensory, viscero-motor, or motor representations of actions and emotions. Such a mapping is supposed to enable the observer of another person's actions and emotions to feel as if he were performing that action or experiencing that emotion himself. Since mirroring mechanisms may constitute sub-personal instantiations of embodied simulations, Gallese (2003) proposes mirror neuron systems as a neuronal basis of empathy.

These findings and theoretical considerations lay the ground for the current study. If the embodied-simulative view of linguistic meaning also applies to emotion words, the processes underlying empathy with other persons' emotions should be not entirely independent of processes underlying the comprehension of emotion words.

Table 1: Stimuli

|  | CON (congruent) | INCON (incongruent,) | UNREL (unrelated) |
| :---: | :---: | :---: | :---: |
| INT (intentional emotion) | Als Adrian von seinen hohen Gewinnen an der Börse erfährt, ist er darüber sehr erfreut. <br> When Adrian hears about his high gains on the stock market, he is very happy about it. | ... besorgt. <br> concerned | ...empört. <br> indignant |
| PROP (proprioceptive emotion | Nachdem Kerstin stundenlang ohne Wasser in der Hitze umherlief, ist sie nun sehr durstig. <br> After Kerstin has been walking around without water in the heat, she is now very thirsty. | ...hungrig. <br> hungry | ...hellwach. <br> awake |
| PHYS (physical control) | Da niemand die Türen jemals geölt hatte, begannen sie nach kurzer Zeit zu quietschen. <br> Since nobody had oiled the doors, they soon began to squeak. | ...bollern. <br> thud | ...tröpfeln. drip |

Furthermore, since the capacity and inclination to empathize with other persons' emotions varies across subjects, we consider it an interesting question whether good emotional empathizers "feel" semantic violations in the context of emotion words more strongly than poor emotional empathizers. One should thus predict that this results in stronger N400 effects.

The examination of the N400 effect in the event-related potentials (ERPs) is a common approach to investigate semantic integration in sentence processing. An N400 is a is a monophasic negativity between 200 and 600 ms after word onset, largest over centro-parietal sites (Kutas \& Federmeier, 2011). When comparing semantically expected and unexpected words, observed higher amplitudes of the N400 are discussed to reflect greater demands of semantic integration of an unexpected word at the sentence or the discourse level. Thus, N400 effects are particularly observed for critical words that do not fit into a sentence's context. Recent evidence from sentence processing has shown that the integration of contextual semantic information is dependent on emotional processing (Chwilla et al., 2011; Federmeier \& Kutas, 2011; Pinheiro et al., 2013).

## Methods

## Participants

25 female students from the University of Bochum ( $\mathrm{M}=24.19, \mathrm{SD}=2.58$ ) volunteered for the experiment. They were compensated with $10 €$ per hour for their time and effort. They were recruited through local advertisements on the university campus. Only healthy, right-handed women without a history of previous head injury, psychiatric and neurological disorders were included in the study. All were German native speakers, had normal or corrected-to-normal vision and were free of medication.

## EEG study

Sentence preparation A total set of $32 \times 3 \times 3 \times 3=864$ test sentences and $3 \times 32=96$ filler sentences was generated. Each sentence consisted of two clauses conjoined by a coordinating or subordinating conjunction. The target word was always the last word of the sentence and consisted in a medium frequent bisyllabic verb, adjective or participle. The logarithmic frequency of each target word was determined
from Wortschatz Leipzig (http://wortschatz.uni-leipzig.de) as the WL index. A WL index of $n$ means that the most frequent German word "der" is $2^{\text {n }}$ times more frequent than the target word. Following a $3 x 3$ design we introduced the three content categories INT "intentional emotion", PROP "proprioceptive emotion", and PHYS "physical control" and three congruency categories CON "congruent", INCON "incongruent", and UNREL "unrelated" for the target words.
The target words of category INT semantically denoted or lexically entailed an emotional relation between an experiencer and an intentional object. A further grammatical criterion was a verb/adjective valence of at least 2 . Words of category PROP semantically denoted or lexically entailed a proprioceptive feeling of an experiencer. Grammatically, these words had either a verb/adjective valence of less than 2 or were causatives resulting in a proprioceptive feeling. Category PHYS was designed as a control with non-mental target words. The target words for each of the content categories were grouped into triplets with one word for each of the three congruency categories (32 triplets for INT, PROP and PHYS each). For each triplet three different, but contentwise similar sentential contexts of the above mentioned two-clause structure were created such that the sentences completed by the word of condition CON would describe a semantically congruent and plausible scenario. The word of condition INCON was closely semantically related to that of condition CON (being typically an antonym or contrastive word), but would make each of the three sentential contexts semantically incongruent and implausible. The word of condition UNREL was not or only distantly semantically related to that of condition CON and would make each of the three sentential contexts grossly semantically incongruent and implausible. By combination altogether 9 sentences were created from each triplet and the three contexts. This allowed us to present the sentences to the subjects in random selection and order such that each subject saw all three target words of each triplet and all three of the corresponding sentential contexts without any repetition of either the target words or the contexts. Priming effects were thus avoided.
There were no significant differences in logarithmic frequency of the target words across the 9 conditions of the

Figure 1. Cluster-based permutation test for intentional emotion words. The test compares the congruency conditions UNREL to CON in the content condition INT for all channels and each 2 ms segment ( $\alpha=0.025$ ). The resulting significant clusters are marked red a) Negative cluster corresponding to an N400 effect with onset at 396 ms and offset at 498ms ( $\mathrm{p}=0.0096$ ). b) Positive cluster corresponding to a P600 effect with onset at 610 ms and offset at $694 \mathrm{~ms}(\mathrm{p}=0.0048)$.
$3 x 3$ design ( $\mathrm{M}=13.49, \mathrm{SD}=2.26$ ). The word classes were balanced between verbs, adjectives, and participles. The reason for the filler sentences was to balance semantically congruent (CON and Fillers) and incongruent (INCON and UNREL) scenarios. Each subject saw 288 test sentences and 96 filler sentences, i.e. altogether 384 sentences. See Tab. 1. Sentence Task Subjects viewed whole sentences, presented in Presentation software (Neurobehavioral Systems Inc., Albany, CA, USA) on the screen in front of them, in small chunks of words at a time for 500 ms each. The sentence started after the presentation of a centered fixation cross that stayed on the screen for 1000 ms . The words were presented in black letters on a grey background in the center of the screen. There was an inter-stimulus interval between the chunks of 50 ms , which showed a blank screen only. The last word was always the target word and determined the onset of the N400 measure epoch. After 33\% of the sentences, a question mark appeared 2000 ms after the offset of the target word which required the subject to press a button ("yes" or "no") for whether they considered the sentence to be sensible or not. The filler sentences mentioned above were necessary to enable an approximately equal number of button presses. The question mark was followed by a 2000ms blank screen until the next sentence started. The main purpose of the question served to keep participants engaged and alert during passive viewing.

## Background Measures

Multifaceted empathy test (MET) As a measure of empathy, the MET depicts 40 different photographs of various people in emotionally charged situations, with a varying degree of expression on their faces (Dziobek, 2008). In the computer task, each picture is presented three times with three different questions. Cognitive empathy is assessed by the question "How does the person feel?". By
pressing a number from one to four, the subject has to choose one of four possible emotional states, only one of which is defined as correct. The maximum score is 40 points. Two kinds of affective empathy are measured. Explicit empathy is assessed by the question "How much do you compassionate with this person?" and implicit empathy is compiled by the question "How strongly aroused are you by the picture". In both conditions, subjects are asked to rate their emotional engaging on a nine-point scale ranging from 1 (not at all) to 9 (very much). The implicit empathy measure reduces the subject's tendency to answer socially desirable. The maximum scores for both affective empathy measures are 9 points each.

## Procedure

Participants were seated comfortably in a chair, at a distance of 75 cm from the screen in a sound-proof and electrically shielded room with ambient lighting. Upon arrival, they signed informed consent, completed the Edinburgh handedness test and the eating disorders subtests of the DIPS (Diagnostisches Interview bei psychischen Störungen, reported elsewhere). Electrodes were applied to the scalp. After receiving task instructions, a short practice task of five training trials was introduced to ascertain comprehension of the task requirements. A total of 384 sentences, presented in a randomized order and split up into three equal presentation blocks, were presented on the screen. A keyboard with two response buttons was positioned in front of the subjects on the table. In between the blocks, participants had resting periods of at least 5 minutes in order to recover from fatigue and concentration loss. The total duration of the experimental task was 1 hour. By the end of the recording procedure, subjects completed the multifaceted empathy test (MET) offline.

## Electroencephalography Recording and Data Analysis

 The analysis is based on 30 active electrode channels that recorded an electroencephalogram (EEG) from the subjects' scalp surface with a BrainAmp acticap EEG recording system (BrainAmps amplifier, München) according to the international 10-20 system. Four additional electrodes measured participants' electrooculogramm (EOG) for both vertical and horizontal eye movements for later removal of eye movement artifacts. The reference electrode was placed in the position of the FCz and AFz served as ground

Figure 2. Grand average ERP waveforms for the electrode Cz. The two congruency conditions UNREL and CON are compared. The dotted lines mark the onsets and offsets of the N400 and, respectively, the P600 effects according to the cluster based permutation test. a) Intentional emotion words (INT). Cluster significance: $p(N 400)=0.0096$, $p(P 600)=0.0048$. b) Proprioceptive emotion words (PROP). Cluster significance: $p(N 400)=0.0004, p(P 600)=0.0325$. c) Physical controls (PHYS). Cluster significance: p(N400)= $0.0016, \mathrm{p}(\mathrm{P} 600)=0.0072$.
electrode. The sampling rate was 500 Hz and impedance was lowered to below $5 \mathrm{k} \Omega$. The EEG data were analyzed using BrainVision Analyzer 2.0 (BrainVision, München). After recording with a $0.5305-70 \mathrm{~Hz}$ online filter, the data were filtered off-line through a $0.5305-30 \mathrm{~Hz}$ bandpass zero phase Butterworth filter. Afterwards eye-blink artifacts were removed by an independent component analysis (ICA) which was performed for each subject. The reference electrode was offline re-referenced retrospectively to the linked mastoids comprising TP9 and TP10. An automatic artifact rejection removed all trials with amplitudes above $90 \mu \mathrm{~V}$ and below $-90 \mu \mathrm{~V}$. Segments from 200 ms pre-target onset until 1000 ms post-onset were separately extracted and averaged for every subject and for each of the $3 x 3$ conditions $\{I N T, ~ P R O P, ~ P H Y S\} \times\{C O N, ~ I N C O N$, UNREL\}.

## Results

## Onset and offset of N400 and P600

In order to determine the onset and offset of N400 and P600 effects, we compared the ERPs in the congruent condition against the ERPs in the unrelated condition for all three content conditions. The onset and the offset of the N400 and P600 were determined by a resampling procedure, the cluster-based permutation test: The averaged ERPs for each subject in the CON and UNREL condition were collected in a single set, which was then randomly partitioned into two equally sized subsets. The data-points (time x channel) were compared between the partitioned sets by a dependent $t$-test. The significantly different $-\alpha=0.025$ (The significance level of 0.05 was Bonferroni corrected by a factor 2 since both negative and positive clusters were of interest) - data points were then clustered according to temporal-spatial adjacency. The cluster-level statistics was calculated by taking the sum over the t-values for each cluster. This procedure was repeated 10,000 times. The p-values of the observed clusterlevel statistics were estimated as the proportion of partitions that resulted in a higher cluster-level statistics than the observed one (Maris \& Oostenveld, 2007).
The resampling procedure revealed the positive and negative clusters, i.e. collections of time-channel points where the measured amplitude in the UNREL condition was significantly higher (resp. lower) than in the CON condition. The onset of the cluster was taken to be the first time point contained in the cluster, whereas the offset was taken as the last time point in the cluster. The results of the cluster-based permutation test for condition INT is shown in Fig.1. Fig. 2 displays the grand averages on electrode Cz for all three content conditions with onsets, offsets and p-values for the N400 and P600 clusters determined by the clusterbased permutation test. Fig. 3 and Fig. 4 show the topographical distribution of the N400 and P600 effects.

## MET scores and N400

We were interested whether subjects' MET scores correlate with the effect-sizes of the N400 effects. To gain insight on

Figure 3. Topography of the $\mathbf{N 4 0 0}$ effects. The topographical mapping shows the difference between the congruency conditions UNREL and CON for the three content conditions averaged between onset and offset of the N400 effect according to the cluster-based permutation test. In all three content conditions the N400 effect has a centro-parietal extension.

Figure 4. Topography of the P600 effects. The topographical mapping shows the difference between the congruency conditions UNREL and CON for the three content conditions averaged between onset and offset of the P600 effect according to the cluster-based permutation test. a) For intentional emotion words (INT) the P600 effect has a medialfrontal focus. b) For proprioceptive emotion words (PROP) the P600 effect has a centro-parietal focus. c) In the physical control condition, the P600 effect has a centro-parietal focus with a right hemispheric dominance.

Figure 5. Comparing the N400 effect for intentional emotion words on the median split between HIGH and LOW cognitive empathizers. a) The difference between the congruency conditions UNREL and CON for intentional emotion words for the HIGH and LOW cognitive empathy group averaged over electrodes in the significant cluster. b) Topographical mapping of the differences between the HIGH and the LOW group (HIGH - LOW) for the N400 effect on the time interval determined by the cluster-based permutation test. The effect difference between HIGH and LOW cognitive empathizers peaks in the fronto-central region.
this matter, we did a median split of the tested group of subjects with respect to the three MET-scores: The subjects were split into HIGH ( $\mathrm{N}=12$ ) and LOW ( $\mathrm{N}=13$ ). We conducted a cluster-based permutation test to find out the significant differences between the HIGH cognitive empathy and the LOW cognitive empathy group in the time window of the main N400 effect for condition INT (396498ms).
The cluster-based permutation test confirmed that the HIGH cognitive empathy group has a significantly ( $\alpha=0.05$, $\mathrm{p}=0.0286$ ) stronger N 400 -effect than the LOW cognitive empathy group in the time interval $462-498 \mathrm{~ms}$ for condition INT, see Fig. 5 Due to space limitation the significant findings regarding proprioceptive emotion words are not discussed here.

## Discussion

As argued above, the embodied-simulative view of meaning predicts that subjects who have a higher capacity to empathize with the emotions of other persons should be more sensitive also to semantic violations that occur when an emotion word is embedded in an incongruent or even unrelated sentence context. This stronger sensitivity should correlate with a stronger N400 effect, which is a widely acknowledged measure for the violation of semantic expectations. As our study revealed, subjects with a high MET score for cognitive empathy with emotions, indeed, show a significantly stronger N400 effect when an intentional emotion word is embedded in a semantically unrelated sentence context than those with a low score. This difference is strongest in fronto-central regions of the brain.

Aside from these results interesting localization differences in the P600 effects were found between intentional and proprioceptive emotion words and the physical control condition while only marginal localization differences occurred for the N400 effects. Due to space limits a discussion of those will be deferred.

# The myth of cognitive decline 

Michael Ramscar, Peter Hendrix \& Harald Baayen<br>Seminar für Sprachwissenschaft, Wilhelmstraße 19<br>Universität Tübingen, Tübingen, Germany

#### Abstract

Across a range of psychometric tests, reaction times slow as adult age increases. These changes have been widely taken to show that cognitive-processing capacities decline across the lifespan. Contrary to this, we suggest that slower responses are not a sign of processing deficits, but instead reflect a growing search problem, which escalates as learning increases the amount of information in memory. A series of computational simulations show how age-related slowing emerges naturally in learning models, as a result of the statistical properties of human experience and the increased information-processing load that a lifetime of learning inevitably brings. Once the cost of processing this extra information is controlled for, findings taken to indicate declines in cognitive capacity support little more than the unsurprising idea that choosing between or recalling items becomes more difficult as their numbers increase. We review the implications of this for scientific and cultural understanding of aging.

## The Age of Tithonus

More and more people live longer and longer lives. Outside of 18 countries the UN describes as 'outliers' (Watkins et al, 2005), increased life expectancy and declining birth rates are raising median ages in populations across the globe. By 2030, 72 million Americans will be aged 65 or older, a twofold increase from 2000. The world's population is more aged than ever before in history, and its rate of aging is increasing.

People are clearly living longer; it is less clear that this is a blessing. In Greek mythology, Tithonus was the mortal lover of Eos, goddess of the dawn. While asking Zeus to make Tithonus immortal, Eos forgot to mention "eternal youth," dooming Tithonus to an eternity of decrepit babbling. The psychological and brain-sciences endorse the Tithonean view of aging, portraying adulthood as an extended period of mental decline: memories dim; thoughts slow; problem-solving abilities diminish (Naveh-Benjamin \& Old, 2008; Deary et al, 2009); and each year, the onset of cognitive decrepitude is set ever younger (Salthouse, 2009; Singh-Manoux et al., 2012). One crumb of comfort is that older adults are, on average, happier (Charles \& Carstensen, 2010), although in the circumstances, this might be taken as further evidence of their declining mental prowess.

In what follows, we show how the slowing response speeds that are taken as evidence of "cognitive decline" in adults emerge naturally in learning models (Baayen et al, 2011) as knowledge increases. These models, which are supported by a wealth of psychological (Ramscar et al, 2010) and neuroscientific (Schultz, 2006) evidence,
correctly identify greater variation in the cognitive performance of older adults, successfully predicting that older adults will show more sensitivity to fine-grained differences in test items than younger adults. The models run (and can be rerun) on computers, eliminating the possibility that aging hardware influences their performance, which instead reflects the informationprocessing costs incurred as knowledge increases. Once the demands of processing this extra information are taken into account, it becomes clear that much of the evidence for agerelated declines in cognitive capacity better supports the idea that information processing costs rise as the amount of information in a system increases.

## The problem with "processing speed"

Findings from a range of psychometric tests suggest that the rates at which the mind processes information increase from infancy to young adulthood, and decline steadily thereafter (Salthouse, 2011). Increasing reaction times are a primary marker for age-related cognitive decline (Deary et al, 2010), and are even considered its cause (Salthouse, 1996), yet they are puzzling. Practice improves speed and performance on individual cognitive tasks at all ages (Dew \& Giovanello, 2011). Since we get more practice using our cognitive capacities as we age, why does our performance on tests of them decline?

The answer lies in the way that psychometric tests neglect learning, and its relationship to the statistical patterns characteristic of human life. Learning is a discriminative process that serves to locally reduce the information processing costs associated with various aspects of knowledge and skill (Rescorla \& Wagner, 1972). However, age increases the range of knowledge and skills individuals possess, which increases the overall amount of information processed in their cognitive systems. This extra processing has a cost.

## Learning and the long tail of linguistic experience

Statistically, the distribution of human experience is highly skewed: Much of our day-to-day life is fairly repetitive, involving a small repertoire of common occurrences, such as reading the newspaper and going to work. At the same time, we experience a far more diverse repertoire of infrequent or even unique occurrences (we rarely read the exact same newspaper twice). When data is distributed like this, comparisons of means are often meaningless. Consider the problem of remembering birthdays: We are reminded of the birthdays of family members on an annual basis, and this usually makes us expert at remembering them. However, as we move through
life, we also learn about other birthdays. Sometimes we hear these dates only once, such as when we attend a party for someone we barely know. As each new birthday is learned, our mean exposure to all the birthdays we know will decline, and the task of recalling a particular birthday will become more complex. Recalling six hundred birthdays with $95 \%$ accuracy need not imply a worse memory than recalling six with $99 \%$ accuracy.

Standard psychometric tests do not take account of the statistical skew of human experience, or the way knowledge increases with experience. As a result, when used to compare age groups, they paint a misleading picture of mental development. This can be demonstrated most clearly in relation to language. Language is a central aspect of cognition, its statistics are more readily quantified than other aspects of human experience, and all psychometric tests involve some linguistic information processing.

Figure 1. The frequencies of the 1000 most common words in the Corpus of Contemporary American English plotted by rank.

Importantly, linguistic distributions are skewed at every level of description (Baayen, 2001). Consider the relationship between word types (e.g., dog) and tokens (how often "dog" occurs; Figure 1). In any large sample of English, a few words occur very frequently (the, and), such that half of a typical sample comprises tokens of only 100 or so high-frequency types. The relative frequency of these types decreases rapidly (the most-frequent word may be twice as frequent as the second-most), while frequency differences between types decrease as their relative frequency declines. This means that the other half of a typical sample is composed of ever-fewer tokens of a very large number of types, with ever-smaller frequency differences between them. Typically, around half of these types occur just once.

This is a very long-tailed distribution: $49 \%$ of the 425 million tokens in the Corpus of Contemporary American English (COCA; Davies, 2009) come from the 100 mostfrequent word types; the remaining $51 \%$ of tokens represent over 2.8 million word types. Although individual lowfrequency types are, by definition, rare, their distribution makes the chances of encountering a low-frequency token in any given sentence extremely high (Möbius, 2003). This distribution ensures that any English speaker learns only a
fraction of its total vocabulary, and that vocabularies grow steadily across the lifespan. However, the tests used to measure cognitive decline assume that vocabulary size is age-invariant in adults (Spearman, 1927; Carroll, 1993; Bowles \& Salthouse, 2008), an assumption seemingly confirmed by psychometric vocabulary measures, which suggest that vocabulary growth in adulthood is marginal (such that slight increases are only reliably detected in metaanalyses; Verhaeghen, 2003).

Psychometric vocabulary measures are virtually guaranteed to register these results, because they attempt to extrapolate vocabulary size from sets of test words. These tests, which are "normed" on the knowledge of schoolchildren, are heavily biased towards frequent wordtypes (Raven, 1965; Heim, 1970; Wechsler, 1997). Unfortunately, while extrapolation is feasible for frequent words, for the millions of low-frequency word-types, knowledge of one randomly sampled word does not predict knowledge of another. Since the distribution of types ensures that adult vocabularies overwhelmingly (and increasingly) comprise low-frequency words, it follows that reliably extrapolating their size or growth from a small test sample is mathematically impossible (Baayen, 2001).

## Simulating the effects of vocabulary learning on information processing

Most infants are sensitive to all the fine-grained phonetic discriminations made by the world's languages. As they learn a native vocabulary, this sensitivity to non-native phonetic distinctions diminishes (Werker \& Tees, 1984). Rather than indicating that cognitive decline begins in infancy, this loss in sensitivity can be seen as an inevitable result of learning. In discriminative learning models, the values of initially undifferentiated sets of cues are shaped by experience, which drives the discovery of cue values that best predict a learning environment (Rescorla, 1988). Because this process involves learning to ignore uninformative cues, it can explain why decreasing sensitivity to uninformative phonetic information goes hand in hand with increasing knowledge about informative phonetic distinctions (Ramscar et al, 2010).

The learning component of the model we use to simulate the effects of experience on reading works in precisely this way. It is an extension of the Naive Discriminative Reader (NDR; Baayen et al, 2011), a two-layer network in which letter unigrams and bigrams serve as input cues, and lexical items serve as outcomes. The values of these cues are initially undifferentiated, and are set competitively as the model learns to predict words from the letters it 'reads.' In the NDR, every predictive cue is linked to each lexical outcome to form a set of subnets. The cue-weights in these subnets are set by the equilibrium equations of the RescorlaWagner learning rule (Danks, 2003), and are completely determined by the distributional properties of the model's training corpus. Simulated latencies derived from these weights accurately capture a wide variety of empirical effects in reading (Baayen et al, 2011).

To model the influence of experience on different populations, the NDR was modified to make it sensitive to the physical and informational consequences of knowledge growth. Given that the amount of activation a given cue receives from the perceptual system remains constant over time (Attwell \& Laughlin, 2001), this modification keeps the total amount of activation spreading from cues to outcomes equal to the amount of activation arriving at them. Analogous to the principle of conservation of electric charge, this means that as vocabulary increases, and each cue becomes connected to an increasing number of outcomes, the amount of activation arriving at any given outcome decreases. Given a vocabulary of size $V$, the network support for any item $i$ is proportional to $a_{i} / V$ where $a_{i}$ is the activation an item receives from the cues in the input.

This modification also accounts for the effects that an increased number of outputs have on information processing in neural systems (Hentchel \& Barlow, 1991; supplementary materials). Shannon's source coding theorem shows that the smallest coding scheme for $V$ words requires, on average, $H(V)$ bits. Since $V$ determines the length of a message in a given code, the effective channel capacity $C$ of an ensemble of neurons decreases as code complexity increases and the amount of redundancy in signals across the network decreases (Hentchel \& Barlow, 1991). We denote these information costs by $f(V)$, where $f$ is an unknown nondecreasing function expressing the coding and signaling costs in a vocabulary of size $V$.

The response latency (RT) associated with reading (operationalized as reaction times to speeded judgments on written words) is modeled as a weighted sum of these components:

$$
R T_{i}=w_{1} V / a_{i}+w_{2} f(V)+c
$$

with $c$ a constant denoting the time required for response execution.

To simulate the effects of vocabulary-growth on adult reading, two NDR networks were trained on data drawn from the Google Trigrams Corpus (a large, naturalistic data set). The first network 'read' 500,000 word-trigram tokens, simulating reading to age 21, the typical age for "young adult" participants in studies; the second 'read' $3,000,000$ word-trigram tokens, ${ }^{3}$ simulating reading to age 70 (the typical age for "old adults"). Consistent with our analysis of the way linguistic distributions influence vocabulary growth, the old model acquired a much larger vocabulary: 32,536 word types, compared to the young model's 21,307 (Figure 2). These growth estimates are very conservative: the Trigram Corpus excludes trigrams with less than 40 occurrences, thereby omitting around $50 \%$ of the word types in the complete Google Corpus. Even with this constrained input, vocabulary expansion was far from asymptote, even after 5 million trigram tokens.

To examine the models' ability to simulate age-related reading differences, we compared their projected reading times for 2,904 English words to empirical latencies from older (mean age 73.6) and younger (21.1) readers for the
same items (Balota et al, 1999). The empirical data exhibit the expected effect of age: mean reaction times are 163 ms shorter for younger than older adults. Simulated reaction times mirror this difference, with an average difference of 167 ms .

Figure 2. Empirically observed vocabulary growth after sampling from the Google Trigrams Corpus.

Figure 3. Left panel: fit of a generalized additive model to the simulated response latencies from the old and young models. Right panel: fit of a generalized additive model to the empirical response latencies from young (mean age: 21.1) and old (73.6) adults (Balota et al, 1999).

The models also correctly predict an important qualitative difference in the empirical word-frequency effect. It is well established that lexical decision responses are slower for lower- (e.g., "whelp") than higher-frequency words ("where"). This overall effect of frequency is present for both young and old adults (Figure 3; right panel). However, while frequency effects asymptote at higher frequencies in both models, they only level off at the lowest frequencies in the younger model, a pattern that is also observed in the empirical data: older adults are far better attuned to frequency variations in the lower range of the test-set than younger adults.

These results can be explained by considering the way the models learn in more detail. In learning, weights on the links between the cues and outcomes are adjusted in two ways: They are strengthened whenever a cue and outcome co-occur; For example, the link between the bigram WH and the lexical target WHERE is strengthened when "where" is encountered in reading, and the link between WH and WHELP is strengthened when the "whelp" is encountered. Conversely, links are weakened when cues occur but outcomes do not.

| 1 | BLASH | 11 | CROME | 21 | TWERP | 31 | WHELP | 41 | BLEAT |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| 2 | SCHNOOK | 12 | GIBE | 22 | THWACK | 32 | SHUCK | 42 | CHIVE |
| 3 | LETCH | 13 | LISLE | 23 | DAUNT | 33 | MOOCH | 43 | WHIR |
| 4 | ZOUNDS | 14 | FLAYS | 24 | RETCH | 34 | JELL | 44 | CROON |
| 5 | JAPE | 15 | SPLOTCH | 25 | GYP | 35 | GROUCH | 45 | TAMP |
| 6 | SOUSE | 16 | VELDT | 26 | YAWL | 36 | AWN | 46 | BOSH |
| 7 | WHIG | 17 | SLOE | 27 | FLUB | 37 | MANSE | 47 | RILE |
| 8 | FILCH | 18 | CONK | 28 | STANCH | 38 | WRACK | 48 | BLANCH |
| 9 | RHEUM | 19 | FRAPPE | 29 | PAUNCH | 39 | HOOCH | 49 | LILT |
| 10 | PARCH | 20 | SKULK | 30 | JOWL | 40 | FLECK | 50 | JEER |

Table 1. The 50 lowest frequency items in the set used to test the models and the older and young adults; BLASH has the lowest frequency of these items, and JEER the highest. As can be seen, many of the letter bigrams in this set of words are comparatively rare in English.

Thus when "where" is encountered, WH occurs without WHELP, weakening the link between WH and WHELP. The distribution of high-frequency words results in their being encountered frequently, at a fairly constant rate over time. This will consistently reinforce the link between WH and WHERE, and consistently weaken the link between WH

In contrast, low-frequency words occur sporadically, so the link between WH and WHELP is reinforced far less (and the link between WH and WHERE weakened less). These imbalances result in "selection pressures" on word types that are reflected in the distribution of orthographic (and phonetic) cues across lexical items (see Zipf, 1949): high-frequency test items are both shorter $(\mathrm{t}(2901)=-10.58$, $\mathrm{p}<0.001$ ) and have higher mean bigram frequencies $(\mathrm{t}(2901)=8.98, \mathrm{p}<0.001)$ than low-frequency items. This means that, on average, low-frequency words contain both more cues, and more rare cues (Table 1). Although rare cues have relatively high values in small vocabularies, they are vulnerable to competition as vocabularies grow: newer vocabulary items also have low frequencies, and are more likely to contain the same rare cues.

All the predicted empirical effects were replicated in an analysis of a second, independent dataset (Figure 4).

Figure 4. Average percentile RT differences (old - young) for the naming latencies of 2,820 Single Syllable words (Yap et al, 2011) by young (mean age: 22.6) and old adults (73.6), plotted against the words' log frequency in the Google 1 -gram corpus, and a generalized additive model fit to the RT differences. As can be seen, the difference between older and younger readers' RTs increases as word frequency decreases.

## Modeling 'decline' in a non-lexical task

To examine whether the relationship between information load and response time also holds for "non-lexical" tests, we considered the letter classification task (Posner \& Mitchell, 1967), a standard non-lexical psychometric test in which two letters are presented in upper or lowercase (A, a, D, d, $\mathrm{E}, \mathrm{e}, \mathrm{R}, \mathrm{r}, \mathrm{H}, \mathrm{h}$ ) and participants judge whether they are alphabetically the same or different. Older subjects are typically slower than younger subjects in this task, a finding that is straightforwardly replicated in the NDR models once the coupling between letters and abbreviated meanings is accounted for (e.g, $H$ for entropy, $R$ for a statistical programming environment, $r$ for correlation, etc.). The network complexity function $f(V)$ in (1), which models response latencies as a function of the activation of the meanings of both letters in a letter pair, predicts longer latencies for older subjects as compared to younger subjects. In short, because the older model has a larger system of outcomes, it has more information to process, making "accessing" a letter harder, and reaction times concomitantly slower (see also Ramscar et al, 2010).

Psychometrically, letter classification is often described as an "information-processing" measure, and older adults' longer response times are taken as evidence of declining information-processing capacity. Yet information theorywhich defines the workings of information-processing system-is, at heart, a set of methods for formalizing the uncertainty in distributions (be they bits of code, or vocabulary items; Shannon, 1948). Information is a property of systems, and processing demands are measured in relation to them (MacKay, 2003). In letter classification, the system comprises the task, a participant, and, crucially, what that participant knows. Because psychometric tests neglect this knowledge, they are formally incapable of measuring information-processing in this task.

## Lexical knowledge and paired-associate learning

Wherever vocabulary size increases with experience, this increased knowledge predicts increasing processing costs and slower responses in psychometric tasks. As a consequence, slower latencies reflect learning, not "decline." Interestingly, this interaction between experience, vocabulary-size and response speed can also be seen in comparisons of monolingual and bilingual picture-
naming (Gollan et al, 2008): the response latencies of young-bilinguals more closely resemble older-monolinguals than younger-monolinguals or older-bilinguals. Notably, slower response times and increased tip-of-the-tongue rates are not taken as evidence of cognitive decline when observed in young-bilinguals (Gollan \& Acenas, 2004), but are instead seen to reflect the demands of processing the larger vocabularies that bilinguals inevitably learn.

The finding that bilinguals experience increased tip-of-the-tongue rates raises a question: could the same systemic effects of learning that account for increased lexical processing latencies explain age-related change in memory measures, such as Paired-Associate Learning (PAL; a psychometric measure of people's ability to learn and recall new information)? In PAL, e.g., the subtest of Wechsler's Memory Scale (WMS; desRosiers \& Ivison, 1988) participants have to learn more or less arbitrary pairings between word cues (e.g., baby; jury) and responses (cries; eagle). Although item-level performance is highly variable (Figure 5), older adults' overall PAL performance is slower and less accurate, and it has been suggested that aging causes encoding (Gilbert, 1941; MacKay \& Burke, 1990) and retrieval processing deficits (Burke \& Light, 1981).

Figure 5. Mean performance by item for 100 older (age 60-69) and 100 younger ( $20-29$ ) adults on forms 1 and 2 of the WMSPAL subtest (desRosiers \& Ivison, 1988). As in the lexical decision and naming data, the relationship between old and young PAL performance is nonlinear: again, older adults exhibit a more marked ability to discriminate between 'harder' (unrelated) and 'easier' (related) items than younger adults.

There is, however, no reason to think PAL performance should be age-invariant. Long-established principles of associative learning predict that well-known items should be harder to learn as Cues $\left(w_{I}\right)$ than newer items (Rescorla \& Wagner, 1972). Likewise, newer Response ( $w_{2}$ ) items should support better learning than well-known, predictable items (Kamin, 1969): $w_{1}-w_{2}$ pairs ought to become harder to learn when $w_{1}$ and $w_{2}$ occur independently at high rates (Rescorla, 1968; compare jury-eagle to baby-cries).

To examine whether age-related PAL differences simply reflect learning, we analyzed the relationship between the age-related variance in the performance of a large sample adults on the WMS-PAL subtest (desRosiers \& Ivison, 1988), and the factors that determine $w_{1}-w_{2}$ learnability. In a
regression analysis of item score differences (mean young mean old), $\underline{w}_{\underline{l}}$ predictability ( $\log$ frequency; $\mathrm{t}=-4.063$, $\mathrm{p}<0.001$ ), the relationship between $w_{2}$ and $w_{l}$ predictability ( $\log \left(w_{2}\right.$ frequency $) / \log \left(w_{l}\right.$ frequency $\left.) ; \mathfrak{t}=-2.935, \mathrm{p}<0.01\right)$ and actual $w_{l}-w_{2}$ co-occurrence rates (log Google frequency; $\mathrm{t}=6.773, \mathrm{p}<0.0001$ ) accounted for more than $75 \%$ of the variance in item performance between 20-29 and $60-69$ year-olds ( $\mathrm{F}(3)=16.432, \mathrm{r}=.87, \mathrm{p}<0.0001$ ).

All things being equal, the relative learnabilty of $w_{1}-w_{2}$ pairs can be estimated from $w_{l}-w_{2}$ co-occurrence and background rates. All things are not equal, however: Older adults have more experience, and learnability is a matter of experience. Accordingly, $w_{2}$ words will become more predictable the more they occur independently of $w_{1}$, and $w_{1}$ words will become less informative the more they occur independently of $w_{2}$; in each case, experience will make $w_{l^{-}}$ $w_{2}$ learning harder. A natural, predictable consequence of this is that PAL performance should increasingly reflect the distributional properties of the $w_{l}-w_{2}$ items as experience grows: if co-occurrence rates are low, a lifetime of learning that jury is uninformative about eagle should make learning jury-eagle harder; whereas high co-occurrence rates will reduce background rate effects, making baby-cries easier for older adults to learn relative to jury-eagle.

Figure 6. Mixed-effects slope estimates for the three learnability predictors and mean item performance of old (60-69) and young (20-29) adults in the WMS-PAL subtest (desRosiers \& Ivison, 1988). All predictor effects and interactions in the model are significant (see supplementary materials), and all slopes (except *) are significantly different from $0(t=>2)$. Older adults are more sensitive to background rate information (negative slopes) than young adults and, as the magnitude of the slopes shows, the overall performance of older adults reflects a far more systematic understanding of the English language.

A mixed-effects analysis of $w_{1}-w_{2}$ item scores by age confirmed the accuracy of this prediction (Figure 6). For each predictor, the magnitude of the slope for the older age group is greater than that for the younger age group, indicating that older subjects bring more lexical experience to the task. Consistent with our earlier findings, older adults' PAL performance reflects their greater knowledge of (and sensitivity to) the distributional properties of $w_{1}-w_{2}$ words, whereas younger adults' less varied performance reflects their more limited knowledge of them. As we noted above, the statistical properties of human experience makes comparing means invidious: in this case, it seems that high
mean PAL performance is a measure of ignorance, not "intelligence."

## Learning and Cognitive Maturation

These results suggest that older and younger adults' performance in psychometric testing largely reflects the same cognitive mechanisms, confronted with the task of processing different quantities of information. The performance of older adults on these tests is evidence of increased knowledge, not declining processing capacity.

When discussing these conclusions with colleagues, a question often arises: "Learning seems to predict linear patterns of change, but cognitive decline seems to kick in around age 60 or 70: how do you explain this?" To explain why, we first note that as people age, they encode less contextual information in memory (Naveh-Benjamin \& Old, 2008). Although this has been taken as evidence that the processes that "bind" contextual information in memory decline with age, learning theory predicts that experience will increasingly make people insensitive to context, because ignoring less informative cues is integral to learning.

Learning is also sensitive to the environment, and its predictions change with it: If a common environmental change-e.g., retirement-was to systematically reduce the variety of contexts people typically encounter in their lives, learning theory predicts that the amount of contextual information they learn will also drop, as the background rates of cues in remaining contexts rise. If these same people were to increasingly spend their time in environments where cues already have very high background rates (e.g., family homes), this effect will be exacerbated. In other words, because learning inevitably reduces sensitivity to everyday context, retirement is likely to make memories harder to individuate and more confusable, absent any change in cognitive processing, simply because it is likely to decrease contextual variety at exactly the time when, as a result of learning and experience, the organization of older adult's memories needs it most.

Learning can explain both the apparent changes in older adults "cognitive performance" around retirement-age, and the fact that these changes are not detected in testing. Similarly, the neglect of learning in the study of cognitive aging makes it highly likely that, like Tithonus, many of our beliefs about cognitive decline are myths. This does not mean that the diseases that can undermine cognition in old age are also mythical: However our understanding of these diseases can only be increased by a better understanding lifelong learning, and its sensitivity to the environment.

#### Abstract

Music is a pervasive phenomenon in human culture, and musical rhythm is virtually present in all musical traditions. Research on the evolution and cognitive underpinnings of rhythm can benefit from a number of approaches. We outline key concepts and definitions, allowing fine-grained analysis of rhythmic cognition in experimental studies. We advocate comparative animal research as a useful approach to answer questions about human music cognition and review experimental evidence from different species. Finally, we suggest future directions for research on the cognitive basis of rhythm. Apart from research in semi-natural setups, possibly allowed by "drum set for chimpanzees" prototypes presented here for the first time, mathematical modeling and systematic use of circular statistics may allow promising advances.

Keywords: The evolution of music; primate cognition; animal-machine interaction; chimpanzee drum set; vocal learning; rhythm; entrainment; beat; synchronization; social cognition; comparative cognition.

## Introduction

## Evolution of Music and Origins of Rhythm

Music as a cognitive system is one of the most prominent and distinctive human features. Since Darwin, the putative role of selection in the emergence of human music has been a topic of great debate. Numerous hypotheses, which attribute an adaptive value to music, have been proposed, all featuring some social component. While hypotheses on music origins are difficult to test directly, the comparative method in cognitive biology enables us to investigate the purported human uniqueness of particular musical abilities (Fitch, 2006). In this paper we focus on one aspect of music cognition, namely rhythm, and propose new perspectives and technologies for investigating its evolution.

## Rhythm and Cognition

Rhythm, characterized as a structured pattern of temporal change, plays a central role in music. Beats, defined as points in time occurring in a perceptually periodic way (Patel, 2008), are a basic element of musical rhythm. Grouping and meter are subsystems of musical rhythmic organization and are considered the basic structural components of rhythmic patterns (Lerdahl \& Jackendoff, 1983). Grouping refers to the organization of the musical stream into motives, phrases, and sections. Meter corresponds to a regular pattern of strong and weak beats. In metrical structures, beats are organized hierarchically according to their relative strength. Moreover, the impression of the speed of the performed pattern, the tempo,
influences the interpretation and perception of rhythmic structures. According to the tempo, humans may assign different organizations to grouping and metrical hierarchy. Hence, the cognition of musical rhythm should not be investigated solely holistically, but also in terms of beat, grouping, meter, and tempo. These, together, yield the flexibility of human rhythmic cognition: humans are able to extract structural properties from music and interpret them in multiple contexts. What are the basic capacities allowing this cognitive flexibility?

The metrical hierarchy mentioned above contains a particular hierarchical level called tactus, which listeners perceive as 'the (primary) beat' (Lerdahl \& Jackendoff, 1983), whose perception is robust to moderate tempo fluctuations (Patel, 2008). It seems that our internal processes underlying rhythm perception can be spontaneously synchronized, entrained, to external regular, periodic sensory cues (Grahn, 2012). In this entrainment model, the relative timing of events is processed by expecting their periods or phase and adjusting the expectations to actual occurrences (Grahn, 2012). This flexible beat processing mechanism is also the basis for synchronizing motor actions to musical stimuli, requiring (i) beat extraction, (ii) synchronization of an internal motor pulse to the inferred auditory beat (beat entrainment), and (iii) a motor pattern generation on the basis of the internal pulse (Fitch, 2012). A fundamental requirement of synchronization is hence the capacity to extract the beat, already present in newborns and infants, though not conclusively innate because of possible prenatal learning (Grahn, 2012). The capacity for beat perception and synchronization could be shared with other animals as an analogous or homologous evolutionary trait. In order to understand the nature and evolution of human cognitive capabilities for rhythm, different species must be tested on tasks requiring the three aforementioned skills.

## Rhythm and Beat Evidence in Non-human Animals

## Vocal Learning and Dissociation Hypotheses

Some non-human animal species have a particularly good control over their vocal tract. Among these, humans, elephants, many bird species and some marine mammals are capable of spontaneously imitating sounds which may or may not belong to their natural communication system. A promising hypothesis has been put forward connecting vocal learning and beat-based rhythmic abilities across species (Patel,

Figure 1: Phylogenetic tree of species showing: vocal learnering skills (underlined), ability to synchronize to a beat (bold) and spontaneous drumming behavior (italics). Notice how, while showing no evidence of vocal mimicry, California sea lions are capable of synchronization, and some apes exhibit natural percussive behavior.
2008): as both sorts of tasks are better performed with a tight connection between motor and auditory brain areas, which is found in some vocal learning species including humans, the skill of vocal mimicry would be a necessary prerequisite for beat perception and synchronization. Considerable experimental evidence supports this hypothesis.

As humans seem to be the only advanced vocal learners among primates, a key question is whether the ability to perceive, produce and entrain to musical rhythm is unique to humans among primates. Recent evidence (Honing et al., 2012) suggests that rhesus macaques (Macaca mulatta) can detect rhythmic grouping but not the downbeat in music. The authors formulate an "auditory timing dissociation hypothesis": Some cognitive skills allowing grouping are expected to exist in several primates due to common ancestry, while some others related to beat induction should be present in humans and other vocal learners due to convergent evolution. In fact, a generalized failure to produce beat-based rhythmic patterns in non-human primates would support the hypothesis of convergent evolution of vocal learning and beat perception and synchronization abilities.

Evidence from Vocal Learners Schachner et al. (2009) searched videos of putative animal entrainment to music using the global database YouTube. 1019 videos of non-human animals, half of which involved vocal mimicking species, were analyzed both for frequency and phase synchronization. Strikingly, all 33 videos showing convincing evidence of entrainment featured vocal learning species. Among species considered unable to learn new vocalizations, there was no evidence of synchronization ability. Within vocal mimics, all animals examined belonged to bird species, except for one Asian elephant (Elephas maximus). Schachner et al. (2009) also analyzed videos of sea lions (subfamily: Otariinae) which showed no evidence of entrainment (but see below for a recent study reporting evidence of entrainment in a sea lion).

This general result on synchronization abilities in vocal learning species is backed up by experimental evidence in three different avian species. Patel et al. (2009) analyzed the head bob movements of a sulphur-crested cockatoo ( Ca -
catua galerita eleonora) in response to a familiar song under unfamiliar tempo manipulations. In the absence of any training, the animal showed periods of entrainment matching phase and frequency of the musical beat. Schachner et al. (2009) provided additional evidence for entrainment in the same individual and a language-trained, African grey parrot (Psittacus erithacus).

Hasegawa et al. (2011) trained budgerigars (Melopsittacus undulates) to peck according to the beat of an audio-visual metronome. This study is particularly relevant as (i) it extends the sample size of the previous studies to 8 birds; (ii) it makes use of powerful analytical techniques from circular statistics and (iii) it compares actual performances to those of computer-simulated birds (simulating a range of neurophysiological constraints) in order to test the hypothesis that experimental subjects use "behavioral shortcuts" which could give the illusion of beat synchronization. Overall, Hasegawa et al. (2011) provide decisive evidence of trained synchronization ability in a vocal-mimicking species.

A Crucial Outlier In a recent study, Cook et al. (2013), investigated beat synchronization abilities in a pinniped, the California Sea Lion (Zalophus californianus). Crucially, sea lions, unlike seals and some other marine mammals, seem to have a low degree of vocal flexibility (Schusterman, 2008) and are usually grouped with non-vocal learners. Cook et al. (2013) trained the animal to bob its head in synchrony with different auditory stimuli at different tempi. This ability, trained first with metronome-like stimuli at different tempi, was easily transferred to novel tempi. Similarly, once trained with actual songs, the Sea Lion was able to transfer the synchronous head bobbing to new tempi and songs with no additional training.

This exciting finding opens new lines of research (see Figure 1). On the one hand, conclusive evidence on vocal mimicking abilities in sea lions is indispensable to contrast this finding with, and eventually update, the vocal learning hypothesis. On the other hand, Cook et al.'s (2013) discovery increases the likelihood of finding beat and (rhythmic) synchronization abilities in some vocal non-mimics. In particular apes and marine mammals, heterogeneous in vocal learn-
ing and advanced cognitive skills, offer a promising "testing field". Unfortunately, the evidence for apes and monkeys is either observational or not conclusive enough to prove or disprove beat entrainment.

## Contrasting Evidence from Macaques

Interval Timing Abilities Zarco et al. (2009) compared the ability of 20 human subjects and 3 rhesus macaques to synchronize to visual and auditory metronomes and to project this interval timing ability once the metric cue has been removed. They concluded that these monkeys were "not able to synchronize their tapping behavior to the sensory metronome as human subjects do" (Zarco et al., 2009). It is essential to notice that the authors based their conclusion on a linear test of "phase matching" (Patel et al., 2009). Zarco et al. calculated the average time difference between metronome cues and tap onset and compared this between species using a repeated measures ANOVA. As monkeys tapped, on average, 300 ms after the metronome and the ANOVA indicated a significant difference only between species, Zarco et al. (2009) interpreted this as evidence against synchronization. Further analyses suggested that the monkeys have, however, some form of timing prediction abilities, having shorter reaction times to stimuli with constant, rather than unpredictable, inter-onset intervals. Zarco et al. (2009) is a crucial contribution to the field, providing the first experimental paradigm for testing one component of rhythm in non-human primates. However it is unclear whether more specific tests from circular statistics would have led to the same conclusions in terms of phase or tempo synchronization.

Subsecond Beat Prediction Konoike, Mikami \& Miyachi (2012) conducted a similar experiment with two Japanese macaques (Macaca fuscata, closely related to rhesus macaques). The monkeys were reinforced for pushing a button in response to an audiovisual metronome. Crucially for our purposes, a synchronization threshold was set a priori: if a metronome beat was not matched with a tap within 350400 ms , the entire trial would be aborted. Reaction times were shorter with regularly-spaced beats when compared to an "unpredictable" inter-beat interval condition, as long as inter-beat intervals did not exceed one second. However, comparing the synchronization thresholds imposed by the authors to the reaction times, there could be a differential effect of the thresholds in shaping reaction times between subjects. As in the previous case, this study contributes to our understanding of what is unique about human rhythmic abilities. A suggestive hypothesis put forward by Konoike et al. (2012) is that their subjects' rhythmic control could depend on an automatic timing system rather than higher cognitive mechanisms. The a priori synchronization threshold and the lack of a statistical test on tempo matching prevent us from drawing conclusions about music-specific rhythmic abilities in these primates.

Synchronization of Arm Motion Nagasaka et al. (2013) reported mutual synchronization between pairs of Japanese
macaques in a laboratory setup. Interestingly, in each interaction, the ratios of BPM of the two subjects were small integers, suggesting periodical occurrence of synchronized taps. However, it seems that visual, rather than auditory, information had a decisive role in the macaques' synchronization accuracy when moving in response to a video of a conspecific.

## The Social Convergence Hypothesis

Recent findings (Large, Velasco \& Gray, 2008; Nagasaka et al., 2013) point towards the importance of social context in obtaining positive results when testing for rhythmic and music-related abilities. Children can already entrain to a pulse from 2.5 years of age onwards, being particularly accurate when drumming along with a human partner, rather than an artificial one (Kirschner \& Tomasello, 2009), suggesting that rhythmic abilities, coordination and cooperation could be partially connected within hominid evolutionary history. The recent "Social Convergence hypothesis" puts forward the importance of human social instincts in the development of rhythmic abilities: isochrony would be an easy way of achieving synchrony, which in turn is a form of coordinate, cooperative auditory signal generation (Fitch, 2012). Hence, evidence of entrainment in interactive contexts or from social species is required to support or refute this hypothesis.
Human-Bonobo Musical Interactions In the context of human-ape interaction, Large et al. (2008) reported an occurrence of entrainment. MIDI recordings from musical interactions between a human and three bonobos (Pan paniscus) were analyzed for evidence of synchronization. The authors claim that, after having identified " 37 episodes of rhythmic interaction, [...] in just under half of these episodes, statistical evidence of phase entrainment was found" (Large et al., 2008). The interactive nature of this study and the little published information leaves unclear the relative contribution of human and bonobo participants to rhythmic synchronization (Patel et al., 2009). Considering that bonobos are capable of synchronous hooting (de Waal, 1988), this result is, in principle, promising and worth further exploration.
Drumming by Wild Chimpanzees All three African Great Ape species engage in spontaneous drumming (Fitch, 2006). Chimpanzees (Pan troglodytes) can be observed hitting objects in order to produce loud sounds, especially during dominance displays. Arcadi, Robert \& Boesch (1998), analyzed chimpanzees' spontaneous drumming behavior on tree buttresses. Among other measures, Arcadi et al. (1998) reported an inter-beat interval distribution ranging up to 1.4 s , with a mean of 0.3 s and "most inter-beat intervals" less than 0.4 s . Transposing this into musical terms, the drumming behavior had a mean of 200 BPM (beats per minute) and was above 43 BPM, with most recorded patterns exceeding 150 BPM. ${ }^{1}$

[^195]Arcadi et al. (1998) found a number of individual differences in drumming behavior, notably in the inter-beat interval duration, the number of beats per "drumming session" and the length of sessions. Finally, the authors tested for statistical dependence between contiguous, non-adjacent beat patterns. One of the chimpanzees produced series of four beats, where a short interval between two beats statistically predicted another short interval between two following beats. This can be interpreted as showing a weak form of regularity in natural beat production and a sporadic, local steadiness in tempo. Percussive behaviors are hence naturally present in primates not capable of vocal mimicry. Together with Honing et al.'s (2012) findings on rhythmic grouping recognition, this suggests that rhythmic abilities across species might be graded, rather than dichotomous, suggesting that the evolution of musical rhythm be better investigated in a fine-grained manner.
Spontaneous Tapping in a Chimpanzee The languagetrained chimpanzee "Ai" has recently been shown capable of synchronizing her movements to an isochronous beat (Hattori, Tomonaga \& Matsuzawa, 2013). Three chimpanzees were trained to alternatively tap two keys of a keyboard at any preferred rate. The task was subsequently accompanied by steady auditory sequences of notes at three different tempos. One of the chimpanzees, Ai, spontaneously synchronized her tapping rate to one of the tempos. This is a remarkable result, presenting the first experimental evidence of behavioral synchronization in non-human primates. However, the authors point out that Ai’s lack of tempo flexibility and low phase accuracy would call for additional studies in order to clarify possible differences with normal human performance. Finally, Hattori et al. (2013) suggest that this study does not necessarily falsify the vocal learning hypothesis: the keyboard produced sounds, hence it is not conclusive proof of entrainment.

## Future Directions

If research on rhythmic cognition aims to advance and break new ground, there are some directions we propose it should take. First, a broader range of animal species should be tested: apes, marine mammals and non-avian vocal learners are key groups whose success or failure in beat and other rhythmic production tasks will arbitrate between a number of proposed hypotheses. We stress that such testing should happen as much as possible in an experimentally-controlled, though ecologically valid environment. Below we propose a viable approach for chimpanzees, using musical instruments explicitly built with those constraints in mind. Second, statistical techniques used to analyze entrainment data should be adequate to the purpose. If we think about statistics as a tool for getting closer to scientific facts, statistical techniques whose assumptions better fit the object under investigation will lead us closer to solid conclusions. Inference drawn from a statistical test resting on inadequate assumptions will lead to less robust conclusions. Third, mathematical modeling of the emergence of beat and rhythm is an important complement to
experiments. Analytical models and agent-based simulations can help sharpen hypotheses about which cultural, social and biological evolutionary processes endowed different species with different cognitive skills in terms of rhythm and music.

## Chimpanzee Drum-Set Prototypes

Towards Understanding Rhythmic Production in Chimpanzees Above we hinted at a viable methodological approach for testing beat and rhythm production abilities in higher primates. Chimpanzees already exhibit drumming behavior in the wild. A first step towards testing rhythm hypotheses in a semi-natural context could be to provide chimpanzees with a device they can use to produce sounds when manipulated. At the same time, such a "music-making device" should be particularly well adapted to the rigor of scientific experiments. No musical instrument or device, specifically designed for chimpanzees, sensing movements and feed-backing sounds, is currently available for purchase. Such a device should: (i) be resistant to chimpanzees' great strength, (ii) enable them to produce sound through object manipulation, (iii) systematically record data sensed from these movements, (iv) allow scientists to experimentally vary the sound properties of the object, without having to physically modify or replace it. We describe two prototypes specifically adapted to chimpanzees, which allow mapping sounds to physical movements and satisfy the requirements above. These prototypes constitute, to our knowledge, the first attempt at animal-computer rhythmic interaction. Here we outline their general features. For a thorough technical description and calibration data, see Ravignani et al. (in preparation).

Desiderata and General Features The prototypes were built with a main idea in mind: spurring the chimpanzee to spontaneous interaction and play. To maximize the chances of interaction, they were constructed and calibrated after scrutinizing videos of chimpanzees playing with objects, including the gum toy used in one of the prototypes. Each prototype consists of a sensing and a feedback unit. Sensing units feature acceleration and strain sensors embedded into manipulable objects. These units send acceleration or strain data to a computer, which converts them into sound and plays it in real time. The drum sets satisfy a number of logistic and technical desiderata. The sensing part is resistant, modular, low-voltage, inexpensive, interesting for the primate and easy to connect and configure. The software allows fast elaboration of data by performing few, simple operations, so as to limit the computational load. ${ }^{2}$
Prototype A: Wired The wired prototype is a parallelepiped containing piezoelectric sensors and connected to

[^196]a Mac computer via an Arduino ${ }^{3}$ board. A dedicated Python ${ }^{4}$ script is in charge of the auditory feedback. It can be mounted vertically on a wall or on the wire-mesh of chimpanzees' enclosures. This prototype has several advantages: (i) it is built with cheap and easy to find components, (ii) it entails no risk of electrocution and (iii) its ricochet property naturally suits the animal's tendency to hit and push objects.

Prototype B: Wireless The wireless prototype consists in a hollow dog toy enclosing a Wii Remote ${ }^{5}$. A computer receives data (via Bluetooth), which is processed and sonified using patches written in $\mathrm{Max}^{6}$. This device has several advantageous features: (i) chimpanzees generally enjoy manipulating objects, and chimpanzees have been both reported (Pruetz \& Bloomsmith, 1992) and observed by us to manipulate the model of toy used here (ii) its construction requires less work than the wired prototype and its components can be easily purchased, (iii) it has a wireless communication system, particularly advantageous in some applications.

## Circular Statistics

Most data coming from beat and rhythm experiments involve a periodic time component. Before applying a statistical test, it is essential to think about the nature and dimensionality of the data. As a parallel, if we wanted to compare the amount of rain falling on Britain over time, we should conceptualize rain as falling onto a 2-dimensional space, rather than on a real number line, $\mathbb{R}$. As the classical t-test for paired samples is defined on $\mathbb{R}$, it may be inappropriate to use it on geographical data. The fact that rhythmic data are originally associated with time makes time series analysis a possible approach to test a range of hypotheses.

The best option to use for periodic data, when possible, is circular statistics (Fisher, 1995). Its key feature consists in assuming that data is distributed on a circle, rather than on the usual real number line. This grants ideal analytical tools for data sets with a periodic time component, such as those deriving from beat and rhythm experiments. Several researchers in the field have successfully used these techniques on human (Kirschner \& Tomasello, 2009) and animal data (Hasegawa et al., 2011).

## The Importance of Modeling

Above we hinted at the importance of developing mathematical models of the emergence of rhythm. The last century has seen a radical increase in the quantitative approaches used in most areas of human knowledge. In particular, mathematical models and computer simulations have proven themselves particularly useful in testing the internal consistency of hypotheses, sharpening scientific assumptions and providing new viable directions for experimental testing. Scholars interested in the evolution and emergence of structure in

[^197]language, for instance, have provided quantitative accounts (Kirby, 2001), which have been later validated through cognitive experiments (Kirby, Cornish \& Smith, 2008).

Similarly, recent experiments (Honing et al., 2012) have shed some light on what can be accounted for by human culture or biology in rhythmic abilities. However, thorough explanations are still missing about the evolutionary forces, whether biological or cultural, that have shaped musical rhythm and the underlying human cognitive abilities. Quantitative evolutionary thinking can be used to study the emergence of music and rhythm, and models linking biology to culture could be an exciting second step.

While investigating what is unique about musical rhythm and which species possess the cognitive abilities to process it, human and animal experimental work should be complemented by models aimed at explaining the ultimate mechanisms of what is observed in everyday musical behavior. The lack of quantitative work trying to explain the emergence, cultural dynamics and biological evolution of music is surprising when we consider its pervasiveness in human lives.

## Conclusions

We suggested directions and methodologies for investigating the evolution of musical rhythm in a comparative, interdisciplinary perspective. Usage of a variety of statistical techniques on the same data set and replication are essential before conclusive claims of lack of synchronization can be made about a species or taxon. Moreover, experiments should be designed keeping in mind the critical theoretical distinctions introduced above.

Recent evidence provided by Honing et al. (2012) and Cook et al. (2013) may lead to newly redefined hypotheses, which in turn make the experimental testing of apes and marine mammals a fundamental prerequisite for a theory of human uniqueness of rhythmic abilities. The drum sets we presented are intended for apes to perform acoustic non-vocal rhytmhic production in a captive, though not restrained context. In general, as technological tools for human-machine interaction become available, new methodological paradigms for animal-machine interaction can be developed and used to test critical species in musical tasks. Mathematical modeling and agent-based simulations can be an important complement to empirical data, hopefully generating the same productive theory-experiments interplay seen in other disciplines.

Similarly to the broad variety of reaction time distributions across species and tasks, evolution has shaped animal brains and motor skills so that different species may require different statistical null hypotheses with respect to attempted synchronized motor behavior (for instance, due to perceptual or motor lower bounds on reaction times). Circular statistics, with its variety of theoretical distributions (von Mises, cardioid, wrapped normal, etc) and time-periodic tests, are ideal for testing hypotheses about rhythmic synchronization with different underlying assumptions.

The Vocal Learning and Social Convergence hypotheses make different predictions on which species should have
rhythmic abilities (Fitch, 2012). Both of them, however, are related to another uniquely human trait: language. Further development of experimental paradigms allowing social interactions under experimentally-controlled conditions will enable scientists to contrast these hypotheses and produce evidence relevant to the evolution and cognition of both music and language.

# Training Principle-Based Self-Explanations: Transfer to New Learning Contents 

Alexander Renkl (renkl@psychologie.uni-freiburg.de), Judith Solymosi (judith.solymosi@gmail.com)<br>University of Freiburg, Germany, Department of Psychology, Engelbergerstaße 41, D-79085 Freiburg Germany

#### Abstract

The present study tested the transfer effects of a short training intervention on principled-based self-explanations. The intervention used fables as well as mathematics examples and problems as "exemplifying" domains for training such selfexplanations. The effects were tested in a new learning environment about attribution theory and feedback messages. In this experiment, 58 German high-school students were randomly assigned to the self-explanation training condition or a control condition (i.e., training of mnemonic strategies). The learning outcomes from the learning environment about attribution theory and feedback did not significantly differ between groups. However, those students who also reported to have applied the strategies from the training intervention actually showed the best learning outcomes. Overall, the selfexplanation training intervention "convinced" just part of the learners to engage in principle-based self-explanations in a new environment. There seems to be two options to achieve more reliable effects by future training interventions: The learners have to be prompted more clearly that they should employ the learned strategies in the transfer learning environment or the short-term training intervention should be extended to have a stronger effect on spontaneous strategy application.

Keywords: Self-explanation, training intervention, transfer.

## Introduction

If students acquire cognitive skills, these skills should ideally be based on an understanding of the underlying domain principles (e.g., Chi \& VanLehn, 2010; Goldstone \& Day, 2012; Renkl, 2002). Such a conceptual underpinning facilitates the transfer of the acquired skills to new problems for which a modified solution procedure has to be found. In addition, deep conceptual understanding is considered to facilitate further procedural learning (e.g., Rittle-Johnson, Siegler, \& Alibali, 2001). In many learning situations, however, the learners acquire cognitive skills without understanding the corresponding domain principles. Thus, a major goal of instruction is to facilitate meaningful learning that strives for a principle-based understanding.
One way to induce a principle orientation for meaningful learning is to prompt learners for principle-based selfexplanations (Kalyuga, 2011). For example, Atkinson,

Renkl, and Merrill (2003) encouraged learners to determine the principle (here: probability rule) behind each step of a worked example. This prompting procedure fostered transfer to isomorphic and to novel problems, for which modified solution procedures had to be found. Principlebased prompting also worked in "verbal" domains without mathematical solution procedures. For example, Schworm and Renkl (2007) provided principle-based prompts to learners when they studied video examples of sound scientific argumentation. Such prompts help determine the argumentative structures and, thereby, the argumentation skill. Whereas the Atkinson et al. and the Schworm and Renkl studies analyzed example-based learning, Aleven and Koedinger (2002) showed that principle-based selfexplanation prompts also enhance learning by problemsolving (here: in the intelligent tutorial environment Cognitive Tutor). Further, there are numerous studies affirming the positive effects of prompting principle-based self-explanations (e.g., Berthold \& Renkl, 2009; Conati \& VanLehn, 2000; Renkl, 1997; Schworm \& Renkl, 2006).

The successful prompting procedures have, however, significant disadvantages. First, when prompts in the form of external guidance are provided, there is no guarantee that the learners do not fall back on rote learning when the prompts are not present anymore (cf. Wecker \& Fischer, 2011). Second, it is a substantial amount of work to enrich learning materials or environments with prompts; it may not be practical to do so for all materials a learner may need, or even to know what learning materials a learner may need in the future. It would be far preferable if the learners acquired self-explanation skills that they can use for further selfregulated learning in new learning environments.

There are several tried-and-tested self-explanation training interventions. However, they all have restrictions with respect to fostering principle-based self-explanations when learners study worked examples and solve problems in order to acquire cognitive skills. McNamara and colleagues focus on reading strategies in their selfexplanation training interventions SERT and iStart (McNamara, 2004; Levinstein, Boonthum, Pillarisetti, Bell, \& McNamara, 2007). These strategies are not tailored to
learning by examples and problem-solving. A restriction of other training interventions for self-explaining examples and problems that have been tested so far is that they employed the same type of materials in the training phase as in a subsequent learning phase (e.g., Bielaczyc, Pirolli, \& Brown, 1995). For example, Renkl, Stark, Gruber, and Mandl (1998) trained participants using examples of (compound) interest calculation in order to prepare them for a later learning phase dealing with the same domain. The self-explanation training of Wong, Lawson, and Keeves (2002) focuses on geometry learning in all phases.

The expectation that the self-explanation strategies addressed by these previous training will solely transfer to similar contents seems to be realistic because transfer to dissimilar contexts (e.g., different learning domain) is very hard to achieve (e.g., Detterman 1993; Goldstone \& Day, 2012; Perkins, 2009). Nevertheless, some researchers found some training effects that transfer over contents. For example, Chi and VanLehn (2010) had their learners work in an intelligent tutoring environment called "Pyrenees" (domain: probability) that demanded, among other things, a focus on domain principles. The learners were prompted to reason about the principles in order to determine sought values and they had to apply the principles to the problems at hand. It was found that this principle orientation transferred when working in another intelligent tutorial environment (i.e., "Andes"; domain: probability and physics); this was in particular true for learners with less prior knowledge. Note that there was not only a transfer across learning environments (Pyrenees to Andes) but also across learning domains (probability to physics).
Whereas Chi and VanLehn (2010) found transfer of a principle orientation acquired during physics learning, Busch, Renkl, and Schworm (2008) developed a training intervention with the "sole" purpose to foster selfexplanations. This short intervention (less than 30 min .) was conducted with the topic "fables." The learners were shown that in order to determine that a short story is a fable one has to self-explain whether some crucial principles were implemented in the story (e.g., animals as actors, hidden message). This intervention showed considerable transfer effects to a rather distant topic: example-based acquisition of scientific argumentation skills. Although this short-term training was surprisingly successful, it had a significant restriction. Although there was transfer from fables to scientific argumentation, it was "just" transfer between verbal domains. As the Busch et al. intervention did not refer to mathematical solution procedures, which are typical not only of mathematics but also of many science subdomains, we did not expect transfer to the latter domains. Hence, it is sensible to modify the Busch et al. training intervention by including mathematical contents.

## The Present Study

We trained high-school students providing selfexplanations in two domains. As in the study by Busch et al. (2008) we used fables as "verbal" exemplifying domain, and
mathematics as an algorithmic exemplifying domain. Afterwards the students learned from an example-based learning environment how to apply psychological attribution theory in order to provide feedback that has favorable motivational effects. This content domain was not taught or mentioned in the training intervention. Hence, we test the hypothesis that the self-explanation training using mathematics problems and fables as materials has positive effects on learning about the provision of productive feedback on the basis of attribution theory.

As control group, we did not use a non-treatment group, as these effects might be rather trivial. Instead, we compared the self-explanation intervention with a training intervention on mnemonic strategies. Although the latter strategies might be useful for remembering facts, we hypothesized that the self-explanation intervention is more favorable for highlevel learning goals (e.g., applying what has been learnt about feedback to evaluating new feedback messages).

When testing the effects of a modified version of the short training intervention by Busch et al. (2008), we tried to keep the training time short, that is, about half an hour (as in the original training intervention). Such a short training intervention is applicable within the usual class periods in schools. In the self-explanation intervention, we kept the basic example of a fable in order to demonstrate the value of principle-based self-explanations. In addition, we used mathematics examples in order to show how to self-explain while studying mathematics examples and while solving mathematics problems. We saved some training time in order to add mathematics contents by focusing on principlebased self-explanations and leaving out other types of selfexplanations (e.g., goal-operation elaborations) that were part of the original training intervention. Nevertheless, we had to shorten the treatment of self-explaining fables in order to keep the intervention time within the limits of about half an hour. A question that arose was whether the training intervention has still transfer effects to other verbal areas, even if the treatment of fables as verbal training examples was substantially reduced. The unique contribution of this study is the evaluation of a self-explanation training intervention that is designed to have across-domain transfer effects, that is, effects that are not bound to the "exemplifying" domains used during training.

## Method

## Participants and Design

We randomly assigned 58 female high-school students (age: $M=16.52, \mathrm{SD}=0.71$ ) to two conditions: training intervention on principle-based self-explanations ( $\mathrm{n}=31$ ) and training intervention on mnemonic strategies ( $\mathrm{n}=27$ ). The participants were members of elective courses in psychology from a "mono-educational" (i.e., just female students) Gymnasium (i.e., highest high-school track of the German three-track system). The main dependent variable was the learning outcomes in a learning environment that followed the different training interventions. This transfer
environment was about attribution theory and its application to providing productive feedback. The contents that the students learned in this experiment were not directly related to their currently treated topics in their psychology courses. However, they were (validly) informed that the topics fit the overall learning goals of these courses.

## Instruments and Materials

Short-term training environments. We compared the transfer effects of two training environments: Training of principle-based self-explanations versus training of mnemonic strategies. They lasted about half an hour. Both training interventions were parallel in a number of features. They both introduced the fictitious character Sarah who had learning difficulties (see Figure 1). In both cases, a friend helps out by suggesting some strategies (i.e., principle-based self-explanations or mnemonic strategies, respectively). Both training modules presented the contents within a dialogue between Sarah und her friend. During the program the learners in both conditions got work sheets in order to practice the respective strategies. Both modules ended with a short summary of the training contents.

Figure 1: Screenshot from the training intervention module on principle-based self-explanations (translated form German)

The training intervention on principle-based selfexplanation was divided into two main modules, which explained and practiced principle-based self-explanations when (a) studying an example and (b) solving a problem. The first example in the example-studying section was Aesop's fable "The fox and the crow." We showed that a fable is characterized by several principles or underlying features (e.g., animals as actors, principle of polarization, hidden message) and that the readers have to self-explain a story in terms of above-mentioned underlying features in order to identify the story as a fable (see Figure 1). Next the learners practiced principle-based self-explanations, supported by corresponding prompts, on a work sheet presenting a worked example applying the Pythagorean

Theorem. Hence, a first instance of inter-domain transfer was practiced. In the second part, we supported further transfer by presenting and practicing principle-based selfexplanations when solving diverse mathematics problems.

The training intervention on mnemonic strategies introduced and practiced three strategies: (a) Using mental images; (b) "Eselsbrücken," which is a German term for (in many cases funny) phrases that interconnect two items (e.g., word in a foreign language and translation). (c) "Mnemonic sentences" similar to "My very educated mother just served us nine pickles" for the planets and their distances to the sun (note, however, that we used other mnemonic sentences because this one does not work in German language).

Transfer environment. The transfer environment first introduced the concept of attribution and explained why attributions are important in learning contexts. Then it introduced the basics of Kelley's (1971) attribution theory, that is, the co-variation model. On this basis, it explained how feedback should be given to students so that functional attributions are fostered. Two small exercises were included in which the participants had to analyze feedback statements. Finally, a summary was provided. The learner worked on average $7.10 \mathrm{~min}(S D=2.02)$ in this module (no significant difference between the conditions).

Posttest. The posttest assessing the transfer effects of the self-explanation training consisted of 15 problems (average time: 23 min ). In addition, the posttest booklet asked three questions that were to be answered on 5-point rating scales at the very beginning (I found the first program useful; I found the second program useful; in the second program I applied the strategies that I have learned in the first program). After these questions, we presented the problems assessing the learning outcomes.

Three problems asked what should be emphasized in feedback in different circumstances. Six items asked for the attribution theory principles behind exemplary feedback messages (e.g., "In a dance class: A lot of people struggle with Tango" (the feedback message itself is printed in italics). Solution: Such feedback suggests attributions to task difficulty and it should "prevent" internal attributions when having difficulties). Four items required writing a short feedback statement for different circumstances. Finally, two items ask for identifying what is problematic with two suboptimal feedback statements. This scale had a good internal consistency (Cronbach's $\alpha$ of .86).

## Procedure

The students participated at experimental group sessions in a university computer laboratory (about 20 students per session). The students worked individually in front of a computer. The different computers were randomly assigned to one of the two experimental conditions. These sessions lasted about 100 min . At first glance, this duration is longer than to be expected from the average time of the single phases such as training intervention, transfer environment, and posttest. Note, however, that the faster students had to wait for the slower ones before going on to the next phase.

After some welcome words, we informed the students that they will learn about some learning strategies in a first computer-based learning environment and that they should apply these strategies in a second computer-based learning environment. Subsequently, students were asked to fill in a short paper-pencil questionnaire on demographic data (one page), previous school grade, and on learning goal orientation (Dweck \& Leggett, 1988). As the latter scale neither predicted learning outcomes nor interacted with the different treatments we did not consider the students' learning goal orientation in the following.
After completing the questionnaire the students worked on the training intervention modules. Subsequently the students learned about feedback and attribution theory in a second learning program. Finally, they took the posttest.

## Results

A significance level of .05 was used for all analyses. We used $d$ as an effect-size measure with values between .20 and .50 classified as small, values between .50 and .80 as medium, and values > . 80 as large (Cohen, 1988).
We did not find any significant differences between the groups with respect to the grade point average on the last report card or the experience with learning programs (both $F \mathrm{~s}<1$ ). Eight students said that they have never heard the term attribution. Fifty students said that they have already heard about this term but did not remember its meaning. No student was able to explain what attribution means. Overall, the student had hardly any prior knowledge.
The self-explanation condition scored descriptively higher on the posttest as compared to the mnemonics condition, $M$ $=.55, S D=.23$ vs. $M=.48, S D=.21(M \mathrm{~s}$ represent the percentage scores as compared to the theoretically possible maximum). However, this difference did not reach the level of statistical significance, $t(56)=1.08, p=.286, d=0.32$. This relatively weak and statistically not significant effect could be due to the following factors: (a) The effect of the self-explanation training intervention interacts with learning prerequisites (aptitude-treatment interaction explanation); (b) some of the learners superficially scanned or quickly read the training module (scan and skim explanation); (c) the training module was too difficult at least for some learners (difficulty explanation); (d) the learned selfexplanation strategies were not applied by some learners in the application environment on attribution and feedback (production deficiency explanation).
(a) Aptitude-treatment interaction explanation. The most important learning variable with respect to aptitudetreatment interaction is prior knowledge or achievement level (Kalyuga, 2007). The grade point average, as indicator of prior school achievement, was significantly related to the posttest ( $r=.37, p=.005$ ). However, there was no interaction between condition and grade point average, with respect to the posttest, $F<1$. Further exploratory analysis with other learning prerequisites (e.g., grades for mathematics or German; experience with computer-based learning program) did not indicate any aptitude-treatment
interaction. Hence, the aptitude-treatment interaction explanation is likely not true.
(b) Scan and skim explanation. If the weak and insignificant transfer effect was due to some learners' just scanning and skimming the training environment, there should be a correlation between learning time and training outcomes. However, the learning time in the training modules was not significantly related to learning outcomes, neither in the whole sample ( $r=.05, p=.699$ ) nor in the two sub-groups (self-explanation group: $r=.11, p=.551$; mnemonic strategies group: $r=-.15, p=.455)$. In this context, it should also be noted that the self-explanation group spend more time in the training module, $M=29.87$, $S D=6.70$, than the mnemonic group, $M=24.07, S D=6.89$, $t(56)=3.25, p<.002, d=0.85$. Overall, there is no indication that some learners in the self-explanation condition just quickly scanned the training module, which impeded their learning outcomes. Hence, the scan and skim explanation is likely not true.
(c) Difficulty explanation. If the self-explanation training intervention was too difficult for some learners, there should be a substantial number of errors in practice sheets that were included in the learning environment, and the number of errors in these practice sheets should predict lack of transfer. To test this explanation, we coded the quality of the students' responses to the four interspersed work sheets in the self-explanation training module from 1 (completely wrong) to 5 (correct, clear principle application). We found a mean of $4.35(S D=0.55)$, clearly indicating that the training was not too difficult for the learners. In addition, there was no significant correlation between the worksheet score and the posttest ( $r=.18, p=.180$ ). Overall, the difficulty explanation is likely not true.
(d) Production deficiency explanation. We asked the participants to rate on a five-point scale whether they applied the strategies learned in the first module (selfexplanation or mnemonics, respectively) in the second module on attribution, as suggested by the experimenter in the beginning of the session. When adding this rating in the prediction of learning outcomes (predictors: condition, rating, and condition by rating), we found a significant interaction effect between condition and reported strategy application with respect to the posttest, $F(1,54)=9.72, p=$ .003. To better understand this interaction, we determined the regression scores and their statistical significance in both conditions. In the self-explanation condition, the more the students reported that they applied the learned strategies, the better the posttest performance, $b=0.09, t(29)=2.59, p=$ .015. In the mnemonics condition, we did not find a significant relation between self-reported strategy application and posttest performance in the transfer environment, $\beta=-0.07, t(25)=-1.89, p=.071$. In accord with a production deficiency explanation, these findings indicate that only part of the students applied the learned strategies in the module on attribution and feedback and, thereby, profited with respect to learning outcomes.

In order to get an idea of how many non-applying students were "responsible" for the insignificant overall training effect, we conducted some post-hoc analyses. When we excluded the three students from the self-explanation condition who stated that they did not at all apply the strategies (i.e., choosing 1 on the 1 to 5 rating scale of strategy application), there was still no significant effect of condition on learning outcomes. However, when excluded an additional nine students, namely, all students who stated that they did not apply the strategies (i.e., choosing 2 on the 1 to 5 rating scale of strategy application), the condition effect gets to be statistically significant (self-explanation condition: $N=19 ; M=.63, S D=.22$; mnemonics condition (as already reported): $N=27 ; M=.48, S D=.21, t(44)=$ $2.23, p=.031, d=.70)$. Hence, only when we consider the (roughly) two thirds of the students that were convinced to apply the strategies, we get a significant effect of the selfexplanation training intervention.

The preceding post-hoc analysis might be criticized because we excluded only participants from the selfexplanation condition and we, therefore, had rather different group sizes. If we also exclude the ten participants from the mnemonic condition (i.e., roughly the lower third) that reported about low strategy application, we also got a significant group difference: self-explanation condition (as already reported): $N=19 ; M=.63, S D=.22$; mnemonics condition: $N=17 ; M=.42, S D=.23, t(34)=2.70, p=.011$, $d=.89$ ). This finding again underlines that the selfexplanation treatment was successful in about two thirds of the cases.

## Discussion

We tested whether we could successfully implement a short-term training intervention on principle-based selfexplanations that has positive effects on learning in a subsequent learning environment. Unfortunately, we got only a weak and statistically insignificant effect. According to our post-hoc analyses, it is unlikely that this weak effect was due to aptitude-treatment interactions with learning prerequisites, a scan-and-skim behavior of some learners, or the difficulty of the training intervention. Instead, only part of the students (about two thirds) was "convinced" by the training intervention to apply the learned strategies in a subsequent learning environment. Students who applied the strategies profited from the training intervention.
Why did some learners not apply the self-explanation strategies? There are at least three possible explanations: (a) These learners did not find the strategies in the selfexplanation training useful; (b) it was not salient enough, at least for some learners, that they were expected to apply the strategies that they have learned in the first environment in the second learning environment; (c) the training intervention was too short to fully change the students' habitual learning behavior.

The perceived usefulness argument can be evaluated by further post-hoc analyses. After completing the learning environment on attribution theory and before they took the
posttest, the learners rated how useful they found the strategy training module. The learners from the selfexplanation condition rated this module as rather useful ( $M$ $=4.03, S D=0.98$ (5-point scale from 1 , not at all, to 5 , fully agree). The perceived utility predicted to some extent whether the strategies applied ( $\mathrm{r}=.36, \mathrm{p}<0.05$ ). However, the perceived utility did not interact with the treatment, in contrast to the reported strategy application. Obviously, the (low) perceived usefulness was not a major cause for not applying the strategies and for reduced training effects.

How salient was it for the learners that they should apply the learned strategies in the second learning environment? In the beginning of the experimental sessions, the experimenter informed the students that they should apply the strategies to be learned in a first environment in the second computer-based learning environment. However, this prompt was not repeated (keep in mind that the question of to what extend the strategies learned in the first program were applied was posed after the transfer phase). Note also that in the beginning of the session, the students got a variety of information and were confronted with many new "impressions," that is, they came to a new building (i.e., Department of Psychology), they were introduced to the computer room and the experimenter, they were informed about various aspects of the study, etc. Thus, for some students, the instructions about strategy application might not have been very salient and they might not have been remembered when they began to work on the second learning environment. It seems plausible that - given the short duration of the training intervention so that no profound effect on habitual behavior can be expected - the students would need at least some form of "kick-off" prompt at the start of the transfer learning environment to apply the learned strategies to new contents.

As already argued, the short training duration makes it implausible that the students' habitual strategy use was changed. Against the background of the present intervention's short duration and the corresponding transfer literature (e.g., Detterman 1993; Goldstone \& Day, 2012), it can even be regarded as success that about two thirds of the learners transferred the newly learned self-explanation strategies across domains.

In this context, it should also be noted that we have replaced the verbal self-explanation training materials of Busch et al. (2008) to a large degree with mathematical examples. Given that Busch et al. found significant transfer effects across two verbal domains, it can be tentatively assumed that the "verbal part" was too much reduced. Hence, a sensible next step in improving the training intervention would be to extend the verbal part roughly to the length of the Busch et al. intervention. Thus, we extend the verbal part of our training intervention in a next step on our way to develop some type of "generic" self-explanation training. We also intend to test transfer effects on mathematical learning environments.

An alternative explanation for the positive training effect when looking at the two thirds of student reporting strategy
application is that the mnemonic intervention suppressed at least some students' tendency to self-explain spontaneously. Hence, further studies should also include a control condition allowing for spontaneous self-explanations.
Overall, the present study and Busch et al. (2008) have taken partly successful steps towards a self-explanation strategy training that has the potential to achieve acrossdomain transfer effects. Nevertheless, there is some further research to be done (e.g., extending the intervention; testing transfer to mathematical contents). However, the available findings justify some optimism that we can step by step come to a successful training approach.

# Predicting similarity change as a result of categorization 

Irene Reppa (i.reppa@swansea.ac.uk)<br>Department of Psychology, Swansea University, Swansea, SA2 8PP<br>Emmanuel Pothos (e.m.pothos@gmail.com)<br>Department of Psychology, City University London, London, EC1V 0HB

#### Abstract

Learning a particular categorization leads to corresponding changes in the similarity structure of the categorized stimuli. The purpose of the current study was to examine whether different category structures may lead to greater or less similarity change. We created six category structures and examined changes in similarity as a result of categorization in between-participant conditions. The bestsupported hypothesis was that the ease of learning a categorization affects change in similarity, with the most change following learning of difficult category structures. There was also support for the hypothesis that similarity change is more likely to occur when the category boundary was not aligned with the physical dimension of variation. Finally, we discuss some methodological challenges in addressing this important research topic.

Keywords: similarity; categorization; learning difficulty; exemplar theory

There is widespread evidence that learning to categorize stimuli in a particular way leads to corresponding changes in the similarity structure of the stimuli (e.g., Gureckis \& Goldstone, 2008; Ozgen \& Davies, 2002; Schyns \& Oliva, 1999; Stevenage, 1998). For instance, stimuli categorized in the same category tend to be perceived as more similar to each other, compared to stimuli categorized in different categories (e.g., Goldstone, 1994; Schyns, Goldstone, \& Thibaut, 1997), and stimuli on either side of a category boundary tend to be more discriminable than stimuli on the same side of the boundary (e.g., Harnad, 1987). Similarly, differences have been reported on color perception across different linguistic communities (Roberson et al., 2005).

Research on the influence of categorization on perception has flourished for several reasons. It is theoretically important since it is at the heart of answering core issues regarding representation and the processing of sensory input. Do we perceive a faithful representation of sensory input? Or are our perceptual representations a compromise between constraints from sensory input and whatever categories are useful for the organism? Such research is also important for formal models of categorization, as most of them assume categorization models that assume representations which are stable across learning (e.g., Nosofsky, 1984).
The present research examined the effects of categorization on similarity. Changes in similarity might
correspond to perceptual changes or changes mediated through the addition of a category label (e.g., Goldstone, Lippa, Shiffrin, 2001; McMurray et al., in press; Roberson \& Davidoff, 2000; Sloutsky \& Fisher, 2004). Choosing to examine similarity is primarily a methodological simplification, since exploring directly changes relating to perception involves the technical challenge of eliminating (possible) effects from linguistic labeling. However, if across broadly matched category structures, for instance, in terms of learning difficulty, we find similarity changes following learning of some structures but not others, then one can make the additional step of inferring similarity changes over and above changes due to just the category label (see also Roberson et al., 2007).

Despite the numerous reports on the effects of categories on similarity, and perception in particular, there have been some reports of failures of such influence (e.g., Goldstone, 1994; Jiang et al., 2007; Freedman et al., 2003). The aim of present research was to examine possible factors might lead to changes in similarity.
We created six two-dimensional category structures, shown in Figure 1. Two category structures were designed so that the width dimension was diagnostic (Width easy and Width difficult), while the height dimension non-diagnostic, and two more category structures were defined so that height was the diagnostic dimension (Height easy and Height difficult) and width was non-diagnostic. Two versions of each category structure were created, one designed to be easy (e.g., Width easy), and one designed to be more difficult (e.g., Width difficult). Finally, two more category structures were created where both dimensions were relevant: the non-linearly separable (NLS) and the Diagonal structure, explained in more detail later.
Three different hypotheses regarding the effect of category learning on similarity changes were examined. One hypothesis was that category learning difficulty would affect the extent of similarity changes. A classification is easy (or more intuitive) if it is more readily obvious to naïve observers (Pothos \& Chater, 2002; Pothos et al., 2011). For example, when asked to freely classify a set of stimuli, participants will generate more intuitive classifications more frequently. These classifications will be typically easier to learn than non-intuitive ones. Category learning difficulty might influence similarity ratings in two ways. One possibility is that learning the easy category structures would lead to greater changes in similarity ratings. This is because, for easy category structures participants are able to
quickly learn the underlying categorization, perhaps with less emphasis on encoding the individual exemplars (cf. Ashby et al., 1999; Ashy \& Ell, 2002). Such inexact initial encoding of the exemplars may mean that exemplar representations end up being developed in a way that is more consistent with the underlying category structure (e.g., Edwards, Pothos, \& Perlman, in press). Support for this prediction comes from Folstein, Gauthier, and Palmeri (2010), who manipulated the complexity of the underlying stimulus space (not of category structure, as in the current study). Unlike previous related evidence showing that categorization does not influence similarity (e.g., Jiang et al., 2007; Freedman et al., 2003), they showed significant effects of categorization on perception, when the underlying stimulus space was simple.
The converse prediction, regarding the effect of category learning difficulty on similarity changes, is that learning a difficult category structure might result in more significant and enduring changes in the similarity structure of the stimuli. This possibility is motivated by evidence showing that supervised categorization processes can involve processes of selective attention or other changes in psychological space (e.g., through the sensitivity parameter; Nosofsky, 1984), though such research does not tell us whether such changes are enduring and on the actual stimulus representations.
A second hypothesis is that the linear separability of the learned categories might moderate changes in similarity. Overall, there is quite a lot of controversy regarding the role of linear separability in category learning and perhaps some of this controversy can be ultimately explained in terms of corresponding changes in the similarity structure of the categorized stimuli. Note that connectionist models require that NLS problems are transformed into linearly separable ones at their hidden layer, otherwise learning is not possible (indeed, the inability of perceptrons to learn NLS category structures has been at the heart of the critique of Minsky \& Papert, 1969; see also Rumelhart \& McClelland, 1986).

To examine possible influences of linear separability in relation to similarity changes, two categories were created to be broadly equal in terms of complexity but differ in whether they were LS or not. One was the NLS and the other was the Diagonal condition (Figure 1). In diagonally separated category structures, the members of one category can only be discriminated from their nearest neighbors in the other category with fine distinctions along both dimensions of variation. They have proved to be challenging for participants to learn (e.g., Ashby, Queller, \& Berretty, 1999; Ashby \& Ell, 2002).
If the cognitive system shares processing constraints with connectionist systems, maybe it would try to re-represent a NLS classification in an LS way, so that there would be more similarity change in learning an NLS classification, compared to an equally complex but LS one (the Diagonal one). Alternatively, it could be the case that more complex classifications are associated with less similarity change, if, for example, category learning of such classifications
involves rote memorization of the training exemplars (Blair \& Homa, 2003). In this case, NLS and Diagonal classification would lead to equivalent similarity changes.

Figure 1. The six category structures employed in the study.

Finally, a third hypothesis is that similarity change depends on whether the category boundary is aligned with a dimension of physical variation (e.g. height). According to the COVIS model of categorization (Ashby et al., 1999; Ashby \& Ell, 2002), whether the category boundary is along a physical dimension of variation can determine whether the executive (frontal) or the procedural system is engaged. To examine this hypothesis, the Diagonal category structure was compared against the condition best matched for difficulty with it (which turned out to be the Height Difficult category structure).

## Participants and Design

One hundred and eighty experimentally naïve participants, all Swansea University students, were tested. There were 20 participants in each of the six experimental groups, each learning one of the six different classifications shown in Figure 1. For all six classifications, successful learning is achieved when participants recognize that items in clusters A and B are in one category and items in clusters C and D are in another category. The dependent variable was changes in similarity as a result of category learning. The procedure for computing changes in similarity is described in the Results section.
Three independent variables were considered, to allow examination of the hypotheses examined. The first was
category structure learning difficulty, which was defined adhoc in terms of the number of trials to criterion. For this variable the Height Easy and Width Easy conditions were compared with their corresponding Height Difficult and Width Difficult conditions. The second independent variable was whether the category boundary was aligned with the dimension of physical variation or not. The third independent variable was linear separability with two levels, linearly versus non-linearly separable category structures.

For each of the six category structures, there was a corresponding control group providing similarity ratings for the stimuli, but without having gone through the categorization task first. For the Width Easy, Height Easy, and NLS conditions there was a common control group of 20 participants. For the Width Difficult and the Height Difficult conditions a different control of 20 participants, and for the Diagonal group yet another control group of 20 participants. The experiment lasted approximately 50 minutes for the experimental groups and 30 minutes for the control groups.

## Materials

We used yellow surface-rendered arrow-like shapes that varied in terms of two dimensions: the width of the arrowhead (horizontal dimension) and the length of the arrow (vertical). The smallest arrow's trunk measured 4.5 centimeters (cm) in height and its head measured 3.0 cm wide. Twenty-four more stimuli were created by incrementing trunk height and head width by $12 \%$. The stimuli employed in the experimental conditions were subsets of this original set of stimuli. The shortest arrow trunk in all six conditions was 4.5 cm high and the narrowest arrow head 3.0 cm wide. The tallest arrow trunk was 12.5 cm in the Width Easy, Height Easy, Diagonal, and NLS conditions and 7.1 cm in the Width Difficult and Height Difficult conditions. The widest arrow head was 8.3 cm in the Width Easy, Height Easy, and NLS conditions, 4.7 cm in the Width Difficult and Height Difficult conditions and 5.3 cm in the Diagonal condition.

## Procedure

A standard supervised categorization task was employed. A stimulus was presented at the center of a computer screen against a white background, until the participant decided whether it belonged to category A or B , at which point he/she received corrective feedback. Participants continued to categorize stimuli until no mistakes were made for 32 consecutive trials (i.e., all stimuli shown twice) or for a maximum of 256 trials. Five participants failed this criterion (three in the NLS condition and two in the diagonal condition) and these participants were not asked to complete the similarity part of the study. Participants, who completed the categorization task successfully subsequently received the similarity ratings task. In that task, each trial started with a 'Ready?' prompt at the center of the screen. Two stimuli appeared at the screen center for 500 ms each, one after the other, with an inter-stimulus interval of 500 ms . All possible
$16 \times 16=256$ stimulus pairs were presented and participants were asked to rate their similarity on a 1-9 scale, such that 1 corresponded to 'very dissimilar' and 9 to 'very similar'. Participants were encouraged to use the entire scale. Participants in the control groups went through the similarity ratings, without having done the categorization task first.

## Results

## Data cleaning

There were two simple checks that the participants were sufficiently attentive during the similarity ratings task. Participants who did not use the whole similarity rating scale (1-9) and those who did not rate two identical stimuli as identical (by giving them an average rating of seven or above) were excluded from the data. This procedure led to the elimination of 3 participants from the Width Easy group, 3 from the Height Easy group, 2 from the Width Difficult, 1 from the NLS group, and 3 participants from the control groups.

## Learning Results

Trials to criterion and errors correlated highly with each other ( $r=.84, p<.0005$ ). Both the trials to criterion and the errors varied across category structures $[F(5,105)=15.25$, $p=.0005$ and $F(5,105)=11.75, p=.0005$, respectively]. The 'easy' versions of category structures were easier to learn than the 'difficult' versions of the classifications. Also, participants found it easier to learn the 'width' classifications than the 'height' ones, a result showing that the perceptual salience of the two dimensions was not equivalent. Category structures defined along a single dimension (Width easy/difficult \& Height easy/difficult) were easier to learn than those defined along two dimensions (NLS and Diagonal), $t(109)=5.94, p=.0001$. There was no difference in ease of learning between LS category structures and the NLS one, $t(109)=.48, p>.05$. Finally, and as expected, the NLS and Diagonal classifications were the most difficult ones to learn, with no difference between them ( $\mathrm{p}>.05$ ).

## Similarity measures

Change in similarity as a result of learning could be quantified in various ways. The measures typically employed in studies of changes of perception, as a result of categorization, emphasize discriminability along diagnostic vs. non-diagnostic dimensions (e.g., Folstein, Gauthier, \& Palmeri, 2010; Goldstone, 1994). However, in the present study, any putative similarity changes as a result of categorization would relate to the categorization objective, that is, learning the different category structures. Therefore, it is more appropriate to consider a measure of similarity change, which is informed by the category structures in each case. Following theory on the determinants of category structure (Rosch and Mervis, 1975; Love, Medin, \& Gureckis, 2004; Pothos \& Chater, 2002; Pothos \& Bailey, 2009) and categorization work in general (e.g., Mathy et al.,
in press), we employed two dependent variables for how the similarity structure might change as a result of categorization: within category and between category similarity change. Note that similarity in these definitions is empirical similarity from participant ratings. Within and between category similarity change allow us to directly explore the circumstances when the similarity structure for a set of stimuli becomes more consistent with a learned categorization. Within category similarity was the average similarity from all possible pairs in the same category and between category similarity was the average similarity ratings for all pairs across different categories.

Table 1. Trials to criterion, errors, and change in within and between similarity values, as a result of learning, for the six category structures employed in this study. The category structures have been ordered in terms of difficulty of learning. Asterisks indicate that the difference between experimental and control groups for each condition, revealed by independent-samples t-tests, was significant. Positive values indicate that the mean similarity value was higher for the experimental group compared to the control group, while negative values indicate the opposite.

|  |  |  | Similarity change |  |
| :--- | :---: | :--- | :--- | :--- | :--- |
| Category structure | Trials to <br> criterion | Errors | Within | Between |
| Width Easy | 45.50 | 7.2 | $.28^{*}$ | -.13 |
| Width Difficult | 71.00 | 5.6 | $.45^{*}$ | .11 |
| Height Easy | 71.50 | 15.0 | .19 | -.07 |
| Height Difficult | 101.35 | 21.1 | $.59^{*}$ | .11 |
| NLS | 102.60 | 34.6 | $.57^{*}$ | .14 |
| Diagonal | 172.00 | 35.9 | .41 | $-.43^{*}$ |

To provide baseline similarity values, within and between category similarity was calculated for the control participants, following the calculation procedure for their respective experimental groups.
Once similarity values were computed for all groups (both experimental and control), similarity change values were computed for each experimental group. Clearly, any changes in similarity as a result of categorization are only meaningful compared to a pre-learning baseline. For example, suppose a participant provided similarity ratings for the stimuli after learning the Width Easy classification. We would then compute her, e.g., between similarity change value as the between similarity value from her similarity ratings minus the average between similarity value of all corresponding control participants. Henceforth, when we
refer to change in similarity values we imply similarity values computed in this way from the similarity ratings of the control participants, for each category structure. Adopting this analytical approach considerably simplifies comparisons of similarity changes across different category structures. Within and between similarity change can be understood as acquired equivalence and distinctiveness, respectively, but defined in terms of the learned categorizations, rather than stimulus dimensions.

Table 2. The $F$-tests examining the three hypotheses regarding similarity changes as a result of category learning.

| Hypothesis | Similarity change |  |
| :--- | :--- | :--- |
| Within | Between |  |
| Learning difficulty   <br> (Height vs. Width, $F(1,68)=5.40$, $F(1,68))=.92$, <br> easy and difficult) $p=.02$ $p=.89$ |  |  |
| Category boundary <br> aligned with physical | $F(1,36)=.48$, | $F(1,36)=5.66$, |
| variation <br> (Height Difficult vs. | $p=.49$ | $p=.02$ |
| Diagonal) <br> Linear separability <br>  | $F(1,55)=.13$, | $F(1,55)=.04$, |
| Diagonal vs. NLS) | $p=.72$ | $p=.84$ |

## Similarity Analyses

Similarity change for the six category structures we employed are shown in Table 1. For within similarity changes, positive values indicate changes in the similarity structure of the items more consistent with the learned classification. For between similarity changes, it is the other way round; between similarity is defined in terms of the similarity of items in different categories, so that if between similarity is negative this means that items in different categories become less similar (and therefore consistent with the learned classification).
The hypothesis that learning difficulty influences similarity change was examined in a 2 (Dimension: width vs. height) x 2 (Difficulty: easy vs. difficult) ANOVA. For within similarity changes, there was a significant main effect of Difficulty (shown in Table 2), with greater similarity change for difficult category structures than easy ones. There was no main effect of Dimension, $F(1,68)=.03$, $p>.05$, nor a significant interaction, $F(1,68)=.90, p>.05$. For between similarity change, there was no main effect of Difficulty, $F(1,68)=.92, \mathrm{p}>.05$, or Dimension, $F(1,68)=.01$, $p>.05$, and no significant interaction, $F(1,68)=.02, p>.05$.
The hypothesis that similarity changes would be determined by whether the category boundary is aligned with the dimension of physical variation, or not was examined in a one-way ANOVA (Height Difficult VS. Diagonal category structures). As shown in Table 2 this hypothesis was supported for between but not for within similarity changes. Finally, linear separability did not predict within or between similarity changes (Table 2).

## Discussion

There has been considerable interest in changes in similarity (and perception) induced as a result of categorization, though few researchers have attempted a systematic study of the factors that make such changes likely (for an exception see Folstein et al., 2010). The overarching question in this research was whether the nature of the category structure is a relevant factor in trying to understand changes in similarity as a result of categorization. Three main possibilities were considered. The first possibility was that category difficulty would influence similarity change. We suggested that in cases where there are well-separated categories, similarity change may correspond more to within similarity change (cf. ChinParker \& Ross, 2004), but for more poorly separated categories between similarity change may be more pronounced. In either case, more difficult category structures were expected to lead to greater similarity change. Our findings supported this hypothesis, but only partially. Difficulty of learning a category structure predicted changes in within category similarity, with stimuli in the same categories becoming more similar for more difficult, compared to the easier category structures.

The second possibility was that similarity changes are influenced by whether the category boundary was aligned with a dimension of physical variation. Indeed, this hypothesis was supported only for between category similarity change: when the category boundary was not aligned with a dimension of physical variation, then stimuli in different categories became less similar following categorization training. Although the influence of this factor could not be anticipated by prior work on similarity changes (e.g., work on categorical perception; Harnad, 1987), its role can be predicted within modern categorization theory (e.g., Ashby et al., 1998; Ashby \& Ell, 2002). For instance, when the category boundary is aligned with a dimension of physical variation, even when the categories are poorly separated, participants focus on within category information, rather than on between category contrasts. Work on the COVIS model of categorization shows that category boundaries aligned with a dimension of physical variation are simpler than ones which are not, even for poorly separated categories (Ashby et al., 1999). Therefore, the complexity of the category boundary instead of the actual difficulty of the category structures (as defined in this study), may be a factor driving between similarity change. This possibility needs further work to be fully supported.

Finally, linear separability predicted neither within nor between similarity changes, even though this factor was manipulated across conditions, which were broadly matched for learning difficulty.

One debate in the literature concerns the extent to which similarity changes reflect perceptual changes, changes in item representation, changes in the category's internal structure, the addition of a label as a feature in determining similarity, or simply task demands. This is an important issue that is beyond the scope of the current research. It is
important to note, however, that our finding that task difficulty influences the magnitude of similarity changes, is inconsistent with the view that similarity changes are due to the addition of category label to stimulus representations. That is, if a category label was added to stimulus representations in all cases, we should not have observed different degrees of similarity change for different category structures.

The current research revealed several methodological challenges in the study of changes in similarity as a result of categorization. First, several kinds of category structures are needed. Second, it is clearly of crucial importance to specify an appropriate index of similarity change, which takes into account possible differences between category structures. Indeed, in the present study, we did not observe equivalent results across the measures we introduced within and between similarity change. Researchers specifically interested in perception often consider acquired distinctiveness or equivalence, as a result of categorization (e.g., Goldstone, 1994; Harnad, 1987). Such measures are suitable when there are stimuli on either sides of a category boundary, but they are perhaps less suitable when the nearest neighbor stimuli on either side of a category boundary may be distant from each other in psychological space. This will often be the case for category structures that are meant to correspond to naturalistic ones (cf. Pothos et al., 2011).

A major methodological challenge was comparing effects of categorization on similarity for the different category structures. To do this we computed similarity values on the basis of similarity ratings, after they have been potentially modified by category learning (experimental participants) and without any categorization learning (control participants). Consequently, the dependent variables corresponded to the change of similarity ratings as a result of categorization. While we believe our solution to this problem to be adequate, it would be worthwhile to explore alternative approaches in future research.

Overall, the issue of whether some category structures are more or less likely to lead to corresponding changes in the similarity structure of categorized stimuli is a novel and exciting one. Here we presented a promising design to address it and a range of preliminary conclusions.

# Inferring Sensory Experiences 

Kevin Reuter<br>kevin.reuter@rub.de<br>Department of Philosophy, Ruhr University Bochum

#### Abstract

Several scholars, e.g. Sellars (1956), Meltzoff \& Gopnik (1993), have construed the attribution of experiences as being governed by a folkpsychological theory in which experiences function as theoretical entities. However, so far this claim has not been convincingly supported by an account of how people infer the existence of experiences. In this paper I argue that the mechanisms that lead to the stipulation of experiences are fundamentally inferential and are applied in both self-attribution and third-person attribution of experiences. The two most common sources for going through such inferential processes are (i) disagreements between two people in how the world is presented to them, (ii) being aware of or suspecting differences between how the world is presented to a person and extraneous information the person has about the world. From situations like these, I show that 'experience' is a theoretically-acquired concept which refers to entities that play an explanatory role in virtue of fulfilling two conditions: a person entertains the concept experience if that person makes an appearance-reality distinction (C1) and considers the appearance to be subjective (C2).

Keywords: experiences, self-ascription, selfattribution, introspection, appearances, appearancereality distintion, theory-theory, Austin

## 1. The Appearance-Reality Distinction

It is widely held that self-ascribing experiences requires a person to conceive of the way things appear and not how they really are. Tye claims that "if you are attending to how things look to you, as opposed to how they are independently of how they look, you are bringing to bear your faculty of introspection" (2000, p. 46), and Dretske argues that when we self-ascribe experiences "we are conceiving of how things seem" (1994, p.266-7). What it means to conceive of how things seem, however, remains mostly unclear. More
specifically, it is hardly ever discussed, which appearance-statements count as attribution of experiences and which do not. This is especially curious as noone believes that every appearancestatement involves the attribution of an experience, e.g. "she looks chic" is an appearance-statement from which we cannot infer the attribution of an experience.

We often make appearance-statements when we know or suspect that we are in a situation in which it would be wrong to take what we seem to perceive at face value. E.g. we state that 'the Müller-Lyer lines only appear to be of different length' (illusion), 'my phone only appears to be ringing' (hallucination), 'the wall looks green to me but it is white' (unusual lighting conditions), 'the sponge looks like a rock' (different surface conditions) - see figure 1 below.

Figure 1: The Müller-Lyer illusion (left) and a sponge looking like a rock (right) are grasped by making an appearance-reality distinction.

It would be wrong, however, to infer without argument that in all of these cases attribution of experiences takes place. Austin makes an observation that deserves our attention. He states:
"It is perhaps even clearer that the way things look is, in general, just as much a fact about the world, just as open to public confirmation and challenge, as the way things are. I am not disclosing a fact about myself, but about petrol, when I say that petrol looks like water." (1962, p.43, my italics)

The case of a white wall looking green because it is illuminated by green light, and the example of a
sponge looking like a rock because it has a surface that has a rock-like structure, seem to support Austin's claim, that the way things look is as much a fact about the world, just as open to public confirmation and challenge, as the way things are. When it comes to visual examples, the photo test seems to be a possible means to track whether the way an object appears is largely a fact about the world: The illuminated wall will yield a greenish tone on the photo picture, and the sponge is indistinguishable from a rock on the photograph. In contrast, the way the Müller-Lyer lines look to a person does not seem to be subject to public confirmation and challenge. Making a photograph of the lines will not yield lines of differing length on the photograph (assuming of course a head-on photo). Hallucinations, dreams and afterimages are also not subject to public confirmation.

What is important for our discussion, is that Austin seems to have established a feature of appearancestatements which does not hold for all cases, and that this criterion supports our intuition that we selfascribe experiences just in cases in which the appearance is not open to public confirmation. However, it is of course possible for a person to ascribe a sensory state despite the reason for why something appears to be different from the way it really is, is dependent on external conditions of perception; and surely, people can self-ascribe their sensory states even though there is no reason to doubt the veridicality of their experiences. Hence, a simple classification of appearance-statements that are made because the senses are deceived as selfascriptive, and appearance-statements that are made because the conditions of perception are unusual as objective, seems false. What really seem to matter, so I will now argue, are the inferences people make when thinking about appearances. To illustrate this point, let us look at two examples: mirages and the moon illusion.

## 2. Inferring the Existence of Experiences

People are often aware or at least suspect that the world appears different from the way it really is. However, they also often lack an understanding of the reasons for why they make an appearancereality distinction. Mirages are most commonly associated with a thirsty and exhausted person traveling through the desert, suddenly seeming to see an oasis. People offer two distinct explanations
to account for this appearance: illusion and optical phenomenon. Whereas it could of course be the case that a traveler starts to hallucinate an oasis, mirages are properly explained (and most frequently happen) by the bending of light rays from distant objects and can be captured on camera - thus they are optical phenomena. The moon illusion, on the other hand, is a phenomenon that often occurs when people look at the moon which is just above the horizon. The moon appears to be larger on the horizon than it is high up in the sky (see figure 2 below). It was originally thought that due to light refraction in the atmosphere, the moon on the horizon occupies more space in the visual field than it would normally do. However, the moon illusion is not an optical phenomenon but is explained by the workings of our perceptual apparatus and is related to the Ponzo illusion, and cannot be captured on a photograph.

Figure 2: Example of the Moon illusion.
We can see from these two examples that people can be justifiably uncertain about whether the appearance of an object is different from its reality due to external physical conditions or internal psychological conditions. Sometimes it is simply very difficult to ascertain the reasons for a difference in appearance and reality. Misattributions of this difference go both ways: mirages are often misattributed to deranged sensory perception, the moon illusion is often misattributed to the physical properties of the atmosphere. But this also has the consequence that the meaning of an appearancestatement depends on which state - physical or psychological - is blamed for the conceived difference between appearance and reality. Although it is correct to say that the appearancestatement 'the moon appears larger on the horizon' cannot be subject to public confirmation or challenge, a person can say the same words but express a different appearance-statement, one that he thinks expresses openness to public
confirmation. Similarly, although the appearancestatement 'there seems to be an oasis' is usually taken to be subject to public confirmation, a person can utter the same sentence, but uses the sentence in a different sense which precludes public confirmation.

If people consider the appearance-statement to be open to public confirmation, they do not focus on their mental states as representing the world in a certain way, but rather talk about how the world is independent of their experiences. In contrast, they might use an appearance-statement to talk about their experiences themselves - statement which then of course should be classified as self-attributive. We are now in a position to formulate the two necessary and jointly sufficient conditions for self-attributing an experience.

Self-attribution of experiences: a subject $S$ selfattributes an experience iff,
(C1) S distinguishes the appearance from the reality of what $S$ experiences,
(C2) $\quad \mathrm{S}$ considers the appearance to be subjective.

Similarly, we can easily specify the conditions for attributing an experience to another person:

Attribution of experiences to others: a subject $S$ attributes an experience to agent O iff,
(O1) S distinguishes the appearance from the reality of what O experiences,
(O2) S considers the appearance to be subjective.

Being aware of or suspecting differences between the way the world presents itself and other beliefs we have about the world, is one of the two main sources for why people attribute experiences. We often suspect that the way the world presents itself is not how it really is with our less dominant senses, e.g. it may seem to us as if there is faint smell of burned toast in the air, but it might as well be just our imagination or a different scent that we misinterpret accordingly. In these and similar cases, suspicion often arises as to whether we experience the world differently from how it really is.

Disagreements between people about the way the world is perceived to be, are the second main source for attribution of experiences. Suppose you are at a ball, talking to a woman, and comment on how the
red-coloured dress suits her style. She responds by politely pointing out that the dress is of an orangecoloured shade. The disagreement about the colour might persist, and you cannot get yourself to see the orange colour. Once again, there seem to be two options: you can either blame the lighting conditions or some other external condition, or you can blame your way of perceiving the world for the disagreement, and thus attribute to yourself an experience.

Both the first-person and the third-person cases are very similar. People attribute experiences to other people for the same reasons that they self-attribute experiences: there is a difference between what seems to be the case for oneself and what seems to be the case for another person. This situation needs an explanation, and thus people postulate the existence of experiences.

We can generalise this case by following inferential theory-theoretic rule (TT):
(TT-A) If the perceptual statements of two honest people differ, and if these people
have sufficient knowledge and are in a position to make correct statements about the world, it is reasonable to draw a distinction between how the world appears and how the world really is.
(TT-B) If there is no obvious worldly cause for why people disagree with each other, it makes sense to consider the possibility that the way the world appears is dependent on the sensory system.
(TT-C) In 'blaming' the sensory system for the way the 'world' appears, attribution of experiences takes place.

## 3. The Explanatory Power of this Theory-Theory

This theory of self-ascription of experiences not only specifies two necessary and jointly sufficient conditions for the self-attribution of experiences, but also (a) analyses the concept of experience, and (b) captures the cognitive requirements that we need to be in possession of in order to be capable of metacognition.
(ad a) There is a need to specify the minimal but also sufficient conditions for the possession of the concept experience. (C1) and (C2) state that a
person entertains the concept of experience, if that person makes an appearance-reality distinction (C1) and considers the appearance to be subjective (C2). These two conditions have the advantage of specifying the conditions for entertaining the concept of experience in a non-circular way, i.e. we do not need to mention experiences in the description of the two conditions.
(ad b) Empirical results from the psychological literature on the appearance-reality task have a direct bearing on this discussion. According to this theory, children need to make two important advancements in their understanding of the nature of the world in order to have the ability to ascribe experiences. First, children need to understand that things can appear to be different from the way they are ( C 1 ). Second, they need to understand that the reason for why things can appear different is not always found in the environment itself (C2). In one of the well-known appearance-reality tasks, a sponge that looks like a rock, is presented to children. Several psychologists and philosophers argue that once children pass the appearance-reality task, they have gained the cognitive ability to selfascribe experiences (Taylor \& Flavell (1984), Nichols \& Stich (2003)). But this conclusion is not warranted. It is possible, and indeed highly plausible, to presume that children do not consider the reason for the appearance-reality distinction to be a matter of perceiving the sponge, but rather to blame the deceptive appearance on a visible property of the sponge. Thus, a child might pass the appearance-reality task because he associates the appearance of the sponge as a rock with the form of the sponge, e.g. the surface, shape, and size of the sponge is rock-like. The child does not need to think that the appearance of rock-like properties is explained by the way the sponge is perceived.

It is of course possible to self-ascribe a veridical experience without having any doubts whatsoever regarding the veridical nature of the experience. A person might entertain the concept of experience for other reasons (e.g. she just read about the brain-in-a-vat thought experiment) or for no obvious reason at all (e.g. sometimes thoughts enter our mind without us knowing where they 'came from'). The main conclusion of this paper is that self-awareness of experiences is often arrived at by an inferential process that is governed by a folk-psychological theory that we learn as children. The concept of experience is therefore a theoretically-acquired concept which refers to entities that play an explanatory role in that theory.

The theory I have presented belongs in certain respects to the group of theories which are commonly labelled 'theory-theories of selfawareness' (TTSA) and which originate in the theories of Ryle (1949) and Sellars (1956). Proponents of TTSA hold a theory according to which a person who self-attributes an experience, uses a theory to do so - hence the name 'theorytheory of self-awareness'. In a sense, I also claim that a person often uses a theory to self-ascribe her experiential states, but it must be clearly differentiated from other theory-theories that have been advocated in the literature. It is often argued that theory-theory accounts of self-awareness state that self-ascriptions of mental states are based on the same or similar processes as ascriptions of mental states to others (Kind (2005), Schwitzgebel (2010)). This claim is ambiguous: it can either mean that we determine the content of other people's mental states by the same or similar mechanisms that we use when determining the content of our own mental states; or it can mean that the mechanisms that lead from thoughts about the world to the attribution of experiences to others are the same or similar to the mechanisms when selfattributing mental states. Whereas I reject the former claim, I endorse a restricted form of the latter thesis. We do not infer what we experience but rather that we experience. What we experience, we know by perceptual attention and recognition. That we experience, we know by theorising about the circumstances we often find ourselves in

## 4. Objections

In this section $I$ evaluate two rather specific objections against construing the self-attribution of experiences in the way I have suggested above. First, Carruthers argues that the theory that children apply when they attribute experiences, is a nativistic theory. I show that Carruthers's claim is not warranted and that instead the inferential mechanisms that we apply when attributing experiences, are learned by children. Second, Papineau argues that experiences cannot be entities embedded in a folk-psychological theory because we can conceive of experiences as epiphenomenal states. I agree that Papineau's argument is valid, but he presupposes a conception of experiences as theoretical entities that my theory is not committed to.

Are self-attributive inferences nativistic or learned?

Carruthers claims:
"I favour such a nativistic theory-theory because if, firstly, young children are pictured as little scientists, constructing a mentalistic theory as the best explanation of the data, then it beggars belief that they should all hit upon the same theory, and at the same tender age too (at about the age of four, in fact). But if, secondly, the theory is supposed to be learned by the child from adult practitioners, then it is puzzling how this can take place without any explicit teaching or training;" (1996, p.23)

I agree with Carruthers that if we do conceive of young children as little scientists who need to construct their mentalistic theory all by themselves, then we should expect diverging theories to emerge from different children at different ages. But what is Carruthers's evidence that adult practitioners do not teach young people their theory of experiences? He gives none. So let me present what I consider to be a plausible story about how adults teach young children to self-attribute their experiences.

I have argued that the capability to make a distinction between appearance and reality is one of two necessary conditions required to grasp the concept experience. Adults not only provide children with the linguistic tools to make this distinction, they also actively educate children in making this distinction in appropriate circumstances and explain why appearance and reality can come apart. If a child asks what a rainbow is, the parent might tell the child that rainbows are not what they appear to be, but are only optical phenomena; or when the lights are switched off, then things do not become black, but only appear to be black. By then, children have also learned that bodily states like pains and itches are only felt by themselves, simply because they are the only ones who are 'connected' with their body. The distinction between public and private objects is, moreover, manifested in everyday conversations with adults. Adults ask children whether they are hungry, and ask them where the pain is located, but they tell them to watch out where they are going, tell them to eat food, and tell them to listen to what they say. Thus, children learn that (a) objects often do not change but rather their perceptual properties do, and that (b) they can draw a distinction between private objects and public objects of discourse. However, if it was not for situations in which children are required to combine
both ideas, the stipulation of experiences would seem unnecessary - at least from a folkpsychological standpoint. These situations exist though, and provide Kuhnian puzzles for children. Although illusions and hallucinations are the prime examples of non-veridical experiences in the philosophical literature, the most common and persistent non-veridical experiences are dream experiences. Children are not only regularly confronted with dreams they also want support from their parents especially after having had nightmares. But now the following curious situation occurs: parents tell their children that they need not worry because what they dreamed was not real. However, they also ask their children about what happened in their dreams. Thus, children are told that they had appearances that are private to them. They now only need to combine these two ideas, and thereby understand the concept of experience. I therefore reject Carruthers's claim that the concept of experience is nativistic.

## Do experiences necessarily have effects?

Papineau considers the possibility that selfattribution like 'this auditory experience', utilises a concept of experience, that is "some kind of theoretical concept, constituted by its role in some theory of experiences" (2007, p.121). He rejects this solution because he argues that if we really derive the concept of experience from some folkpsychological theory then we conceive of experiences as states with causes and effects. These causes and effects do not need to be specified by folk-psychology but they would be nonetheless an analytic part of our conception of experience. However, Papineau states, we can without contradiction think of experiences as epiphenomenal states without any subsequent effects like behaviour.

Papineau's argument is sound but only under a more specific reading of what a theoretical concept involves, which we do not need to accept. I argue that when children learn how to distinguish appearance from reality, they theorise that experiences have causes but not necessarily any effects. Possessing the concept of experience enables a person to conceptually distinguish veridical from illusory or hallucinatory experiences, and if there is a difference between appearance and reality, the person understands that the experience was not merely caused by worldly objects and events. However, I do not see any reason why we
should believe that this concept of experience is committed to the fact that experiences have cognitive or behavioural effects. Applying the appearance-reality distinction only implies that appearances are caused by the world, but not that appearances themselves have any effects. Thus, epiphenomenalism is consistent with phenomenal concepts being constituted by a theoreticallyacquired concept of experience.

## 5. Conclusion

In this paper I have argued that we understand experiences to be (a) appearances that are (b) subjective. In most circumstances in which a person attributes an experience, there are very good reasons for doing this. These reasons follow the twofold structure of the concept of experience. I have argued that there are two main 'sources' of experience attribution. First, a person might become aware of or suspect differences between how the world appears and how it really is. Second, disagreements between two people about how the world 'presents itself', can make people aware of such differences. The inferential nature of attribution of experiences was defended against two objections.

#### Abstract

Longitudinal data of conventionalization in emerging languages, combined with computational models explaining such data, are lacking in the literature on language emergence. In the present study we report on the emergence of gestural communication systems ("homesigns") invented by deaf individuals in Nicaragua. Analysis of longitudinal data from several families shows gradual convergence toward a gestural system with the essential characteristics of a shared lexicon. We propose a general computational framework to formalize the linguistic and social interactions among the individual signers such that a shared lexicon may arise. More specifically, a reinforcement learning process that adjusts the individual's probability of gesture use in response to others' actual gesture use provides a suitable account of the observed gestural convergence. Implications for language emergence are discussed.

Keywords: lexicon; homesign; conventionalization; language emergence; computational modeling; sign language; multiagent reinforcement learning model

## Introduction

How do languages emerge? What kinds of learners and environments, and particularly patterns of interaction among learners, give rise to language? The spontaneous emergence of gestural communication systems in deaf individuals not exposed to spoken or signed language (homesigners; Coppola \& Newport, 2005; Brentari \& Coppola, 2012) and of natural languages in deaf communities (Polich, 2005; Meir, Sandler, Padden \& Aronoff, 2010) offer unique opportunities to study the process of natural language emergence. Computational models, in contrast, allow formalization and testing of theories of language emergence. These two approaches clearly complement each other, yet there have been no integrations of the two in the literature on language emergence. To begin to rectify this, in this paper we compare empirical data from emerging sign systems to computational models to investigate emergence of a fundamental component of language: the lexicon. In particular, we investigate the process of conventionalization
of lexicons among small groups of individuals. We begin by reviewing extant literature on conventionalization.

Conventionalization of form-meaning mappings among interacting agents has been a major focus of language emergence research, mostly in experimental (see Galantucci, Garrod, \& Roberts, 2012 for review) and computational (Hutchins \& Hazlehurst, 1995; Barr, 2004; Steels \& Loetzsch, 2012) investigations. Human adults are brought into the lab to develop novel communication systems under various conditions (Selten \& Warglien, 2007), but in nearly all cases, conventionalization is observed among participants. In a related literature, researchers have investigated how language-learning biases shape communication systems as they are transmitted and learned across multiple generations (Kirby, Cornish, \& Smith, 2008). The basic finding is that human learners exposed to unsystematic form-meaning mappings will restructure these form-meaning mappings to be more compositional and learnable.

Conventionalization in natural language emergence is far less studied-the opportunities to observe the process are of course few and far between, and, when researchers become aware of a case, it is often well after a basic lexicon has conventionalized (R. Senghas, 1997). In fact, we are not aware of any studies observing conventionalization over time in emerging natural languages. We are only aware of studies of emerging systems that examine either inter-user consistency at a single point in time (e.g., Osugi, Supalla \& Webb, 1999), or intra-user consistency across a span of time (e.g., Goldin-Meadow, Butcher, Mylander \& Dodge, 1994). Showing images of objects and eliciting gestures for them, Osugi et al. (1999) investigated consistency in formmeaning mappings of lexical items among 21 deaf and hearing individuals in the geographically and genetically isolated Koniya region of Amami Island south of Japan. They show that individuals either Deaf or hearing were consistent with each other to the extent that they interacted. Goldin-Meadow et al. (1994) investigated the consistency over time of form-meaning mappings of gestures produced in a naturalistic context by a child homesigner called David
and his hearing mother. They found that David was more internally consistent than was his mother (and concluded that it was he who introduced into his system a noun-verb distinction, their primary object of interest).

In all, then, the two homesign studies, while shedding light on the outcome of conventionalization, reveal very little about the underlying process. The experimental research on conventionalization reviewed earlier, while suggestive, has not addressed conventionalization in natural linguistic settings. Computational modeling may provide explicit proposals of conventionalization mechanism, but it also suffers from the lack of connection with the empirical work. For instance, Barr (2004) investigated the effect of local vs. global information in conventionalization but the simulations are carried out on artificial data without making reference to experimental results or naturalistic case studies. The disconnect between experimental and computational approaches is a general concern for research on collective and cooperative behavior (see Goldstone \& Gureckis, 2009 for review).

In this paper, we take a step toward unifying empirical and computational work. We first, present new longitudinal data on conventionalization from naturally emerging homesign systems. We compare this data to preexisting non-longitudinal data on lexical consistency in Nicaraguan Sign Language (NSL), a natural sign language emerging in a vibrant Deaf community (Senghas \& Coppola, 2001; Senghas, 2003). We then present a general framework for studying conventionalization that incorporates elements of learning and social interactions. A specific implementation with reinforcement learning (Yang, 2002) appears to capture the observed trends of conventionalization. We conclude with a general discussion on the conditions for language emergence in a naturalistic setting.

## Homesign lexicons

In the present study, we examine conventionalization over a 9 -year period in form-meaning mappings for basic objects and concepts among deaf Nicaraguan homesigners and their family and friends.

## Method

Participants Participants were four deaf Nicaraguan homesigners [ 3 male; aged 11 to 33 years $(M=24)$ at various times of testing] and nine of their hearing family members and friends [4 male; aged 10 to $59(\mathrm{M}=30)$ at various times of testing; we henceforth refer to these family and friends as communication partners]. The homesigners have minimal or no interaction with other deaf individuals, including each other, and have minimal or no knowledge of Nicaraguan Sign Language or spoken or written Spanish, Instead, these homesigners have been using their respective invented gestural homesign systems all their lives. Despite their lack of linguistic input, they socialize with others, hold jobs, have families, and otherwise have typical lives. See Table 1
for relations between the homesigners and their family members.

Table 1: Homesigning groups

| Family 1 | Family 2 | Family 3 | Family 4 |
| :---: | :---: | :---: | :---: |
| Homesigner | Homesigner | Homesigner | Homesigner |
| Mother | Mother | Mother | Younger |
| brother |  |  |  |

Stimuli Stimuli were images of 22 basic objects and concepts. All items were familiar to participants. Nineteen of these objects and concepts were taken from Osugi et al. (1999), which itself was derived from Swadesh (1971). The stimulus items were: boy, cat, cold, cook, cow, dog, egg, fire, fish. flower, ice, girl, hot, moon, orange, palm tree, potato, rain, snake, stones, and sun.

Procedure In 2002, 2004, 2006, and 2011, M.C. showed participants images of the objects and concepts outlined above. Participants were tested individually. Using gesture and facial expressions, M.C. elicited participants' gestural responses to these images. Hearing participants were asked to use their hands to respond, and all were easily able to do the task. Participants responded to the camera, not to each other, and were not allowed to see each other's productions. All responses were videotaped for later analysis.

Coding Participants' responses were coded by a research assistant in consultation with R.R. A majority of responses contained more than one gesture (2 gestures: $40 \%$, 3 gestures: $15 \%, 4$ gestures: $4 \%$, and 5 gestures: $2 \%$ ), and so we coded every gesture individually for its Conceptual Component (CC), or aspect of the item's meaning that the gesture iconically represented. For example, a response to 'cow' might contain two gestures, one iconically representing horns (its CC is thus HORNS) and another iconically representing milking (its CC is thus MILKING) ${ }^{1}$.

## Results

Treating every CC as a dimension in a combinatorial space, every response can be represented as a binary-valued vector, with 1 representing the presence of a given CC and 0 the absence. The distance between two responses to the same object is thus a measure of conventionalization. We define distance here as the number of vector values by which two responses differ, and weight more heavily those vector values corresponding to CC's used more frequently (i.e. disagreement on the use of the CC ROUND will lead to a greater distance than disagreement on the infrequent CC

[^198]

Figure 1: Average distances, across objects tested, between a partner's lexicon and his/her homesigner's lexicon, per year. Partners converge with their respective homesigners.

MILKING) ${ }^{2}$. For a given object in a given year, we calculated this distance between each homesigner's response and that of each homesigner's communication partner's responses. For example, we calculate the distance between Homesigner 1's 2011 response to 'cow' and his mother's 2011 response to 'cow', as well as their 2006, 2004, and 2002 responses to 'cow'. For each homesignerpartner pair and year, we average these distances across all tested objects, yielding an overall measure of lexicon distance or conventionalization between a pair. Results are summarized in Figure 1 which shows decreases in lexicon distance across partners. To give a sense of the scale of weighted distance, consider a partner that with probability $P$ will agree with a homesigner in the usage of a CC. Simulations show that a partner agreeing with a homesigner $92.5 \%$ of the time gives a weighted distance of .069 , and agreeing $96 \%$ of the time gives a weighted distance of 0.036 $-\mathrm{a} \sim 50 \%$ reduction in error. This is roughly the change a typical communication partner (CP13) undergoes from 2002 to 2011.

We ran two tests to establish that (1) communication partners gradually converge with their respective homesigners, but that (2) even in 2011, convergence was not complete (where distance would be zero). To investigate our first question, we first extracted, for every partner, slopes of the linear regressions predicting homesigner-partner distance from year of testing. A one-tailed, one-sample Wilcoxon Signed Rank test on the nine slopes indicated that the median of this sample was significantly below 0 ( $\mathrm{W}=0$, $p<.01$ ), confirming the gradual convergence between homesigners and partners. To investigate our second question, we ran a series of one-tailed, one-sample

[^199]Wilcoxon Rank-Sum tests on the 2011 homesignercommunication partner distances. We found that these distances, despite decreasing over time, are still significantly greater than 0 ; all 9 of 9 such tests are highly significant (W's $\geq 91, p$ 's $\leq .001$ ).

## Discussion

We showed above that deaf homesigners slowly converge on form-meaning mappings with their hearing communication partners, but that convergence is not complete, even in 2011, the latest year in which we collected data. This contrasts sharply with the state of convergence in Nicaraguan Sign Language. The Deaf community in Managua, Nicaragua initially formed in 1978 (Polich, 2005), and by 1993 was holding 'standardization seminars' in smaller cities and towns outside the capital of Managua to spread the signs developed in Managua to the rest of the country (R. Senghas, 1997; López Gómez, Perez Castellón, Rivera Rostrán, \& Baltodano Baltodano, 1997). Thus, the NSL users in Managua must have converged on at least a basic lexicon in less than 15 years after coming together ${ }^{3}$. By 2011, all of the present homesigners had been using their respective systems for well more than 15 years, yet none of them had converged completely with any of their communication partners. What might explain this difference in rate of conventionalization between homesign and NSL? One possibility concerns the differences in patterns of interaction between users of homesign systems and users of NSL (and other Deaf community sign languages, Woll \& Ladd, 2003). While the deaf user of a homesign system uses the system for all interactions, the

[^200]hearing users only use the system to interact with that deaf user. In NSL and other deaf community sign languages, however, all users of the system interact with other users of the system using the system. In other words, the homesign interactive structure is one-to-many, while the NSL/deaf community structure is many-to-many. We now turn to our model, which replicates convergence, and allows us to test these predictions.

## Modeling Conventionalization

What are the conditions for conventionalization, whereby a shared lexicon emerges through strictly local linguistic interactions among linguistic individuals? At least two elements of process suggest themselves. First, the individuals must be "lexicon ready". In the simplest case, they must be able to maintain a list of form-meaning pairings. Similar to our study of homesigns, the individuals must be capable of making combinatorial use of constitutive units as in our case of Conceptual Components. Second, the individuals must be capable of learning, or modifying their lexicon as the result of linguistic and social interactions. In this section, we first describe a general framework to study lexical conventionalization. We then study its dynamics through the use of reinforcement learning (Bush \& Mosteller, 1951; Yang, 2002) as a model of learning and social interactions. Last, we use the model to test the hypothesis regarding the difference in conventionalization between homesign and NSL.

## The Framework

Consider a population of $N$ agents communicating a set of meanings through the combinatorial use of $C$ binary signs that are analogous to Conceptual Components in the homesign data. For a specific meaning, agent $i$ accesses a vector of probabilities $P_{\mathrm{c}}=\left\{p_{c}^{i}\right\}$, defined over these signs ( $j$ $=1,2, \ldots, C$ ) such that with probability $p_{c}^{i}$, the $c$ th sign is used by agent $i$ and with probability $\left(1-p_{c}^{i}\right)$, the $c$ th sign is not used. This representation can also be used to encode atomic use of signs, i.e., each meaning is expressed by one sign, in which case the vector $\sum_{c} p_{c}^{i}=1$ (i.e., agent $i$ has a probabilistic distribution of the signs and only one of them is chosen at each instance of use).

The central premise of the conventionalization model is that individuals adjust their choices of linguistic encoding in attunement with their communicative partners. To communicate a meaning, agent $i$ instantiates a vector $U_{i}$ of 0 's and 1's according to $P_{i}$. Agent $j$, the listener, generates a vector $U_{j}$ for that meaning according to its own $P_{j}$. (Note that the instantiations $U_{i / j}$ are not deterministic since the values are probabilistically chosen.) For each sign, agent $j$ compares $U_{j}$ against $U_{i}$ and makes adjustments to $P_{j}$ to agree with agent $i$ by the use of some learning algorithm. The changes in the distance between $P_{j}$ and $P_{i}$ over time represent the extent of convergence or conventionalization.

Linguistic communications among agents may also have a social component. Consider a matrix $S=\left[s_{i, j}\right]$, which defines the probabilities of communication between agents $i$ and $j$
such that $\forall i, \sum_{j} s_{i, j}=1$. The social matrix provides a general platform to encode patterns of interactions among agents. A matrix with positive probabilities only among the neighboring agents, for instance, is a straightforward implementation of Schelling (1971)'s classic model of segregation. The matrix may be fixed or it may change as the result of communication. For instance, it seems reasonable that agents would modify their partner preferences based on past successes or failures of communication, which can be modeled as $s_{i, j}$ increasing if a successful communication has occurred between agent $i$ and $j$ and decreasing upon failure.

As the result of the communicative interactions, the probability vectors for agents $\left\{P_{i}\right\}^{t}$ change over time, which characterizes the evolution of the lexicons in the population. In general, the dynamics of $\left\{P_{i}\right\}^{t}$ can be analyzed as a Markov Chain, first used by Berwick \& Niyogi (1997) to study language learning and change. Different choices of the learning algorithm ( $L$ ), which may be discrete or probabilistic (including Bayesian inference), the social matrix $S$ (and its own evolution), together with the current values in $\left\{P_{i}\right\}^{t}$ define the transition matrix $T^{t}$ at time $t$, which can be multiplied with $\left\{P_{i}\right\}^{t}$ to produce the next state of lexicon $\left\{P_{i}\right\}^{t+1}$. Similar models have been developed in the iterated learning framework (e.g., Kirby, Dowman \& Griffiths, 2007).

## Conventionalization through Reinforcement Learning

In what follows, we propose a specific learning model and consider several variant implementations relevant to the present study of sign convergence. The learning model is an instance of reinforcement learning (Bush \& Mosteller, 1951), a simple, efficient and domain general model of learning now with considerable behavioral and neurological support (see Niv, 2009 for review), and one which has been used in computational and empirical studies of language acquisition (Yang, 2002). Let agent $j$ 's current probability for sign $c$ be $p$. Upon each communication, the listener $j$ adjusts $p$ to match agent $i$ 's choices, following the Linear-Reward-Penalty ( $L_{R P}$ ) scheme of Bush \& Mosteller (1995) where the magnitude of change is a linear function of the current value of $p$ :

- Agent $i$ chooses 1: $p^{\prime}=p+\gamma(1-p)$
- Agent $i$ chooses $0: p^{\prime}=(1-\gamma) p$
where the learning rate $\gamma$ is typically a small real number. All probabilities are subsequently renormalized. Again, other models of learning can be studied in this fashion.

Social matrix: static vs dynamic We also consider the social communicative factors in conventionalization by manipulating the social matrix that defines the modes of individual interactions. As suggested above, we consider a case of adaptive social interactions where $\mathrm{s}_{\mathrm{i}, \mathrm{j}}$ increases if listener $j$ agrees with agent $i$ in all the choices of signs and decreases otherwise. The update rules for $S$ also follow the

LRP reinforcement learning scheme described above. Contrast this with static interactions where $\mathrm{s}_{\mathrm{i}, \mathrm{j}}$ 's remain constant.

Social matrix: homesign vs language An additional dimension of variation directly concerns the present study, for which we construct a homesign matrix in which one individual, the deaf signer (say agent 1 ), communicates with all other (hearing) individuals who do not use signs to communicate with each other. The matrix is initialized such that $\mathrm{s}_{\mathrm{i}, \mathrm{j}}=1 /(\mathrm{N}-1)$ where N is the total number of agents, $\mathrm{s}_{\mathrm{i}, 1}=1(\mathrm{i} \neq 1)$ and $\mathrm{s}_{\mathrm{i}, \mathrm{j}}=0(\mathrm{i}, \mathrm{j} \neq 1)$. We also consider what can be referred as the language matrix, where all agents are deaf and use signs to communicate with each other ( $\mathrm{s}_{\mathrm{i}, \mathrm{j}}=1$ / ( $\mathrm{N}-1$ ), $\mathrm{i} \neq \mathrm{j}$ ), which corresponds more closely to the sociolinguistic settings of typical sign language emergence (Woll \& Ladd, 2003). In all, we have four different modes of social interaction, that is, (home sign, sign language) $x$ (adaptive, static) and we explore their dynamical properties below.

Results In our simulations, we consider a population of $N=$ 5 agents. For each sign, we initialize the values in $P_{i}$ for each agent randomly between 0 and 1 ; they start out preferring either the use or the non-use of each sign with random probabilities. The learning rate $\gamma$ is set to 0.01 and is used for the adjustment of both $P_{i}$ 's and $S$, the social matrix that encodes the probabilities of inter-agent communications. For each simulation, we run the simulations over 2 million instances of communications; in the case of convergence, i.e., all $N$ agents in complete agreement with respect to sign usage (all $P_{i}$ 's at the value of 0 or 1 ), we record the number of iterations required for convergence. The main results are summarized in Table 2. Two things can be gleaned from these results: (1) there is no difference in convergence time between adaptive ( $p=0.412$ ) and static ( $p=0.435$ ) social structures and (2) there is a significant difference in convergence time between the homesign-type model and the language-type model ( $\mathrm{p}<10^{-12}$, for both social matrixes), indicating the importance of a mutually engaged community for the rapid emergence of a true linguistic system, and offering a potential explanation for the difference in rates of conventionalization between homesign and Nicaraguan Sign Language.

Table 2: Average number of iterations to convergence (percentage of simulations reaching convergence in 2 million iterations)

|  | Homesign | Language |
| :---: | :---: | :---: |
| Dynamic | $757 \mathrm{~K}(87 \%)$ | $281 \mathrm{~K}(100 \%)$ |
| Static | $698 \mathrm{~K}(80 \%)$ | $260 \mathrm{~K}(100 \%)$ |

## General Discussion

In the current work, we (1) presented longitudinal data showing conventionalization of lexicons among users of naturally emerging language-like systems (homesign gesture
systems); (2) showed that conventionalization in these homesign systems is slower than in Nicaraguan Sign Language (NSL), a recently emerging sign language used by a Deaf community; (3) formulated a general framework and causal model of conventionalization, in the form of a multiagent reinforcement learning model that obtains conventionalization; and (4) showed that an NSL-inspired model where all agents interact with each other converges significantly faster than a homesign-inspired model in which one agent (i.e. a deaf individual) interacts with every other agent (i.e. hearing individuals), but these other agents interact only with the first agent. We discuss implications our findings below, as well as open questions.

To the best of our knowledge, the present study is the first published observation of the lexicon, a fundamental component of language, emerging in natural human communication systems. Conventionalization has of course been obtained and studied numerous times in experimental settings (Galantucci et al., 2012), but our study is the first to connect the richness and complexity of real linguistic situations with well motivated models of learning. Surprisingly, variations in the dynamics of communications (the adaptive vs. static conditions in Table 1) led to little difference in the rate of convergence. The role of social/communicative factors in language emergence therefore deserves more careful consideration.

Our study is likewise, as far as we know, the first published paper to compare longitudinal or cross-sectional empirical data of naturally emerging languages to computational models of language emergence. As argued in the introduction, this synthesis is critical to a better understanding of language emergence. For example, many previous studies had established differences in linguistic complexity between homesign systems and natural sign languages (e.g., Coppola \& Senghas, 2010 regarding incorporation of deictic forms into syntax; Flaherty \& Senghas (2011) with respect to the existence of a count list), and had hypothesized about what differences between these systems' users affect language emergence (Senghas, 2005), but it has not been clear how exactly these differences influence language emergence. Our present data and model begin to answer this last question: more connected networks among users of the systems may accelerate conventionalization and language emergence.

Of course, alternative explanations of the different rates of conventionalization, and of complexity in general, in homesign systems and NSL do of course exist. For example, the hearing users of the homesign system have a spoken language to communicate with, and are thus under less pressure to use and conventionalize the homesign system. This contrasts with the situation faced by the deaf homesigner and users of NSL, who can only use their signed communication system and are thus behooved to conventionalize at a greater rate. Likewise, other learning models, e.g. Bayesian, can be studied in the general dynamic framework of language emergence. However, in the absence of more data to test the unique predictions of
different models, we opt here for one of the simpler possible models. We speculate that the general effects of network structure on conventionalization do not differ by class of model. These and other possibilities are not mutually exclusive and can be subject to future research. To identify a set of empirically motivated and verified conditions under which emergence takes place, or fails to do so (in a timely fashion), is an important first step toward to understanding the emergence of language.

## Acknowledgments

We would like to thank our deaf and hearing Nicaraguan participants and the members of the Coppola lab and the Sign Language Reading Group at the University of Connecticut. This research was supported by NSF IGERT grant \#1144399 to UConn and NIH grant P30 DC010751 to MC and Diane Lillo-Martin.

# A Bottom-up approach to the cultural evolution of bilingualism 

Seán G. Roberts (sean.roberts@mpi.nl)<br>Language and Cognition Department, Max Planck Institute for Psycholinguistics<br>Wundtlaan 1, Nijmegen 6525 XD The Netherlands

#### Abstract

The relationship between individual cognition and cultural phenomena at the society level can be transformed by cultural transmission (Kirby, Dowman, \& Griffiths, 2007). Top-down models of this process have typically assumed that individuals only adopt a single linguistic trait. Recent extensions include 'bilingual' agents, able to adopt multiple linguistic traits (Burkett \& Griffiths, 2010). However, bilingualism is more than variation within an individual: it involves the conditional use of variation with different interlocutors. That is, bilingualism is a property of a population that emerges from use. A bottom-up simulation is presented where learners are sensitive to the identity of other speakers. The simulation reveals that dynamic social structures are a key factor for the evolution of bilingualism in a population, a feature that was abstracted away in the top-down models. Top-down and bottom-up approaches may lead to different answers, but can work together to reveal and explore important features of the cultural transmission process. Keywords: Language; Cultural evolution; Bilingualism;

 Bottom-up.
## Introduction

Bilingualism is prevalent in many communities, but this is, intuitively, an unstable situation. What drives the emergence of bilingualism? Previous top-down computational models have emphasises the role of the learning biases of individuals such as a language's prestige (Abrams \& Strogatz, 2003), or expectations about variation in the input (Smith, 2009; Burkett \& Griffiths, 2010; Smith \& Thompson, 2012). However, these models assume that languages are monolithic, discrete and static. A bilingual is defined as an individual that adopts more than one linguistic variant from a set of discrete languages that has been defined a priori. This paper questions this assumption and explores how differences arise between the linguistic codes of communities in the first place and how they are subsequently adopted and maintained. In doing so, reveals that social factors, such as cultural identity and the dynamics of population structure, are crucial to the process of cultural evolution.

While low-level linguistic variants such as word order may plausibly have a discrete psychological reality (Diamond, 1991), 'languages' are more complex entities. Dividing continuous linguistic variation into categorical units or distinguishing 'languages' from 'dialects' is not straightforward and often involves complex notions such as politics, history, geography and identity (Sober, 1980; Haugen, 2009; Croft, in press; S. Roberts, 2012). The features of a language and the way it contrasts with others also changes over time. Therefore, this paper assumes that monolithic, static 'languages' (e.g. English, Welsh) have no psychological reality, but are emergent properties of populations and use. An abstract definition of bilingualism is presented which does not require
discrete categories: bilingualism is the amount of linguistic variation that is conditioned on social variables. That is, if I speak differently to Mary than to John, then I'm bilingual to some extent. This definition is compatible with the notion of audience design in sociolinguistics (Bell, 1984), and identifies bilingualism as a gradient property of interaction rather than a categorical feature that is identifiable in an isolated individual.

In order to explore the cultural evolution of bilingualism in this way, a bottom-up simulation is presented where learners are embedded in dynamic social structures and are sensitive to the identity of speakers. The top-down models assumed that social structures were static and focussed on cognitive explanations. In contrast, the bottom-up simulation will demonstrate that changes to social structures are an important factor. Rather than arguing that the bottom-up simulation is 'better' than the top-down model, this paper argues that different modelling tools tend to bias researchers towards making certain kinds of assumptions.

## Simulation definition

Bilingual cultural transmission is simulated as iterated stepwise linear regression. The representation of language is highly abstract, but allows the simulation of the emergence of bilingualism in a complex social structure. The linguistic space is a continuous one-dimensional space. A linguistic utterance is a point on this space (a real number). A meaning is represented as a point in a multi-dimensional meaning space. Each dimension of the meaning space represents a different semantic variable, such as properties of the environment that a linguistic utterance might be referring to (e.g. colour, number, size, tense etc.). A point in the meaning space, then, represents a particular combination of semantic elements (e.g. one big yellow thing). Each semantic variable has a set of hidden parameters which describe the distribution from which values are sampled. This systematic variation ensures that the linguistic signal has some structure to emulate. An important exception s a semantic variable that represents the identity of the speaker who described the event (speaker ID).

A 'learner' observes 'teachers' describing meanings with utterances and learns a mapping between the linguistic signal and the meaning space. The learning mechanism is a linear regression which results in an linguistic model that maps points in the meaning space to points in the linguistic space. The learner can then use this model to produce linguistic utterances itself.

Real languages exhibit flexibility with regards to which aspects of meaning condition linguistic variation. For example, in French, the form of a demonstrative (ce,cette,ces) depends

Figure 1: A diagram of how the bottom-up simulation works. Teachers produce linguistic and semantic data for a learner to observe. The learner uses stepwise regression to build a linguistic model, which is then used to describe some new semantic variables for the next generation.
on the grammatical gender of the referent and whether it is singular or plural, while the distance of the referent from the speaker is not important. In contrast, in Panjabi, the form of a demonstrative ( $i h, u h$ ) is conditioned on distance from the speaker, but not gender or number. In order to capture this flexibility, the linguistic model is selected by stepwise linear regression. A stepwise regression selects the minimum number of salient (semantic) variables that maximises the statistical fit, according to an information criterion. This allows the learner's linguistic model to prioritise or ignore different semantic variables in its linguistic utterances, including the identity of the speaker.

This learning process is iterated (Smith, Kirby, \& Brighton, 2003) in the following way. Learners observe a number of 'teachers' describing points in the meaning space with linguistic utterances, as above. The observations are affected by a small amount of noise. The probability of observing an utterance from a particular speaker depends on the structure of the community (see below). After the learners induce a linguistic model, the teachers are removed from the population. The learners become teachers for a new generation that is added to the population. This process repeats for many generations.

Learners have no explicit biases for particular 'languages', and the speaker ID variable is not privileged over other aspects of meaning. However, the learner is biased in a general way by the information criterion for the stepwise regression $I C$, which affects the number of variables an individual is willing to include in their linguistic model. The results presented below use the Akaike information criterion ( $I C=2$ ). In general, iterated stepwise linear regression has a bias towards shallow slopes and small intercepts. These do not affect the general results regarding bilingualism.

Population parameters Generations of individuals are separated by discrete timesteps $t_{1}, t_{2} \ldots t_{n}$. A population of $P_{t}$ learners in the current generation observe data produced by $P_{t-1}$ teachers in the previous generation. There are a number of communities in each generation and a set $C(t)$ of $P_{t}$ discrete labels represents which community each individual belongs to. A community interaction matrix $I(t)$ defines how much contact there is between each community. The probability $W(t)_{i, j}$ of learner $i$ receiving data from teacher $j$ is calculated as:

$$
\begin{equation*}
W(t)_{i, j}=\frac{I(t)_{C(t)_{i}, C(t-1)_{j}}}{S_{u} m_{W}} \tag{1}
\end{equation*}
$$

Where $\operatorname{Sum}_{W}$ is the sum of all weights between individuals. The community structure can therefore reflect situations from simple ones such as 'there are two communities' to a weighted, directed graph between individuals.

The community interaction matrix $I(t)$ can be simplified to a vector of single numbers by assuming that the probability of receiving data from any community that a learner does not belong to is equal.

$$
W(t)_{i, j}= \begin{cases}\frac{I(t)_{i}}{S_{u} m_{W}} & \text { if } C(t)_{i}=C(t-1)_{j}  \tag{2}\\ \frac{1-I(t)_{i}}{\text { Sum }_{W}} & \text { otherwise }\end{cases}
$$

This assumption will be adequate for the examples in this paper, and allows manipulation of the social structure through a single parameter for each community.

This framework allows different types of social structures. Given a situation where there are two teachers and two learners $P_{t-1}=P_{t}=2$ and two communities at each generation $C(t)=C(t-1)=\{A, B\}$, different settings of $I$ can then result in many social dynamics. Below I give some examples of matrices, with the learners (rows) labelled as $L_{1}$ and $L_{2}$ and the teachers (columns) labelled as $T_{1}$ and $T_{2}$. For example, a society with two communities that are completely integrated and balanced (effectively a single community):

$$
I(t)=\{0.5,0.5\} \longrightarrow \begin{array}{ccc} 
& T_{1} & T_{2}  \tag{3}\\
L_{1} & 0.5 & 0.5 \\
L_{2} & 0.5 & 0.5
\end{array}
$$

In the matrix above, for example, learner $1\left(L_{1}\right)$ has an equal probability of receiving data from either teacher. Alternatively, $L_{1}$ only receives data from $T_{1}$ and $L_{2}$ only receives data from $T_{2}$. This simulates two communities that are completely isolated:

$$
I(t)=\{1,1\} \longrightarrow \begin{array}{ccc} 
& T_{1} & T_{2}  \tag{4}\\
L_{1} & 1 & 0 \\
L_{2} & 0 & 1
\end{array}
$$

The prestige of a community can also be manipulated. Below is a matrix for a situation where one community only receives input from its own members (superstrate), while the other community receives input from both communities (substrate). It is predicted that this will lead to an analogue of a
minority language situation where everyone speaks one language (the majority language), and some speak a second language (the minority language).:

$$
I(t)=\{0.5,1\} \longrightarrow \begin{array}{ccc} 
& T_{1} & T_{2} \\
L_{1} & 0.5 & 0.5  \tag{5}\\
L_{2} & 0 & 1
\end{array}
$$

Measuring bilingualism Since 'languages' are not encoded in the simulation, the amount of bilingualism must be calculated from the bottom-up. This is defined as the amount of linguistic variation that is conditioned on social variables. In the simulation this is based on two measures of intelligibility, assuming that utterances are intelligible to speakers if their linguistic model would produce the same utterance given the same meaning (obverter assumption, similar to Oliphant \& Batali, 1997). The first is a measure of comprehensive intelligibility: the proportion of utterances that one speaker typically produces that another understands. For example, a monolingual speaker of English understands half of the utterances spoken by a balanced bilingual speaker of English and Welsh. In the simulation, this is a measure of the proportion of the variance in one learner's productions that is explained by another learner's linguistic model. If we're comparing individual $A$ and $B$, this is implemented in the following way (see figure 2):

1) Take identical samples of meanings $M_{A}$ and $M_{B}$
2) Sample speaker ID evenly in $M_{A}$ and $M_{B}$
3) Given $M_{A}$, produce utterances $U_{A}$ with $A$ 's linguistic model and given $M_{B}$, produce utterances $U_{B}$ with $B$ 's linguistic model
4) Calculate the correlation between $U_{A}$ and $U_{B}$

If two learners have the same linguistic model, then this correlation should be high. Individual A with a very different model from individual B will produce linguistic signals with a variation that is poorly explained by learner B's model, and so the correlation will be low.

We can also define a functional intelligibility score which is the proportion of utterances that interlocutors understand when they design their utterances for each other (figure 3). That is, a bilingual speaker of English and Welsh and a monolingual speaker of English could always make themselves understood by using English. In the simulation, this is calculated in a similar way to the comprehensive intelligibility score, except step (2) above is changed to

## 2) Set the speaker ID in $M_{A}$ to $B$ and in $M_{B}$ to $A$

In this case, an individual with a linguistic model that used speaker identity as a conditioning factor would adjust its variation to better suit its receiver (i.e. in the Welsh-English example, by speaking only English).

The two intelligibility measures can be combined to get a measure of bilingualism by subtracting the comprehensive intelligibility from the functional intelligibility. This can be
calculated for a population by taking the mean bilingualism score for all pairs of speakers.

$$
\begin{equation*}
B(t)=\frac{2}{n^{2}-n} \sum_{i=0}^{P_{t}-1} \sum_{j=i+1}^{P_{t}} \operatorname{Func}(i, j)-\operatorname{Comp}(i, j) \tag{6}
\end{equation*}
$$

Where $\operatorname{Func}(i, j)$ and $\operatorname{Comp}(i, j)$ calculate the functional and comprehensive intelligibility between two speakers.

If $B(t) \approx 0$, the comprehensive and functional intelligibility are, on average, similar. This means that everyone shares the same mapping between linguistic utterances and meanings what might be called the same linguistic code or 'medium' (Gafaranga, 2008). While this code might exhibit variation, this could be interpreted as a single 'language' (monolingualism).

If $B(t)<0$, the functional intelligibility between speakers is, on average, lower than the comprehensive intelligibility. For example, in the functional measure, speaker A would adapt their linguistic signal for speaker $B$ and $B$ would adapt their linguistic signal for speaker A . This yields a low functional similarity. However, their comprehensive similarity is high (their overall linguistic system is similar), so $B(t)$ is negative. This would be interpreted as bilingualism in the sense that each community is associated with a different mapping or 'code', and individuals can use each others' codes to some extent. A lower $B(t)$ means 'more' bilingualism in the lay sense. This is meant to represent the amount of linguistic variation that is conditioned on social variables, and so is analogous to an entropy-like measure where lower values indicate more order (the linguistic system is more conditioned on social factors $=$ bilingualism) and higher values indicate more disorder (the linguistic system is less conditioned by social factors $=$ monolingualism).
If $B(t)>0$, the comprehensive intelligibility score is lower than the functional intelligibility score. For example, A adapts their linguistic signal for B, but B does not adapt their linguistic signal for A . This leads to a high functional intelligibility, but a low comprehensive intelligibility. This means that both communities share one code, but one community has at least one other code. This might be interpreted as a minority situation in which one community speaks a minority language as well as the majority language. As we well see below, it's useful to be able to distinguish between 'balanced' communities $(B(t)<0)$ and 'minority' situations $(B(t)>0)$.

## Results

Since simulation is complex, basic findings are presented for simulations with 2 communities with 2 individuals each and 2 semantic variables, but the results scale up many semantic variables and hundreds of individuals. To summarise: unconditioned variation is unstable and bilingualism tracks social change. Figure 4 shows how $B$ changes in different social structures. When the two communities are completely integrated (integration parameter $I=0.5$ ), then they quickly converge to using the same linguistic code $(B=0)$. When the

Comprehensive intelligibility

Figure 2: The comprehensive intelligibility measure. Two individuals are given the same meanings and produce linguistic utterances with their linguistic models. The correlation between these utterances in the linguistic space is measured.

Figure 3: The functional intelligibility measure. Two individuals are given the same meanings, but the speaker ID is set to the other individual in the pair. They produce linguistic utterances with their linguistic models, and the correlation between the utterances in the linguistic space is measured.
two communities are partially isolated ( $I=0.8$ ), their varieties will take longer to converge and 'bilingualism' $(B<0)$ persists for some generations. The results are slightly different in a substrate/superstrate situation where learners from one community receive input equally from both communities (the minority, $I=0.5$ ), but the other community mainly receives input from speakers from its own community (the majority, $I=0.9999$ ). In this case, $B$ remains positive for many generations (a 'minority' language situation).

These results are for communities with static social structures. We can manipulate the social structure to demonstrate that linguistic diversity also tracks the change in social structures. Figure 5 shows the results of simulations with dynamic social structures. The communities go through cycles of being integrated, isolated, integrated and isolated again, with a few transition generations between each phase where the integration parameter is interpolated. As shown above, if two communities are integrated, they will come to speak effectively a single code ( $B \approx 0$, see figure 4 ). However, as the

Figure 4: The bilingualism score (means for 100 simulations) over generations for 2 communities of 2 individuals in three social structures: Integrated (circles), Isolated (triangles) and Minority (crosses).
communities become more isolated, $B$ increases. This is also in line with the results above. However, as the communities increase their interactions after this, $B$ decreases (everyone speaks a single code). Then we can split the communities apart and two codes will emerge again with some amount of bilingualism. That is, the distribution of linguistic variation tracks the changes in social structure.

More complex factors that affect $B$ were determined by analysing many runs of the simulation (analysis done using linear regression and stepwise linear regression). $B<0$ is inherently unstable in this simulation. As soon as individuals start mutually accommodating the linguistic signal of other communities, this neutralises the distinction over speaker ID. This is in line with the expectation that unconditioned linguistic variation is unstable (e.g. Smith \& Wonnacott, 2010).
$B<0$ is much more likely to emerge if speaker identity is the most important conditioning factor, while positive bilingualism scores can emerge if speaker identity is less important. Negative bilingualism is also more likely if individuals rank speaker identity in their models similarly. There are some more complex interactions. For example, $B<0$ tends to emerge when: the speaker ID is more important in the previous generation, except when communities are diverging, when it can be higher; when the community with the most complex linguistic model also considers speaker ID to be less important; when the mean and standard deviations of the speaker id rank are correlated; and when there is a stronger correlation between the difference in linguistic signal means and model fit ratio between communities.

Figure 5 shows that, after the first contact situation, only $B>0$ tends to emerge. This is partly due to the linguistic signal of two communities adapting to the same semantic distributions, and so becoming more alike. Situations where $B<0$ requires that there are large differences in the utterances of each community so that speaker ID conditions a large amount

Figure 5: How the integration parameter $I(t)$ (top, identical for both communities) affects the levels of bilingualism (bottom) in 2 communities with 2 learners each, which are alternatively integrated and semi-isolated (means over 100 runs with $95 \%$ confidence intervals).
of variation. When $B>0$ there is an imbalance in the extent to which different communities adapt to each other's linguistic signal.

It is possible to identify a 'superstrate' community as the one whose linguistic signal changes least between the generations of contact (as measured by the difference in a community's comprehensive intelligibility between generations). The difference in the linguistic utterance means between generations is the main determiner of the superstrate community. If community X's mean is absolutely greater than community Y's mean in the previous generation, then community X's linguistic models will change more than community Y. This affect arises due to the bias in the learning mechanism for small intercepts. However, this trend is only strong in the first generation of contact. During diverging generations, there is a $41 \%$ chance of a switch in superstrate community in the first two generations of divergence (from 100 simulations, significantly different from no switch: $\mathrm{t}=16.7, \mathrm{df}=399$, p -value $<0.001$, but also random switching: $\mathrm{t}=-3.55, \mathrm{df}=399, \mathrm{p}<$ 0.001 ). In contact situations, there is a $49 \%$ chance change of a switch in superstrate community in the first two generations (from 100 simulations, significantly different from no switch: $\mathrm{t}=13.8, \mathrm{df}=199, \mathrm{p}<0.001$; but not significantly different from random switching: $\mathrm{t}=-0.28, \mathrm{df}=199, \mathrm{p}=0.78$ ). In one generation a community might adapt to another, but this can cause the models in that community to better fit the data, leading to a pressure for the other community to adapt in the subsequent generation. Although a preliminary result, this may be compatible with phenomena such as 'mixed languages' where the emerging language in a contact situation uses the lexicon of one source language, but the grammar and
morphology of the other (e.g. Muysken, 1997). If lexical items and morphology take different amounts of time to learn (as suggested by Clahsen, Felser, Neubauer, Sato, \& Silva, 2010), then the 'mixing' might be partially due to this alternation in the community that adapts: the lexicon is taken first from one language, and later the morphology from another.

## Discussion

Dynamic social structures are a key aspect for explaining the emergence of bilingualism in this simulation. In the top-down models, social structures were static and so they could not form a part of the explanation. The bottom-up simulation can be more flexible because it doesn't require learners to be fully rational or optimal, as opposed to some Bayesian models.

The linguistic contrast between communities will diminish if there is no contrast in the social variables. However, it does not mean than bilingualism in the lay sense is unstable. Firstly, $B$ is not necessarily an index of an intuitive idea of bilingualism. Communities like those in Catalonia might actually have $B \approx 0$, because many people speak both Catalan and Spanish. Secondly, in the real world, linguistic variation might be dictated by social factors not simulated here, such as location, formality or stage of the conversation (e.g. Labov, 1963; Meyerhoff, 2008). Finally, this simulation includes no pressures to maintain a linguistic identity such as prestige, politics or resistance to freeriders (G. Roberts, 2010). Rather, it shows that bilingualism that can emerge just from the process of cultural transmission - a kind of baseline behaviour on top of which more complex factors may be applied.

The top-down models specified a prior bias over the amount of variation to expect in an agent's input, fitting the learning mechanism to the problem being addressed. In contrast, bilingualism emerges in the bottom-up simulation without individuals having a specific mechanism for dealing with bilingualism. All that is required is a general learning mechanism which conditions a linguistic signal on semantic variables. There are no expectations over the amount of variation to expect within or between speakers. Indeed, if social variables do not explain any of the variance, they do not play any role in an agent's linguistic internal representation.

Furthermore, the simulation maintains a division between population level phenomena and individual learning mechanisms: 'bilingualism' can emerge at the population level without discrete, static languages being encoded in the linguistic model of individuals. This suggests that that 'bilingualism' is a property of populations which is not necessarily related to specific individual learning biases. That is, whether humans have an expectation about the number of languages that will be in their input, or whether learning two languages is more difficult than learning one are not necessarily the most relevant questions. Rather, one should ask how contrasts in social variables support the maintenance of linguistic variation.

## Conclusion

The simulation works as a proof-of-concept for the abstract definition of bilingualism. Bilingualism is measurable in this simulation without encoding a discrete, monolithic, static concept of a 'language'. The measure behaves as we would expect in integrated, isolated and substrate/superstrate population structures. The results suggest that dynamic social structures are an important part of explaining the cultural evolution of bilingualism. This differs from the conclusions of top-down models, demonstrating that different kinds of models may be biased towards certain conclusions.

Top-down models considered the stability of bilingualism given assumptions about individual learning (Burkett \& Griffiths, 2010) and the most likely expectation for individuals to have about the number of languages in their input (Smith \& Thompson, 2012). These might suggest research directions such as estimating the expectations human learners have about the number of languages to expect in their input, the amount of noise in transmission or whether the social structure was one that caused bottlenecks on learning. However, in the bottom-up simulation, because bilingualism tracks social change, asking whether individuals should expect many languages in their input does not make sense without also thinking about dynamic social structures. This suggests that the questions asked by the top-down model are misleading. The bottom-up simulation suggests researching dynamic social structures, and how linguistic variation, social structures and learning biases coevolve.

Both the top-down and bottom-up models are very abstract, and it would be a difficult to determine which was more 'realistic' or fitted real data better. Instead, both approaches can be seen as converging on a common solution to the problem from different angles. The top-down model is better at yielding good analytic results, but the bottom-up model allows more flexibility in terms of social dynamics. The bottom-up simulation presented here has suggested that some of the assumptions of the top-down models require more scrutiny. In response, a top-down model could be built which addressed the most relevant points raised by the bottom-up simulation perhaps using techniques such as variational Bayesian analysis (e.g. Kurihara \& Sato, 2006). This process of exploring results and uncovering important assumptions using mutually supporting approaches can lead to more robust theories.

# Integration and Inference: Cross-situational Word Learning Involves More than Simple Co-occurrences 

Alexa R. Romberg and Chen Yu<br>\{aromberg, chenyu\}@indiana.edu<br>Department of Psychological and Brain Sciences, 1101 E. 10th Street<br>Bloomington, IN 47405 USA

#### Abstract

Statistical word learning involves forming and aggregating associations between words and objects that co-occur across contexts (e.g., Vouloumanos \& Werker, 2009; Smith \& Yu, 2008; Yu \& Smith, 2007). However, the mechanisms that support such learning are currently under debate, including the extent to which learners carry forward multiple ambiguous associations (e.g., Trueswell et al., 2013). The current study presented adults with a set of statistical word learning tasks designed to measure the statistical computations learners employ to build label-object mappings and to probe what information from past contexts is available to further process and integrate with new information. Results reveal that learners use the co-occurrence of label-object pairings to make inferences both about objects and labels currently present and those presented on previous trials. Further, the strength of learners' memory for past contexts moderated their inferences, suggesting a role for a rich information structure in cross-situational word learning.

## Introduction

Imagine an infant on a walk with his father. The father, like many parents, comments on the things they see together: "There's a doggie and a kitty in the window!" and a few moments later: "Look, the man is walking the doggie!". How might the father's comments help the infant learn the meanings of words like doggie, kitty and man? Recent research has demonstrated that learners readily form label-object mappings by gathering co-occurrence statistics. Human infants (Smith \& Yu, 2008; Vouloumanos \& Werker, 2009), children (Scott \& Fisher, 2011) and adults (Kachergis, Yu \& Shiffrin, 2012; Suanda \& Namy, 2012; Yu \& Smith, 2007) are all capable of converting multiple individually ambiguous learning instances into specific knowledge as demonstrated by above-chance performance on a post-learning test or by an improvement in selection of the correct referent in a combined training and test procedure (Trueswell, Medina, Hafri \& Gleitman, 2013). However, the precise ways in which learners resolve the local ambiguities have been relatively unexplored.

Specifying how exactly learners use the information available is an important step to understanding the mechanisms contributing to success. When learners perform some computations but not others, this offers important constraints to any model of their learning and can inform discussion about the nature of the information stored. In the context of cross-situational word learning, two primary mechanisms, associative learning and hypothesis testing,
have been proposed for how learners accrue information over time. These mechanisms differ largely in the amount of information stored and, consequently, in how prior information influences later learning (Yu \& Smith, 2012). In particular, associative learning proposes that learners form multiple associations between the objects and labels present during each learning instance, storing a relatively rich information network. Hypothesis testing proposes that learners store only a single link between a label and possible referent, discarding other co-occurrence information. Distinguishing these possible mechanisms has been challenging thus far because of a lack of data regarding how learners process information on a trial-by-trial basis.

Details about what information learners store and how they use it during cross-situational word learning is vital for advancing theories of this process. The typical crosssituational word learning experiment uses a fairly large novel vocabulary (up to 18 to-be-learned label-object mappings) and consists of a series of trials that each present a subset of the labels and objects. Thus, the learner is faced with the difficult task of tracking these many labels and objects across trials (typically between 27 and 60 trials) and using what co-occurrences they can glean to generate as many correct mappings as possible. While this experimental design is daunting for the participant, it is also daunting for the experimenter, as there are inevitably many possible paths to success. One cannot know definitively how participants arrived at a particular mapping over the course of statistical learning or whether the same types of computations were used for all learned mappings.

The present study sought to alleviate these analytical ambiguities for the experimenter while maintaining the learning ambiguities for the participants. Rather than have participants view many trials across which to learn many mappings, learners were presented with a series of "miniature" cross-situational word learning tasks. These tasks consisted of only 2 or 3 trials and were constructed so that some, though not all, label-object mappings could (theoretically) be disambiguated, depending on which information learners stored and which inferences they made. The miniature tasks were constrained so that there was only one pathway to disambiguation, allowing us to infer the computations successful learners employed.

We focused on three fundamental processes that could serve as building blocks for sophisticated statistical learning. The first was the tracking of co-occurrence information - noticing that some labels and some objects appear together across multiple trials. The simplest of
statistical learning models, such as the "dumb associative model" outlined by Yu \& Smith (2012) do only this cooccurrence tracking to fill an association matrix. The second process was "forward integration", by which learners use information that they carry forward across trials about some objects and labels to make an inference about another object-label mapping. Mutual exclusivity (Markman, 1990) would be a strong form of forward integration, when one rules out objects with known labels as possible referents for a novel label. Recent evidence indicates that learners do employ mutual exclusivity during cross-situational word learning and that this type of inference could arise through basic attentional processes (Kachergis, Yu \& Shiffrin, 2012). The third process was "backward inference," by which learners use information on the current trial to infer something about an object/label experienced on a previous trial (but not on the present trial). This last process can be thought of as learning from negative evidence, as it entails noting the absence of particular objects and labels.

We compare performance on three different "miniature" cross-situational word learning tasks to assess learners' ability to use the available information in the three processes of co-occurrence tracking, forward integration and backward inference. The tasks were designed to look specifically at how trial-by-trial information is retained and processed. We also relate performance on the miniature tasks to a "full" cross-situational word learning task, to investigate whether these fundamental processes are also employed in larger-scale statistical word learning.

## Method

## Participants

Participants were 38 undergraduates (20 females) at Indiana University who earned course credit for their participation. The mean age was 20.9 years.

## Materials

The auditory stimuli consisted of 108 nonce words synthesized with the Ivona voice Jennifer using the TextSpeaker program. Nonce words consisted of one or two syllables ( 264 ms to 795 ms in duration) and followed English phonotactics. The visual stimuli were 123 color photographs of real objects or 3D models either of novel objects or objects that were not readily nameable. Images were displayed in the 4 corners of a 17 " monitor, on a white background at a size of approximately 3 " square.

## Experimental Design

There were 3 types of "mini-tasks" (see Figure 1), each made up of 2-3 training trials and then 3-4 test trials. Each mini-task was independent of the others and no stimuli were repeated across tasks. When objects and labels were repeated on multiple trials they were always presented in different spatial or temporal positions.

Across all parts of the experiment, each trial consisted of viewing 4 objects on a screen and listening to 4 nonce
words. Each trial began with the objects displayed in silence for 3 seconds. The onsets of the words were 3 seconds apart and the total trial length was 15 seconds. Every time an object was on screen the corresponding label was provided.

The training trial structure of each of the 3 types of minitasks is given in Figure 1. For all tasks, the R items refer to the object-label pairs $R_{1}, R_{2}$ and $R_{3}$, which were presented on Trials 1 and 2. T1 refers to the object-label pair presented on Trial 1 but not Trial 2. T2 refers to the object-label pair presented on Trial 2 but not Trial 1. The Base and Familiar Context tasks each consisted of a total of 5 word-object pairings: $\mathrm{R}_{1-3}$, T 1 and T2. The Novel Context task consisted of a total of 8 word-object pairings: $\mathrm{R}_{1-3}, \mathrm{~T} 1$ and T 2 and the 3 novel, label-object pairs presented only on Trial 3 ( $\mathrm{N}_{1-3}$ ).

Figure 1. Schematic representing the training trial structure for the 3 mini-tasks, with letters representing objects filling different roles in the design.

For each of the mini-tasks, the training trials were followed immediately by a series of test trials. On each test trial one word was presented auditorally and participants were instructed to click on the object the word most likely referred to out of all objects presented on the task plus a novel distracter object. For the Base and Familiar Context tasks, participants selected from 6 objects and for the Novel Context task participants selected from 9 objects. The tested words came from the different categories of items in the task (R, T1, T2 and, for Novel Context only, N). While the tested items aligned structurally across tasks, the information available to participants differed, enabling us to test hypotheses about what information participants track and what inferences they make.

All participants also completed a "full" cross-situational word learning task, based on Yu \& Smith, 2007, which consisted of 18 label-object pairings. These were presented 4 at a time across 27 training trials, so that each label cooccurred with its referent object 6 times. With the $4 x 4$ design, objects co-occurred with other labels, but such "spurious" correlations were limited to no more than 3 times across the 27 trials. Training was followed immediately by 18 test trials. On each test trial all 18 objects were displayed, one auditory label was presented and participants selected the best referent by mouse click.

## Procedure

Participants were given an overview of the experiment and informed consent was obtained. All participants first completed the Full CSL task. They were told that they there were 18 words and 18 objects, that they would see them 4 at a time and that the order of the labels on any trial did not correspond to the spatial location of the objects. They were instructed to learn as many label-object mappings as they could. Once participants completed the test for the Full task, they moved on immediately to the mini-tasks. There were a total of 15 mini-tasks, 5 of each task type. The tasks were grouped so that there was one of each type in each block of 3. The order of the 15 tasks was the same across all participants but the order of the test questions within each task were randomly determined for each participant. In the instructions for the mini-tasks, participants were told they would see a series of 15 tasks that were miniature versions of what they had just done and that they would be tested after just 2 or 3 training trials. They were told that no objects or words would be repeated across the mini-tasks. Participants were tested one at a time and listened to the auditory stimuli over headphones. The entire experiment took approximately 30 minutes.

## Predictions

The Base task provides a baseline measure of each of the three processes we are examining: The R items represent the co-occurrence tracking process. For each of the tasks, the precise object-label mappings within this group remain ambiguous. However, successfully tracking the repetition of this group of objects and labels theoretically enables learners to perform two types of inference to disambiguate the T1 and T2 mappings. The T2 items represent forward integration: whether participants can use the familiarity of the $R_{1}, R_{2}$ and $R_{3}$ pairs on Trial 2 to make a mapping between the relatively novel T2 label and object. Finally, the T1 items represent backward integration: whether participants use the absence of T 1 on Trial 2 to make a mapping between that label and object.

Backward integration relies on participants remembering the T1 pair across multiple ambiguous trials and was expected to be difficult. Thus, the other two mini-tasks were designed to test participants' memory for T1 by presenting it in either a novel or familiar context. This necessarily changes the interpretation of the T1 pair in the Novel and Familiar Context tasks, as participants no longer need rely solely on backward integration to learn the mapping.

In the Novel Context task, T1 is presented with 3 new objects and labels on the $3^{\text {rd }}$ trial. This task is the only task in which the association matrix distinguishes the T1 mapping, enabling a correct mapping if participants recognize T 1 from the first trial. It is also possible that learners could employ forward integration, mapping the familiar-looking object to the familiar-sounding label without any memory specifically linking the two. If, however, participants do not retain any memory of T 1 , they
should choose randomly from T1 and $\mathrm{N}_{1}, \mathrm{~N}_{2}$ and $\mathrm{N}_{3}$ on both the T1 and the N test trials.

Unlike the Novel Context task, the Familiar Context task does not provide any additional statistical certainty relative to the Base task. While participants get an additional T1 pairing, it occurs with the same items on both trials. However, participants could infer the T1 mapping by using forward integration in the same manner as the T2 item on Trial 2. Comparing performance between the Base and Familiar Context tasks provides further insight into how learners track information. In the most straightforward extrapolation from the Base task, accuracy on R and T 1 should improve due to the extra trial and accuracy on T 2 should decrease due to the extra trial between when T 2 is presented and tested. Further, within the Familiar Context task, accuracy on T1 is expected to be higher than T2, as participants can use the same process to infer them and T2 is presented on the last trial of the experiment.

## Results

All objects from the ambiguous groups ( $\mathrm{R}_{1-3}$ and $\mathrm{N}_{1-3}$ ) were scored as correct. The baseline for chance performance varied between test items and between tasks. For the Base task and Familiar Context task participants selected from 6 objects, so chance performance was $50 \%$ for R test trials and $16.7 \%$ for T1 and T2 test trials. For the Novel Context task, participants selected from 9 objects, so chance performance was $33.3 \%$ and $11.1 \%$, respectively. Statistical comparisons between trial types and tasks were performed with logistic mixed-effects models with random effects of subject (other random effect structures were tested but in no case improved model fit).

## Forward integration and backward inference

We first address performance on individual mini-tasks before turning to relationships between the mini-task and full task and comparisons between mini-tasks. Mean accuracy for each type of test item is shown in Figure 2. The results from the Base task reveal that learners do engage the three processes it was designed to test: co-occurrence tracking, forward integration and backward inference. Each of the three trial types has accuracy significantly above chance performance (see confidence intervals on figure). While forward integration accuracy was quite high, our prediction that backward inference would be relatively challenging was confirmed, with participants performing significantly better on T 2 items than T 1 items on the Base task ( $b=1.898, z=7.88, p<0.001$ ).

Results from the Novel Context and Familiar Context tasks point to the robustness of co-occurrence tracking and forward integration. In the Novel Context task, neither R items nor T 2 were presented in the final trial, so learners must maintain that information while concurrently learning about additional objects and labels. Despite this challenge, participants were significantly above chance on both R and T2 items for the Novel Context task (see Figure 2). In the Familiar Context task, T2 information must be maintained
while familiar objects and labels from Trial 1 are repeated in Trial 3. Again, learners were quite successful, performing significantly above chance. Surprisingly, there was no decrement in performance for T2 from the Base to the Familiar Context task (see further discussion below).

While accuracy was significantly above chance for backward integration T1 items on the Base task, it was not very high. Backward integration relies on memory for the T1 pair, as the inference must be made in the absence of the object and label. Remembering the T1 label and object may pose a particular challenge since the mapping between them is ambiguous when they are first presented; it is possible that rapid decay of this information is responsible for the relatively low performance on backwards inference.

However, results from the Novel Context task demonstrate that participants recognized the T1 pair as familiar on Trial 3 and distinguished it from $\mathrm{N}_{1-3}$. Indeed, accuracy on T1 is numerically much higher than the Base and Familiar Context tasks even though the chance baseline is lower. The error pattern also suggests that participants were not likely to confuse T 1 and $\mathrm{N}_{1-3}$. On N trials, participants selected T1 only $4.7 \%$ of the time, less than they selected T2 (10\%), which did not co-occur with the N group. On T1 trials, participants selected one of $\mathrm{N}_{1-3} 18.4 \%$ of the time, less than is expected for random guessing (33.3\%) and much less than they selected T1 (65.3\%).

Figure 2. Mean percentage correct for each of the three mini-tasks. The error bars are $95 \%$ confidence intervals of the mean. The horizontal lines within each bar represent chance performance for that test item.

Are forward integration and backward inference relevant for statistical word learning beyond the mini-tasks? While the mini-tasks used in our experiment are structured similarly to the design of the larger cross-situational word learning paradigm employed in previous research (e.g., Yu \& Smith, 2007; Yu, Zhong \& Fricker, 2012) the mini-tasks had much more trial-to-trial overlap than other crosssituational learning paradigms. Thus, it is possible that learners don't rely on these inferential computations in the larger task, but simply accumulate co-occurrence statistics.

In order to verify that forward integration and backward inference were relevant for cross-situational word learning in a larger set, we correlated participants' scores on the Base
task with their scores on the Full CSL task (see Figure 3). The proportion of correct object-label mappings was positively correlated for the Base mini-task and Full CSL task ( $r=0.485, p=0.002$ ), suggesting that these tasks tapped similar skills. We also tested correlations between participants' accuracy on the Full CSL and on each of the individual trial types in the Base task to investigate the role of the individual computations. Positive correlations were found for both backward inference (T1) items ( $r=0.407$, $p=0.011$ ) and forward integration (T2) items ( $r=0.387$, $p=0.016$ ). The relationship between accuracy on the cooccurrence tracking (R) items and Full CSL accuracy was marginally significant ( $r=0.303, p=0.065$ ). Accuracy on R items was in general quite high and this measure of cooccurrence tracking may not have been sensitive enough to detect a significant relationship. However, as described above, the tracking of co-occurrence information is necessary for the other two computations. Together, these results strongly suggest that forward integration and backward inference are processes integral to crosssituational learning.

Figure 3. Scatterplot depicting the correlation between percentage correct on the Base Mini-Task (horizontal axis) and the Full Task (vertical axis). Values have been jittered so that all data may be seen. Overall performance on the Base Task is shown in the top left panel, R test trials in top right, T 1 test trials in bottom left and T2 test trials in bottom right. Lines represent linear best fit.

## The role of tracking multiple co-occurrences

We now turn to comparisons between the mini-tasks to further explore the computations learners employed to infer label-object mappings and participants' memory for ambiguous prior information. The Familiar Context task repeated the information from Trial 1 on Trial 3. We predicted that this repetition would lead to higher accuracy
relative to the Base task for R and T 1 items and lower accuracy for T 2 items (because of the addition of Trial 3 between training on T 2 in Trial 2 and test). Of these predictions, only the improvement on T1 is confirmed by the data. Accuracy on R items was not significantly different between the two tasks ( $p>0.29$ ), suggesting that the additional co-occurrence information did not lead to better mappings.

Changes in performance on T1 and T2 items were tested with a logistic mixed-effect model with Task (Base or Familiar Context) and Trial Type (T1 or T2) as fixed effects and Subject as a random effect. This revealed a significant Task by Trial Type interaction ( $b=-1.00, z=3.13, p=0.002$ ). However, follow-up analyses confirmed that the pattern of effects was not as predicted. While accuracy on T1 was higher for the Familiar Context task than the Base task ( $b=0.631, z=2.94, p=0.003$ ), accuracy on T2 was not different across the two tasks ( $b=-0.347, z=1.48, p=0.14$ ). Accuracy was significantly higher for T 2 than T 1 for both tasks (Base: $b=1.898, z=7.88, p<0.001$; Familiar Context: $b=0.785, z=3.64, p<0.001$ ). Surprisingly, even though participants could use the same forward integration process to infer the T1 and T2 mappings and the T1 object and label were presented on the last training trial while T2 had to be maintained across this trial, participants were more accurate on T2 than T1.
Why might the results differ so much from our initial prediction? One possibility is that, for some participants, rather than increasing certainty, the repetition of the Trial 1 information on Trial 3 actually increased spurious correlations, and therefore the confusability, between $\mathrm{R}_{1-3}$ and T1. The pattern of errors across tasks supports this interpretation. On R trials participants were significantly more likely to incorrectly select T1 for the Familiar Context task than the Base task ( $b=1.153, z=2.92, p=0.004$ ). Selection of an R item on T 1 test trials was equivalent across the two tasks, despite the improved performance on T1 for the Familiar Context task ( $b=-0.282, z=1.06, p=0.29$ ).

The participants with the best memory of the first trial should be most likely to confuse $\mathrm{R}_{1-3}$ and T 1 . The nature of the backward inference requires memory for T 1 , as well as memory for the context in which T1 occurred (i.e., the other objects and labels), since it is the absence of T1 from this context on Trial 2 that allows the inference. If memory of Trial 1 increases confusability between $\mathrm{R}_{1-3}$ and T 1 , participants who were successful on backward inference in the Base task should improve less on T1 items for the Familiar Context task than participants who were not successful on backward inference.

Participants were split into two groups at the median for backward inference on the Base mini-task ( $\mathrm{N}=19$ in each group). Participants with $20 \%$ or less correct on T1 items for the Base task were labeled low-backward inference (low-BI, $M=0.116, S D=0.322$ ) and those with more than $20 \%$ correct were labeled high-backward inference (high-BI, $M=0.537$, $S D=0.501$ ). A logistic mixed-effect model predicting accuracy on T1 test items with Task (Base or Familiar

Context) and BI (high or low) as fixed factors and Subject as a random factor revealed a significant Task by BI interaction ( $b=-2.346, z=4.86, p<.001$ ). The low-BI group had significantly higher accuracy on the Familiar Context task ( $M=0.484, S D=0.502$ ) than the Base task ( $b=1.973$, $z=5.18, p<0.001$ ), while the high-BI group did not ( $M=0.453, S D=0.500 ; b=-0.349, z=1.19, p=0.23$ ). Thus, participants with a weak memory of T1 from the first trial benefitted from the repetition of that information on Trial 3, while participants with a strong memory did not. This is further confirmed by the pattern of accuracy for R items across the two tasks, which was also subject to a Task by BI-group interaction ( $b=-1.122, z=2.01, p=0.044$ ). The lowBI group improved slightly from the Base task to the Familiar Context (Base $M=0.768, S D=0.424$; FC $M=0.80$, $S D=0.402$ ) while the high-BI group actually declined (Base $M=0.905, \quad S D=0.294 ; \quad$ Familiar Context $\quad M=0.789$, $S D=0.410$ ), suggesting that the Trial 1 repetition disrupted their memory for the R items.
In contrast to the Familiar Context task, performance on the Novel Context task should only be aided by improved memory for T1 (and its first-trial context). Both high-BI and low-BI participants benefitted from the presentation of T1 in a novel context with high accuracy on T1 items (high-BI $M=0.726, S D=0.448$; low-BI $M=0.579, S D=0.496$ ).
While a better memory for context impeded performance on the Familiar Context mini-task, such memory should generally improve statistical word learning, as learners would have a more complete association matrix on which to build. We tested the role of contextual memory in crosssituational word learning by comparing performance in the Full CSL task for the high- and low-BI groups. As predicted, high-BI participants were significantly more accurate in the Full CSL task than low-BI participants (highBI $M=0.444, S D=0.192$; low=BI $M=0.254, S D=0.173$, $t(36)=3.2, p=0.003)$.

## Discussion

The present study investigated three fundamental processes that may contribute to cross-situational word learning. We found that learners readily tracked cooccurrence information trial by trial and used those cooccurrence statistics to infer label-object mappings in new learning situations, a process we termed forward integration. We also found that learners inferred label-object mappings when the disambiguating evidence was the absence of the label and object on trials on which they would otherwise be expected, a process we termed backward inference. Further, we found that participants retained multiple co-occurrences between objects and labels presented on previous trials. Importantly, participants who best remembered multiple object-label co-occurrences within a learning trial were most successful at cross-situational word learning.
Our results support the argument that cross-situational word learning involves learning a system of label-object mappings, in which learning about one set of items influences knowledge about other items. From a
straightforward co-occurrence information point of view, the T1 and T2 objects are not more strongly associated with the T1 or T2 labels than the $\mathrm{R}_{1}, \mathrm{R}_{2}$ and $\mathrm{R}_{3}$ labels for either the Base or Familiar Context task. In order to disambiguate these mappings participants must use the information available not just about the T1 and T2 pairs but also about the $R_{1}, R_{2}$ and $R_{3}$ pairs. In this way, participants draw on the entire association matrix to make inferences that are reasonable given their experience. Our results provide empirical evidence of these inferences, but do not tell us whether inferences were made by explicit reasoning or emerged from the dynamics of attention within and across trials (Kachergis, Yu \& Shiffrin, 2012; Yu \& Smith, 2012; Yu, Zhong \& Fricker, 2012). If replicated in young word learners, these results suggest an important role for the contexts in which word learning occurs.

There has been debate about the nature of information selection and information processing by cross-situational word learners. The presence of multiple objects and multiple labels on an individual learning instance means that learners could potentially associate all labels with all objects - the multiple association account (e.g., Yurovsky, Smith \& Yu, 2012). While equal attention may not be given to all possible mappings, this account predicts that learners will have a rich store of statistical information to draw on, so that if evidence for one particular mapping is contradicted (e.g., the label is given but the object is not present) there are other associations already in place that can inform the learners' inferences about the label's likely referent.

Alternatively, in the single-association account learners retain a single hypothesis for each object, discarding all other associations from a particular learning instance (Medina, Snedecker, Trueswell \& Gleitman, 2011; Trueswell, Medina, Hafri \& Gleitman, 2013). This account predicts that when a particular hypothesis is contradicted the learner must start from scratch, forming a new hypothesis at random based on the current learning instance.

These two accounts make disparate predictions for the present study, specifically within the Familiar Context task. The single-association account proposes that learners may form a hypothesis linking the T1 object and label during Trial 1 and that this hypothesis would be confirmed on Trial 3. However, because choice of hypotheses is random, there should not be systematic differences between which learners benefit from this extra information from one mini-task to the next. In direct contrast to this, our results suggest that for some learners, the repetition of information in Trial 3 was beneficial, improving accuracy on R and T1 items, and for some learners it was not. Crucially, what defined whether Trial 3 was beneficial was whether the participant had formed a strong memory for the first trial, both the potential T1 mapping AND the other objects present, as measured by their ability to perform backward inference. These findings raise important questions about how memory development may influence word learning in toddlers, as we found that better in the mini-tasks with high overlap, better memory led to potential interference, while in the larger task with
little trial-by-trial overlap, better memory (i.e., backward inference) led to better performance. Our data suggest that those learners who are successful in cross-situational learning tasks carry multiple possible associations forward. These associations are integrated in both the forward and backward directions to discover likely object-label pairs. Thus, statistical associative learning is a powerful mechanism that is within the repertoire of human cognitive systems.

#### Abstract

How and to what extent the speech production and perception systems are linked is a question of longstanding debate (cf. Diehl, Lotto, \& Holt, 2004; Galantucci, Fowler, \& Turvey, 2006). Despite the long history of this debate and a vast number of studies providing experimental evidence indicating an intimate link between perception and production, formal proposals of this link have been conspicuously lacking in the literature. In this paper, we provide a computationally explicit, dynamical model of the process of phonological planning. In this model, the properties of a perceived utterance automatically serve as input to the ongoing planning of an intended utterance. Using tools from non-linear dynamics, we formalize how incoming inputs from perception influence the ongoing choice of phonological parameter values to be used in production. The use of a dynamical model enables establishing explicit bridges between phonological representations and response time data. Our model provides an account of response time modulations reported in independent experimental work, and makes additional concrete predictions that can be tested experimentally. In sum, our model provides a foundation for better understanding the cognition of speech perception, speech production, and the interaction between the two.

Keywords: Speech production; speech perception; dynamical modeling; perceptuo-motor effects; phonological planning.

## Perceptuo-Motor Effects

Many studies have provided evidence for the influence of the speech production system during the process of speech perception. Yuen, Brysbaert, Davis, \& Rastle (2010) showed that the articulations subjects produced could be modulated by stimuli they perceived immediately before producing a cued utterance. Specifically, subjects had increased alveolar closure in producing $s$ - or $k$-initial utterances when they heard a $t$-initial distractor, compared to baseline cases $(t$ is a sound produced with the tongue-tip making full contact at the alveolar ridge, but for fricatives like $s$ the tongue-tip contact is not complete, and for $k$ the contact is by a different articulator in a different location). D'Ausilio et al. (2009) administered transcranial magnetic stimulation to the areas of subjects' motor cortex that control lip or tongue movement and had subjects identify acoustic stimuli that were ambiguous as to place (labial vs. lingual). They found that subjects were more likely to mistakenly perceive stimuli as having the place whose corresponding motor cortex
area was being stimulated. Kerzel \& Bekkering (2000) and Galantucci, Fowler, \& Goldstein (2009) found that subjects response times (RTs) can be modulated systematically and involuntarily by various stimuli they perceive while speaking. We refer to these effects broadly as "perceptuo-motor effects" (Galantucci et al., 2009) because they are effects that indicate an influence of speech motor plans during the process of speech perception.

Much of the debate in the literature on the speech percep-tion-production link has centered on the claim of the Motor Theory of Speech Perception (Liberman \& Mattingly, 1985) that motor codes are the sole object of speech perception. However, as Lotto, Hickok, \& Holt (2009) point out, "there is no debate that speech production and perception interact in some manner [...] It is the 'nature' of the productionperception link that has not been established." The purpose of this study is not to disprove either side of the debate around that particular claim of the Motor Theory, but rather to address this latter point and provide a specific computationally explicit proposal regarding the nature of the percep-tion-production link.

In this paper, we propose a specific formalization of the perception-production link within a computational model of the dynamics of phonological planning. To illustrate our model, we focus on the response time data from the re-sponse-distractor experimental task used by Galantucci et al. (2009). In this task, subjects learned visual stimulus-spoken syllable pairings (e.g., if you see \&\& say ba, if you see \#\# say $d a$ ). While subjects were preparing the required responses (either $b a$ or $d a$ ), distractors were presented at varying delays (i.e., Stimulus Onset Asynchronies, "SOAs") relative to the presentation of the visual cue indicating the required response. The distractors were either a short tone, the same syllable the subject was preparing to say (e.g., $d a$ $d a$ ), or another syllable that differed in place of articulation from the response (e.g., $b a-g a$ ). In the Kerzel \& Bekkering (2000) study, video distractors were used instead of auditory distractors, with similar results.

Figure 1 summarizes the experimental results from Galantucci et al. (2009). First, the presence of any distractor resulted in longer RTs. Second, there was a monotonic effect of SOA on RTs. Both of these effects can be seen by looking at the Tone condition. RTs in the Tone condition (at both SOAs) were slower than on trials when there was no
distractor, and RTs in the Tone condition were longer at SOA 200 than at SOA 100 . From these two effects, it is evident that the mere presence of any distractor (linguistic or not) results in a slow-down in RTs. The Identity and Mismatch conditions introduce effects of linguistic (in)congruency between the responses and distractors in addition to whatever process generates the non-linguistic effects seen in the slow down due to a distractor presence and SOA. Crucially, RTs in the Mismatch condition were longer than in the Identity condition.

Figure 1: Result patterns from Galantucci et al. (2009).
These results motivate two broad computational principles, which in turn will inform the design of our model. These are the principles of excitation and inhibition. The fact that RTs were shorter in the Identity condition than in the Tone condition indicates the influence of excitation, since linguistic congruency offsets the slow-down introduced by the presence of a distractor. The longer RTs in the Mismatch condition compared to the Tone condition show the influence of inhibition due to linguistic incongruency, increasing the RTs beyond the effects of the mere presence of a distractor.

## Dynamical Model of Phonological Planning

We propose a formal, dynamical, computational model of the perception-production link, situating it in the planning process by which phonological parameters are set in speech production. The components of the model are shown in Figure 2. The model includes four dynamical planning fields (shaded rectangles), Inputs to these planning fields (ovals) that determine the actual parameter values to be produced, and a Monitor function that decides when all of the required values have been determined.

Figure 2 also shows an Implementation system that executes the motor plans for the intended utterance based on the production parameter values determined by the model. This Implementation system is not part of our model. The focus in our modeling work is on planning, that is, on the process of choosing values for phonological parameters. This process unfolds in time and, in the schematic shown in Figure 2, takes place before articulatory movement initiation and control, which are the business of the Implementation system. The Implementation system could be, e.g., either the Task Dynamics Model (Saltzman \& Munhall, 1989) or the DIVA model (Guenther, 1995).

Figure 2: Components of the model.
Planning Fields A key concept in the model is that of the planning field. Each phonological parameter of an intended utterance is assigned a planning field. Planning fields evolve over time and determine the specific parameter settings of the phonological parameters in an intended utterance. A planning field is defined by three axes: an axis representing the possible phonological parameter values, an axis representing the activation level associated with each possible phonological parameter value, and an axis representing time (see Figure 3).

Figure 3: Tongue Tip (TT) articulator planning field.
The phonological parameter relevant to the TT field is that of the constriction location for the tongue-tip articulator. Therefore, the phonological parameter axis in this field is represented by a continuum of constriction locations from dental (most anterior) to post-alveolar (most posterior). The use of a discrete planning field for each parameter is motivated by the desire to have our model be maximally compatible with extant models of phonological representation. The planning fields here correspond closely to the parameters used in Articulatory Phonology (Browman \& Goldstein, 1986, et seq.), with a field for each "tract variable", though our model could be applied to any appropriate system. As with the tongue-tip articulator, there are also planning fields for the other two primary oral articulators used in producing the syllables relevant to the experimental setting at handthe lower lip (LL) and tongue body (TB) -and one field for voicing. The parameter axis for the Voicing planning field is represented by the well-known continuum of Voice Onset Time ("VOT").

The planning fields evolve based on inputs to these fields. As we make explicit below, the dynamics of that evolution
are formalized within the computational framework of Dynamic Field Theory ("DFT", e.g., Erlhagen \& Schöner, 2002). Each field evolves such that after sufficient input(s), a peak of activation builds up and eventually stabilizes, with one parameter value having a maximum activation level. In Figure 3, following increasing values on the time axis, we can see the gradual evolution of a localized peak in activation at some value of constriction location intermediate between anterior and posterior.

Representing each articulator as its own field in the model with voicing as one separate field reflects the purpose of a planning field, which is to compute a single production value based on one or more potentially conflicting inputs. Our model assumes that these planning fields are the mechanism by which phonological planning of any utterance is achieved, that is, they are not specific to this experimental task. The design of the planning fields therefore reflects the general demands of speech production.

Input There are two sources of input to the evolving planning fields. One corresponds to the parameter values for the required response, and the other corresponds to the parameter values for the auditory distractor perceived during the planning of the utterance. Inputs are represented as twodimensional distributions of activation levels across the spectrum of possible values for a given parameter. Although not required by the framework, each given input in the present model is a normal distribution defined by the equation:

$$
\text { activation }_{\text {input }}=e^{-(x-\text { val }+ \text { noise })^{2}} / 2 \sigma^{2}
$$

val indicates the mean of the distribution, and was varied from trial to trial by adding a small noise term. Since constriction location does not vary in the examples used in the model of this task, the input values for constriction location did not materially change in the simulations. The standard deviation of the distribution $(\sigma)$ defines its width. Both responses and distractors in the task modeled here are voiced, so the input to the Voicing field was always the same.

Dynamics The purpose of the planning fields is to determine the phonological parameter values to be sent to implementation. Planning fields have two possible stable states. They either stay flat at their resting value, or they can have a single, sustained peak of activation. The value sent to implementation for a given field is the parameter value that has the maximum amount of activation when the field stabilizes in this second stable state. The fields in the model evolve based on the mechanisms of DFT. The dynamics of each of the three articulator planning fields (LL, TT, and TB ) are controlled by the equation:

$$
\begin{aligned}
& \tau d A(x, t)=-A(x, t)+h+r\left(\operatorname{input}_{\text {RESPONSE }}(x, t)\right) \\
& \quad+d\left(\text { input }_{\text {DISTRACTOR }}(x, t)\right)-\text { inhibition }_{\text {CROSS-FIELD }}(x, t) \\
& \quad+\text { interaction }(x, t)+\text { noise }^{\text {and }}
\end{aligned}
$$

$d A(x, t)$ is the change in activation level $A$ of $x$ at time step $t$. The rate of evolution of the field is controlled by $\tau$, with larger values of $\tau$ resulting in slower evolution of the field. $h$ is the resting level of the field. The inputs are added to the field, when appropriate, by the terms $\operatorname{input}_{\text {RESPONSE }}(x, t)$ and input $_{\text {DISTRACTOR }}(x, t) . r$ and $d$ encode the relative strengths of the inputs. The cross-field inhibition (indicated in Figure 2 by the bidirectional arrows between the articulator planning fields) introduced by any other articulator field(s) is added by the term $\operatorname{inhibition~}_{\text {Cross-FIELD }}(x, t)$ when the activation peak in another fields exceeds a threshold value $(\chi)$. The DFT dynamics (Erlhagen \& Schöner, 2002) capture the case of parameter setting for one effector. In our case, we have several articulators, and a single one must be chosen for any given speech segment. This is the motivation for the crossfield inhibition. In our model, cross-field inhibition follows a basic property of DFT in which inhibition comes into play when some threshold is crossed (we illustrate this with simulations below). Noise is added to introduce stochastic behavior into the model evolutions. The equation that defines the evolution of the Voicing field differs from the one that defines the evolution of the articulator fields only in that it does not contain a term for cross-field inhibition, because the Voicing field neither inhibits nor is inhibited by any other planning field. This design reflects the fact that voicing and articulator are cross-classifying parameters for English consonants (Chomsky \& Halle, 1968).

The interaction term, interaction $(x, t)$, the DFT "engine" that drives the evolution of the activation field through local excitation and global inhibition, is defined by:

$$
w(x)=w_{\text {excite }} e^{-\left(x^{2} / 2 \sigma_{w}^{2}\right)}-w_{\text {inhibit }}
$$

The interaction term induces changes in the field as some value(s) of $x$ approach a "soft" threshold ( $\theta$ ), which is determined by a sigmoid threshold function, defined by:

$$
f(u)=\frac{1}{1+\exp [-\beta(u-\theta)]}
$$

The use of a soft threshold means that some $x$ values below $\theta$ do engage the interaction term, but the contribution to the interaction of activation values less than $\theta$ diminishes with distance from $\theta$. The system is non-linear due to this soft threshold, in that incremental changes in activation levels have a non-uniform effect on the field's evolution. ${ }^{1}$

[^201]Since the required response and the perceived distractor both serve as input to the model, the evolution of the fields is driven by a combination of excitation and inhibition, depending on whether the two inputs have congruent parameter values. Congruent inputs to the model introduce excitation, while incongruent inputs inhibit each other.

Monitor The Monitor determines when activation has built up in required fields to a level that is sufficient to send to Implementation, based on a criterion value ( $\kappa$ ), which is the same across all four planning fields. The decision criteria for the Monitor are straightforward. The Monitor waits until the activation level for some $x$ value in both the Voicing field and one articulator field reach criterion. At that point it chooses the parameter values from those two fields with the highest activation level to be sent to Implementation. This has the effect that sometimes it is the Voicing field and sometimes an articulator field-whichever field evolves more slowly-that determines the RT on the trial.

## Simulations

Figure 4 illustrates the model dynamics by showing how the planning fields evolve during a single trial in three different conditions of the experimental study from Galantucci et al. (2009). The figures show the maximum activation level over time for each of the four planning fields. The dot-dashed red line shows the TT field evolution, the dashed blue line shows the LL field, the solid pink line shows the TB field, and the solid black line shows the Voicing field. Differences in the rate of rise of the maximum activation level of the fields predict differences in experimental RTs.

Figure 4A shows the evolution of the fields in the Tone condition. Since the tone distractor has no linguistic content, it serves as a baseline reference of how the planning fields evolve in the unperturbed case. The vertical dotted lines at time steps 100 and 500 indicate the duration of the required response input to the fields. Thus, the activation levels of the TT and Voicing fields start to rise at time step 100, the point at which the subject begins planning the required utterance based on the visual cue on that trial (here \# \# instructing the subject to say $d a$ ). The horizontal dotdashed black line drawn at activation level 0.7 indicates the soft threshold $(\theta)$ that determines the engagement of the within-field interaction term. The effects of the interaction term can be seen in that the rate of increase in the activation level of the TT and Voicing fields is not linear: as the activation level of each field approaches $\theta$, the steepness of the curve increases due to the local excitation being generated
activation fields: $\theta=0.7, w_{\text {excite }}=0.45, w_{\text {inhibit }}=0.1, \sigma=1$. For the sigmoid function, $\beta$ was always 1.5 . The constriction location input distribution for all articulator fields had a mean (val) of 0 and $\mathrm{SD}=$ 2, defined on an arbitrary scale of constriction locations that ranged from -10 to 10 . For the Voicing parameter, distributions for all voiced stimuli input had a mean of 5 ms VOT and $\mathrm{SD}=45 \mathrm{~ms}$. The criterion value ( $\kappa$ ) was 5 . The specific values of the variables in the above equations are not meaningful in and of themselves. Their values relative to each other are more informative.
in those fields by the interaction term. The TB and LL fields receive no input, and there is no change in their activation levels until around time step 200. At that point their activation levels start to drop due to the TT field reaching the cross-field inhibition threshold $(\chi)$, indicated by the horizontal dot-dashed teal line drawn at activation level 0 . The TT and Voicing activation levels continue to rise until they both have passed the criterion value ( $\kappa$ ), indicated by the solid line drawn at activation level 5. The time step at which the second field passes $\kappa$ (minus 100 , since that is the time step at which the cue is presented) is marked as the RT on that trial (the solid vertical line at about time step 425). The Monitor takes the maximum parameter values from the Voicing and TT fields and passes them to Implementation.

Figure 4: Evolution of planning fields in (A) the Tone, (B) Identity, and (C) Mismatch conditions. Dashed blue lines show the maximum activation level of the LL field, dot-dashed red of the TT field, solid pink of the TB field, solid black of the Voicing field. The horizontal black line at activation $=5$ shows the threshold $\kappa$ at which the Monitor chooses values for production, and the vertical black line perpendicular to it shows the simulated RT on the trial.

Figure 4 B shows the evolution of the fields in the Identity case on a trial with a $d a$ response and $d a$ distractor. From time step 0 to 200, all fields evolve in the same way as in the Tone condition. The vertical dashed lines at time steps 200 and 325 indicate the duration of the input from the distractor. Since the distractor inputs are qualitatively the same as those for the response, the activation level for the TT and Voicing fields rises at a much greater rate than in the Tone condition because both inputs add activation to the same range of parameter values, in addition to the local excitation being generated by the interaction term. The fields therefore cross $\kappa$ earlier than in the Tone condition, and the simulated RT is shorter.

Figure 4C shows the evolution of the fields in the Mismatch case on a trial with a $d a$ response and $b a$ distractor. Since the response and distractor share the same value of voicing, the evolution of the Voicing field in this condition is qualitatively the same as in the Identity case. The evolution of the TT field, however, is different. When the distractor input starts at time step 200, the activation level of the LL field begins to rise, and eventually crosses $\chi$, introducing cross-field inhibition to the TT field. The distractor input ends at time step 325, but by that time the LL field maximum is well above $\theta$, so it maintains a peak of activation for some time due to the interaction term, and the cross-field inhibition of the TT field by the LL field therefore persists. As a result, the rate of rise of the TT field activation level slows down compared to its rise in the Tone condition. The Monitor has to wait longer for the TT field to cross $\kappa$, and thus the RT on this trial is longer than in the Tone condition.

Figure 5: (A) Model simulations of the Galantucci et al. experiment. (B) Predictions for a scenario where distractor and response differ in Voicing rather than articulator.

Using our model, we simulated 150 trials for each of the three conditions (Identity, Tone, and Mismatch) at an SOA of 100 time steps for a total of 450 trials. On each trial, the time step at which the Monitor determined the RT was recorded. The activation level of each planning field was reset to its trial-initial state at the beginning of each trial. The simulated results are shown in Figure 5A. The model qualitatively replicates the experimental results from Galantucci et al. (2009). RTs in the Identity condition were shorter than the Tone condition, due to the reinforcing inputs and lack of any inhibition. On the other hand, RTs were longer in the Mismatch condition than in the Tone condition (and than the Identity condition). This is because the distractor and
response differed in articulator. As explained above, in this case cross-field inhibition slows down the evolution of the articulator field for the required response.

## Discussion

Our model fills a gap in the speech planning literature. Models of speech motor implementation (Saltzman \& Munhall, 1989; Guenther, 1995) explicitly capture how articulators move through space and over time to achieve their linguistic targets, but existing models of the sources of those target values either do not address the timecourse of the planning process (Chomsky \& Halle, 1968; Browman \& Goldstein, 1986), or assign little to no role to representations at the level of phonological features (Dell, 1986; Roelofs, 2000). Our results show the benefit of a model that addresses timecourse and phonological features explicitly.

Our model makes additional predictions for the cuedistractor task that can be tested experimentally. The model predicts that similar RT effects should be obtained when the Mismatch condition is such that the distractor and response differ in voicing rather than in articulator. The model predicts longer RTs in this Mismatch condition (e.g., da-ta) than in the Tone or Identity condition (e.g., da-da). In our model, the source of this difference in RTs is the withinfield inhibition that arises from the introduction of two incompatible inputs to the same field. This within-field inhibition is an inherent property of the DFT computational framework. Galantucci et al. (2009) did not test this condition, but results reported by Roon (2013) show perceptuomotor effects of voicing in the response-distractor task that are independent of articulator. This prediction is thus borne out. Figure 5B shows the model predictions for an experiment where the Identity condition is the same as the one reported in Figure 5A ( $d a-d a$ ), but where the Mismatch condition is da-ta. The model predicts slower RTs in the Mismatch condition than in the Tone condition. Future work will involve expanding the model to accommodate these new experimental results.

A second set of predictions concerns variation and phonetic detail in representations and processes. Since categories like voicing are defined as distributions on a phonetic continuum like VOT, compatible inputs need not be exactly the same in order to mutually excite each other: it is sufficient for the maximum activation peaks of two inputs to be near enough to each other. This excitation happens automatically, without any need to classify inputs categorically by defining category ranges. We plan to pursue this set of predictions in future work as well.

Most speech consists of utterances that are longer than monosyllables. Our present model does not address the planning field dynamics beyond CV syllables, which is what is required to account for reported perceptuo-motor effects. Future expansion of the model will address the dynamics involved in the planning of larger utterances.

Our model of the observed experimental effects bears directly on establishing the nature of the perceptionproduction link. In our model, speech perception is linked to
speech production as part of the process by which parameter values are set. The link between perception and production is the obligatory input of the perceived distractor to the motor planning field shown in Figure 2. Given the facilitation and inhibition based on (in)congruency between distractors and responses, there must be some intersection between the motor codes activated during motor planning of the required response and the codes activated during the perception of the distractor. The term "codes" refers to parameters such as voicing and articulator, and more precisely to the parameter values represented in our model. Our claim is not that the codes activated by perceiving the distractor must exclusively be motor codes. Rather, it is that the codes activated in the perception of the distractor must minimally be motor codes. Our study was not designed to address whether nonmotor codes are also activated. Our results are fully compatible with the Motor Theory (Liberman \& Mattingly, 1985). Our results are also consistent with theories that do or could propose a link between auditory-acoustic (or other) codes that are activated during the perception of the distractor, and motor codes corresponding to these auditory-acoustic codes (cf. Viviani, 2002: Figure 21.12), as long as a link between these other codes and the motor codes is assumed.

In sum, the perception-production link must be specified at the level of setting motor parameter values, including articulator and voicing, that need to be activated either directly or via associated codes. The effects of the perceptionproduction link are seen as the influence of a perceived distractor on the process of setting those parameters, i.e., on a production process, as seen in the reported RT modulations and their simulation by our model.

## Conclusions

During speech production, a speaker must retrieve the phonological representations of the required utterances by assembling a set of parameter values that specify the vocal tract actions corresponding to these utterances. We have presented a formal, dynamical, computational model of this process. In the model, assigning values to these parameters is a time-dependent process, captured as the evolution of a dynamical system over time. The model accounts for experimental results that have been proposed as evidence for an intimate link between perception and production. In our model, the perception-production link consists of the phonological parameter values of a perceived stimulus obligatorily contributing to the evolution of the activation levels of the fields engaged with the ongoing phonological planning of a required response. The present model can explain reported effects on response times, and makes new, experimentally testable predictions about similar response time modulations. The model therefore provides a foundation for a better understanding of speech production, perception, and the link between the two.

# The spatial representation of grammatical number 

Timo B. Röttger (timo.roettger@uni-koeln.de)<br>IfL Phonetik, University of Cologne, Herbert-Levin-Str. 6, D-50931 Köln, Germany<br>Frank Domahs (domahs@uni-marburg.de)<br>Department of Germanic Linguistics, University of Marburg, Wilhelm-Röpke-Str. 6a, D-35032 Marburg, Germany

#### Abstract

Research on numerical cognition suggests a strong link between mental representations of space and quantity. The SNARC effect (Spatial-Numerical Association of Response Codes effect) is characterized by the association of small quantities with left space and large quantities with right space. While the majority of research on the spatial representation of number has been on number words or Arabic numerals, this study investigates quantity representations that are involved in the processing of grammatical number. We found that German words that were inflected for singular had a relative left hand advantage, and conversely, plurals had a relative right-hand advantage. However, this pattern was only found in relatively late responses. Moreover, it appeared to interfere with the opposite pattern caused by the MARC effect (Markedness Association of Response Codes effect) leading to a relative right-hand advantage for singulars. This interference appeared to depend mainly on response latency with MARC effects being more pronounced in early responses and SNARC-like effects being more pronounced in late responses. This work sheds light on the interaction of different stimulus-to-response mappings operating on the same stimulus dimension - grammatical number. Moreover, it suggests that spatial numerical associations go beyond explicit numerical information, as in number words or Arabic numerals.

Keywords: grammatical number, MARC effect; numerical representation; SNARC effect.

## Introduction

Many researchers have argued that the mental representation of quantity is intimately connected to space. This connection is often described using the metaphor of a mental number line, which (in Western cultures) is oriented from left to right. In line with this assumption, it has been shown that spatial response dimensions are associated to numerical magnitude: the SNARC effect is characterized by the association of small quantities to the left hand and large quantities to the right hand. In their seminal work, Dehaene, Bossini, and Giraux (1993) found that in a parity judgment task ("is the number even or odd?"), responses to larger numbers were consistently faster with the right hand than with the left hand, whereas responses to smaller numbers showed the opposite pattern. As the task was not explicitly focused on quantity information but on parity, the interaction between quantity and spatial orientation was taken to suggest automatic access to quantity representations which are organized horizontally. Several studies have found similar effects without hand movements, suggesting that the SNARC effect is not genuinely due to a
mapping to hands but to perceptual space (e.g., Fischer, Castel, Dodd, \& Praat, 2003; Loetscher, Schwarz, Schubiger, \& Brugger, 2008). The SNARC effect has been shown for both Arabic numbers and for spoken or written number words (cf., Landy, Jones, \& Hummel, 2008; Nuerk, Iverson, \& Willmes, 2004; Nuerk, Wood, \& Willmes, 2005).

In an alternative account, the SNARC effect could be attributed to polarity alignment (Landy et al., 2008; Proctor \& Cho, 2006; Santens \& Gevers, 2008). This account posits that in binary representations of dimensions, across both stimulus and response properties, one value of the dimension is "generally more available than the other" (Landy et al., 2008: 358). To account for the SNARC effect, e.g. the polarity correspondence principle (Proctor \& Cho, 2006) assumes that small numbers are coded as [-] polarity and large numbers as $[+]$ polarity. The response location is coded in a similar way: [-] polarity for a left response and $[+]$ polarity for a right response. Congruent polarities (small numbers/left space, large numbers/right space) cause faster response selection than incongruent polarities.
This model also accounts for the MARC effect (Markedness Association of Response Codes effect, cf., Nuerk et al., 2004; Reynvoet \& Brysbaert, 1999; Willmes \& Iversen, 1995). An example of the MARC effect are faster right hand responses to even numbers and faster left hand responses to odd numbers (see e.g., Nuerk et al., 2004). It is assumed that this effect is closely related to the concept of linguistic markedness (see Haspelmath, 2006, for an overview) which refers to the formal and conceptual asymmetry between linguistic categories: in a parity judgment task, in which the hand-to-response relation is manipulated within participants, the adjectives "right" and "even" are assumed to be linguistically unmarked (Zimmer, 1964). On the contrary, "left" and "odd" are assumed to be linguistically marked. Interference is observed if the markedness association between stimulus and response is incongruent, while facilitation is observed if the markedness association is congruent.
At least for numerals, SNARC and MARC effects may cooccur (e.g., Nuerk et al., 2004). However, they do not interfere with each other since they are linked to independent stimulus properties (SNARC is linked to relative magnitude, MARC is linked to parity).

## Grammatical number, quantity, and markedness

In addition to symbolic and lexical number representations, many languages encode quantity grammatically. In particular, languages such as English and German employ morphological markers that decode the distinction between one entity ("singular") and more than one entity ("plural"). Most commonly, nouns are grammatically marked for number by inflection, e.g., by adding an affix such as $-s$ to English nouns. The most frequent grammatical number systems restrict the number of available categories to singular (one entity) and plural (more than one entity) (Corbett, 2000). For a German example, compare (1), where the suffix $-n$ adds plural meaning to the noun lion.
(1) Löwe 'lion' vs. Löwen 'lions'

While, most research on mental quantity representation has focused on Arabic numerals or number words; much less is known about the semantic interpretation of grammatical number. Several developmental and behavioral studies demonstrated a tight connection between grammatical and conceptual number (Barner, Thalwitz, Wood, Yang, \& Carey, 2007; Berent, Pinker, Tzelgov, Bibi, \& Goldfarb, 2005; Sarnecka, Kamenskaya, Yamana, Ogura, \& Yudovina, 2007). For example, in a Stroop-like task, Berent et al. (2005) asked their participants to judge the quantity (one or two) of visually presented words while ignoring their contents. Letter strings consisted of both singular and plural nouns (Exp. 1), and of pseudowords with or without regular plural inflection (Exp. 3). Response latencies were higher when there was a mismatch between grammatical number and the quantity of words presented (e.g., dog dog vs. $d o g s d o g s$ ). The authors concluded that the extraction of semantic number from grammatical number is automatic and represented in a way that is comparable to the conceptual number that they extract from visual perception.
The present study follows up on those findings and links it to numerical cognition research. Grammatical number is an excellent testing ground for the interaction of contradicting stimulus-to-response mappings because it allows us to pit SNARC-based and MARC-based accounts against each other.

## The present study

The present study applies a binary classification task to German nouns inflected for singular or plural. Conceptual quantity is involved in the process of specifying the grammatical number of nouns because, typically, singular nouns refer to one entity and plural nouns refer to multiple entities. Although the plural does not represent a specific quantity, we assumed it to represent a quantity which is - on a (Western) mental number line - localized more towards the right relative to a singular quantity $(=1)$, thus leading to a SNARC-like effect. In other words, singular forms should
be responded to faster with the left hand whereas plurals should be responded to faster with the right hand.

This prediction goes against the predictions based on the MARC effect: In linguistic theory, singular is thought to be unmarked, and plural is thought to be marked (cf., Greenberg, 1966). For example, within a language, singulars are used more frequently than plurals. And, if a language has a morphological coding of number (such as an affix), then the plural is typically overtly coded, thus formally more complex, whereas singulars often lack an overt coding, as in the German example (1) above. The MARC effect predicts that if markedness of a stimulus (singular vs. plural) is congruent with the markedness of a response side (right vs. left), there should be facilitation. Hence, singular forms should be responded to faster with the right hand (unmarked) whereas plurals should be responded to faster with the left hand (marked).

Apparently, grammatical number poses a problem to polarity accounts. Two conflicting polarity alignments are potentially at work operating on the same stimulus dimension: one alignment coding singulars as [ + ] polarity due to its linguistically unmarked status, and one coding singulars as $[-]$ polarity due to the conceptual quantity representations. Typically, however, polarity alignment accounts do not deal with conflicting polarity associations and therefore they make no prediction about which polarity association should occur in a given setting. Moreover, if competing associations interfere with each other the model does not predict how interference affects behavior.

One level of dissociation of those effects might operate on processing depth: the SNARC effect may become stronger when magnitude processing is activated more intensively (Gevers, Verguts, Reynvoet, Caessens, \& Fias, 2006), i.e. the size of the SNARC effect depends on response latencies and the amount of semantic number processing required. In their meta-analysis, Wood, Willmes, Nuerk, \& Fischer (2008) found a positive correlation of the SNARC effect size and response latencies across studies. Moreover, they found SNARC effects to be more pronounced in studies in which the task required the active processing of numerical magnitude (see also De Brauwer \& Duyck, 2008; Fias, 2001). Because the SNARC effect requires a certain amount of semantic magnitude processing, we expect it to occur only in semantic tasks. The MARC effect on the other hand, could already occur in an asemantic task, since no semantic information is necessarily required to encode a plural inflection, which is a surface characteristic of a word. Thus, one might hypothesize that those two effects are potentially dissociated in respect to task requirements. To explore this possibility and to investigate a potential dissociation of SNARC and MARC, we introduced tasks requiring different processing depths.

## Method

We designed four different tasks corresponding to different stages of processing depth. In the first task, participants had
to decide whether the presented words were written in italics or not (surface processing, SURF). The second task was a lexical decision task: participants had to decide whether the presented letter strings were existing German words or not (lexical processing, LEX). In the third task, participants had to make animacy judgments, where they had to decide whether the nouns denoted creatures (animate) or objects (inanimate) (nonspecific semantic processing, SEM). In a fourth task, participants had to decide whether the nouns denoted one entity or more than one (specific semantic quantity processing, QUANT).
Because quantity information is assumed to be represented at a conceptual level of processing and the SURF and LEX conditions do not require conceptual access, we expected no SNARC effect to occur at SURF and LEX. On the other hand, both decisions in SEM and QUANT required access to conceptual representations, thus a SNARC effect is expected to occur at SEM and QUANT. A MARC effect, however, could already occur in asemantic tasks, thus we do not predict any task dependency of a potential MARC effect. In their interaction, with increasing processing depth the impact of the MARC effect should be increasingly attenuated by the impact of the SNARC effect.

## Participants

Fifty-two native speakers of German ( 33 female, 19 male), with an average age of 26.9 years ( $\mathrm{SD}=7.0$ ) volunteered to participate for payment. All of them had normal or corrected-to-normal vision.

## Stimuli

The stimuli consisted of four German nouns in both their singular and plural form, respectively (Kuh/Kühe 'cow(s)', Löwe/Löwen 'lion(s)', Münze/Münzen 'coin(s)', and Stuhl/Stühle 'chair(s)'). We applied the following selection criteria to fit the stimuli to the experimental design: two items were animate beings (Kuh, Löwe); the other two were inanimate entities (Stuhl, Münze). There were two grammatically masculine (Stuhl, Löwe) and two grammatically feminine nouns (Münze, Kuh). Plural forms of all nouns contained an umlaut. Because both singular and plural forms can have an $-e$ suffix and an umlaut, neither of these cues was valid for unambiguously detecting plural inflection. This was done to ensure that participants access lexical knowledge rather than focus their attention just to one particular orthographic cue.

## Procedure

All subjects participated in eight blocks of trials, i.e. two blocks per processing depth (SURF, LEX, SEM, and QUANT). After the first block of each processing depth, there was a short break, in which participants were instructed to reverse the assignment of response buttons. The order of response assignments to the right hand and the left hand, respectively, was counter-balanced across participants. Each block started with a training session in which all words were presented
once. In the test blocks, each word was presented ten times in randomized order.

The experiment was controlled using Superlab 2.04 software (Abboud, 1991) and a RB-830 response box (both Cedrus Corporation, San Pedro, CA, USA). Stimuli were displayed on a 16 "-monitor screen using black symbols against a white background. Stimuli were presented in Times New Roman, font size 90 , resulting in a maximum height of 15 mm and a maximum width of 50 mm . Responses were recorded by two response keys placed at a distance of 30 cm in front of the participants, centered in egocentric space and separated 10 cm from each other. At the beginning of each trial, a fixation stimulus consisting of five asterisks $(* * * * *)$ was presented in the center of the screen for 300 ms . Then, the target appeared and remained for 1300 ms , during which response time was measured. The inter-trial-interval was 1500 ms (blank screen). The instructions given to participants stressed both speed and accuracy.

## Analysis

Six participants were excluded from analyses because they showed difficulties in changing the response assignment in at least one task. In the remaining data set, $5.8 \%$ of the trials had to be excluded due to wrong responses (3.45\%), anticipations (RT faster than 200 ms ) ( $0.05 \%$ ), or RTs outside $\pm 3$ standard deviations from the individual mean of each task per hand association per speaker ( $2.31 \%$ ). There was no trade-off between mean RT and error rate ( $r=-.182$; $\mathrm{p}>.05$ ).

Reaction times were analyzed using a series of generalized linear mixed effects models implemented in the R software ( R Core Team, 2012) and the package lme 4 (Bates, Maechler, \& Bolker, 2012). We used a Gaussian error distribution and identity link function. Both subjects and items were used as crossed random intercept effects. Since we are interested in the interaction of stimulus and response, we included the factor Number (singular, plural) interacting with the factor responding Hand (right, left) as a fixed effect in the models.

In a first step, we tested if this interaction is dependent on task requirements, thus we included a three-way interaction of Hand $\times$ Number $\times$ Task (SURF, LEX, SEM, QUANT) as a fixed effect. In subsequent analyses we tested the Hand $\times$ Number interaction for each task separately.

We computed p -values comparing the models with the interactions in question to the models with only the noninteracting fixed effects via Likelihood ratio tests (LRTs).

## Results

Overall, responses to tasks differed substantially in terms of response latency, such that SURF was responded to fastest ( 513 ms ) followed by SEM ( 548 ms ), LEX ( 579 ms ), and QUANT ( 631 ms ). Crucially, the Hand $\times$ Number $\times$ Task interaction was significant $(\chi(9)=81.514, \mathrm{p}<0.0001)$, indicating that there was a stimulus-response interaction modulated by task specific effects (cf. Figure 1).

Figure 1: Estimated RT differences (dRT) and standard errors between right hand and left hand responses as a function of grammatical number ( $\mathrm{SG}=$ singular; $\mathrm{PL}=$ plural). Negative slopes indicate SNARC-like effects; positive slopes indicate MARC-like effects. Mean RT of each depth is given in brackets.

Subset analyses of each processing depth separately revealed that SURF showed a significant Hand $\times$ Number interaction $(\chi(1)=4.096, \mathrm{p}=0.043)$, such that the model estimated a greater right hand advantage for singular forms ( 9 ms ) than for plural forms ( 1 ms ) ( $\mathrm{SE}=3.88 \mathrm{~ms}$ ), as predicted by a MARC-based account. The two-way interaction Hand $\times$ Number did not reach significance in the LEX or SEM condition $(\chi(1)=1.226, \mathrm{p}=0.27$ and $\chi(1)=0.303$, $\mathrm{p}=0.58$, respectively). For the QUANT processing depth, there was a significant interaction of Hand $\times$ Number $(\chi(1)=35.11, \mathrm{p}<0.0001)$ such that the model estimated a left hand advantage for singular forms ( 6 ms ) and a right hand advantage for plural forms ( 26 ms ) ( $\mathrm{SE}=5.36 \mathrm{~ms}$ ), as predicted by a SNARC-based account.

Table 1: Overview of stimulus-to-response mappings as a function of task and RT bin.

| Task | Bin | dRT SG | dRT PL | Slope | SE |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | 1 | -3,71 | -1,31 | -2,40 | 2,18 |
|  | 2 | -1,28 | 0,09 | -1,37 | 1,22 |
|  | 3 | -0,23 | -1,16 | 0,94 | 1,67 |
|  | 4 | -0,53 | -3,21 | 2,68 | 6,12 |
| 芹 | 1 | -2,04 | 2,46 | -4,50 | 2,59 |
|  | 2 | -0,33 | -1,59 | 1,26 | 1,34 |
|  | 3 | 1,69 | 1,21 | 0,47 | 1,80 |
|  | 4 | -4,52 | -7,16 | 2,64 | 6,04 |
| $\sum_{\sqrt[y]{n}}^{N}$ | 1 | -1,56 | 3,42 | -4,99 | 2,55 |
|  | 2 | -1,83 | 0,47 | -2,30 | 1,41 |
|  | 3 | 1,37 | 1,48 | -0,11 | 1,53 |
|  | 4 | 7,39 | -0,99 | 8,38 | 6,22 |
| $\frac{5}{2}$ | 1 | -3,33 | -3,40 | 0,07 | 3,19 |
|  | 2 | 2,09 | 1,73 | 0,36 | 1,97 |
|  | 3 | 1,96 | -3,14 | 5,10 | 2,56 |
|  | 4 | 3,65 | -16,95 | 20,60 | 8,57 |

Figure 2: Estimated RT differences (dRT) and standard errors between right hand and left hand responses as a function of grammatical number for RT bins (centered around zero). Negative slopes indicate SNARC-like effects; positive slopes indicate MARC-like effects. Mean RT of each bin is given in brackets.

Since the mean response latencies of the tasks differed substantially, the observed dissociation between SNARC and MARC might be due to overall processing time rather than required magnitude processing. To obtain a view of the time course, we rank ordered RTs for each subject and processing depth and divided them into four equal bins (Ratcliff, 1979). We tested if the Hand $\times$ Number interaction was dependent on the factor RT $\operatorname{bin}$ (bin 1-4) for each task separately. This was not the case for SURF, LEX or SEM $(\chi(9) \leq 12.75, p \geq 0.17)$. It was, however, for QUANT as indicated by a significant interaction of Hand $\times$ Number $\times$ $R T \operatorname{bin}(\chi(9)=20.77, \mathrm{p}=0.014)$. In this condition, there was a significant SNARC-like effect in late responses (bin 3 and 4) $(\chi(1) \geq 3.94, \mathrm{p} \leq 0.047)$, but not for early responses in bin 1 and $2(\chi(1) \leq 0.035, \mathrm{p} \geq 0.85)$ (cf. Table 1, Figure 2).

Numerical trends further indicate that SNARC-like effects are found in all tasks depending on overall processing time. This pattern of evidence suggests that these SNARC effects
could be accounted for by processing time only rather than processing depth. Visual inspection of the slopes over time yielded a similar pattern: Early responses exhibit positive or flat slopes indicating MARC-like patterns and/or the absence of SNARC-like effects, while late responses exhibit negative slopes indicating SNARC-like patterns. Moreover, the change of slope over the time course appears to be roughly linear.

## Discussion

The present study investigated stimulus-to-response mappings when processing grammatical number in binary tasks. We demonstrated that grammatical number markers elicit a SNARC-like effect, i.e. German words inflected for singular had a relative left hand advantage; plurals had a relative right hand advantage. At the same time, we demonstrated a MARC effect that showed the opposite pattern. There was a reliable MARC effect in a font classification task (SURF) and a reliable SNARC effect in a magnitude classification task (QUANT). In the light of our task dependent pattern of results, this evidence suggests that the SNARC effect is elicited in relatively late processing stages. A look at the overall RTs obtained reveals that QUANT indeed required the longest processing time. A significant interaction of reaction times and stimulus-toresponse mapping in the magnitude classification task as well as numerical trends in all tasks (cf. Table 1, Figure 2) underpin this interpretation. So, one may conclude that a simple explanation based on processing time is sufficient to account for the present pattern of results ("A MARC effect already appears in early responses while a SNARC effect only appears in late responses"). The appearance of SNARC in relatively late responses is in line with earlier findings on Arabic numerals and number words (e.g., Wood et al., 2008).

Polarity alignment accounts (Landy et al., 2008; Proctor \& Cho, 2006; Santens \& Gevers, 2008) explain both the SNARC and the MARC effect within the same framework. According to this account, congruent polarities lead to faster response selection than incongruent polarities. However, this account makes contradicting predictions regarding the response association for grammatical number: Based on the linguistic markedness dimension, singulars should be coded as $[+]$ polarity and plurals as $[-]$ polarity, thus leading to a facilation of right hand responses for singular forms. A quantity-based account makes the opposite prediction, which assumes that singulars are coded as [-] polarity and plurals as $[+]$ polarity (in analogy to numerals). Interestingly, the present study found both patterns, thus two conflicting polarity alignments have been shown to operate on the same stimulus dimension. Polarity alignment accounts in their present state, however, do not predict which polarity associations occur in a given setting and - if competing associations interfere with each other - how their interaction affects behavior. The present data indicate a temporal dissociation of these stimulus-to-response
associations with MARC effects being more dominant in early responses and SNARC-like effects being more dominant in late responses. Given the apparent linear change of slopes as a function of processing time, we might speculate that both effects co-occur, interfering with each other. Over time, the relative strength of one stimulus-toresponse mapping (MARC) decreases (or remains constant) while the alternative mapping (SNARC) increases. Due to the lack of statistically significant results for some conditions, this remains, however, speculative.

Generally, the presence of a SNARC effect in the quantity task demonstrates that a mental quantity representation may - in principle - be accessed from grammatical number in a similar way as during the processing of Arabic numbers and number words. One might argue, that the present data are ambivalent with respect to the question whether this quantity representation of grammatical number can be conceived as organised in a left-to-right oriented mental number line or not. One could, of course, doubt the relevance of the quantity-to-space nature of the response-tostimulus mapping and stick with a more neutral polarity account arguing that there is a coding of singular as [-] polarity and a coding of plural as [+] polarity. This interpretation does not require any reference to spatial quantity representation, and consequently our data would say nothing about the association between conceptual number and grammatical number. However, one would have to explain why singular is associated with [-] polarity and plural with a [+] polarity. To us, one possible interpretation is grounded in the spatial nature of the conceptual quantity representation.

Future research might shed light on these issues. An excellent testing ground are languages which have more complex morphological number systems: In addition to singular and plural, some number systems also have an additional grammatical category that is called "dual", which serves to refer to two distinct real-world entities (cf., Corbett, 2000). Other, more rarely occurring grammatical systems also contain a so-called "trial", in which nouns are marked for groups of exactly three distinct entities, or even a "paucal", in which a separate grammatical marker is used to refer to a small number of distinct entities. Grammatical systems in which more than two morphological categories are used to refer to quantity might further our understanding of the interaction of different stimulus-to-response associations in general and the interrelationship of linguistic and conceptual number in particular.

## Conclusion

To conclude, grammatical number elicits two contradicting stimulus-to-response mappings. A MARC effect based on the linguistic markedness of the grammatical categories singular and plural; and a SNARC-like effect based on its semantic reference to magnitudes. Similar to Arabic numbers and number words, this quantity representation seems to be organised in a rightward direction for increasing quantities. This SNARC-like effect,
however, only appears in relatively late responses, while the MARC effect appears to be restricted to relatively early responses. Linear trends in slope changes over time indicate that both effects interfere with each other.
In general, the use of linguistic categories beyond number words appears to be an interesting and promising avenue to investigate the relationship of different stimulus-to-response mappings.

#### Abstract

This paper demonstrates a new quantitative approach to identify what is behind universally sensed sound symbolism and sound symbolism detected only by speakers of a particular language. We presented 70 locomotion videos to Japanese and English speakers and asked them to create a word that would sound-symbolically match each action, then to rate the action on five semantic dimensions. Multivariate analyses revealed that certain sound-meaning links (e.g., voicing and speed) were more consistent than others within and across languages. Language-specific sound symbolism was also found for some sound-meaning links (e.g., the affricate manner of articulation was associated with light motions in Japanese, but with heavy motions in English). This implies that cross-linguistically shared and language-specific parts of sound symbolism are intricately intertwined within each language. This research underscores the importance of a bottom-up approach which can exploratorily investigate the complex sound-symbolic systems as a whole.

Keywords: sound symbolism; mimetics; canonical correlation analysis

## Introduction

Traditional linguistics has long assumed that the relationship between the form and meaning of a word is arbitrary (de Saussure, 1916/1983). However, words whose forms are motivated by their meanings (i.e., sound-symbolic words) are widely found across languages. For example, bump and thump sound like what they mean: events with an abrupt end (Firth, 1935/1957). Some languages have a large lexical class of sound-symbolic words called "ideophones," "expressives," or "mimetics" (Voeltz \& Kilian-Hatz, 2001; Kita, 1997). For example, Japanese is rich in not only onomatopoeic (e.g., piyopiyo 'tweet-tweet') but also nononomatopoeic mimetic words (e.g., tobotobo 'plodding').
Sound symbolism is not limited to ideophones and mimetics. Sapir (1929) points out that English speakers associate novel words containing the vowel /i/ with
smallness more frequently than words containing /a/. Another celebrated example of sound symbolism is the association between sonorancy and roundness (Köhler, 1929/1947). It has been repeatedly observed that speakers of many languages prefer a round shape for maluma and an angular shape for takete (Brenner, Caparos, Davidoff, Fockert, Linnell, \& Spence, 2013; Davis, 1961; Holland \& Wertheimer, 1964).

Thus, there has been accumulating evidence that language does contain some non-arbitrary sound-meaning correspondences and people are sensitive to them. However, the exact nature of sound symbolism has not been fully clarified and one of the most important questions about sound symbolism is still open: what sound-meaning associations are shared by speakers of different languages, and why? In fact, researchers have recognized that not every case of sound symbolism may be detected as commonly as maluma/bouba vs. takete/kiki.

For example, Iwasaki, Vinson, \& Vigliocco (2007) examined whether English speakers can detect the meanings of some Japanese mimetics depicting motion events, by asking them to rate the mimetics on a set of semanticdifferential scales (e.g., energetic vs. non-energetic; fast vs. slow). Iwasaki et al. demonstrated that English and Japanese speakers' ratings agreed on some dimensions but not others. Specifically, Japanese speakers associated mimetics starting with a voiced consonant with the meaning component of "big person," and the mimetics with voiceless consonants with "feminine" and "formal" walking. English speakers agreed only with the former association (see also Haryu \& Zhao, 2007 for the language-specific nature of magnitudevoicing symbolism).

## Limitations of Comprehension Tasks

The question of universal and language-specific facets of sound symbolism has not been properly addressed or pursued in previous studies, mainly due to the nature of
their experimental method. Most experimental studies on sound symbolism have aimed at detecting the universality of sound symbolism and mainly employed comprehension tasks, such as forced-choice and semantic-differential rating tasks. These experiments were designed to examine whether subjects can detect "correct" sound-meaning correspondences, or how they rate each sound or word on a predetermined set of semantic scales, such as size and brightness. These tasks are effective in the examination of particular sound-meaning associations. However, no one knows how many such associations-how many sound patterns, how many meaning dimensions, and how many combinations of sounds and meanings-we have to examine before we reach the whole picture of the sound-symbolic system of a language, let alone its universality.

## The Present Study

The goal of the present research was to extract crosslinguistically shared and language-specific parts of sound symbolism and to give phonological or phonosemantic explanations to them. We approach this issue by examining intuitions for sound symbolism in Japanese speakers and English speakers. To rectify the above mentioned limitations in using comprehension tasks, we employed a production method in which participants were asked to make mimetic words that matched human locomotions in short video clips. This method would reveal an unlimited set of phonologically and phonotactically possible phoneme sequences available to the subjects. We then conducted a multivariate analysis which detects underling correlations between sounds and sounds, meanings and meaning, and sounds and meanings, and evaluates what sound-meaning correlations are more significant than others in Japanese and English. The comparison of the detected sound-meaning pairs in each language shows us the shared and languagespecific sound symbolism.

We will present the Japanese and English speakers' data separately in Experiments 1 and 2 , respectively.

## Experiment 1: Japanese

## Method

Materials We created 70 short video clips of various types of human locomotion ( $M=7.3 \mathrm{sec}, S D=2.7$ ). In each video, a person appeared from the left side of the monitor and moved to the right out of the frame in a certain manner of walking or running.

Participants and Procedure Ninety-three native Japanese speakers, all undergraduate students, participated in the experiment. They went through both an attribute rating task and a word creation task. The participants were first presented with the 70 video clips on a computer screen in random order and asked to evaluate them on five 11-point semantic-differential scales (from 1 to 11): "size" (bigsmall), "speed" (slow-fast), "weight" (heavy-light), "energeticity" (energetic-non-energetic), and "jerkiness"
(jerky-smooth). After the rating task, the videos were shown again to the participants in a random order. They were asked to generate sound-symbolic words and type them on a keyboard.

Data Preparation For analysis, we excluded soundsymbolic words that were obviously made on the analogy of existent nouns and verbs (e.g., robo-robo, cf. robotto 'robot'). We also excluded the data obtained for the videos whose most common semantic rating was " 6 " (neutral), which we assumed to blur the rest of the data. A total of 1,442 mimetics were submitted for analysis. They were phonetically coded and listed with the rating scores. For phonetic coding, we limited ourselves to the first moras $\left(C_{1} V_{1}\right)$ of the obtained mimetics, as they have been discussed to have particular sound-symbolic significance (Kawahara, Shinohara, \& Uchimoto, 2008; see also Hamano, 1998). The coding scheme for consonants, shown with the one for vowels in Table 1 (the coding for English will be used in Experiment 2), is based on Bailey \& Hahn (2005). The data is thus a $1,442 \times 13$ matrix, consisting of five semantic ratings and eight phonetic values for each mimetic.

Table 1: The coding scheme for phonetic features

|  | Japanese | English |
| :---: | :---: | :---: |
| $\mathrm{C}_{1}$ place of articulation | labial (Lab), velar (Vel), alveolar (Alv), glottal (Glot), palate (Pal), dental (Dent) | labial, <br> velar, <br> alveolar, <br> glottal, <br> palate, <br> dental |
| $\mathrm{C}_{1}$ sonorancy | sonorant (Son), <br> obstruent (Obs) | sonorant, obstruent |
| $\mathrm{C}_{1}$ manner of articulation | stop (Stop), <br> affricate (Aff), <br> fricative (Fric), <br> glide (Gld), <br> flap (Flap) | stop, affricate, fricative, glide, lateral (Lat), nasal (Nas), rhotic (Rhot) |
| $\mathrm{C}_{1}$ voicing | voiced, voiceless | voiced, voiceless |
| $\mathrm{C}_{1}$ palatalization | palatalized, not palatalized | n/a |
| $\mathrm{C}_{1}$ nasality | nasal, not nasal | n/a |
| $\mathrm{V}_{1}$ height | high, mid, low | high, mid-high, mid-low, low |
| $\mathrm{V}_{1}$ backness | front, central, back | front, central, back |

## Analysis and Results

Canonical Correlation Analysis We conducted a variant of canonical correlation analysis (CCA) designed for categorical variables (see Thompson, 2005 for its detailed algorism) developed by Van der Burg (1988). Generally speaking, CCA enables us to visualize an implicit structure underlying multiple datasets. In common with other multivariate analyses, such as principle component analysis, CCA attempts to explain all possible correlations in a lowdimensional space. While principle component analysis is applied to only one dataset, CCA investigates relationships
among two or more different variable sets and derives estimates by applying weights to the variables.

In the current context, CCA examines all possible correlations both within and across the two sets of variables (i.e., the sound and meaning datasets). This means that we can explore not only sound-meaning associations but also sound-sound or meaning-meaning correlations simultaneously, not limiting ourselves to a predetermined set of sound-meaning pairs. Notice that this analytical method is meaningful due to the very nature of sound symbolism, in which sound and meaning are intertwined with each other.

The Consistency of Sound-Meaning Associations The data matrix was fed into the program for canonical correlation analysis packaged in IBM SPSS Statistics 20 (IBM, 2012). We employed a two-dimensional solution, as the canonical correlation values of the first and second dimensions, which represent the latent correlations between the canonical variable of sounds and that of meanings, were significantly high ( $r \mathrm{~s}=.56$ (first dimension) and .25 (second dimension), $p \mathrm{~s}<.001$ ). These values guarantee consistent sound-meaning associations in the two dimensions, indicating systematic sound symbolism in the present free production experiment.

The Focal Sound-Meaning Associations in the SoundSymbolic System of Japanese To examine how sound and meaning are correlated in the present dataset, we considered the component loadings of each variable (see Table 2). As in principle component analysis, component loadings represent the correlation between the data and the extracted dimensions; each absolute value approximates the importance of the variables on each dimension.

Table 2: Component loadings of canonical correlation
analysis in Japanese

| Dataset | Variable (positive - negative ) | Dimension 1 | Dimension 2 |
| :---: | :---: | :---: | :---: |
| Meaning | Size (large - small) | . 40 | -. 36 |
|  | Speed (slow - fast) | . 56 | . 39 |
|  | Weight (heavy - light) | . 85 | . 07 |
|  | Energeticity (energetic - non-energetic) | -. 21 | -. 56 |
|  | Jerkiness (jerky - smooth) | . 31 | -. 35 |
| Sound | $\mathrm{C}_{1}$ _place | . 05 | . 17 |
|  | $\mathrm{C}_{1}$ _sonorancy | . 36 | . 26 |
|  | $\mathrm{C}_{1}$ _manner | . 05 | -. 42 |
|  | $\mathrm{C}_{1}$ _voicing | . 74 | -. 24 |
|  | $\mathrm{C}_{1}$ ppalatalization | -. 43 | -. 05 |
|  | $\mathrm{C}_{1}$ _nasality | . 38 | . 29 |
|  | $\mathrm{V}_{1}$ _height | . 05 | -. 40 |
|  | $\mathrm{V}_{1 \_}$backness | . 28 | . 33 |

Table 2 shows that the semantic attribute "weight" in the meaning group and the phonetic feature " $\mathrm{C}_{1}$ voicing" in the sound group obtained high positive loadings on Dimension 1 (. 85 and .74 , respectively). This suggests that the voicingweight association was critically important in Japanese
sound symbolism for motion. Noteworthy contributions were also observed for "speed" (.56), "size" (.40), and "jerkiness" (.31) among the meaning features and " $\mathrm{C}_{1}$ palatalization" (-.43), " $\mathrm{C}_{1}$ nasality" (.38), and " $\mathrm{C}_{1}$ sonorancy" (.36) among the sound features. The four semantic variables were positively correlated. Heavy, large, slow, and jerky (or light, small, fast, and smooth) manners of motion tended to appear together, corresponding to the four consonantal features. On the other hand, in Dimension 2, "speed" (.39) and " $\mathrm{V}_{1}$ backness" (.33) obtained high positive absolute values, while "size" ( -.36 ), "energeticity" (-.56), "jerkiness" (-.35), " $\mathrm{C}_{1}$ manner" ( -.42 ), and " $\mathrm{V}_{1}$ height" ( -.40 ) obtained high negative absolute values. This suggests that the correspondences between this set of consonantal and vocalic features and slow, small, nonenergetic, and smooth (or large, fast, energetic, and jerky) manners have the second most important status in Japanese sound symbolism for motion.

Details of the Sound-Meaning Associations The loading scores tell us which variables (e.g., manner of articulation) play a primary role in the discrimination of the dimensions, but it does not specify how much individual values in each variable (e.g., "affricate" in manner of articulation) contribute to those dimensions. We therefore computed the centroids of object scores for the semantic and phonetic values (see Van der Burg, 1988 for the details of this algorism). Specifically, each point in Figure 1 represents the weight of each value on the two dimensions. Note that the figure only shows sound variables for the sake of clarity; relevant meaning variables are indicated in the dimension labels, based on their loading scores above. The all abbreviations in Figure 1 is corresponds to those in Table1.

First, it is evident that the "voiced" and "voiceless" points are contrastively located in the positive and negative sides of Dimension 1, respectively. This is consistent with the large contribution of the voicing feature to this dimension in component loading. Moreover, Figure 1 reveals large positive contributions of the two phonetic values, "nasal" and "sonorant," to the same dimension, although the component loadings of the " $\mathrm{C}_{1}$ nasality" and " $\mathrm{C}_{1}$ sonorancy" variables were not as large as that of " $\mathrm{C}_{1}$ voicing." These coordinates indicate that voiced consonants that are nasal and sonorant (i.e., $[\mathrm{m}],[\mathrm{n}]$, as in moji and noro) have particular significance in Dimension 1. In contrast, the negative half of Dimension 1 features the voiceless obstruent that is "palatalized" and "affricate" (i.e., /ty/, realized as [tf]) as a sound that is strongly associated with a small, fast, light, smooth motion (e.g., tyoko).

Dimension 2 also shows clear contrasts for the variables which received high loading scores in Table 2: "fricative" and "affricate" ( $\mathrm{C}_{1}$ manner), "high" and "low" ( $\mathrm{V}_{1}$ height), and "back" and "central" ( $\mathrm{V}_{1}$ backness). Each of these contrasts is paired with a set of positive (slow, small, nonenergetic, smooth) or negative semantic values (fast, large, energetic, jerky) in Figure 1. The positive half of the same figure also contains "glottal," "palatal," "sonorant," and
"nasal." These results allow us to think of particular phones to be relevant to the present case of sound symbolism, such as [ $\mathrm{h}(\mathrm{j})]$ (fricative, glottal, (palatal)), [m] and [ n$]$ (nasal), and [u] (high, back) (e.g., heto, hura, moso). Similarly, in the negative half of Dimension 2, [tf] and [ts] (affricate) and [a] (central, low) are associated with large, fast, energetic, and jerky manners of motion (e.g., tyaki).

Figure 1: Category centroids for individual phonetic values in Japanese (See Table 1 for the explanations for the abbreviations)

## Experiment 2: English

## Method

Participants and Materials Twenty-seven English speakers at University of Birmingham, UK, participated in the experiment. The same 70 videos as we used in Experiment 1 were used as stimuli.

Procedure As in Experiment 1, English participants first saw randomly presented videos and were asked to rate them on five semantic dimensions. After the rating task, they watched the videos again and produced sound-symbolic words to depict the human motions shown in the video clips. Unlike Experiment 1, however, the participants were instructed to create $\mathrm{C}_{1} \mathrm{~V}_{1} \mathrm{C}_{2} \mathrm{~V}_{2}$ words that intuitively (or "sound-symbolically") matched the motions. This change was made because English speakers were not likely to be familiar with the notion of mimetics.

Data Preparation The data went through the same noise exclusion procedure as in Experiment 1. 1,227 "mimetic" words were retained for analysis. The $\mathrm{C}_{1} \mathrm{~V}_{1}$ of each mimetic was phonetically coded according to the scheme in Table 1. Thus, the resultant data matrix consisted of 1,227 rows of mimetics and 8 columns of phonetic/evaluative features.

## Analysis and Results

The Consistency of Sound-Meaning Associations Nonlinear canonical correlation analysis was conducted with the

English data matrix. We adopted a two-dimensional solution. The canonical correlation values for Dimensions 1 and 2 were .17 and .15 , respectively ( $p s<.01$ ). These values were substantially lower than their Japanese equivalents, indicating that the associations between the sound and meaning datasets in English are relatively weaker than those in Japanese. This may suggest that Japanese speakers have a better established sound-symbolic sense than English speakers due to the existence of the sound-symbolically systematized lexical class of mimetics in Japanese.

The Focal Sound-Meaning Associations in SoundSymbolic System of English The component loadings of each variable are listed in Table 3. It shows that "size" $(-.40)$, "speed" (.56), "energeticity" $(-.62)$, " $\mathrm{C}_{1}$ voicing" (.58), and " $\mathrm{V}_{1}$ height" ( -.39 ) obtained high absolute values in Dimension 1, while "weight" (.47), "energeticity" (-.32), "jerkiness" ( -.46 ), and " $\mathrm{C}_{1}$ place" ( -.70 ) were heavily weighted in Dimension 2. Thus, Dimension 1 is associated with small, slow, non-energetic motions, and Dimension 2 with heavy, non-energetic, smooth motions.

Table 3: Component loadings of canonical correlation analysis in English

| Dataset | Variable (positive - negative) | Dimension 1 | Dimension 2 |
| :---: | :---: | :---: | :---: |
| Meaning | Size (large - small) | -. 40 | . 12 |
|  | Speed (slow - fast) | . 56 | . 06 |
|  | Weight (heavy - light) | -. 11 | . 47 |
|  | Energeticity <br> (energetic - non-energetic) | -. 62 | -. 32 |
|  | Jerkiness (jerky - smooth) | -. 09 | -. 46 |
| Sound | $\mathrm{C}_{1}$ _place | . 04 | -. 70 |
|  | $\mathrm{C}_{1}$ _sonorancy | . 27 | . 07 |
|  | $\mathrm{C}_{1}$ _manner | . 18 | -. 19 |
|  | $\mathrm{C}_{1}$ _voicing | . 58 | -. 03 |
|  | $\mathrm{V}_{1}$ _height | -. 39 | -. 15 |
|  | V1_backness | . 07 | . 12 |

Details of the Sound-Meaning Associations Figure 2 plots the centroids of object points, which indicate how each value of the sound/meaning categories was weighted. Dimension 1 is clearly divided by the two phonetic features " $\mathrm{C}_{1}$ voicing" and " $\mathrm{V}_{1}$ height," with "voiced" and "mid-low" being positive and "voiceless" and "high" being negative. The figure also contains "nasal," "lateral," "rhotic," and "sonorant" in the positive area, suggesting that [n], [1], and [ r ], as in medi, lela, and reso, are strongly connected with small, slow, non-energetic motion. Likewise, the negative domain contains a voiceless glottal fricative (i.e., [h], as in hali), which was associated with large, fast, energetic motion.

Dimension 2 exhibits a wide distribution of the places and manners of articulation. A marked contrast is observed between the two positive phonetic features "glottal" and "affricate" and the three negative ones "palatal," "velar," and "glide." Among these features, "glottal" and "affricate" can be unambiguously identified as [h] (e.g., hopi) and [t]], respectively, which are linked with heavy, non-energetic,
smooth motion. Similarly, the combination of "palatal" and "glide" is synonymous with [j].

Figure 2: Category centroids for individual phonetic values in English (See Table 1 for the explanations for the abbreviations)

## General Discussion

Comparing the detected sound-meaning correlations in Japanese and English shows us the shared and languagespecific sound symbolism. Table 4 summarizes the soundsymbolic mappings found in the two languages, which shows what sound and meaning components have priority in motion sound symbolism of the two languages.
First, the results suggest that the two languages share in a large part a set of "sound-symbolically relevant" phonetic features. For example, both languages utilized the phonetic features "sonorancy," "voicing," "nasality," and "vowel height," and specific phonetic values "glottal," "palatal," "affricate," and "fricative." It should be noted here that some phonetic values, such as "alveolar," "labial," and "stop," did not make a large contribution in the present data. This might reflect the unmarked nature of these sounds in the phonological systems of the two languages. In the present data, alveolar, labial, and stop consonants were found in $66 \%, 16 \%$, and $61 \%$ of all Japanese mimetics and $51 \%, 28 \%$, and $37 \%$ of all English mimetics, respectively.
Second, the two languages share many semantic features in their primary sound symbolism. Most notably, both of them use "weight" and "energeticity" as the most significant semantic features in sound symbolism of manner of motion. The two features are correlated with "size" and "speed" (see Tables 2 and 3).
Thus, speakers of Japanese and English use a similar set of phonetic and semantic features in sound symbolism of locomotion. However, these similarities do not directly mean that English and Japanese speakers mapped these sounds and meanings in the same way. They shared the
most important sound-symbolic mapping: the voicing-speed mapping in the primary dimension. This can be accounted for by the long VOT (voice onset time) of voiced consonants, which appears to be readily mapped to the long duration of slow motion. Phonosemantic descriptions in the literature support this interpretation (Hamano, 1998; Tamori \& Schourup, 1999). Further, the present study revealed that this sound-symbolic effect is especially strong in nasals (i.e., [m], [n]).

Table 4: Sound-meaning associations obtained in the two experiments

| Dimension | Japanese | English |
| :---: | :---: | :---: |
| Dimension 1 | heavy, slow, jerky, large voiced, nasal + sonorant , | non-energetic, <br> slow, small <br> voiced, <br> nasal + sonorant, <br> lateral , <br> rhotics, <br> mid-low |
|  | light, fast, smooth, small Voiceless, palatalized + affricate | energetic, <br> fast, large, <br> voiceless , <br> glottal + fricative, <br> high |
| Dimension 2 | small, <br> slow, non-energetic, smooth <br> glottal + fricative, <br> palatal + fricative, <br> nasal + sonorant, <br> high + back | heavy, <br> non-energetic, smooth glottal, affricate |
|  | large, fast, energetic, jerky central, low vowel, affricate | light, energetic, jerky palatal + glide, velar |

Note: Sound-meaning associations shared by the two languages are given in boldface.

The present results also established the presence of language-specific sound symbolism. Most strikingly, Japanese and English speakers mapped some sounds to opposite meanings. For example, Japanese speakers associated the palato-alveolar affricate [t 5 ] with light, fast, smooth, small motion in the primary dimension, whereas English speakers linked it to heavy, non-energetic, smooth motion in the secondary dimension. Likewise, the high back vowel /u/ was connected to slow, non-energetic motion in Japanese, but to fast, energetic motion in English.
These disagreements may be explained by the crosslinguistic differences in the phonological status of these sounds. First, in Japanese, the phone [t $\int$ ] often appears secondarily, in a palatalized environment (i.e., /ty/), whereas this is not the case in English. Moreover, another affricate in Japanese (i.e., [ts]) is analyzed into [t] and [s] in English. Second, /u/ is realized as [ w ] (unrounded) in Japanese, but as [ $\mathrm{\sigma}$ ] (rounded) or [ $\mathrm{u}(:)$ ] (rounded) in English. This crosslinguistic contrast in the roundedness of high back vowels suggests an articulation-based link between roundedness and energetic (hence, fast) motion. Thus, the present comparative observation illustrates the possibility that at least some parts of language-specific sound symbolism may
be accounted for in terms of phonological typology. This possibility has been assumed widely in the literature, yet has not been much investigated.
Our study provides some important insights for theories of sound symbolism. We revealed that the sense of sound symbolism is realized in a complex system, which involves both universality and language-specificity. Sound symbolism is often alluded as "phonetic iconicity," but despite the name, this linguistic phenomenon is subject to a certain degree of arbitrariness, which originates from our language experience (Brenner et al., 2013 for a similar discussion). Our holistic and exploratory approach greatly contributes to the clarification of the complexity of iconic and arbitrary mappings in sound symbolism.

## Acknowledgements

We are grateful to Shigeto Kawahara for his insightful and helpful comments from the perspective of phonetics and phonology. We also thank Farzana Bhaiyat, Alicia Griffiths, Junko Kanero, and Yayoi Tajima, who participated in the current project as annotators. Remaining inadequacies are ours. # Polarity correspondence does not explain the SNARC effect 

Julio Santiago (santiago@ugr.es)<br>Department of Experimental Psychology, University of Granada<br>Campus de Cartuja, 18071 Granada, Spain<br>Daniel Lakens (D.Lakens@tue.nl)<br>School of Innovation Sciences, Eindhoven University of Technology<br>Postbus 513, 5600 MB Eindhoven, The Netherlands

#### Abstract

Conceptual metaphor congruency effects have been interpreted as evidence for the notion that the representation of abstract conceptual dimensions (e.g., power, evaluation) rests on more concrete dimensions (e.g., space, brightness). However, an alternative account based on the notion of polarity correspondence has recently received empirical support from studies about the mapping between affective evaluation and morality on vertical space. We tested the polarity correspondence account in the domain of number, which shows well-known congruency effects with lateral left-right space (the SNARC effect). Response polarity was manipulated by varying keyboard eccentricity in both parity (odd-even) and quantity (larger-smaller than 5) tasks. Response eccentricity did not modulate the SNARC effect. In a final experiment, the orthogonal Simon effect was modulated by the manipulation of response eccentricity. We conclude that polarity correspondence does not provide an adequate explanation of conceptual congruency effects in the domain of number.

Keywords: conceptual metaphor; polarity correspondence; SNARC; number; space; response eccentricity; orthogonal Simon.

## Introduction

Recent years have witnessed a strong interest in the possibility that the mental representation of abstract concepts relies in a deep sense on more concrete concepts (see Landau, Meier, \& Keefer, 2010, and Santiago, Román, \& Ouellet, 2011, for reviews). Under this view, an abstract concept or conceptual domain imports structure and content from a better understood, more clearly delineated, more concrete conceptual domain. For example, time is understood as physical motion from one location to another (Clark, 1973), and power is linked to physical size (Sorokowski, 2010). Such a view suggests that the mental representation of concepts is hierarchically structured, such that more concrete concepts are more directly linked to perceptual-motor experiences, and these in turn are used to support the understanding of more abstract levels. Therefore, the whole human conceptual structure is anchored to, or founded upon our embodied interaction with the external world, which is why Santiago, Román, and Ouellet (2011) called it the Solid Foundations view.

An important source of evidence for such a view comes from conceptual congruency tasks. In these tasks, a concrete and an abstract dimension are factorially crossed.

Participants' main task requires the processing of the abstract dimension, and the effects of the concrete, task-irrelevant dimension are measured. Typically, both dimensions interact, such that a particular combination of concrete and abstract conditions shows better performance. This metaphorical congruency effect is often interpreted as revealing the use of underlying concrete representations to support the abstract judgment. A well-known example is the Spatial-Numerical Association of Response Codes (SNARC) effect (Dehaene et al., 1993). In a typical SNARC task, the participant has to make a numerical discrimination, such as deciding whether a number is odd or even, by means of key presses. The responding hand (left or right) is the task-irrelevant concrete dimension: in some blocks the "odd" response is given by a left-hand key press and the "even" response by a right-hand key press. In other blocks, the mapping is reversed. The standard result, now widely replicated, consists in better performance when responding to a small number with the left hand and to a large number with the right hand versus using the reverse mapping (see Wood, Willmes, Nuerk, \& Fischer, 2008, for a review). The SNARC effect has most often been interpreted as evidence for the use of a spatial left-right line to mentally represent number magnitude.

However, Lakens and coworkers (Lakens, Semin, \& Foroni, 2012; Lakens, 2012) have proposed that it may not be necessary to resort to concrete representations of any kind in order to account for many of the published metaphorical congruency effects. Their view rests on purely structural features of dimensional concepts based on the concept of markedness and on the principle of polarity correspondence proposed by Proctor and Cho (2006), which applies when two or more dimensions are simultaneously manipulated in a task. The concept of markedness has a long standing tradition in linguistics (Greenberg, 1963) and psycholinguistics (Clark, 1969). The two poles of most conceptual dimensions (e.g., happiness or tallness) do not seem to enjoy the same representational status. One of them, which we will refer to as the + pole, is used to refer to the whole dimension, whereas the other, the -pole, is used to refer only to itself (e.g., compare "how tall is John?" versus "how short is John?": the former does not presuppose that John's height is in any specific range, whereas the second question suggests that John is short). The +pole is more frequent in language and enjoys a processing advantage compared to the -pole (Clark, 1969). Proctor and Cho
(2006) proposed a polarity correspondence principle that predicts an extra processing advantage in those conditions where the pole signs match. Thus, a polarity correspondence account of conceptual congruency effects does not require the postulation of concrete mental representations.

One key piece of evidence for Proctor and Cho's argument (2006) relies on how response eccentricity modulates the orthogonal Simon effect. In a typical orthogonal Simon task, participants are presented with a stimulus in one of two vertical locations (e.g., above or below fixation) and are asked to discriminate its location by means of a left or right key press or a leftward or rightward response. The standard result is that the mapping of the upper location with the right response and down with left produces better performance than the up-left down-right mapping (e.g., Proctor \& Cho, 2003). Proctor and Cho (2006) proposed that the up-right advantage is due to polarity correspondence, being up and right the +poles of the vertical and lateral spatial dimensions, respectively.

Supporting this conclusion, response eccentricity interacts with the up-right advantage. Response eccentricity refers to the lateral displacement of the response set. Placing the response box, keyboard, or joystick to the right of the screen makes the up-right advantage to grow stronger, while it turns into an up-left advantage when the response set is located on left space (Proctor \& Cho, 2003). Proctor and coworkers suggested that response eccentricity changes the saliency of the right and left poles of the lateral spatial dimension, effectively turning the left pole into the +pole when the responses are placed on left space and thus generating the up-left advantage through polarity correspondence.

These results illustrate an important characteristic of the polarity correspondence account: polarities are not fixed, but can be changed by attentional and saliency factors, which opens the possibility of manipulating them experimentally. Lakens (2012) and Lakens et al. (2012) applied this perspective to conceptual congruency effects between the concrete dimensions of vertical location (up-down) and brightness and the abstract dimensions of power and affective evaluation. They showed that those conceptual congruency effects require the simultaneous presence of the two contrasting poles in the task and that it is possible to change the effect by changing the frequency of use of each pole.

To summarize the argument so far, there seems to be good support for the idea that conceptual congruency effects are of a flexible and contextual nature (Lakens et al., 2012; see also Santiago, Ouellet, Román, \& Valenzuela, 2012), thus contradicting their interpretation as indexes of stable semantic memory mappings favoured by the Solid Foundations view. There is also evidence that suggests that polarity differences and cross-dimensional polarity correspondence can account for some conceptual congruency effects without resorting to underlying concrete dimensions, or even to any internal alignment of the relevant dimensions. However, the relevant evidence so far
has concentrated on a small set of conceptual dimensions, namely morality, power and affective evaluation. Can these conclusions be generalized to other abstract dimensions? Such is the question that we seek to answer in the present experimental series.

In order to increase the contrast with already available studies, and therefore the generalizability of our results, we decided to test the abstract dimension of numerical magnitude. In contrast to morality, power and evaluation, which are thought to be associated to vertical space, numbers have been linked to lateral left-right space. Proctor and Cho (2006) explicitly argued that polarity correspondence might explain the standard SNARC effect that obtains in parity tasks. They argued that number processing in parity judgment does reveal markedness effects. Responding "odd" is slower than responding "even", especially in contexts that foster a comparison between odd and even numbers (Hines, 1990). Moreover, responding "odd" with the left hand and "even" with the right hand is faster than vice versa (Nuerk, Iversen, \& Willmes, 2004, called it the Markedness Association of Response Codes, or MARC effect). The SNARC effect would arise because large numbers would be +polar and small numbers -polar and these polarities would match with the +polar right response and the -polar left response. Therefore, Experiment 1 used a parity judgment task on Arabic numerals.

In contrast to parity tasks, Proctor and Cho (2006) suggested that magnitude comparison tasks (e.g., to say whether the number is smaller or larger than 5) induce a continuous representation and, as a result, neither a SNARC nor MARC effect are observed in them (they cite Ito \& Hatta, 2004, Experiment 3, as a relevant case). However, other studies have successfully reported SNARC effects in magnitude judgments, including some which have interpreted their results as support for the polarity correspondence hypothesis (Santens \& Gevers, 2008). We believe that, if polarity correspondence effects underlie the SNARC effect in parity judgments, they should be even clearer when the task explicitly asks participants to categorize the stimuli into the two polar opposites "small" and "large". So, we decided to extend our observations to a magnitude judgment task in Experiment 2.

The rationale of the current set of experiments relies on the manipulation of response eccentricity, thereby influencing the polarities of the left or right hand response alternatives. We manipulated response eccentricity in a procedure that closely followed the procedure used by Proctor and Cho (2003, Experiment 1), but instead of presenting stimuli in upper or lower locations, digits were presented in the centre of the screen. Participants discriminated their parity (Experiment 1) or magnitude (Experiment 2) by means of left or right key presses. Response set location was manipulated within-participants by placing the input device left, centre, or right of the computer monitor. If the left-right numerical and/or temporal congruency effects are due, in all or in part, to
polarity correspondence, then changing the polarity of the response dimension should influence the observed reaction time pattern. The polarity correspondence account predicts standard congruency effects when the response set is either central or to the right. Crucially, it predicts a reduced or inverted effect when the response set is located on the left side. Under this condition, the left response would be +polar and the right response -polar. Therefore, the polarity correspondence principle should induce an advantage for up-left and down-right mappings. To preview the results, response eccentricity failed to interact with the SNARC effect in any task. We concluded this series of experiments by showing that it is possible to replicate the interaction between response eccentricity and the orthogonal Simon effect when upper and lower stimuli are used instead of numbers (Experiment 3).

## Experiment 1

Experiment 1 used centrally presented single digits from 1 to 9 (with the exception of 5) in a parity judgment task. Responses were left and right key presses in a keyboard which could be located at either the left, centre, or right of the screen.

## Method

Participants Twenty Psychology students (17 women, all right-handed, age range $18-39 \mathrm{y}$.) from the University of Granada volunteered to participate, and received course credit in return.
Materials and Procedure The single digits 1 to 4 and 6 to 9 were centrally presented on a computer screen. A single digit was presented in each trial, and the participant's task was to decide whether the digit was odd or even. The participant responded by pressing the keys F (left) or J (right) on a standard computer keyboard. Each trial consisted of a central fixation cross ( 1000 ms ) followed by the target digit (until response). Incorrect trials were followed by the word "Incorrecto" for 500 ms in red font, also at the same location. Each was followed by a 1000 ms blank screen. Experimental trials were divided into six blocks of 54 trials. All digits were presented once every eight trials. The mapping of responses (odd-even) to keys (left-right) was kept constant during three blocks, and then reversed in the following three blocks. The order of presentation of the two mappings was counterbalanced over participants. Keyboard location was varied within-participants. In the left and right locations, the keyboard was moved 30 cm to each side (as in Proctor \& Cho, 2003). Half the participants experienced the three locations in the order left, centre, and right, and the other half in the reversed order. The sequence of keyboard locations was repeated twice over the six blocks.
Design and Analysis Data were analyzed using a factorial ANOVA with the following factors and levels:

Parity (odd-even) X Magnitude (smaller-larger than 5) X Response (left-right) X Keyboard location (left-centre-right). Counterbalance group was also included as a factor in the design in order to exclude noise due to order of conditions, but because its effect and interactions are theoretically uninteresting, they will not be reported below (but note that the inclusion of this factor in the analyses leads to a reduction in the degrees of freedom of the error). Markedness effects would be evident in the main effects of Parity (with faster responses to even than odd numbers) and Magnitude (with faster responses to larger than smaller numbers). A main effect of Response (with faster responses with the right than left hand) could also be interpreted as a markedness effect, although it could just be due to greater perceptuo-motor fluency of the preferred hand. Potential polarity correspondence effects would consist in significant interactions between Parity and Response (MARC effect) and Magnitude and Response (SNARC effect). Three-way interactions of either the MARC and/or the SNARC effects with Keyboard location would support the conclusion that polarity correspondence is indeed their underlying cause.

## Results

Errors occurred in 280 trials (4.32\%). Latencies in correct trials were trimmed by means of fixed cut-off points, set at 300 and 1300 ms after inspection of the RT distribution, which led to the rejection of 100 trials $(1.54 \%)$ as outliers. Average latency and accuracy were analyzed independently.

The analysis of latency showed a very clear pattern. There were main effects of Parity $(F(1,16)=13.52, p<.01)$ and Response $(F(1,16)=9.30, p<.01)$, both in the direction predicted by a markedness effect (faster latencies for even and right-handed responses). There was a clear interaction between Magnitude and Response $(F(1,16)=8.12, p=.01)$, which took the standard form of the SNARC effect. No other effect had a probability level smaller than 0.10 . In particular, the interaction between Parity and Response (the MARC effect) and any second order interactions between either the SNARC and the MARC effects with Keyboard location were far from significance (all $F \mathrm{~s}<1$ ). Figure 1 (upper panel) shows the main results. These results were not qualified by the analysis of accuracy.

## Discussion

Experiment 1 showed that keyboard location did not modulate the SNARC effect, what contradicts the predictions from a polarity correspondence account. The data also showed main effects of parity and response side such that the + pole (even and right) was easier to process. However, there were no interactions between these dimensions and keyboard location. Moreover, there was neither an interaction between parity and response side
(MARC effect) nor a modulation of this interaction at different keyboard locations.

Figure 1: Average latencies (in ms) in the congruent vs. incongruent conditions in Experiment 1 (SNARC, parity task), Experiment 2 (SNARC, magnitude task), and Experiment 3 (orthogonal Simon task). Congruency in the SNARC experiments is defined with respect to numerical magnitude (smaller or larger than 5) and response (left or right), assuming a standard SNARC effect (smaller-left, larger-right). Congruency in the orthogonal Simon experiment is defined with respect to vertical location (up or down) and response (left or right), assuming a standard orthogonal Simon effect (up-right, down-left).

Thus, the full pattern of results shows no support for a polarity correspondence account. Experiment 2 extended these results to a magnitude judgement task.

## Experiment 2

Experiment 2 was an exact replication of the Experiment 1 with a single difference: participants judged whether the central digit was smaller or larger than 5.

## Method

Participants Twenty new participants (17 women, 1 left-hander, age range $18-39$ y.) from the same population took part in the study and received credit course in return.
Materials and Procedure Everything was kept identical to Experiment 1 with the main exception of the task: participants judged whether the digit was smaller or larger than 5. Additionally, there were 56 trials in each block (exactly 7 presentations of each digit).
Design and Analysis Data were analyzed using a factorial ANOVA comprising Parity (odd-even) X Magnitude (smaller-larger than 5) X Response (left-right) X Keyboard location (left-centre-right) X Counterbalance group (not reported).

## Results

There were errors in 216 trials (3.32\%). Latencies of correct trials were trimmed by fixed cut-off points ( 300 and 1300 $\mathrm{ms})$ : 120 trials ( $1.78 \%$ ) were rejected as outliers.

The analysis of latencies once again rendered a clear pattern. Only the main effect of Parity was significant $(F(1,16)=20.34, p<.001)$, with faster responses to even numbers. Out of all possible two-way interactions, only Magnitude by Response was significant $(F(1,16)=6.55$, $p=.02$ ), taking the shape of a standard SNARC effect. These were the only findings that reached standard reliability levels. Keyboard location did not modulate the SNARC effect at all. Figure 1 (middle panel) shows the main results.

The accuracy measure showed a clear effect of Parity $(F(1,16)=10.15, p<.01)$ which went in an unexpected direction: even numbers had more errors than odd numbers. However, an inspection of accuracy means for each number indicated that this is due to a distance effect that concentrates on the two numbers that surround 5 (4 and 6), which are both even. Because this reduced accuracy was associated to faster latencies, it may be revealing a speed-accuracy trade-off. There was also a significant interaction between Parity and Response $(F(1,16)=7.32$, $p=.02$ ), which was in the direction expected for a MARC effect: greater accuracy for the even-right and odd-left mapping. No other effect added to or qualified the findings from the latency analysis.

## Discussion

Experiment 2 found a clear SNARC effect. In contrast to the prior experiment, there was also a MARC effect on accuracy. None of those potential polarity correspondence effects where modulated by the location of the keyboard. There was also a main effect of parity, both in latency and accuracy, but its interpretation is complicated because it went in opposite directions (even numbers were both faster and less accurate), what may suggest a speed-accuracy trade-off.

Summing up, Experiments 1 and 2 found SNARC effects which did not show any trace of being modulated by keyboard location. Other significant main effects and interactions also failed to provide clear indications of being related to markedness or polarity correspondence. Before turning to discuss the general implications of the present results, a final possibility must be discarded: that eccentricity effects on orthogonal Simon tasks cannot be replicated. Thus, our final experiment used a procedure that mirrored Proctor and Cho (2003, Experiment 1).

## Experiment 3

Experiment 3 was an exact replication of our two first experiments with the single difference that the stimulus was a rectangle made of asterisks (as in Proctor \& Cho, 2003, Experiment 1), which could be presented either above or below fixation. Participants' task was just to discriminate its location by pressing the right or left key.

## Method

Participants Participants were 18 Psychology students from the University of Granada (all female, 2 left-handers, age range $18-30 \mathrm{y}$.), who received course credit for their participation.
Materials and Procedure The target stimulus was an array of $3 \times 3$ asterisks that looked like a rectangle. The target was presented horizontally centred midway between fixation and either the upper or lower border of the screen. Participant's task was to judge whether the target appeared above or below fixation.
Design and Analysis The design included Vertical location (up-down) X Response (left-right) X Keyboard location (left-centre-right) X Counterbalance group (not reported).

## Results

There were errors in 137 trials (2.26\%). Cut-off points were set at 250 and 1250 ms , which led to the rejection of 119 (1.85\%) outliers.

The analysis of latency revealed an interaction between Vertical location and Response $(F(1,14)=11.05, p<.01)$. Unexpectedly, this interaction took the form of an up-left advantage (possible causes are discussed below). However, the crucial aspect of the data is that such interaction was strongly modulated by Keyboard location $(F(2,28)=25.73$,
$p<.001$; see Figure 1, lower panel). The up-left advantage was present when the keyboard was located on the left and on the centre, and turned into a slight up-right advantage when the keyboard was moved to the right. Other significant findings of less theoretical importance were the interaction between Vertical location and Keyboard location $(F(2,28)=5.56, p<.01)$ and the main effect of Keyboard location $(F(2,28)=6.81, p<.01)$ due to slower latencies with the keyboard on the left. Accuracy data supported the findings of the latency measure.

## Discussion

Experiment 3 allows very clear conclusions: an up-left advantage was observed both in latency and accuracy when the keyboard was placed at midline and on the left, and this turned into a small up-right advantage when the keyboard was placed to the right of the computer monitor. Proctor and Cho (2003) found an up-left advantage with the keyboard on the left, a very small up-right advantage with keyboard on the centre, and an up-right advantage with the keyboard on the right side. Therefore, we take the present results to constitute a successful replication of their findings (as well as those by Cho, Proctor, \& Yamaguchi, 2008): keyboard eccentricity affects the saliency of the side of space where the keyboard lies, and the most salient side of the left-right dimension attracts the mapping of the +pole of the vertical dimension (up).

The main contrast between present results and those reported by Proctor and Cho (2003) and others is the finding of an up-left (instead of up-right) advantage when the response set is placed at midline. As a post-hoc speculation, we think that the cause may be related to the spatial arrangement of the experimental equipment with respect to the whole room. The computer and keyboard were located on a corner of the lab, with a window to the right of the participant, and the room extending to the left. This may have made the participant to conceptualize the equipment as being located to the left of the wall. Both Weeks, Proctor, and Beyak (1995) and Proctor and Cho (2003) have shown that environmental factors can increase the saliency of either left or right space: placing an unused response apparatus to the right of the response keyboard was enough to turn the up-right advantage into a (very small) up-left advantage. A similar phenomenon may have occurred in the present experiment with the highly salient window located on the right side of the participant. Alternatively, the wall on the right may have provided a clear boundary to lateral space, which may have made the unbounded left space +polar, conforming existing explanations for the asymmetry in vertical space (Clark, 1973; Tversky, Kugelmass, \& Winter, 1991).

## General Discussion

The present experiment series clearly showed that the SNARC effect, both in parity and magnitude judgements, is not modulated by response eccentricity. This occurred in the context of a successful modulation of the orthogonal Simon
effect by our manipulation of response eccentricity. Proctor and coworkers (Cho et al., 2008; Proctor \& Cho, 2003, 2006; Weeks et al., 1995) accounted for eccentricity effects in the orthogonal Simon task as a consequence of a change in polarity in the spatial left-right dimension: Placing the response set on one side increases the saliency of that side, turning it effectively into the +pole. Then, that side now matches the +pole of the vertical dimension (up). If this interpretation is correct, and the SNARC effect is due to polarity correspondence between larger numbers and right responses, placing the response set on the left should reverse the SNARC. However, we found no traces of any influence of response eccentricity on the SNARC effect. This complete absence of eccentricity effects suggests that polarity correspondence is not affecting this particular congruency effect whatsoever, not even as an additional source of influence that acts together with other factors on number tasks. Many questions remain. As a first step, current work in our labs is focusing on extending present results to a different conceptual dimension which is also known to generate congruency effects with left-right space: the dimension of time.

#### Abstract

We investigated the time course of sentence formulation in Tagalog, a verb-initial language in which the verb obligatorily agrees with one of its arguments. Eye-tracked participants described pictures of transitive events. Fixations to the two characters in the events were compared across sentences differing in agreement marking and post-verbal word order. Fixation patterns show evidence for two temporally dissociated phases in Tagalog sentence production. The first, driven by verb agreement, involves early linking of concepts to syntactic functions; the second, driven by word order, involves incremental lexical encoding of these concepts. These results suggest that even the earliest stages of sentence formulation may be guided by a language's grammatical structure.

Keywords: eye tracking; sentence production; incrementality; Austronesian; verb-initial word order.

## Introduction

In the process of transforming thoughts into speech, speakers begin with a preverbal message, which must then be encoded linguistically. In English, this process may proceed in a highly lexically incremental manner: for example, when describing events like the one shown in Figure 1, speakers may have encoded as little as the first element (the syntactic subject, e.g., "the boy") of the to-be-uttered sentence prior to speech onset (Gleitman, January, Nappa, \& Trueswell, 2007). The encoding of additional event participants (e.g., "the ball") and the relation between them (e.g., "kicking") may be delayed until after speakers finish encoding the first element. This type of incremental planning is compatible with English morphosyntax, arguably in part because full noun phrases do not morphologically mark dependencies with other elements in the sentence. For many sentence types, speakers therefore do not have to commit to a particular syntactic structure upon beginning to encode one of the event participants as the syntactic subject. However, not all languages offer this flexibility: in some languages the first word is overtly marked for a dependency
with word(s) occurring only later in the sentence. In such cases, is there an effect of dependency marking on early sentence encoding as speakers begin to map the preverbal message onto linguistic structure?

One such language that exhibits dependency marking on the first word of a sentence is the Austronesian language Tagalog. The predicate is in sentence-initial position and agrees with one of its arguments. Thus, the grammatical properties of Tagalog allow us to test whether and how linguistic structure influences the earliest phases of sentence production; specifically, we test whether the overt dependency marking on the first word in a sentence leads to differences in the time course of sentence formulation in Tagalog compared to languages with no overt dependency marking on the first word (such as English).

In the following, we first sketch the relevant grammatical properties of Tagalog and then report the results of a picture description experiment in which eye-tracked speakers described pictures of simple transitive events.

## Tagalog

Tagalog is spoken by approx. 21.5 million speakers in the Philippines; it belongs to the Western Malayo-Polynesian branch of the Austronesian language family. We provide a brief overview of the morphosyntactic properties that are relevant for the reported experiment. For more comprehensive descriptions of Tagalog morphosyntax, see Himmelmann (2005), Kroeger (1993), and Schachter and Otanes (1972).

Basic declarative Tagalog sentences are predicate ${ }^{1}$-initial, i.e., predicates are followed by their arguments. One argu-

[^202]ment phrase in each sentence hosts the case marker ang. The semantic relation between the ang-marked argument and the predicate is signaled by affixes on the predicate.

The ang-marked argument will henceforth be referred to as the privileged syntactic argument (PSA). It is morphosyntactically prominent in being the only argument with which the predicate agrees in semantic role (see sentences (1-4)) and also in being the target of many syntactic operations (e.g., Kroeger, 1993) ${ }^{2}$. Arguments marked by $n g$ do not exhibit these properties and are therefore referred to as non-privileged syntactic arguments (NPSA).
$s<u m>$ isipa
$<$ AV $>$ kick $^{3,4}$
predicate
undergoer
The child kicks the ball.'
(2)
$<A V>$ kick $\quad$ PSA $=$ child $\quad$ NPSA $=$ ball
predicate actor
"The child kicks the ball."
(3)
$s<$ in>ispa $\quad n g=b a t a$
$<\mathrm{UV}>$ kick $\quad$ NPSA $=$ child
predicate actor
"The child kicks the ball."
(4)

| $<$ UV $>$ kick | PSA=ball | NPSA=child |
| :--- | :--- | :--- |
| predicate | undergoer | actor |

"The child kicks the ball."
The sentences in (1-4) illustrate three properties of Tagalog grammar that are relevant for this study. First, the predicate always agrees in semantic role with the PSA in basic sentences. In sentences (1) and (2), the PSA denotes the actor ${ }^{5}$ of the event so the predicate takes actor voice marking (AV); in sentences (3) and (4) the PSA denotes the undergoer of the event so the predicate takes undergoer voice

[^203]marking (UV) ${ }^{6}$. NPSAs marked by the case marker $n g$ do not agree with the predicate. Second, there are no syntactic constraints on the ordering of arguments for the constructions dealt with in this paper. Sentences (1) and (2) have the same meaning but they differ in their word order: in (1) the PSA is sentence-final, whereas it is sentence-medial in (2); the same holds for (3) and (4), respectively. However, canonically, the PSA is in sentence-final position (as in sentences (1) and (3)). Third, the Tagalog voice system is a socalled "symmetrical voice system" (Foley, 2008): sentences in which the undergoer is selected as PSA and sentences with an actor PSA are equally transitive. This contrasts with languages with asymmetrical voice systems such as English in which valency-changing operations, such as passivization which detranstivizes the verb, are required to allow the patient/undergoer argument to be the PSA (syntactic subject in English). Detransitivization is the key part of the asymmetrical voice system in contrast to Tagalog. Thus, all Tagalog sentences analyzed in this paper are transitive (exhibiting one PSA and one NPSA phrase), regardless of the semantic role of the PSA.

## How Do Speakers Plan Sentences in Tagalog?

The sentence-initial position of the predicate in a Tagalog sentence means that speakers must encode enough information about the relationship between the two discourse entities ("boy" and "ball") to select a suitable predicate ("kick") very early in the formulation process. The predicate's agreement in semantic role with the PSA also means that very early in the formulation process one discourse entity from the preverbal message has to be selected to be the PSA and linked to that syntactic function so that appropriate voice marking for the predicate can be selected. Importantly, speakers can produce the PSA immediately after the predicate (as in sentences (2) and (4)) or may delay its production until the end of the sentence (as in sentences (1) and (3)).

To what extent do speakers then have to encode the PSA at the outset of formulation in sentences like (1-4)? We tested whether the processing of the overt dependency between the predicate and the PSA is temporally separate from lexical encoding of the character selected to be the PSA by comparing the time course of formulation for sentences differing in voice and word order.

Native speakers of Tagalog performed a picture description experiment similar to Griffin and Bock (2000) while their eye movements and speech were recorded. The pictures showed events with one actor and one undergoer (Figure 1). We compared the distribution of fixations to the actor and the undergoer in these pictures for different sentence

[^204]

Figure 1: example target stimulus picture (eliciting the example sentences (1-4))
types. First, we compared sentences differing in voice marking and word order, i.e., the actor voice sentence type in (1) and the undergoer voice sentence type in (3), to investigate whether the semantic role of the PSA has an early influence on sentence planning. Second, comparisons between sentences with different voice marking but the same word order (such as in (2) vs. (3)) and sentences with the same voice marking but different word order (such as in (1) vs. (2)) were carried out to investigate whether a possible PSA effect on planning is solely due to the planning of the dependency between the predicate and the PSA (i.e., voice marking) or whether it is also influenced by word order.

## Experiment

## Method

Participants 53 native speakers of Tagalog ( 13 male; mean age $=17.5$ years; range $=15-28$ years) were recruited at De La Salle University in Manila and participated for payment. All participants reported that they spoke Tagalog a total of at least five hours a day and to at least one of their parents.

Materials and Design Target pictures were 44 cartoon drawings of transitive events (see Figure 1). They were interspersed among 76 filler pictures of intransitive events, with at least one filler separating any two target pictures. Two versions of each target picture were created by mirrorreversing the picture. Pictures were then arranged in four lists created by randomizing the order of the target and filler pictures and counterbalancing the two mirror-reversed versions of each target picture.

Equipment The experiment was run with a Tobii T120 eye tracker ( 120 Hz sampling frequency) on a Panasonic CF-F9 computer. Participants' responses were recorded with a microphone.

Procedure Each experimental session lasted approx. 40 minutes. Participants first read instructions for the experiment in Tagalog and completed a questionnaire about their linguistic background. The experimenter (a native speaker of Tagalog) then explained the procedure and repeated the
instructions: participants were asked to describe the events shown in the pictures with one sentence that named all event participants as accurately and as quickly as possible.

Stimuli were presented in two blocks, each block lasting approx. 10-15 minutes. Calibration was performed before each block. The experiment began with a practice phase in which participants saw 11 pictures presented one at a time and heard a recorded description of each depicted event; these example sentences had predicate-initial word order and were mostly PSA-final. After presentation of the example descriptions, participants saw the same pictures again and were asked to describe them themselves. The experimenter provided feedback after each training picture if participants produced non-predicate-initial structures (e.g., existential constructions) or started speaking very late after picture onset.

In the experimental phase, each picture trial was preceded by a display showing a fixation dot at the top of the screen. Participants were asked to look at the fixation dot and the experimenter initiated the trial with a mouse click. Participants completed the experiment without further instructions from the experimenter; however, the experimenter monitored the entire experimental session and repeated the instructions if participants started consistently using non-predicate-initial structures or dropping arguments.

## Results

Picture descriptions Speakers produced 384 sentences with actor voice marking and predicate ${ }_{\mathrm{AV}}$-undergoer $\mathrm{NPSA}^{-}-$actor $_{\mathrm{PSA}}$ word order (as in sentence (1)), 67 sentences with actor voice marking and predicate ${ }_{\mathrm{AV}}$-actor $_{\mathrm{PSA}}-$ undergoer $_{\mathrm{NPSA}}$ word order (as in sentence (2)), 787 sentences with undergoer voice marking and predicate ${ }_{\mathrm{UV}}$-actor NPSA -undergoer ${ }_{\mathrm{PSA}}$ word order (as in sentence (3)), and 26 sentences with undergoer voice marking and predicate ${ }_{\mathrm{UV}}$-undergoer $\mathrm{PSA}_{\mathrm{PA}}-$ actor $_{\mathrm{NPSA}}$ word order (as in sentence (4)). Analyses were limited to the first three sentence types.

First Fixations The majority of first fixations ${ }^{7}$ (58.3\%) across all trials fell on the actor in the event. Contrary to earlier work on English (e.g., Gleitman et al., 2007), first fixations did not predict choice of voice or word order (both $z$ 's $<1.4$, n.s.).

Time Course of Fixations Consecutive fixations to each character were aggregated into "runs" of fixations directed to those characters. The distributions of fixations directed to the actor and to the undergoer were then compared across the three most frequent sentence types in this dataset (i.e., the sentence types in (1-3)) with quasi-logistic regressions (Barr, 2008, for details about random effects). We selected three time windows for analysis $(0-600 \mathrm{~ms}, 600-1600 \mathrm{~ms}$, and $1600-2600 \mathrm{~ms}$ after picture onset). Selection of time windows was based on three theoretically important distinc-

[^205]

Figure 2: graphs showing fixation proportions to actor and undergoer characters over time for three sentence types
tions and to facilitate comparisons across the three sentence types, as explained below.

In all three sentence types included in the analysis (Figure 2), speakers directed more fixations to the character selected to be PSA than to the NPSA character in an early time window ( $0-600 \mathrm{~ms}$ ). The $0-400 \mathrm{~ms}$ time window is argued to correspond to a period of event apprehension (Griffin \& Bock, 2000), and here we extended this window to 600 ms based on the distribution of fixations in all three sentence types in Figure 2. Fixations to the two characters in this time window were aggregated into 50 ms time bins. Griffin and Bock (2000) propose that after the initial period of event apprehension, speakers begin fixating the two characters in the order of mention in order to retrieve their names; indeed, the distribution of fixations after 600 ms in this dataset largely shows that speakers fixated characters in the order of mention. Thus between 600 ms and speech onset (approx. 1600 ms after picture onset), speakers preferentially fixated the character that was mentioned immediately after the predicate (independently of syntactic function - i.e., whether it was the PSA or the NPSA - or semantic role). After speech onset, speakers then began shifting their gaze to the second character, and we compared the distribution of fixations to the two characters up to 1 second after speech onset (i.e., between 1600 and 2600 ms ). Fixations were aggregat-
ed into 200 ms time bins for the analysis of the $600-1600$ ms and $1600-2600 \mathrm{~ms}$ time windows.

Three analyses were performed to compare the distribution of actor-directed fixations in sentences differing in voice and word order in more detail. All analyses included time bin and sentence type as predictors. All models included random slopes for the two predictors. In the text, we report only the interactions between these factors from the byparticipant analyses using the full random structure. ${ }^{8}$ Effects were considered to be reliable at $p<0.05$ (most effects were also reliable according to the more conservative pMCMC estimates calculated for models without random slopes; in cases of discrepancy between $p$ values calculated for models with random slopes and pMCMC values calculated for models without random slopes, we used the more conservative criterion to indicate significance and provide the corresponding pMCMC value). ${ }^{9}$

[^206]First, to test whether differences in voice marking and word order predict differences in early encoding of the PSA and NPSA characters, we compared actor voice sentences with predicate ${ }_{A V}$-undergoer ${ }_{\text {NPSA }}-$ actor $_{\text {PSA }}$ word order (example (1), Figure 2a) and undergoer voice sentences with predicate ${ }_{\mathrm{UV}}-$ actor $_{\mathrm{NPSA}}-$ undergoer ${ }_{\text {PSA }}$ word order (example (3), Figure 2c). Between 0 and 600 ms , speakers fixated the actor character more often and more quickly when it was selected to be the PSA (i.e., in the actor voice sentences with predicate ${ }_{\mathrm{AV}}$-undergoer $\mathrm{NPSA}^{-}$actor $_{\text {PSA }}$ word order, Figure 2a) than when it was not (Figure 2c; sentence type $\times$ time bin: $\beta=-0.92, t=-7.16$ ). After 600 ms , speakers fixated the characters in the order of mention. Between 600 and 1600 ms they fixated the actor character more often when the actor argument phrase immediately followed the predicate, i.e., in the undergoer voice sentences with predicate $\mathrm{UV}^{- \text {actor }_{\mathrm{NPSA}^{-}}}$ undergoer ${ }_{\text {PSA }}$ word order (Figure 2c), then when it was sen-tence-final (Figure 2a; sentence type $\times$ time bin: $\beta=1.14$, $t=49.48$ ). They shifted their gaze to the second character between 1600 and 2600 ms , and thus fixated the actor character less often when the actor argument phrase was not sentence-final (Figure 2a; sentence type $\times$ time bin: $\beta=-1.70$, $t=-73.93$ ). These results suggest early encoding of the PSA character only for the purposes of selecting the appropriate agreement marking on the predicate; lexical encoding of the PSA character occurred either before or after encoding of the NPSA character, according to word order.

Second, we tested whether differences in voice marking alone can influence the time course of formulation by comparing sentences with the same word order, i.e., actor voice sentences with predicate ${ }_{\mathrm{AV}}$-actor $\mathrm{PSA}_{\mathrm{PA}}$-undergoer ${ }_{\mathrm{NPSA}}$ word order (example (2), Figure 2b) and undergoer voice sentences with predicate ${ }_{\mathrm{UV}}$-actor ${ }_{\mathrm{NPSA}}$-undergoer $\mathrm{r}_{\mathrm{PSA}}$ word order (example (3), Figure 2c). Speakers fixated the actor character more often and more quickly between 0 and 600 ms when it was selected to be the PSA (Figure 2b) than when it was not selected to be the PSA, i.e., in the undergoer voice sentences (Figure 2c; sentence type $\times$ time bin: $\beta=-1.76, t=-7.46$ ). However, there were no differences between the actor voice and the undergoer voice sentences in the overall likelihood of speakers to fixate the actor character or direct fixations to it over time between 600 and 1600 ms (sentence type: $\beta=0.13, t=4.40, \mathrm{pMCMC}=0.65$; sentence type $\times$ time bin: $\beta=-0.03, t=-0.56, \mathrm{pMCMC}=0.93)$ and between 1600 and 2600 ms after picture onset (sentence type: $\beta=-0.06, t=-1.64$, $\mathrm{pMCMC}=0.84$; sentence type $\times$ time bin: $\beta=-0.18, t=-3.09$, $\mathrm{pMCMC}=0.70$ ) because speakers produced the actor character first and the undergoer character second in both sentence types. This confirms that differences in the time course of early sentence formulation reflect encoding of features of the PSA character relevant only for agreement marking.

Finally, we compared actor voice sentences with predica-$\mathrm{te}_{\mathrm{AV}}$-undergoer ${ }_{\text {NPSA }}$-actor ${ }_{\text {PSA }}$ word order (example (1), Figure 2 a ) and actor voice sentences with predicate $\mathrm{AV}^{- \text {-actor }_{\mathrm{PSA}^{-}}}$ undergoer $_{\text {NPSA }}$ word order (example (2), Figure 2b) to test whether word order influences fixations to picture characters when voice marking is kept constant. Comparing fixa-
tions to the actor character between 0 and 600 ms showed no reliable differences between the actor voice sentences with predicate ${ }_{\mathrm{AV}}$-undergoer $\mathrm{NPSA}^{-}$actor $_{\text {PSA }}$ word order (Figure $2 a)$ and the actor voice sentences with predicate $\mathrm{AV}^{- \text {actor }_{\mathrm{PSA}^{-}}}$ undergoer $_{\text {NPSA }}$ word order (Figure 2b) in this time window (sentence type: $\beta=-0.36, t=-3.15, \mathrm{pMCMC}=0.23$; sentence type $\times$ time bin: $\beta=0.88, t=3.00, \mathrm{pMCMC}=0.16)$. The distribution of fixations to the actor and undergoer characters did, however, differ after 600 ms because the linear order of these characters in the two sentence types was different. Thus in the 600 and 1600 ms time window, speakers fixated the actor character more often if the actor argument phrase immediately followed the predicate (predicate $\mathrm{AV}^{- \text {actor }_{\mathrm{PSA}^{-}}}$ undergoer ${ }_{\text {NPSA }}$ word order) then if it was sentence-final (sentence type $\times$ time bin: $\beta=1.13, t=15.79$ ), whereas speakers fixated the actor character less often between 1600 and 2600 ms if the actor argument phrase directly followed the predicate than if it was sentence-final (sentence type $\times$ time bin: $\beta=-1.75, t=-18.39)$.

Speech onsets Speech onsets are shown in Figure 2 for each sentence type. Onsets were somewhat shorter in actor voice sentences with predicate ${ }_{\mathrm{AV}}$-undergoer ${ }_{\mathrm{NPSA}}$-actor ${ }_{\mathrm{PSA}}$ word order than in actor voice sentences with predicate ${ }_{A V}$ actor $_{\text {PSA }}$-undergoer ${ }_{\text {NPSA }}$ word order and undergoer voice sentences with predicate ${ }_{\mathrm{UV}}$-actor ${ }_{\mathrm{NPSA}}$-undergoer ${ }_{\text {PSA }}$ word order (word order $\times$ voice: $\beta=-0.19, \quad t=-1.99$, $\mathrm{pMCMC}=0.052$ ). More importantly, we note a difference from results obtained with English speakers (Griffin \& Bock, 2000): here, speech onsets occurred while speakers were still fixating the character that was mentioned first, suggesting that they had only fully encoded the predicate before initiating production, whereas English speakers begin their sentences only after encoding the first character. The sentence-initial position of the predicate may have allowed speakers to begin their sentences before completing the encoding of the first-mentioned character.

## Discussion and Conclusion

We interpret the results of this experiment as evidence for linguistic guidance in the earliest stages of sentence production in Tagalog and for a temporal dissociation of the mapping of message-level concepts to syntactic functions and the lexical encoding of these concepts.

Linguistic guidance in early sentence production is suggested by differences in fixation patterns in the $0-600 \mathrm{~ms}$ time window across the three sentence types we analyze here: a depicted character was fixated more often if it was to become the sentence's PSA than when it was not. Specifically, speakers fixated the actor character more often than the undergoer character before 600 ms if the actor character was selected as the PSA, regardless of the position of the actor argument in the sentence (i.e., this pattern held for both, actor $_{\text {PSA }}-m e d i a l$ or actor ${ }_{P S A}-$ final word orders). In contrast, there was no difference in early fixations directed to the actor character in actor voice sentences with different word orders (i.e., in actor ${ }_{\mathrm{PSA}}-$ medial or actor $_{\mathrm{PSA}}$-final sentences).

In other words, the results suggest that differences in voice marking (signaling differing semantic roles of the PSAs) but not differences in word order have an effect on fixation patterns in the earliest stage of sentence planning.

Early fixations of the PSA character suggest that the PSA effect is a reflex of linking message-level concepts of discourse entities to prominent syntactic functions. Speakers select a participant of the depicted event to be the PSA and encode its semantic role in order to produce an appropriate voice affix at the predicate. We propose that this process happens very early during formulation as speakers begin encoding information about the relationship between the two characters in the event.

Comparisons of the fixation patterns in the two later time windows ( $600-1600 \mathrm{~ms}$ and $1600-2600 \mathrm{~ms}$ ) suggest that the PSA effect, i.e., the linking of a discourse entity concept to a prominent syntactic function, and the lexical encoding of the PSA are temporally dissociated. Whereas speakers are more likely to fixate the character selected to be the PSA before 600 ms , fixations to the two characters after 600 ms are contingent on word order. In the $600-1600 \mathrm{~ms}$ time window, the character that is to be mentioned immediately after the predicate is fixated more often by speakers than the character that is to be mentioned sentence-finally. Specifically, in actor voice sentences with predicate $\mathrm{AV}^{-}$ undergoer ${ }_{\text {NPSA }}$-actor $_{\text {PSA }}$ word order, speakers shift their gaze from the actor character (the PSA) to the undergoer character (the NPSA) after 600 ms , and similarly, in undergoer voice sentences with predicate ${ }_{\mathrm{UV}}-$ actor $_{\mathrm{NPSA}}$-undergoer ${ }_{\mathrm{PSA}}$ word order, the speakers' gaze shifts from the undergoer character (the PSA) to the actor character (the NPSA) after 600 ms . Finally, in actor voice sentences with predicate $\mathrm{AV}^{-}$ actor $_{\text {PSA }}$-undergoer ${ }_{\text {NPSA }}$ word order speakers continue looking at the actor character (the PSA) because it is to be mentioned directly after the predicate. In the $1600-2600 \mathrm{~ms}$ window, speakers then fixate the character to be mentioned sentence-finally more often than the other character (i.e., the actor character in the first mentioned sentence type and the undergoer character in the two latter types). We interpret this as incremental encoding of the two character names in the order of mention that is distinct from the early phase of linking concepts to syntactic functions ( $0-600 \mathrm{~ms}$ ).

The results suggest that there are two observable phases in the sentence production process in Tagalog: an early phase of sentence planning that includes the planning of the dependency relation between the predicate and the PSA (i.e., the voice marking), which is neither influenced by the actual semantic role of the PSA nor the word order of the to-be-uttered sentence, and a later phase that involves the incremental lexical encoding of the two arguments of the predicate.

Importantly, these analyses of the time course of sentence formulation in Tagalog provide insight into a process that is not easily observable in a language like English, namely the linking of conceptual discourse entities to prominent syntactic functions. The rigid subject-initial word order of English prevents dissociating the linking of concepts to syntactic
functions from planning and encoding of the subject argument; thus our results on Tagalog highlight the need for controlled studies on typologically diverse languages that allow dissociations between different processes at the interface of thinking and speaking.

Ultimately, more fine-grained models of early message and sentence formulation are needed to address the relationship between formulation of a preverbal message and the mapping of this message onto language, and it is important for the development of such models to consider languages with grammatical properties that support investigations of these phenomena (Jaeger \& Norcliffe, 2009).

#### Abstract

Psychological experiments have revealed remarkable regularities in the developmental time course of cognition. Infants generally acquire broad categorical distinctions (i.e., plant/animal) before finer ones (i.e., bird/fish), and periods of little change are often punctuated by stage-like transitions. This pattern of progressive differentiation has also been seen in neural network models as they learn from exposure to training data. Our work explains why the networks exhibit these phenomena. We find solutions to the dynamics of error-correcting learning in linear three layer neural networks. These solutions link the statistics of the training set and the dynamics of learning in the network, and characterize formally how learning leads to the emergence of structured representations for arbitrary training environments. We then consider training a neural network on data generated by a hierarchically structured probabilistic generative process. Our results reveal that, for a broad class of such structures, the learning dynamics must exhibit progressive, coarse-to-fine differentiation with stage-like transitions punctuating longer dormant periods.

Keywords: neural networks; hierarchical generative models; semantic cognition; learning dynamics

## Introduction

Our world is characterized by a rich, nested hierarchical structure of categories within categories, and one of the most remarkable aspects of human semantic development is our ability to learn and exploit this structure. Experimental work has shown that infants and children acquire broad categorical distinctions before fine categorical distinctions (Keil, 1979; Mandler \& McDonough, 1993), suggesting that human category learning is marked by a progressive differentiation of concepts from broad to fine. Furthermore, humans can exhibit stage-like transitions as they learn, rapidly progressing through successive levels of mastery (Inhelder \& Piaget, 1958; Siegler, 1976).

Many neural network simulations have captured aspects of these broad patterns of semantic development (Rogers \& McClelland, 2004; Rumelhart \& Todd, 1993; McClelland, 1995; Plunkett \& Sinha, 1992; Quinn \& Johnson, 1997). The internal representations of such networks exhibit both progressive differentiation and stage-like transitions. However, the theoretical basis for the ability of neuronal networks to exhibit such strikingly rich nonlinear behavior remains elusive. What are the essential principles that underly such behavior? What aspects of statistical structure in the input are responsible for driving such dynamics? For example, must networks exploit nonlinearities in their input-output map to detect higher order statistical regularities to drive such learning?

Figure 1: The three layer network analyzed in this work.
Here we analyze the learning dynamics of a linear three layer network and find, surprisingly, that it can exhibit highly nonlinear learning dynamics, including rapid stage-like transitions. Furthermore, when exposed to hierarchically structured data sampled from a hierarchical probabilistic model, the network exhibits progressive differentiation of concepts from broad to fine. Since such linear networks are sensitive only to the second order statistics of inputs and outputs, this yields the intriguing result that merely second order patterns of covariation in hierarchically structured data contain statistical signals powerful enough to drive certain nontrivial, high level aspects of semantic development in deep networks.

We outline our approach here in brief. We begin by decomposing the training set to identify important dimensions of variation using the singular value decomposition (SVD), which will turn out to be fundamental to our analysis. Next, we examine the equations governing gradient descent learning and show that they can be solved in terms of the SVD of the training set. This solution analytically expresses the weight values of the neural network at any point in time during learning as a function of the input training set. Finally, we consider generating the training set from a hierarchical probabilistic generative model. We analytically calculate the SVD of training sets so generated, which in combination with our previous results gives a formal grounding for how neural networks will learn about hierarchical categorical structure. We show that networks must exhibit progressive differentiation of categorical structure and stage-like transitions for any training set generated by a class of hierarchical generative models.

## Decomposing the training set

Our fundamental goal is to understand the dynamics of learning in neural networks as a function of the training set. Toward this goal, in this section we introduce the singular
value decomposition, which identifies important dimensions of variation in the training set. The SVD will turn out to be fundamentally linked to learning dynamics, a connection we develop in the next section. We wish to train a neural network to learn a particular input-output map from a set of $P$ training examples $\left\{x^{\mu}, y^{\mu}\right\}, \mu=1, \ldots, P$. These $P$ pairs of vectors constitute the training set. In the model of semantic development introduced by Rumelhart and Todd (1993), for instance, elements of $x^{\mu}$ correspond to input units representing items such as Canary or Rose. The elements of $y^{\mu}$ correspond to output units representing possible predicates or attributes such as can Fly or has Petals that may or may not apply to each item. Hence each example links a particular item to a set of properties, and the training set contains the semantic content in the world to be learned by the network.

For concreteness, we consider a simple example dataset with four items (Canary, Salmon, Oak, and Rose) and five properties. The two animals share the property that they can Move, while the two plants cannot. In addition each item has a unique property: can Fly, can Swim, has Bark, and has Petals, respectively. In a more natural data set, the plantanimal, bird-fish, and tree-flower distinctions are based on clusters of covarying properties, for which the single properties identified here serve as proxies.

An important function of the training set is the input-output correlation matrix

$$
\begin{equation*}
\Sigma^{31} \equiv \sum_{\mu=1}^{P} y^{\mu} x^{\mu} \equiv E\left[y x^{T}\right] \tag{1}
\end{equation*}
$$

For our example dataset, this matrix is shown in Fig. 2. Each column corresponds to an item, and denotes the properties possessed by that particular item.

Our example dataset contains important shared structure. The Canary and Salmon, for instance, both can Move, and hence may naturally be grouped together. Intuitively, they are both animals, and as a consequence have certain properties in common that are typical of animals. How can we identify these coherently covarying groups of items and their properties? We will show that the singular value decomposition of the input-output correlation matrix accomplishes exactly this.

The singular value decomposition (SVD)

$$
\begin{equation*}
\Sigma^{31}=U^{33} S^{31} V^{11^{T}}=\sum_{\alpha=1}^{N_{1}} s_{\alpha} u^{\alpha} v^{\alpha T} \tag{2}
\end{equation*}
$$

decomposes any matrix into the product of three matrices. Each of these matrices has an important real world interpretation. We call the $N_{1} \times N_{1}$ orthogonal matrix $V^{11}$ the object analyzer-it determines the position of a particular item along a number of important dimensions of the training set. The first row of $V^{11^{T}}$, for instance, determines where items sit on an animal-plant dimension, and hence has positive values for the Canary and Salmon and negative values for the plants. In our example dataset, the three dimensions identified by the SVD are animal-plant, bird-fish, and flower-tree.

Figure 2: First three modes of the singular value decomposition of a toy dataset. Left: The learning environment is specified by an input-output correlation matrix. Right: The SVD decomposes $\Sigma^{31}$ into modes that link a set of coherently covarying items (object analyzer vectors in the rows of $V^{T}$ ) to a set of coherently covarying properties (feature synthesizer vectors in the columns of $U$ ). The overall strength of this link is given by the singular values lying along the diagonal of $S$. In this toy example, mode 1 distinguishes plants from animals; mode 2 birds from fish; and mode 3 flowers from trees.

The $N_{3} \times N_{3}$ orthogonal matrix $U^{33}$ can be interpreted as a feature synthesizer-it contains those features typical of a particular dimension in each column. Hence the feature synthesizer associated with the animal-plant dimension has positive values for can Move, since animals typically can move while plants cannot.

Finally the $N_{3} \times N_{1}$ association strength matrix $S^{31}$ captures the overall strength of the association between an input dimension and output dimension. It is nonzero only on the diagonal; these elements are the singular values $s_{\alpha}, \alpha=$ $1, \ldots, N_{1}$ ordered so that $s_{1} \geq s_{2} \geq \cdots \geq s_{N_{1}}$. The large association strength for the animal-plant dimension reflects the fact that this one dimension explains more of the training set than the finer-scale dimensions like bird-fish and flower-tree.

In a larger training set, the SVD will extract modes that capture patterns of coherent covariation in the properties of items in the training set. The quantities defining each mode, $\left\{s_{\alpha}, u^{\alpha}, v^{\alpha}\right\}$, are connected to the learning dynamics of neural networks in the next section.

## Gradient descent dynamics in multilayer neural networks

We examine learning in a three layer network (input layer 1 , hidden layer 2, and output layer 3) with linear activation functions, simplifying the network model of Rumelhart and Todd (1993). Let $N_{i}$ be the number of neurons in layer $i, W^{21}$ be an $N_{2} \times N_{1}$ matrix of synaptic connections from layer 1 to 2 , and similarly, $W^{32}$ an $N_{3} \times N_{2}$ matrix of connections from layer 2 to 3 . The input-output map of the network is $y=W^{32} W^{21} x$, where $x$ is an $N_{1}$ dimensional column vector representing inputs to the network, and $y$ is an $N_{2}$ dimensional column vector representing the network output (see Fig. 1).

Training is accomplished in an online fashion via stochas-
tic gradient descent; each time an example $\mu$ is presented, the weights $W^{32}$ and $W^{21}$ are adjusted by a small amount in the direction that minimizes the squared error $\left\|y^{\mu}-W^{32} W^{21} x^{\mu}\right\|^{2}$ between the desired feature output, and the network's feature output. This gradient descent procedure yields the standard back propagation learning rule

$$
\begin{align*}
\Delta W^{21} & =\lambda W^{32^{T}}\left(y^{\mu}-\hat{y}^{\mu}\right) x^{\mu T}  \tag{3}\\
\Delta W^{32} & =\lambda\left(y^{\mu}-\hat{y}^{\mu}\right) h^{\mu T} \tag{4}
\end{align*}
$$

for each example $\mu$, where $\hat{y}^{\mu}=W^{32} W^{21} x^{\mu}$ denotes the output of the network in response to input example $x^{\mu}, h^{\mu}=W^{21} x^{\mu}$ is the hidden unit activity, and $\lambda$ is a small learning rate. Here $W^{32^{T}}\left(y^{\mu}-\hat{y}^{\mu}\right)$ in (3) corresponds to the signal backpropagated to the hidden units through the hidden-to-output weights. These equations emphasize that the learning process works by comparing the network's current output $\hat{y}^{\mu}$ to the desired target output $y^{\mu}$, and adjusting weights based on this error term.

By a substitution and rearrangement, however, we can equivalently write these equations as

$$
\begin{align*}
\Delta W^{21} & =\lambda W^{32^{T}}\left(y^{\mu} x^{\mu T}-W^{32} W^{21} x^{\mu} x^{\mu T}\right)  \tag{5}\\
\Delta W^{32} & =\lambda\left(y^{\mu} x^{\mu T}-W^{32} W^{21} x^{\mu} x^{\mu T}\right) W^{21^{T}} \tag{6}
\end{align*}
$$

This form emphasizes two crucial aspects of the learning dynamics. First, it highlights the importance of the statistics of the training set. In particular, the training set enters only through two terms, one related to the input-output correlations $y^{\mu} x^{\mu T}$ and the other related to the input correlations $x^{\mu} x^{\mu T}$. Indeed, if $\lambda$ is sufficiently small so that weights change only a small amount per epoch, we can rewrite these equations in a batch update form by averaging over the training set to obtain the mean change in weights per learning epoch,

$$
\begin{align*}
\tau \frac{d}{d t} W^{21} & =W^{32^{T}}\left(\Sigma^{31}-W^{32} W^{21} \Sigma^{11}\right)  \tag{7}\\
\tau \frac{d}{d t} W^{32} & =\left(\Sigma^{31}-W^{32} W^{21} \Sigma^{11}\right) W^{21^{T}} \tag{8}
\end{align*}
$$

where $\Sigma^{11} \equiv \sum_{\mu=1} x^{\mu} x^{\mu T} \equiv E\left[x x^{T}\right]$ is an $N_{1} \times N_{1}$ input correlation matrix, $\Sigma^{31}$ is the $N_{3} \times N_{1}$ input-output correlation matrix defined previously, and $\tau \equiv \frac{P}{\lambda}$. Hence we see that linear networks are sensitive only to the second order statistics of inputs and outputs. In general the learning process is driven by both the input and input-output correlation matrices. Here we take the simplifying assumption that these input correlations are insignificant; formally, we assume $\Sigma^{11}=I$, the identity matrix. Concretely, this assumption corresponds to the supposition that input representations for different items are highly differentiated from, or orthogonal to each other. While this is unlikely to hold exactly in any natural domain, we take this assumption for two reasons. First, it was used in prior simulation studies (Rogers \& McClelland, 2004), and hence our attempt to understand their results is not limited by this assumption. Second, Rogers and McClelland (2004)
have shown that relaxing this assumption to incorporate more complex input correlations leaves intact the basic phenomena of progressive differentiation and stage-like transitions in learning. Nevertheless, understanding the impact of input correlations is an important direction for further work.

Second, the form of Eqns. (7)-(8) highlights the coupling between the two equations: to know how to change $W^{21}$ we must know $W^{32}$, and visa versa, since each appears in the update equation for the other. This coupling is the crucial element added by the addition of a hidden layer, and as we shall see, it qualitatively changes the learning dynamics of the network compared to a "shallow" network with no hidden layer. Intuitively, this coupling complicates the learning procedure since both weight matrices must cooperate to produce the correct answer; but crucially, it enables knowledge sharing between different items, by assigning them similar hidden unit representations. Without this coupling, the network would learn each item-property association independently, and would not be sensitive to shared structure in the training set.

The temporal dynamics of learning To understand the connection between learning dynamics and training set statistics, then, we can solve Eqns. (7)-(8). We have found a class of exact solutions (whose derivation will be presented elsewhere) that describe the weights of the network over time during learning, as a function of the training set. In particular, the composite mapping at any time $t$ is given by

$$
\begin{equation*}
W^{32}(t) W^{21}(t)=\sum_{\alpha=1}^{N_{2}} a\left(t, s_{\alpha}, a_{\alpha}^{0}\right) u^{\alpha} v^{\alpha T} \tag{9}
\end{equation*}
$$

where the function $a\left(t, s, a^{0}\right)$ governing the strength of each input-output mode is given by

$$
\begin{equation*}
a\left(t, s, a_{0}\right)=\frac{s e^{2 s t / \tau}}{e^{2 s t / \tau}-1+s / a_{0}} \tag{10}
\end{equation*}
$$

That is, the network learns about the $N_{2}$ strongest inputoutput modes identified by the singular value decomposition, progressively incorporating each mode into its representation. The coefficient $a\left(t, s^{\alpha}, a_{0}\right)$ describes how strongly input-output mode $\alpha$ has been learned by time $t$, starting from some small initial value of $a_{0}$. As can be seen from Fig. 3, this function is a sigmoidal curve, capturing the fact that the network initially knows nothing about a particular dimension (the animal-plant dimension, say), but over time learns the importance of this dimension and incorporates it into its representation, ultimately reaching the correct association strength $s^{\alpha}$. At this point the network correctly maps items onto the animal-plant dimension using the object analyzer vector $v^{\alpha T}$, and generates the corresponding correct features using the feature synthesizer vector $u^{\alpha}$.

Eqns. (9)-(10) describe the fundamental connection between the structure of a training set and learning dynamics. In particular, the dynamics depends on the singular value decomposition of the input-output correlation matrix of the

Figure 3: Close agreement between theoretically predicted time course and numerical simulations. Simulations were performed with a dataset sampled from the hierarchical diffusion process described in detail in a later section, with $D=3$ hierarchical levels, binary branching, flip probability $\varepsilon=0.1$, and $N=10,000$ sampled features. This data set had 3 unique singular values. Red traces show ten simulations of the singular value dynamics of $W^{32}(t) W^{21}(t)$ in Eqns. (7)-(8) starting from different random initializations, and blue traces show theoretical curves obtained from (10).
training set. Further, they reveal important properties of these learning dynamics.

First, each input-output mode is learned on a different time scale, governed by its singular value $s_{\alpha}$. To calculate this time scale, we can assume a small initial condition $a_{0}=\varepsilon$ and ask when $a(t)$ in (10) rises to within $\varepsilon$ of the final value $s_{\alpha}$, i.e. $a(t)=s_{\alpha}-\varepsilon$; then the timescale of learning in the limit $\varepsilon \rightarrow 0$ is

$$
\begin{equation*}
t(s, \varepsilon)=\frac{\tau}{s_{\alpha}} \ln \frac{s_{\alpha}}{\varepsilon} \tag{11}
\end{equation*}
$$

Hence up to a logarithmic factor, the time required to learn an input-output mode is inversely related to its association strength, quantified through its singular value.

Second, these dynamics reveal stage-like transitions in learning performance. Intuitively, this property arises from the sigmoidal transition in (10) from a state in which the network does not represent a particular input-output relation at all, to a state in which the network fully incorporates that relation. Because of the sigmoidal shape, the solution can remain very small for a long period of time before rapidly transitioning to mastery. To formalize this, we note that the time it takes to reach half mastery (i.e. $a\left(t_{\text {half }}\right)=s / 2$ ) is

$$
\begin{equation*}
t_{\text {half }}=\frac{\tau}{2 s} \log \left(\frac{s}{a_{0}}-1\right) \tag{12}
\end{equation*}
$$

In contrast, the duration of the transition period in which the weights change rapidly is $t_{\text {trans }}=\frac{2 \tau}{s}$ (using a linear approximation). Thus, by starting with a very small initial condition for the weights (i.e. $a_{0} \approx 0$ ), it is clear that one can make the ratio $t_{\text {trans }} / t_{\text {half }}$ arbitrarily small, i.e., the transition period can be very brief relative to the long initial period of dormancy. Hence the learning dynamics of (7)-(8) exhibit
sharp stage-like transitions. Importantly, we can prove that networks with only direct input-output connections and no hidden layer are not capable of such stage-like transitions. Their existence is an emergent property of nonlinear learning dynamics in deep networks with at least one hidden layer.

The result in (9) is the solution to (7)-(8) for a special class of initial conditions on the weights $W^{21}$ and $W^{32}$. However this analytic solution is a good approximation to the time evolution the network's input-output map for random small initial conditions, as confirmed in Fig. 3.

Summary of learning dynamics The preceding analyses have established a number of crucial features of gradient descent learning in a simple linear network, making explicit the relationship between the statistical structure of training examples and the dynamics of learning. In particular, the learning dynamics depend crucially on the singular values of the inputoutput correlation matrix. Each input-output mode is learned in time inversely proportional to its associated singular value, yielding the intuitive result that stronger input-output associations are learned before weaker ones.

## The singular values and vectors of hierarchically generated data

In this section we introduce a hierarchical probabilistic generative model of items and their attributes that, when sampled, produces a dataset that can be supplied to our neural network. By analytically calculating the SVD of this data, we will be able to explicitly link hierarchical taxonomies of categories to the dynamics of network learning. A key result in the following is that our network must exhibit progressive differentiation with respect to any of the underlying hierarchical taxonomies allowed by our generative model.
Hierarchical feature vectors from a branching diffusion process We propose a simple generative model of hierarchical data $\left\{x^{\mu}, y^{\mu}\right\}$, and compute for this model the inputoutput modes $\left(s_{\alpha}, u^{\alpha}, \nu^{\alpha}\right)$ which drive learning. The hierarchical structure in the generative model is represented by a tree (see e.g. Fig. 4). Each leaf node of this tree corresponds to an item in the dataset. Our generative process assigns features to these items such that items with more recent common ancestors are more likely to share features. For instance, our example dataset might have been generated by a three level binary tree with four leaf nodes. The top level would separate the animals from the plants, while the next level would separate the birds from the fish and the flowers from the plants.

In detail, to sample one feature's value across items, the root node is randomly set to $\pm 1$ with equal probability $\frac{1}{2}$; next this value diffuses to children nodes, where its sign is flipped with a small probability $\varepsilon$. This process continues until the leaf nodes have been assigned values. These assignments yield the value of this feature on each item.

Under this process, the can Move feature, for example, might have arisen as follows: randomly the root node of the three level binary tree was assigned a value of 1 . This value
diffused down to the two second level nodes, maybe in this instance changing sign to -1 for the parent node of the plants, but not changing for the parent node of the animals. Then these values diffused down to the leaf nodes representing the individual items, perhaps not flipping sign for any of them. Hence the ultimate feature assignment would be +1 on the Canary and Salmon and -1 on the Flower and Tree. This is just one possible sample from the generative model, but serves to illustrate how hierarchical structure arises from the feature generation process. To generate more features, the process is repeated independently $N$ times.

For simplicity, we consider trees with a regular branching structure. The tree has $D$ levels indexed by $l=0, \ldots, D-$ 1 , with $M_{l}$ total nodes at level $l$. Every node at level $l$ has exactly $B_{l}$ descendants. Thus $M_{l}=M_{0} \Pi_{k=0}^{l-1} B_{l}$. The tree has a single root node at the top $\left(M_{0}=1\right)$, and again $P$ leaves at the bottom, one per example in the dataset $\left(M_{D-1}=P\right)$.

We have thus far described the output feature vectors $y^{\mu}$. To complete the specification of the training set, we assume that the input vectors $x^{\mu}$ are simply chosen to be highly distinct (i.e., orthogonal). One such choice is a localist coding scheme in which a different element is active to represent the presence of each item.

Input-output modes of hierarchical data How will our neural network learn about training sets generated as just described? To understand this, we calculate the SVD of such training sets. We will see that the input-output modes identified by the SVD exactly mirror the tree structure used to generate the dataset. The feature generation process described in the previous section generates a training set with $N$ features. In the limit of large numbers of features, we obtain the following (the full derivation to be presented elsewhere):

The object analyzer vectors exactly mirror the tree structure, as shown in Fig. 4. One mode will correspond to a broad, high level distinction (e.g., animal-plant) near the root of the tree, while another will correspond to a more detailed distinction (e.g., bird-fish). For binary trees, each object analyzer vector will have positive weights on all items on one side of a binary distinction, and negative weights on all items on the other side. The rest of the entries will be zero. Hence this object analyzer vector will only be able to tell items apart with respect to this one distinction. It contains no information about higher or lower level distinctions in the tree. For trees with other branching factors, the situation is the same: additional object analyzer vectors are introduced to permit distinctions between more than two options, but these vectors contain no information about distinctions at other levels in the tree.

The association strength or singular value $s_{l}$ associated with level $l$ of the binary tree is

$$
\begin{equation*}
s_{l}=\sqrt{N P\left(\sum_{k=l}^{D-1} \frac{\Delta_{l}}{M_{l}}\right)} \tag{13}
\end{equation*}
$$

where $q_{k}=(1-4 \varepsilon(1-\varepsilon))^{D-1-k}$ and $\Delta_{l} \equiv q_{l}-q_{l-1}$, with the caveat that $q_{-1} \equiv 0$.

Figure 4: Statistical structure of hierarchical data. (a) Example hierarchical diffusion process with $D=4$ levels and branching factor $B=2$. (b) Analytically derived input singular vectors, or modes, (up to a scaling) of the resulting data, ordered top-to-bottom by singular value. Besides mode 0 , each mode, or object analyzer, can discriminate objects, or leaves of the tree, whose first common ancestor arises at a given level of the tree. This level is 0 for mode 2,1 for modes 3 and 4 , and 3 for modes 5 through 8 . Singular modes corresponding to broad distinctions (higher levels) have larger singular values, and hence will be learned earlier. (c) The covariance matrix between pairs of objects in the output feature space consists of hierarchically organized blocks.

While this equation gives the correct quantitative value for the association strength in terms of the parameters of the generative process, its most important property is its qualitative behavior: it is a decreasing function of the hierarchy level $l$ (see, e.g., Fig. 5). Crucially, this means that the input-output modes corresponding to broader distinctions like animal-plant have a stronger association strength than those corresponding to finer distinctions like bird-fish. Since we have previously shown that modes with stronger association strengths are learned more quickly, this immediately implies that broader distinctions among examples will be learned faster than fine-grained distinctions among examples.

Figure 5: Agreement between theoretically computed singular values in the limit of large numbers of features (obtained from (13)) and simulation for hierarchically structured data. The simulations show singular values arising from sampling 200 features from a hierarchical generative model with six levels, binary branching, and $\varepsilon=0.1$. The singular values are a decreasing function of the hierarchy level, implying that finer distinctions among examples will be learned more slowly.

Summary of the statistics of hierarchical data Thus we have shown that the singular vectors of data from a hierarchical diffusion process correspond exactly to the hierarchical distinctions in the underlying tree, and furthermore, that singular vectors corresponding to broader hierarchical distinctions have larger singular values than those corresponding to finer distinctions (Fig. 4AB). In combination with the preceding analysis of neural network learning dynamics, this result shows that our deep neural network must exhibit progressive differentiation on any dataset generated by an instance of this class of hierarchical, branching diffusion processes.

## Discussion

Our results explore the rich dynamics arising from gradient descent learning in a deep neural network, despite a completely linear input-output mapping. We have shown that these dynamics, driven solely by second order statistics, identify coherently covarying input and output modes in the learning environment, and we expressed the full time course of learning in terms of these modes. Finally, we moved beyond particular datasets to extract general principles by analyzing the covariance structure of hierarchical probabilistic models, showing that progressive differentiation is a general feature of learning hierarchically structured training data in deep neural networks.

We have focused our analysis on a few notable features of the learning dynamics-progressive differentiation and stagelike transitions-but our framework yields insights (to be presented elsewhere) into many other phenomena in semantic development such as, erroneous "illusory correlations" early in learning, familiarity and typicality effects, inductive property judgements, and the impact of perceptual correlations on learning dynamics. Moreover, this approach enables quantitative definitions of important intuitive notions like "category coherence", and yields precise theorems delineating how category coherence controls network learning rates.

By connecting probabilistic models and neural networks, our framework quantitatively links structured environments to learning dynamics. In future work, it will be important to compare the features of our neural network learning model with those of structured probabilistic learning models (e.g., Kemp and Tenenbaum (2008). Like structured models, neural networks can learn a range of different structure types, but unlike structured models, networks can learn without prior enumeration of such structures. Furthermore, networks can easily learn to represent data that are approximations or hybrids of different structure types-features that, we believe, characterize natural domains, such as the domain of living things considered here.

# Hierarchical Bayesian Modeling: Does it Improve Parameter Stability? 

Benjamin Scheibehenne (benjamin.scheibehenne@unibas.ch)<br>Economic Psychology, Department of Psychology, Missionsstrasse 62a 4055 Basel, Switzerland<br>Thorsten Pachur (pachur@mpib-berlin.mpg.de)<br>Center for Adaptive Rationality, Max Planck Institute for Human Development, Lentzeallee 94<br>14195 Berlin, Germany

#### Abstract

Fitting multi-parameter models to the behavior of individual participants is a popular approach in cognitive science to measuring individual differences. This approach assumes that the model parameters capture psychologically meaningful and stable characteristics of a person. If so, the estimated parameters should show, to some extent, stability across time. Recently, it has been proposed that hierarchical procedures might provide more reliable parameter estimates than nonhierarchical procedures. Here, we examine the benefits of hierarchical parameter estimation for assessing parameter stability using Bayesian techniques. Using the transfer-of-attention-exchange model (TAX; Birnbaum \& Chavez, 1997), a highly successful account of risky decision making, we compare parameter stability based on hierarchically versus non-hierarchically estimated parameters. Surprisingly, we find that parameter stability for TAX is not improved by using a hierarchical Bayesian as compared to a nonhierarchical Bayesian approach. Further analyses suggest that this is because the shrinkage induced by hierarchical estimation overcorrects for extreme yet reliable parameter values. We suggest that the benefits of hierarchical techniques may be limited to particular conditions, such as sparse data on the individual level or very homogenous samples.

Keywords: cognitive modeling; parameter consistency; risky choice; hierarchical Bayesian modeling; transfer-of-attentionexchange model

## Introduction

In cognitive science, a highly popular approach to describing and understanding behavior is to develop models with adjustable parameters that can be fitted to data. As parameters of cognitive models are usually supposed to represent meaningful aspects of cognitive processing, they are often used to study, measure, and describe individual differences between people. For illustration, consider cumulative prospect theory (CPT; Tversky \& Kahneman, 1992), one of the most prominent models of decision making under risk. According to CPT, responses to a risky alternative (which lead to different outcomes with particular probabilities) are a function of several factors including a person's sensitivity to probability information and her relative overweighting of losses as compared to gains ("loss aversion"). In the model, both probability sensitivity and loss aversion can be quantified by adjustable parameters, and several studies have employed CPT to investigate how
differences in age (Harbaugh, Krause, \& Vesterlund, 2002), gender (e.g., Fehr-Duda, Gennaro, \& Schubert, 2006), or personality (Pachur, Hanoch, \& Gummerum, 2010) affect risky decision making. Cognitive modeling thus allows individual differences in behavior to be decomposed into underlying cognitive components.

Using individually fitted model parameters to measure individual differences relies on the assumption of parameter stability-that is, that the parameter values estimated for a person remain relatively invariant across time (Yechiam \& Busemeyer, 2008). This applies in particular when modeling risky decision making, where it is often assumed that people's choices and their cognitive underpinnings reflect stable preferences (Yechiam \& Ert, 2011). In principle, however, it is possible that differences in parameter estimates between people simply reflect unsystematic variability (i.e., noise) rather than stable characteristics. In that case, fitting parameters of cognitive models would not be very useful because the results obtained would not generalize beyond a given task or situation.

Glöckner and Pachur (2012) found some evidence for temporal stability of the parameters of CPT: parameters fitted to individual participants' choices at each of two separate experimental sessions were (moderately) correlated. But does this finding also extend to other models of risky decision making? And-more importantly-do conclusions regarding a model's parameter stability depend on how the parameters are estimated? Whereas parameters are traditionally estimated independently for each single participant, it has recently been proposed that more reliable estimates might be achieved by using hierarchical Bayesian procedures, which exploit group-level distributions to inform individual-level estimation (e.g., Gelman \& Hill, 2007; Lee \& Webb, 2005).

Our goal is to examine whether conclusions regarding the parameter stability of a cognitive model are affected by the statistical method used to obtain the estimates. In particular, we compare hierarchical Bayesian techniques against nonhierarchical Bayesian procedures in a decision-making context. We investigate this issue for the transfer-of-attention-exchange model (TAX; Birnbaum \& Chavez, 1997), which has been claimed to provide a better account of decision making under risk than CPT (Birnbaum, 2008). For example, Birnbaum (2008) showed that TAX can correctly account for several violations of CPT, such as violations of gain-loss separability, coalescing, and
stochastic dominance, while being able to also accommodate apparent loss aversion and risk aversion.

## Hierarchical Bayesian Parameter Estimation

The application of hierarchical Bayesian techniques is becoming an increasingly popular tool to estimate cognitive models, including models of judgment and decision making (Lee \& Wagenmakers, 2013; Nilsson, Rieskamp, \& Wagenmakers, 2011; Scheibehenne, Rieskamp, \& Wagenmakers, 2013). Hierarchical Bayesian techniques are attractive because the approach naturally lends itself to the hierarchical data structure inherent in many psychological experiments, where a single individual provides many observations and researchers aim to draw conclusions on the aggregate group level. The alternative, "independence" approach, by contrast, is to first estimate the parameters of each individual participant separately and then aggregate these measures in a second step (Gelman \& Hill, 2007). While feasible, this approach ignores possible similarities between individuals and does not take into account that some participants might allow more precise and reliable estimates than others. Bayesian hierarchical techniques account for these differences and thus promise to yield more consistent and accurate estimates (Rouder \& Lu, 2005).
The Bayesian approach achieves this because the imposed hierarchical structure simultaneously informs the individual level, such that potentially unreliable individual estimates can borrow strength from the other estimates (Gelman, Carlin, Stern, \& Rubin, 2004). Furthermore, parameter estimates that are deemed unlikely given the distribution of the remaining parameter values (i.e., because they are located at the extremes of the distribution) are pulled closer towards the group mean and implicitly receive less weight. This property is referred to as "shrinkage." For these reasons, it has been argued that hierarchical methods often provide a more thorough evaluation of models in cognitive science (Shiffrin, Lee, Kim, \& Wagenmakers, 2008).
Though increasingly popular, Bayesian hierarchical implementations have been developed for only relatively few cognitive models of decision making under risk (but see Nilsson et al., 2011; Wetzels, Vandekerckhove, Tuerlinckx, \& Wagenmakers, 2010). Below we develop, to our knowledge for the first time, a hierarchical model for estimating individual participants' TAX parameters.

## Transfer-of-Attention-Exchange Model

TAX is a model of how people evaluate risky alternatives that can lead to certain outcomes $x$, each of which occurring with probability $p$. For instance, consider whether you would prefer to play a lottery with a $90 \%$ chance of winning $\$ 100$ (otherwise nothing) or a lottery with a $10 \%$ chance of winning $\$ 1000$ (otherwise nothing). According to TAX, the valuation of a lottery is a weighted average of the utilities of the outcomes; the weight that each outcome receives depends on its rank among all possible outcomes (the $n$ outcomes being ordered such that $x_{1}<x_{2}<x_{3} \ldots x_{\mathrm{n}}$ ) and its probability. To account for the typically found risk aversion
(risk seeking) in gains (losses), is the model assumes that attention (i.e., weight) is "transferred" from better (worse) to worse (better) outcomes. Specifically, the valuation, $V$, of a lottery $A$ is calculated as

$$
\begin{equation*}
V(A)=\frac{\sum_{i=1}^{n}\left[t\left(p_{i}\right)+\frac{\delta}{n+1} \sum_{j=1}^{i-1} t\left(p_{j}\right)-\frac{\delta}{n+1} \sum_{j=i}^{n} t\left(p_{i}\right)\right] u\left(x_{i}\right)}{\sum_{i=1}^{n} t\left(p_{i}\right)} \tag{1}
\end{equation*}
$$

where $\delta$ is a free parameter governing the attention shift from higher to lower outcomes (or vice versa); with $0<\delta<$ 1 attention is shifted from higher (lower) to lower (higher) outcomes in gains (losses), with $0>\delta>-1$ the opposite would occur. The function $u(x)$ is the utility function, $u(x)=$ $x^{\beta}$, transforming objective outcomes into subjective utilities. The free parameter $\beta$ indicates the curvature of the value function and reflects the decision maker's sensitivity to outcome information (with lower values of $\beta$ indicating lower sensitivity). $t(p)$ is the probability weighting function, transforming objective into subjective probabilities, and equals $t(p)=p^{\gamma}$. $\gamma$ is a free parameter reflecting the decision maker's sensitivity to probability information (with lower values of $\gamma$ indicating lower sensitivity). To derive the predicted probability that lottery $A$ is preferred over lottery B, we used an exponential version of Luce's choice axiom:

$$
\begin{equation*}
p(A, B)=\frac{e^{\theta \cdot V(A)}}{e^{\theta \cdot V(A)}+e^{\theta \cdot V(B)}}, \tag{2}
\end{equation*}
$$

where $\theta$ is a choice sensitivity parameter, indicating how sensitively a decision maker reacts to differences in the valuation of lotteries $A$ and $B$. To summarize, TAX as implemented here has four free parameters: attention shift $(\delta)$, outcome sensitivity ( $\beta$ ), probability sensitivity $(\gamma)$, and choice sensitivity $(\theta)$.

Data We applied TAX to model the data reported in Glöckner and Pachur (2012). In this study, 63 participants ( 25 male, mean age 24.7 years) indicated their preference between two-outcome monetary lotteries at two experimental sessions that were one week apart. At each session, the participants were presented (on a computer) with 138 lottery problems that contained pure gain, pure loss, and mixed lotteries, all drawn from sets of lottery problems used in previously published studies; 38 of the problems were shown at both sessions (see Glöckner \& Pachur for details). The outcomes of the lotteries ranged from $-€ 1000$ to $€ 1200$. At the completion of each session, one of the chosen lotteries was picked randomly, played out, and the participant received an additional payment proportional to the outcome.

## Parameter Estimation

To estimate the free parameters of TAX, we implemented two Bayesian versions of the model-a hierarchical version and an independent (i.e., non-hierarchical) version. Bayesian modeling requires a detailed specification of the likelihood function and the prior probability distributions of all model parameters. For the independent version, we
specified the likelihood function based on Equations (1) and (2). The priors for the free parameters were set to uniform probability distributions that span a "reasonable" range that excluded theoretically implausible values and allowed for ample space to include parameter values found in previous research (Michael Birnbaum, personal communication). In particular, the priors ranged from -2 to 2 for the $\delta$ parameter and from 0 to 5 for the $\beta, \gamma$, and $\theta$ parameters.
In the hierarchical version, we utilized the same functions as in the independent version but partially pooled the individual parameters using normally distributed grouplevel distributions. Uninformative priors were assigned to the respective means and standard deviation of these grouplevel distributions. The group-level means were assumed to be normally distributed with mean 0 and variance 1 . The prior on the group-level standard deviation was uniformly distributed ranging from 0 to 10 . To ensure proper parameter scaling, the group-level parameters were linked onto the individual level through a probit transformation (Rouder \& Lu, 2005). As this transformation yields a parameter range from 0 to 1 on the individual level, an additional, linear linkage function was interposed that stretched the parameter range to match the scale used in the independent model implementation outlined above (i.e., a range from -2 to 2 for the $\delta$ parameter, and a range from 0 to 5 for the $\beta, \gamma$, and $\theta$ parameters).

For both the individual and the hierarchical model we estimated the joint posterior parameter distributions using Monte Carlo Markov Chain methods implemented in JAGS, a sampler that utilizes a version of the BUGS programming language (Lunn, Spiegelhalter, Thomas, \& Best, 2009; Plummer, 2011) that was called from the R statistics software (version 2.14.0; R Core Team, 2012). A total of 10,000 representative samples were drawn from the posterior distributions after a "burn-in" period of 1,000 samples. The sampling procedure was efficient as indicated by a low autocorrelation of the samples, the Gelman-Rubin statistic, and visual inspection of the chains.

## Quantifying Parameter Stability

To the extent that the parameters of a cognitive model capture stable characteristics of an individual, the parameters should be invariant across time-at least for relatively short time intervals and under comparable measurement conditions (Bland \& Altman, 1986). One way to quantify parameter stability (or reliability) is to correlate individual parameter estimates between two points in time (i.e., test and re-test). Higher correlations indicate higher parameter stability.

As outlined above, one rationale for using hierarchical Bayesian techniques for parameter estimation is to obtain more reliable estimates. Thus, one might expect a higher test-retest correlation when parameters are estimated hierarchically than when they are estimated for each participant independently. To test this prediction, we calculated correlations between the parameter values estimated for each participant at the two measurement
points ( tl and t 2 ), separately for the individual model and the hierarchical model.

Correlations were calculated based on the mean posterior parameter estimates for each measurement point, using Bayesian techniques implemented in BUGS. A Bayesian approach to calculating correlations allows correlation coefficients to be compared based on their posterior distributions. This avoids many problems inherent in traditional frequentist statistical procedures that rely on nullhypothesis significance testing (Kruschke, 2011).

## Results

Table 1 reports the best-fitting TAX parameter values on the group level, obtained from the hierarchical model. As indicated by the $\delta$ parameter being larger than 0 , participants displayed risk aversion in gains and risk seeking in losses, and some reduced sensitivity to outcomes ( $\beta$ being smaller than 1) and probabilities ( $\gamma$ being smaller than 1). Overall, the parameter values obtained are within the range of values obtained or used in previous applications of TAX (e.g., Birnbaum, 2008).

Table 1: Best-fitting group-level TAX parameters and their $95 \%$ highest density intervals $\left(\mathrm{HDI}_{95}\right)$.

|  | TAX parameters |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  | $\delta$ | $\beta$ | $\gamma$ | $\theta$ |

| M | . 35 | . 63 | . 61 | . 16 |
| $\mathrm{HDI}_{95}$ | [.27,.43] | [.60,.65] | [.51,.72] | [.13,.20] |

Figure 1 shows Pearson's product-moment correlations (across participants) between t 1 and t 2 for each of the four TAX parameters. As can be seen, the mean correlation coefficient for the $\delta$ and the $\gamma$ parameters is slightly higher when they are estimated hierarchically than when they are estimated independently. However, this difference is not credible, as the $95 \%$ highest posterior density interval $\left(\mathrm{HDI}_{95}\right)$ includes zero. For the $\beta$ parameter, the correlation is slightly higher when parameters are estimated independently, and for the $\theta$ parameter the test-retest correlation is clearly lower for the hierarchical than for the independent estimates. A similar picture emerges based on Spearman's rank correlations (not shown).

## Why Does Hierarchical Estimation Fail to Improve Parameter Stability?

The results indicate that applying a hierarchical TAX model does not yield higher parameter stability on the individual level. At first sight, this seems surprising given the supposed advantages of hierarchical techniques that "borrow strength" from distributional information on the group level to improve estimations on the individual level.

Figure 1: Stability of each TAX parameter as indicated by the mean product-moment correlation across participants between t 1 and t 2 . Circles indicate independent estimates, triangles indicate hierarchical estimates. Error bars $=\mathrm{HDI}_{95}$.

To explore the reasons for this result, it is instructive to take a closer look at the distribution of the parameter estimates obtained. For illustration, Figure 2 displays the posterior means for the independently estimated $\beta$ parameter values at t 1 and t 2 (upper and lower row, respectively) as well as the hierarchically informed estimates at t 1 (middle row) for a subset of 20 representative participants; for each person the estimates are connected by a line. As could be expected, given the partial pooling enforced through the introduction of the higher level group distribution in the hierarchical model, the hierarchical estimates show a lower dispersion than the individually estimated parameters (the same holds for the hierarchical estimates at t 2 , which are not shown). This shrinkage is particularly pronounced for extreme parameter estimates, that is, those that are far away from the group-level mean. The reason is that these estimates appear rather unlikely with respect to the grouplevel distribution and are thus implicitly treated as outliers in the hierarchical model.

Unwarranted Shrinkage Importantly, however, Figure 2 further shows that the shrinkage of the hierarchical method is not necessarily warranted: for the independently estimated parameter values there is rather good correspondence between tl and t 2 even for participants with rather extreme parameter values. That is, individuals who have a high $\beta$ value at t 1 also tend to have a high $\beta$ value at t 2 ; the same applies for small $\beta$ values. Thus, our analysis shows that in the context on hand extreme estimates often reflect meaningful and reliable characteristics of individuals. The partial pooling enforced by the hierarchical modeling somewhat distorts the individual parameter estimates by pulling them too much towards the group-level mean.

Figure 2: Mean posterior estimates of the $\beta$ parameter of TAX separately for each individual at t 1 and t 2 (upper and lower row) and the hierarchically estimated parameters at tl (middle row) for a representative subset of 20 participants.

Diminished test-retest correlation The unwarranted shrinkage imposed by hierarchical modeling does not inevitably lead to lower test-retest correlations. After all, it could be that the compressed hierarchical estimates are nevertheless more reliable and thus stable over time than the (more dispersed) parameter values estimated on the individual level. As we will outline next, however, that does not seem to be the case.
Figure 3 displays a scatterplot for the $\theta$ parameter separately for the independent and the hierarchical estimates. The $\theta$ parameter provides an instructive example because here the difference between the correlations for the individual and the hierarchical estimates is particularly large (Figure 1). Figure 3 shows that the high correlation for the independent estimates is partly due to some individuals having high values on the $\theta$ parameter at both measurement points. As mentioned above, although these values are much higher than for most individuals in the group, they nevertheless seem to be reliable in the sense that they are equally high at both measurement points. In contrast, the range of the hierarchically estimated parameters is much narrower (note that the axis scales in the figure were adjusted to best display the data). Furthermore, the hierarchical model seems to affect the individual parameter estimates to different degrees. This occurs because the influence of the group-level depends, among other aspects, on the variance and the mean of the individual estimates. As indicated by the shape of the scatterplot in the lower panel of Figure 3, this effect pulls the parameter estimates towards the mean and thus leads to a lower (linear) relationship between the two measurement points. In that sense, the hierarchical method also induces shrinkage on the
correlation coefficients. In situations where the correlation of the individually estimated parameters is reduced due to unreliable outliers, however, applying hierarchical techniques will shrink these outliers and may then yield higher parameter stability.

Figure 3: Scatter plot of the mean posterior estimates for the $\theta$ parameter at tl and t 2 . Each point represents one participant. The upper panel shows the parameter values obtained by individual estimation; the lower panel shows the parameter values obtained by hierarchical estimation. Note that the value ranges on the axes are much smaller in the lower panel.

## Discussion

The psychological content and generalizability of a cognitive model hinges on the extent to which its parameters reflect stable characteristics of an individual. Conclusions regarding a model's parameter stability may be affected by the statistical procedures used to estimate these parameters. Specifically, researchers must decide whether to employ hierarchical techniques or to estimate each person individually.

Our analyses show that the free parameters of the TAX model are rather consistent across time, indicating that the model captures stable aspects of decision makers' risk attitude and their outcome and probability sensitivity. This finding parallels previous results obtained for CPT based on the same data using maximum likelihood estimates (Glöckner \& Pachur, 2012). Most importantly-and rather unexpectedly-our analysis provided no evidence that hierarchical Bayesian techniques yield more stable parameter estimates than the alternative approach of estimating each participant independently from the others.

Why did the shrinkage of the hierarchical procedure yielding distorted estimates? In principle, one possibility is that the distribution of the individual parameter values is bimodal, which would render group-level means futile. As indicated by visual inspection, however, the parameter distributions for our data were mostly unimodal in shape, so this cannot explain why the hierarchical procedure distorted the estimates.

Another possibility could be the prior distribution used for shrinkage. To achieve an optimal balance between complete pooling and complete independence, the degree of shrinkage in the hierarchical model is represented by a free parameter (representing the variance of the group-level distributions) estimated from the data. In principle, the choice of prior on the variance could impose an unwarranted amount of shrinkage (i.e., a low variance), for instance, if much weight is put on low variances, or if the prior does not allow for large variances in the first place. For the current data, however, the posterior estimates for the group-level standard deviations were far away from the upper boundaries of the uniform prior distributions on the grouplevel. The choice of prior on the variance of the group-level distributions is thus an unlikely reason for the undue amount of shrinkage.

Generalizability Although our demonstration focused on one particular cognitive model, we suspect that the conclusions will hold for other models as well-particularly in the domain of judgment and decision making; here, people often rely on different strategies (e.g., Pachur \& Olsson, 2012; Scheibehenne et al., 2013) and parameter heterogeneity thus reflects genuine differences between people. In such a case, the parameter estimates will not regress towards the mean if more data or more precise measures are collected.

Advantages of Hierarchical Approaches The case on hand may be different from situations in which hierarchical Bayesian techniques have been shown to outperform independent parameter estimates. In a classic example, Efron and Morris, (1975) predicted the success rate of professional baseball players for an entire season based on their success rate early in the season. This prediction was greatly improved through the application of hierarchical techniques. Presumably, this improvement occurred because the differences in the success rates of professional baseball players are rather small (they are all pretty good players) and random noise will equal out throughout the season.

Under this condition, there will be regression towards the mean, which benefits hierarchical Bayesian techniques.

Another situation in which hierarchical Bayesian estimates presumably provide more accurate results than independent estimates is when only very little data is available for each individual, yielding high uncertainty on the individual level. Here, the unreliability on the individual level might be reduced through partial pooling.

Finally, hierarchical modeling techniques might be beneficial for comparisons on the group level (Gelman \& Hill, 2007), where the goal is not to improve the reliability on the individual level but to derive robust estimates for the group as a whole. As a consequence, the implicit weighting imposed through hierarchical estimation methods might also be advantageous for making out-of-sample predictions for new group members.

## Summary

Our results indicate that hierarchical Bayesian techniques do not necessarily improve the reliability of individual parameter estimates. Therefore, researchers aiming to predict individual behavior may be better advised to rely on individual estimates instead. As discussed above, hierarchical models might have specific strengths in situations in which very little information is available on the individual level, when the group is very homogenous, or when the goal is to describe and compare groups as a whole.

# Subjective Awareness during Cross-Language Speech Perception Attending Unattended Regions of an Acoustic Continuum 

Jordan Schoenherr (psychophysics.lab@gmail.com) John Logan (john_logan@carleton.ca)<br>Department of Psychology, Carleton University<br>1125 Colonel By Drive, Ottawa, ON K1S5B6 Canada

#### Abstract

Linguistic experience attenuates adult listeners' attention to acoustic differences that are not phonemic in the listener's language. In the present study we found that acoustic information is available to listeners after acoustic cues have been processed to identify phonemic categories. Moreover, we also found that listeners maintained an awareness of these differences by comparing the identification function to typicality ratings and confidence reports.

Keywords: speech perception, category boundaries, confidence processing

## Introduction

When adult listeners are presented a continuum of speech stimuli varying along an acoustic dimension, they divide the continuum into distinct categories defined by sharp boundaries (Liberman, Harris, Hoffman, \& Griffith, 1957), a phenomenon known as categorical perception (Liberman, Cooper, Shankweiler, \& Studdert-Kennedy, 1967). Categorical perception was originally taken as evidence that adult listeners are no longer capable of detecting stimulus differences in within-category regions of a speech continuum (Eimas, 1975). A developmental account of categorical perception assumes that when infants acquire phonemes they learn to segment acoustic information into discrete categories. Consistent with this view, research indicates that by the end of their first year, infants develop a reduced sensitivity to differences between stimuli within a given phoneme category (Werker, 1989), with category boundaries becoming more distinct as they become older (e.g., Hazan \& Barrett, 2000). Rather than processing all stimulus dimensions, infants learn to attend to specific acoustic cues that determine category membership (Jusczyk, 2000). The question that the present study attempts to answer is whether dults are subjectively aware of attended and unattended acoustic properties.

Extending the concept of categorical perception to the perception of non-native phonemes implies that adult listeners might experience difficulties in perceiving these speech sounds due to a desensitization to acoustic information. In effect, non-native speech sounds are thought to be perceptually assimilated into existing native phonemic categorical representations (cf. Best, 1995, Flege, 1995). Although previous research indicates that listeners can learn to perceive non-native phoneme categories (e.g., Pisoni, Aslin, Perey, \& Hennessy, 1982), limited work has been done to examine the metacognitive awareness associated with learning a non-native phoneme category. In the present
study, we examined whether feedback could be used to allocate attention to a previously unattended region of an acoustic continuum that corresponded to a non-native phoneme category and whether attention was accompanied by awareness.

## Categorical Perception of Speech Sounds

A variety of acoustic cues are used by listeners to define phoneme categories. Voice-onset time (VOT), the interval between aspiration and the vibration of the vocal cords is one such cue. Lisker and Abramson (1967) presented English and Thai listeners with synthetic speech sounds ranging from -150 VOT (prevoiced) to +150 VOT (voiced). The Thai listeners' identification performance resulted in two category boundaries corresponding to $/ \mathrm{p} /$, $/ \mathrm{b} /$, and $/ \mathrm{p}^{\mathrm{h}} /$ whereas English listeners' identification performance yielded only one category boundary corresponding to the phonemes $/ \mathrm{b} /$ and $/ \mathrm{p} /$. These findings illustrate how nonnative speech sounds are assimilated into existing phonemic categorical structure.

## Learning to perceive non-native speech sounds

When categorizing stimuli, participants must attend to stimulus properties along the physical continuum that defines the stimuli (Nosofsky, 1986). With training, participants become sensitized to specific regions along the continuum that can affect performance in other tasks (e.g., discrimination tasks; Goldstone, 1994). Thus, once a phonemic category has been acquired listeners will limit their attention to only those psychophysical characteristics where attention has been directed (Jusczyk, 1992).

In order to promote attention to previously unattended acoustic characteristics, listeners typically require some form of training. For example, in order to examine the effectiveness of feedback, Pisoni et al. (1982) provided English listeners with three exemplars of speech sounds from the three regions of the VOT continuum corresponding to voiceless unaspirated, voiced aspirated, and voiceless aspirated stops (i.e, /p/, /b/, and $/ \mathrm{p}^{\mathrm{h}} /$, respectively). Following a short period of laboratory training, listeners were capable of identifying and discriminating speech sounds from the non-native $/ \mathrm{p}^{\mathrm{h}} /$ category.

Pisoni et al.'s (1982) results have several implications. First, acoustic information must be accessible to listeners in order to classify stimuli into a non-native phoneme category. Further support for the availability of acoustic information also comes from studies using typicality ratings wherein gradedness is exhibited in response functions (e.g., Miller \& Volaitis, 1989). Second, when compared to
previous studies (e.g., Mackain et al., 1981) the amount of exposure to non-native phonemes is less important than the method used to present the non-native phonemes. Finally, methods that allocate selective attention to previously unattended regions can facilitate acquisition of these phonemic categories. Although attention is drawn to these stimulus features, it remains unclear whether participants have a subjective awareness of these acoustic properties.

## Confidence reports and subjective awareness

One method frequently used to quantify subjective awareness in a perceptual discrimination task is to have participants provide a subjective probability that they have provided a correct answer. The use of numeric response scales is particularly useful given that a direct comparison can be made with the proportion of correct responses obtained from the primary task. In this case, $50 \%$ represents a response associated with a guess whereas $100 \%$ represents absolute certainty in a response. Thus, listeners are well calibrated when they assign a level of confidence (e.g., $60 \%$ ) that corresponds to their obtained accuracy (e.g., $p(c o r)=0.6)$. Listeners frequently demonstrate failures in assigned appropriate subjective probabilities, evidencing miscalibration.

Rather then miscalibration being random, systematic deviations have been observed which some argue represent a differential ability to assess the performance of specific cognitive operations (Dawes, 1980), with still others arguing that these measures represent contributions of implicit and explicit knowledge (e.g., Dienes \& Berry, 1997; cf. Lichtenstein \& Fischhoff, 1977). For instance, underconfidence has been observed in perceptual tasks (e.g., Bjorkman, Juslin, \& Winman, 1993) whereas overconfidence is typically observed in tasks requiring assess to general knowledge (e.g., Gigerenzer, Hoffrage, \& Kleinbolting, 1991). Dawes (1980) has argued that these findings are the result of participants' uncertainty in their perceptual processes and certainty about information stored in long-term memory. This suggests that confidence processing uses a second set of operations to assess the content and output of the primary decision process (e.g., stimulus classification).

An alternative class of confidence models assumes an additional set of operations wherein primary decision information is rescaled (e.g., for a review see, Baranski \& Petrusic, 1998). These accounts are supported by the observation that the requirement of confidence reports increase primary decision response time (Baranski \& Petrusic, 1998) and the dissociable effects of nondiagnostic information on the primary decision response selection and confidence reports (e.g., Schoenherr, Leth-Steensen, \& Petrusic, 2010). In the present study, we assume that both acoustic and phonemic information will affect confidence reports and that the correspondence of identification accuracy and mean confidence will demonstrate whether
participants have an awareness of acoustic information when identifying phonemes.

## Present Study

In the present study, English listeners were asked to classify stimuli from a VOT continuum into phoneme categories corresponding to either two categories, /p/ and /b/ (both found in English), or three categories, /p/, b/, plus the prevoiced category $/ \mathrm{p}^{\mathrm{h}} /$ (found in Thai). If listeners are aware of acoustic differences, their subjective confidence should differ across regions of the VOT continuum as evidenced by miscalibration. If underconfidence is evidenced, it suggests that listeners did not have subjective awareness of a well-defined phonemic category whereas if overconfidence is evidenced, it suggests that listeners believed that they had a better understanding of the phonemic category then they in fact did.

## Experiment 1

Previously, Schoenherr, Logan, and Winchester (2012) observed slight overconfidence for responses made for $/ \mathrm{b} /$ stimuli located at the category boundary on the VOT continuum. In Experiment 1, we sought to see whether we could increase uncertainty in this region by presenting stimuli from the prevoiced region. The addition of stimuli with these novel acoustic properties should increase uncertainty for stimuli from the $/ \mathrm{p}^{\mathrm{h}}-\mathrm{b} /$ portion of the continuum if acoustic properties are being used to identify stimuli whereas the participants should remain certain in their judgments of stimuli associated with the /p/ category.

## Method

## Participants

Nine Carleton University students participated in the study for course credit; all were native speakers of English or had extensive experience with English and reported normal hearing and no speech pathologies.

## Materials

Fifteen synthetic speech stimuli were used, obtained from the Haskins Laboratories website (HL, 2011; Lisker \& Abramson, 1967). These stimuli varied along the VOT continuum from -70 to 70 ms VOT. As per the method used by Pisoni et al. (1982), listeners were presented with stimuli which corresponded to the voiceless unaspirated, voiced aspirated, and voiceless aspirated stops. The latter categories are present in English while the former is not. The sounds were originally recorded on reel-to-reel tape and later converted into AIFF format at Haskins Laboratories. Stimuli were pre-processed using a DC offset correction to eliminate clicks present in the AIFF versions and then converted into WAV files.

Figure 1a. ID Function without the Requirement of Confidence

## Procedure

Modelled after the procedure used by Pisoni et al. (1982), listeners were presented with a brief training block in which they heard three stimuli prior to the identification tasks, one from each region of the VOT continuum ( $-70,0$, and 70 ms VOT, corresponding to the $/ \mathrm{p} / \mathrm{h} / \mathrm{h} /$, and $/ \mathrm{p} /$ categories). Ten replications of these stimuli were presented in the order $/ \mathrm{p}^{\mathrm{h}} /, / \mathrm{b} /$, and $/ \mathrm{p} /$. Following this initial training, listeners also were trained using an identification (ID) task with feedback. They were presented with a stimulus and then reported whether it was a $/ \mathrm{p}$ ' $/ \mathrm{/} / \mathrm{b} /$, or $/ \mathrm{p} /$ using the ' V ', ' B ', or ' N ' keys, labeled as '_B', 'B', and 'P', respectively. After they had indicated their response, 'Correct' or 'Incorrect' was presented visually on the screen. Listeners completed a total of 80 trials in the training task.

Following training, listeners again identified the stimulus presented as a $/ \mathrm{p} /$ /, $\mathrm{b} /$, or $/ \mathrm{p} /$ using the keyboard but no feedback was provided. In the first block, after they completed each ID trial they also indicated their level of confidence in their response using the 'E' through 'I' keys, on a 6 -point scale with $50 \%$ representing a guess and $100 \%$ representing certainty. In the second block, confidence was not reported. Each block was composed of a total of 150 trials.

The duration of the experiment was approximately 30 minutes. Replicating the procedure of Pisoni et al. (1982), stimuli were presented randomly except for the sequential presentation of the training stimuli. Listeners were presented with the stimuli over headphones at a comfortable listening level using PsychoPy software (Peirce, 2007).

## Results

Proportion Identification. Unlike studies that have examined two-category identification performance using confidence reports (e.g., Schoenherr et al., 2012), only the $/ \mathrm{p} /$ phoneme category showed a sharp identification function (Figures 1a and 1b). In general, however, listeners could consistently identify stimuli associated with the $/ \mathrm{p}$ h/ and $/ \mathrm{b} /$ category with greater than chance accuracy (i.e., stimuli with VOTs of $-70,-60,-50,0$, and 10 ), indicating that even with a brief period of training, listeners can begin to acquire a non-native speech category. Supporting this, we obtained a significant effect for VOT stimulus, $F(14,112)=7.389$, $M S E=.435, p=.001, \eta^{2}=.480$. Given that we did not

Figure 1b. Identification Function with the Requirement of Confidence

obtain a main effect or interaction of confidence reports, it suggests that confidence reports did not significantly affect ID performance thereby permitting a straightforward interpretation of the remaining results.
(In an alternate version of Experiment 1 the order of confidence and no confidence blocks was reversed [see Schoenherr and Logan, in preparation]. Under these conditions, participants' ( $n=12$ ) identification performance for the non-native phoneme category was reduced in the first block when confidence was required. Participants generally paired neighbouring stimuli together in alternating clusters of 2-4 speech sounds [e.g., VOTs 10 and 0 ms were identified as $/ \mathrm{b} /$, VOTs -10 and -20 ms identified as $/ \mathrm{p}^{\mathrm{h}} /$, and VOTs -30 to -60 ms identified as $/ \mathrm{b} /$ ]. Such a finding suggests that the requirement of producing confidence reports can interfere with the primary task.)

Table 1. Mean identification RTs (ms) along the critical regions of the VOT continuum with standard error reported in parentheses.

| Condition | $/ \mathbf{p}^{\mathrm{h}} /$ | $/ \mathbf{p}^{\mathrm{h}}-\mathbf{b} /$ | $/ \mathbf{b} /$ | $/ \mathbf{b}-\mathbf{p} /$ | $/ \mathbf{p} /$ |
| :--- | :--- | :--- | :--- | :--- | :--- |
| No Conf. | 888 | 910 | 893 | 933 | 796 |
|  | $(45)$ | $(51)$ | $(54)$ | $(75)$ | $(43)$ |
| Conf. | 1,009 | 1,137 | 1,072 | 992 | 855 |
|  | $(47)$ | $(124)$ | $(113)$ | $(83)$ | $(41)$ |

Identification Response Time. Prior to conducting an analysis of the response time (RT) data, we collapsed stimuli into regions five regions along the VOT continuum corresponding to two category boundaries (CBs) $/ \mathrm{p}^{\mathrm{h}}-\mathrm{b} /$ and $/ \mathrm{b}-\mathrm{p} /$ corresponding to $\mathrm{CB}_{1}(-30,-20)$ and $\mathrm{CB}_{2}(20,30)$, respectively, and equivalent within-category pairs corresponding to $/ \mathrm{p}^{\mathrm{h}} /(-70,-60), / \mathrm{b} /(0,10)$, and $/ \mathrm{p} /(60,70)$, respectively. Using the criterion of 3 standard deviations, $4.3 \%$ of the responses were identified as outliers and removed from the final analysis.

An analysis of the remaining responses times revealed a main effect of VOT region, $F(4,32)=4.45, M S E=.041, p=$ $.025, \eta^{2}=.357$. Table 1 indicates that response latencies were longer at category boundaries as well as for the nonnative $\left(/ \mathrm{p}^{\mathrm{h}} /\right)$ and modified native ( $/ \mathrm{b} /$ ) categories relative to the native $/ \mathrm{p} /$ category. A main effect of the requirement of confidence report was also obtained, $F(1,18)=14.55, M S E$
$=.026, p=.005, \eta^{2}=.645$. Again, Table 1 demonstrates longer latencies with the requirement of confidence relative to the no confidence condition. Given that the confidence block always followed the no confidence block, this finding cannot be attributed to automaticity. The interaction of confidence condition and VOT region was only marginally significant, $F(4,32)=2.724, M S E=.019, p=.099, \eta^{2}=$ . 254.
Confidence Reports. Figure 1a and 1 b also demonstrate the effect of confidence measures. Listeners expressed less confidence in their responses to stimuli located within the $/ \mathrm{p}$ / and /b/ categories. As was the case with ID accuracy, we observed a main effect of the stimulus location along the VOT continuum on mean confidence, $F(14,112)=6.931$, $M S E=1011.371, p=.018, \eta^{2}=.464$. Our comparison of over/underconfidence bias did not reveal any significant effects, $F(14,112)=2.146, M S E=.0354, p=.133, \eta^{2}=$ .212. Unlike previous studies that have observed graded responses indicative of perception of acoustic properties (e.g., McMurray, Tanenhaus, \& Aslin, 2002), our findings suggest that listeners are not fully aware of the processes allowing them to identify stimuli.

## Discussion

An instructive comparison can also be made between the results of the present study and conditions in which participants identify two native phonemes. Schoenherr et al. (2012) observed a small decrease in confidence around the /b-p/ category boundary when only the voiced and voiceless portions of the continuum were presented to listeners. When the prevoiced portion of the continuum was additionally presented, Schoenherr et al. (2012) observed lower confidence in the $/ \mathrm{p}^{\mathrm{h}}-\mathrm{b} /$ portion of the continuum. When compared to identification accuracy, this pattern of responses leads to underconfidence in comparison to the overconfidence observed in the present study. Taken together with our results, this suggests that training does result in the allocation of attention to newly relevant acoustic properties of the stimuli in this region of the VOT continuum, thereby reducing certainty. Although listeners are somewhat more conservative in their confidence reports, they are still overconfident suggesting that the phonemic representations that they are subjectively aware of are less accurate than the acoustic information necessary to identify the stimuli.

## Experiment 2

The pattern of overconfidence observed in Experiment 1 suggests two features of a listener's awareness of acoustic properties. First, the observation that mean confidence exceeded identification accuracy in the $/ \mathrm{p}^{\mathrm{h}}-\mathrm{b} /$ region of the VOT continuum indicates that listeners did not have complete access to acoustic properties on a trial-to-trial basis. Second, mean confidence in identification responses to stimuli within the $/ \mathrm{p}^{\mathrm{h}}-\mathrm{b} /$ region was lower relative to stimuli from the $/ \mathrm{p} /$ region. These findings suggest that
while participants confidence reports are influenced by their two native phoneme categories, they might have some awareness of the acoustic properties of stimuli within the $/ \mathrm{p}^{\mathrm{h}}-\mathrm{b} /$ region which cause uncertainty in their responses. To assess the extent to which acoustic and phonemic properties are available to subjective awareness, Experiment 2 required participants to additionally provide typicality ratings that have previously been shown to reflect acoustic properties (Miller \& Volaitis, 1989).

## Method

## Participants, Materials, and Procedure

Fifteen Carleton University students participated in the study. Other participant and stimulus characteristics were the same as in Experiment 1.

We replicated the methods of identification block in Experiment 1 and required post-decisional confidence reports. In a subsequent another block, listeners rated the typicality of each stimuli on a scale of 1 through 9 where ' 9 ' represented highly typical of a category and ' 1 ' represented a highly atypical member of a category. Listeners were presented with the same number of trials as the identification block.

## Results

Proportion Identification. Replicating the general results of Experiment 1, the location of the stimuli along the VOT continuum significantly affected identification performance, $F(14,112)=9.149, M S E=.124, p=.005, \eta^{2}=$ .533. Figure 1b demonstrates, participants had a sharp category boundary between stimuli for the $/ \mathrm{b} /$ and $/ \mathrm{p} /$ categories. A noticeable difference was evident in the location of the boundary. Whereas in Experiment 1 the boundary was located between VOT 20 ms and 30 ms , a shift such that the boundary was now located at VOT 20 ms with a resulting decrement in performance for VOT 10 ms stimuli. We assume that these results are due to range effects. In general, these findings permit a straightforward interpretation of the remaining results.

Confidence Reports. Figure 2 also demonstrates the effect of confidence measures. Like ID accuracy, we found that subjective confidence varied along the VOT continuum, $F(1,14)=6.55, M S E=44.11, p=.008, \eta^{2}=.319$. Relative to Experiment 1, we did observe greater underconfidence in the negative portion of the VOT continuum.

Typicality Task. Typicality ratings also varied significantly as a function of stimulus location along the VOT continuum, $F(14,112)=5.820, M S E=.3 .295, p=.009, \eta^{2}=$ .421. Unlike accuracy, but like mean confidence, typicality ratings appeared to be more responsive to the acoustic properties of the stimuli. Participants considered stimuli in the $/ \mathrm{b} /$ and $/ \mathrm{p}^{\mathrm{h}} /$ range as less typical then stimuli in the $/ \mathrm{p} /$ range even though they exhibited equal accuracy. Moreover, within-category ratings exhibited more graded responses.

Figure 2. ID, Subjective Ratings, and Interpolated Function

Interpolated Function. The similarities in patterns observed in confidence and typicality suggested a potential relationship between these two functions. As Figure 2 indicates, mean confidence ratings are situated between accuracy in the identification task and typicality ratings in the typicality task. Pearson's correlations revealed the strongest relationship between confidence and typicality ratings, $r^{2}=.960, p<.001$. The correlation between identification responses and mean confidence was also significant, $r^{2}=.446, p=.007$, although the correlation between identification and typicality was only marginally significant, $r^{2}=.261, p=.051$. These findings suggest that confidence is associated with both identification accuracy and typicality ratings but that identification accuracy and typicality ratings are only weakly related.

In order to examine the relationship between accuracy, typicality, and confidence ratings we converted typicality to a proportion, summed it with proportion correct, and produced an interpolated function. A paired-samples t-test revealed that the mean confidence function and the interpolated function did not significantly differ from one another, $t(14)=.309, p=.762$. This suggests that confidence reports were closely associated with information from both identification accuracy (associated with phonemic representations) and typicality ratings (associated with acoustic information). All other paired-sample $t$-tests were significant (all $t \mathrm{~s}>3.283, p \mathrm{~s}<.005$ ) indicating that different sources of information contributed to response selection for each dependent measure.

## Discussion

The typicality results provide strong support for the accessibility of acoustic information during speech perception. When normalized along a common scale, typicality ratings were lower in the $/ \mathrm{p}^{\mathrm{h}}-\mathrm{b} /$ region of the VOT continuum relative to identification responses, suggesting that participants had an awareness of acoustic properties. This finding replicates previous studies (e.g., Miller \&

Volatis, 1989). A similar pattern was again observed in confidence ratings. More importantly, when typicality and identification functions were interpolated, a near perfect fit was obtained with the confidence function. This finding is of particular interest as it suggests that confidence is affected by both phonemic representations stored in longterm memory and acoustic properties available in short-term memory.

## Conclusion

The findings of the present study have several implications. First, we replicated results from early studies (e.g., Pisoni et al., 1982) showing that participants can learn a non-native speech category using only three exemplars selected from the VOT continuum. Second, our results indicate that the acquisition of non-native phonemes likely resulted from the allocation of attention to regions along the VOT continuum that were previously unattended (e.g., Jusczyk, 1992). In comparison to tasks where participants must identify two categories, such as in Experiment 2 and Schoenherr et al. (2012), participants exhibited well-defined $/ \mathrm{b} /$ and $/ \mathrm{p} /$ phonemic categories. The induction of a novel category boundary requires attention to acoustic properties. In the present study, support for the detection of acoustic properties of stimuli from the same phonemic category comes from both confidence reports and typicality ratings. Both subjective confidence and typicality decreased in the $/ \mathrm{p}^{\mathrm{h}}-\mathrm{b} /$ region of the VOT continuum relative to ratings within the $/ \mathrm{b}-\mathrm{p} /$ region.

As briefly noted above in reference to Experiment 1, this pattern appears to hold provided that participants do not need to concurrently monitor their performance (i.e., provide confidence reports). Thus, although feedback directs attention toward previously unattended regions of the VOT continuum, additional top-down monitoring might emphasize differences between exemplars to the detriment of the formation of novel phonemic categories. Similar findings of top-down interference have been observed in visual search tasks wherein activation of object-level representations in long-term memory creates interference in detection of stimuli based on visual features (e.g., Zhaoping \& Firth, 2011).

Finally, our study also has implications for models of confidence. The identification function and typicality ratings are believed to reflect the detection of phonemic and acoustic information, respectively. When interpolating between these two functions, we obtained a function that approximated that obtained from confidence reports. This suggests that additional processing is required to create a confidence report and that such a process can integrate information from short- and long-term memory.

# Virtues and Vices in Monetary Tradeoffs 

Marc Scholten (scholten@ispa.pt)<br>ISPA University Institute<br>Lisbon, Portugal<br>Daniel Read (daniel.read@wbs.ac.uk)<br>Warwick Business School<br>Coventry, United Kingdom

#### Abstract

Monetary intertemporal tradeoffs are a restricted, yet underexplored, domain. In this extended abstract, we provide an integrative analysis of monetary tradeoffs involving single dated outcomes, unmixed sequences, virtues (schedules of investment), and vices (schedules of debt). Results include debt aversion, aversion to vices (which adds to debt aversion) and relative vices, and attraction to virtues and relative virtues. The results motivate a comparative mental accounting model, which includes direct comparisons between the outcomes delivered by the options at consecutive delays. The model accommodates not only the results reported in this extended abstract, but also other puzzling phenomena in choices involving sequences.

Keywords: Intertemporal choice, discounting; virtues; vices; sequences; mental accounting.

Intertemporal choices are those in which outcomes of choice are traded off against their timing. One example is the choice between a chocolate mousse and a fruit salad for dessert, where immediate gratification may favor the former, but future health may favor the latter. Another example is the decision of whether to consume on credit now and pay off debt in the future or invest income now and consume more in the future. Again, there is a tradeoff between what is best now and what is best in the future.

The above choices can be viewed as choices between a relative vice and a relative virtue (Wertenbroch, 1998), where the relative vice is better in the short run but worse in the long run or overall, whereas the relative virtue is worse in the short run but better in the long run or overall. Many intertemporal choices fit this definition, and also elementary choices between single dated outcomes. Consider the choice between $\$ 150$ today and $\$ 200$ in 1 year. By the above definition, the smaller-sooner outcome is a relative vice, and the larger-later outcome is a relative virtue. The notion of relative virtues and vices is inherently comparative in nature. However, current models of intertemporal choice do not consider the possibility that people actually make the relevant comparisons, and frame the options as relative virtues and vices. For instance, the above choice between single dated outcomes may be represented as a decision of whether to
accept or reject receiving $\$ 150$ less today and $\$ 200$ more in 1 year. This is a relative virtue: Less money in the short term (-\$150), but more in the long term (\$200) or overall (\$50). Alternatively, the choice may be represented as a decision of whether to accept or reject receiving \$150 more today and $\$ 200$ less in 1 year. This is a relative vice: More money in the short term (\$150), but less in the long term (-\$200) or overall (-\$50). These mental operations involve direct comparisons between the options: Comparisons between the outcomes available today (\$150 and $\$ 0$ ) and in 1 year ( $\$ 0$ and $\$ 200$ ). The question is whether and when people perform these operations, and how it affects the decisions they make.

While most experimental research of intertemporal choice has focused on single dated outcomes, many reallife choices involve prospects of multiple outcomes. A distinction can be made between mixed and unmixed sequences. Unmixed sequences can be goods, which are composed of only positive outcomes, and bads, which are composed of only negative ones. Mixed sequences include, but are not restricted to, absolute virtues, or virtues in short, which exchange sooner costs for largerlater benefits, and absolute vices, or vices in sort, which exchange sooner benefits for larger-later costs.

With the exception of Prelec and Loewenstein's (1998) work on the mental accounting of investment and debt, experimental research on virtues and vices has focused almost exclusively on consumption, such as consumption of healthy or unhealthy food items (Read \& van Leeuwen, 1998, and thereafter), as in the dessert example given above, and consumption of highbrow or lowbrow movies (Read, Loewenstein, \& Kalyanaraman, 1999, and thereafter). In that research, there is no rigorous control over whether the options are treated as absolute or relative virtues and vices. Monetary tradeoffs, often the focus of experimental research on single dated outcomes and unmixed sequences, lend themselves perfectly for that purpose. One goal of this extended abstract is, therefore, to conduct an integrative analysis of choices involving single dated outcomes, unmixed sequences, virtues, and vices in monetary tradeoffs, where monetary virtues are schedules of investment, and monetary vices are schedules of debt.

As a whole, our results cannot be accommodated by
any current model of intertemporal choice, so that a new approach is needed. We propose an extension of Prelec and Loewenstein's (1998) double-entry mental accounting model of preferences for schedules of investment and debt. Essentially, the extension is that, in choices involving sequences, people do make direct comparisons between the outcomes available at consecutive delays, which often means that they reframe the options as relative virtues and vices. We discuss how this comparative mental accounting model accommodates the results reported in this extended abstract, and also results reported elsewhere.

We collected data from many samples in three nations (the United States, the United Kingdom, and Portugal), sometimes with paid, sometimes with unpaid participants, as we went along perfecting the experimental comparisons in order to counter, as much as possible, explanations offered by the current models of intertemporal choice. The comparisons that we report are the most challenging ones. This extended abstract, however, can only cover a few. All choices reported were part of surveys including a larger set of intertemporal choices, the order of which was randomized across participants.

## Debt aversion

A basic assumption underlying models of intertemporal choice is positive time preference: People would prefer a gain sooner rather than later (impatience), and a loss later rather than sooner (procrastination). To test this assumption, we presented 36 participants with different timings of receiving $€ 100$ and 78 participants with different timings of paying $€ 100$. The results were as follows:

## Set 1

W Receive $€ 100$ in 1 year (11\%)
B Receive $€ 100$ today (89\%)

## Set 2

W Pay €100 today (65\%)
B Pay $€ 100$ in 1 year (35\%)
Here and elsewhere, B denotes the best option in the long run, whereas W denotes worst option in the long run. An overwhelming chose B among receipts (positive time preference), $\chi^{2}(1)=21.78, p<.005$ (Pearson's $\chi^{2}$ ), but a smaller yet significant majority chose W among payments, $\chi^{2}(1)=7.38, p<.05$ (negative time preference).

The observed pattern of results can be explained by combining the discounting of delayed outcomes with an aversion to delayed losses, or debt aversion. Discount-ing favors immediate gains over delayed ones, and delayed losses over immediate ones. Debt aversion, however, favors immediate losses over delayed ones, thus countervailing discounting. Therefore, while choice is not conflicted for different timings of a gain, because
discounting unambiguous-ly favors the immediate gain, it is conflicted for different timings of a loss, because discounting, which favors the delayed loss, is countervailed by debt aversion, which favors the immediate loss. In this study, discounting was outweighed by aversion to delayed losses.

Debt aversion operates in addition to loss aversion, which is that the pain of loss is greater than the pleasure of an equal gain (Kahneman \& Tversky, 1979). We next report an aversion to vices, which operates in addition to debt aversion.

## Aversion to Vices

We asked 429 participants to choose from the following pairs of options:

## Set 3

Referent pair
W Pay \$600 in 1 year (26\%)
B Pay $\$ 450$ today (74\%)
Target pair
W Receive $\$ 50$ today and pay $\$ 600$ in 1 year (20\%)
B Pay $\$ 450$ today (80\%)
W in the target pair is obtained from W in the referent pair by adding an immediate $\$ 50$. Because W in the target pair dominates W in the referent pair, it should be more popular. However, the opposite was true, $\chi^{2}(1)=7.72, p<$ .05 (McNemar's $\chi^{2}$ for dependent samples), suggesting that a later payment, or a debt, hurts more when it is the cost of a sooner benefit than when it is an uncompensated loss. This is aversion to vices.

One possible explanation is offered by Loewenstein and Prelec's (1993) sequences model, according to which people have a preference for improvement tempered by a preference for spreading. A vice, however, exhibits deterioration, which decreases preference for it. Another possible explanation is offered by Prelec and Loewenstein's (1998) double-entry mental accounting model: The pleasure of the immediate benefit is attenuated by the pain of the delayed cost (debt), and the experience of the immediate benefit may, through attenuation, change into a negative one.

## Attraction to Virtues

Two principles of outcome valuation are loss aversion and diminishing sensitivity (Kahneman \& Tversky, 1979): The impact of a loss is greater than that of an equivalent gain, and the marginal impact of an outcome decreases with its magnitude. In the following set, we see both principles being violated. We asked 435 participants to choose from the following option pairs:

## Set 4

Referent pair
W Receive $€ 450$ today (54\%)
B Receive $€ 600$ in 1 year (46\%)

Target pair
W Receive €300 today (46\%)
B Pay $€ 150$ today and receive $€ 600$ in 1 year (54\%)
The target pair is obtained from the referent pair by subtracting a common amount (\$150) from both options in period 1. This does not change the interest rate implied by the options (33\%), so that, objectively, the preference between W and B should not change. Moreover, by loss aversion and diminishing sensitivity, the value difference between 300 and -150 in the target pair is more strongly in favor of W than the value difference between 450 and 0 in the referent pair, so that W should be more popular, and B less popular, in the target pair than in the referent pair. Instead, B was more popular in the target pair than in the referent pair, $\chi^{2}(1)=4.90, p<.05$, suggesting that the same receipt is more appealing when it is the benefit of an investment than when it is an uncompensating gain. This is attraction to virtues.

One possible explanation is offered by the sequences model: Preference for improvement. Another possible explanation is offered by the mental accounting model: The pain of the immediate cost (investment) is buffered by the pleasure of the delayed benefit, and the experience of the immediate cost may, through buffering, change into a positive one.

## Unmixed Sequences

We asked the same 435 participants from the section on attraction to virtues to choose from the following option pairs:

## Set 5

Referent pair
W Receive $€ 75$ today (68\%)
B Receive €100 in 1 year (32\%)
Target pair
W Receive €300 today (57\%)
B Receive $€ 225$ today and receive $€ 100$ in 1 year (43\%)

The target pair is obtained from the referent pair by adding a common amount ( $€ 225$ ) to both options in period 1. This does not change the interest rate implied by the options (33\%), so that, objectively, the preference between W and B should not change. However, B was more popular in the target pair than in the referent pair, $\chi^{2}(1)=9.33, p<.005$.

One possible explanation for the above result is diminishing sensitivity: The value difference between 300 and 225 in the target pair is less strongly in favor of W than the value difference between 75 and 0 in the referent pair, so that W should be less popular, and B more popular, in the target pair than in the referent pair. However, diminishing sensitivity is being violated by the results below:

## Set 6

Referent pair
W Receive $€ 300$ today (58\%)
B Receive €400 in 1 year (42\%)
Target pair
W Receive $€ 300$ today and receive $€ 300$ in 1 year (47\%)
B Receive $€ 700$ in 1 year (53\%)
The target pair is obtained from the referent pair by adding a common amount ( $€ 300$ ) to both options in period 2. This does not change the interest rate implied by the options (33\%), so that, objectively, the preference between W and B should not change. However, B was more popular in the target pair than in the referent pair, $\chi^{2}(1)=21.59, p<.005$. By diminishing sensitivity, the value difference between 700 and 300 in the target pair is less strongly in favor of $B$ than the value difference between 400 and 0 in the referent pair, so that $B$ should be less popular in the target pair than in the referent pair.

The above results are incompatible with the sequences model: In Set 5, B deteriorates and yet it gained popularity, and, in Set 6, W neither deteriorates nor improves, and yet it lost popularity. The results cannot be explained by the mental accounting model either, because, in the absence of mixed sequences, i.e., schedules of costs and benefits, this model reduces to a standard delay discounting model.

The results are consistent with the notion that choice involving sequences promotes comparative accounting. In the choice between a single immediate outcome and a sequence (Set 5), the sequence is framed as a relative virtue (' $€ 75$ less today and $€ 100$ in 1 year’), and attraction to virtues increases the preference for this option. In the choice between a single delayed outcome and a sequence (Set 6), the sequence is framed as a relative vice (' $€ 150$ today and $€ 200$ less in 1 year'), and aversion to vices decreases the preference for this option.

## A Core Anomaly

We asked the same 429 participants from the section on aversion to vices to choose from the following option pair:

## Set 7

Receive \$500 in 1 year and receive \$500 in 3 years (29\%) Receive $\$ 1,000$ in 2 years (71\%)

A large and significant majority preferred the single delayed receipt to the flat sequence of delayed receipts, $\chi^{2}(1)=74.69, p<.005$. We call this a core anomaly, because no model of intertemporal choice accounts for it. As to standard delay discounting models, such as Loewenstein and Prelec's (1992) hyperbolic discounting model, discounting per se contributes to a preference for the sequence, which is compounded by hyperbolic discounting and diminishing sensitivity. As to the
sequences model, the sequence neither improves nor deteriorates, which contributes to indifference between the sequence and the single delayed receipt. Finally, the mental accounting model reduces to a standard delay discounting model, because the choice does not involve mixed sequences. In the next section, we try to account for the whole set of results.

## Theory

Our theory is an extension of Prelec and Loewenstein's (1998) mental accounting model of investment and debt. In this model, sooner benefits are attenuated by later costs, and sooner costs are buffered by later benefits. This, by itself, accounts for aversion to vices and attraction to virtues, as observed in Sets 3 and 4. The model incorporates loss aversion, in that negative experiences are augmented relative to positive ones. Negative experiences include sooner benefits when their attenuation by later costs results in a sign reversal, and positive experiences include sooner costs when their buffering by later benefits results in a sign reversal. Experiences in each period are discounted as a function of the delay to the experiences, and the option with the highest discounted value is chosen.

Our extension of the mental accounting model draws on two considerations. First, operating in addition to loss aversion is debt aversion, meaning that delayed costs are augmented relative to immediate ones. This accommodates the preference observed in Set 2. It also increases the aversion to vices observed in Set 3.

Second, the option that has the longest interval between its soonest and latest outcome, i.e., the longest duration, becomes the target option, the outcome of which in any given period is compared with the outcome of the referent option in that period. Thus, for instance, in the choice between a sequence and a single dated outcome, the sequence becomes the target option, and the single dated outcome becomes the referent option. In the choice between two single dated outcomes, neither option has duration, and so there is no targeting and referencing. In the choice between options of equal duration, either option can become the target option.

From the vantage point of the extended mental accounting model, the preference pattern observed in Set 5 shows attraction to relative virtues. In the target pair, the sequence is the target option and the single immediate receipt is the referent option. Thus, the choice is framed as whether to accept or reject the prospect of 'receiving $€ 75$ less today and receiving $€ 100$ in 1 year.' To the degree that the immediate comparative loss is buffered by the delayed receipt, possibly resulting in a positive experience of the immediate comparative loss, the tendency will be to accept this prospect.

The preference pattern observed in Set 6 shows aversion to relative vices. In the target pair, the sequence is the target option and the single delayed receipt is the referent option. Thus, the choice is framed as whether to
accept or reject the prospect of 'receiving $€ 300$ today and receiving $€ 400$ less in 1 year.' To the degree that the immediate receipt is attenuated by the delayed comparative loss, the tendency will be to reject this prospect.
Finally, our explanation of the preference observed in Set 7 is that, the sequence was framed as two gains interleaved with a comparative loss, and that, due to attenuation of the gain in period 1 and aversion the comparative loss in period 2, the tendency was to reject the mixed prospect, notwithstanding a buffering of the comparative loss in period 2 by the gain in period 3.

## Some Implications

The comparative mental accounting model resolves several puzzles. Consider, for instance, the widely investigated preference for improving sequences over deteriorating ones. Loewenstein and Prelec (1993) discuss a number of explanations of this phenomenon, which all invoke within-option operations. One explanation is adaptation and loss aversion. People adapt to ongoing stimuli over time, and evaluate ensuing stimuli relative to their adaptation level. An improving sequence becomes a series of positive departures (gains) from the adaptation level, while a deteriorating sequence become a series of negative departures (losses) from the adaptation level. Preference for improving sequences over deteriorating ones then follows from loss aversion (Kahneman \& Tversky, 1979).

Our explanation, in contrast, invokes between-option operations. When people focus on the improving sequence and compare it with the deteriorating one, they experience an increasing series of comparative losses and gains. Attraction to relative virtues increases the attractiveness of this option, making choice of improvement more likely. Alternatively, when people focus on the deteriorating sequence and compare it with the improving one, they experience a decreasing series of comparative gains and losses. Aversion to relative vices decreases the attractiveness of this option, making choice of deterioration less likely. According to our explanation, preference for improvement over deterioration is fundamentally a choice-related phenomenon, because, without direct comparisons between options, there would be no mental construction of relative virtues and vices. Indeed, it has been shown that preference for improvement over deterioration evaporates in elicitation tasks other than choice, in which other motives and mental operations come to the fore (Frederick \& Loewenstein, 2008).

Another puzzle is the hidden-zero effect (Magen, Dweck, \& Gross, 2008), which is that the preference for B over W increases when two single dated receipts are changed into sequences by explicating the zero receipt. Thus, for instance, choice of ' $\$ 0$ today and $\$ 400$ in 1 year' over ' $\$ 300$ today and $\$ 0$ in 1 year' is more likely than choice of ' $\$ 400$ in 1 year' and ' $\$ 300$ today.' The comparative mental accounting model explains the
hidden-zero effect as follows. Both sequences, each with duration of 1 year, can become the target option. When B is the referent option, W becomes a relative vice, and, by aversion to relative vices, the preference for B over W increases. When W is the referent option, B becomes a relative virtue, and, by attraction to relative virtues, the preference for B over W increases.

Yet another puzzle is the mere token effect (Urminsky \& Kivetz, 2011), which is a violation of independence in which the preference for B over W increases when two single dated receipts are changed into sequences by adding a common consequence before both receipts. For instance, choice of ' $€ 50$ tomorrow and $€ 400$ in 1 year' over ' $€ 50$ tomorrow and $€ 200$ in 1 week’ is more likely than choice of ' $€ 400$ in 1 year' over $€ 200$ in 1 week.' The comparative mental accounting model can explain the mere token effect as well. With the introduction of the token, the sequence of longer duration, B , becomes the target option, whereas the sequence of shorter duration, W , becomes the referent option. As a result of the comparison process, the choice between $B$ and $W$ is framed as a decision of whether to accept the relative virtue ' $€ 200$ less in 1 week and $€ 400$ in 1 year.' By attraction to relative virtues, the tendency will be to accept this prospect.

In our article, we provide a much more exhaustive analysis of recently discovered anomalies in choices involving sequences. The comparative mental accounting accommodates most.

## Conclusion

Our results show an interesting pattern: People are extremely impatient in gains, with many declining to receive a $33 \%$ interest rate, much and much higher than riskless market rates, but they become more farsighted when faced with other intertemporal arrangements. First, their impatience in gains decreases when future benefits are preceded by immediate costs (attraction to virtues). Furthermore, they are averse to procrastination in losses (debt aversion), and become even more farsighted when future costs are preceded by immediate benefits (aversion to vices).

Our theoretical reconstruction suggests that, people make direct comparisons between options. Specifically, the outcomes of the option with the longest duration are compared, period by period, with the outcomes of the options with the shortest duration. The result is that even sequences are cognitively represented as relative virtues, relative vices, or, more generally, mixed prospects. This proposal of comparative framing greatly increases the scope of a mental accounting approach to intertemporal choice.

It also opens avenues toward a better understanding of real-life decisions. The paradigmatic example of intertemporal choice is whether to get a job and earn a living now or go to college and earn a better living later. How is such a complex decision made? Plausibly, people
would make direct comparisons between the features of the options under consideration. In this case, comparisons between studying (or partying) and working, between the jobs available with and without a college degree, between prospective earnings, and between incurring and foregoing tuition debt. Current models of intertemporal choice are notably ignorant of such comparisons in decision making: Each option receives its discounted value, regardless of how it compares to other options, and the option with the highest value is chosen. Our analysis suggests that intertemporal choice is comparative in a carefully crafted choice environment, and we would be surprised if people suddenly ceased to make comparisons in the wild.

#### Abstract

Comparison of the ability of different computational cognitive models to simulate empirical data should ideally take into account the complexity of the compared models. Although several comparison methods are available that are meant to achieve this, little information on the differential strengths and weaknesses of these methods is available. In this contribution we present the results of a systematic comparison of 5 model comparison methods. Employing model recovery simulations, the methods are examined with respect to their ability to identify the model that actually generated the data across 3 pairs of models and a number of comparison situations. The simulations reveal several interesting aspects of the considered methods such as, for instance, the fact that in certain situations methods perform worse than model comparison neglecting model complexity. Based on the identified method characteristics, we derive a preliminary recommendation on when to use which of the 5 methods. Keywords: computational cognitive models, model comparison, model mimicry, model generalization

When computationally modeling cognition, often several different models are available or conceivable as explanations for the cognitive ability in question. In such a situation, the aim is to select the best of these candidate models according to a set of criteria. Among others (e.g., falsifiability or interpretability) the extent to which the different models are able to simulate observed human behavior is usually considered a key criterion for selecting from the candidate models.

A naïve approach to gauge the models' ability to simulate the existing observations is to fit each model to the available data and choose the model that provides the tightest fit as indicated, for instance, by the models' Root Mean Squared Error (RMSE). Such an approach is problematic, because it does not take into account the complexity of the compared models. As a result, there is a tendency for overfitting and for selecting more complex models even if simpler models provide the better explanation of the considered cognitive ability (Pitt \& Myung, 2002).

Several methods taking into account model complexity have been proposed to avoid the pitfalls of the naïve approach (see Shiffrin, Lee, Kim, \& Wagenmakers, 2008, for an overview). However, common use of such more sophisticated model comparison methods is partly hampered by the fact that many properties of the different methods are insufficiently investigated. Only very few studies (e.g., Cohen, Sanborn, \& Shiffrin, 2008) have systematically examined different comparison methods with respect to their differential advantages and disadvantages. Consequently, when
faced with a situation that requires comparing models regarding their ability for simulating human behavior, modelers are often faced with the problem that it is unclear which model comparison methods could reasonably and should ideally be employed in a given situation.

In this contribution we present the results of a systematic comparison of 5 model comparison methods. The methods are examined with respect to their ability to select the model that actually generated the data across 3 pairs of models and a number of contextual variations (e.g., tightness of fits, amount of noise in the data). The obtained results highlight important properties of the different comparison methods. Together with the fact that all 5 considered methods are general in the sense that they place no restrictions on the type of models that can be compared, these results are, we believe, conducive to increasing the frequency with which more sophisticated comparison methods instead of the naïve approach will be employed for model evaluation and comparison.

The remainder of this article is structured as follows. First, we list and briefly describe all considered methods. Second, the employed models, contextual variations, and procedural details of the method comparison are described. Subsequently, comparison results are presented and discussed before we conclude our considerations and highlight topics for future work.

## Methods

The 5 methods we compared are the bootstrap, the bootstrap with standard error (SE) and confidence interval (CI), the data-uninformed parametric bootstrap cross-fitting method, henceforth called cross-fitting method (CM), the simple holdout, and the prediction error difference method (PED). Each of these was applied to 3 pairs of models and will be described in turn below.

## Bootstrap

Given a set of $n$ observations, the bootstrap method of model comparison proceeds as follows (see Efron \& Tibshirani, 1993, for an overview of bootstrapping procedures). First, an arbitrary but fixed number $B$ of bootstrap samples is generated. A bootstrap sample is a set of $n$ data points randomly drawn with replacement from the $n$ original observations. Due to sampling with replacement, most bootstrap samples will contain only a subset of all original observa-
tion (but some of these more than once). Second, each of the to-be-compared models is fitted to each bootstrap sample. Third, for each bootstrap sample, the fitted models are used to predict those data points that were not in the bootstrap sample and the deviation of the predictions from the original data points is measured (e.g., by the mean squared error). Fourth, the measures of deviation are combined for each model across all bootstrap samples to obtain an overall measure for the prediction error ( $\overline{E r r}$ ) of each model. The model that has the lowest $\overline{E r r}$ is assumed to be the best approximation to the process that actually generated the $n$ original data points.

Due to the randomness in generating the bootstrap samples as well as the noise that is likely included in the original observations, $\overline{E r r}$ only constitutes an estimate of the models' true prediction error. Accordingly, the model showing the lowest $\overline{E r r}$ may do so because of chance and not because it is the best model. Knowing the variability, that is, the SE, of the error estimates can potentially help alleviating this problem. Given the standard error, CIs on the true prediction error can be derived. If the CIs of the models' error estimates do not overlap, one may conclude with more confidencedepending on the confidence level employed to construct the intervals-that the model with the lower $\overline{E r r}$ in fact provides the better approximation to the process that generated the $n$ original data points.

In our simulations we assess both the bootstrap considering the SE and the bootstrap not considering the SE for deciding which of the two models is more appropriate. We construct the CIs by (a) computing the SE as proposed in Efron and Tibshirani (1997), (b) employing a confidence level of $99 \%$, and (c) assuming that the prediction error estimates are distributed approximately normal. The runtime complexity of both bootstrap variants is $O(B *$ fitCost $)$, where $B$ is the number of bootstrap samples and fitCost is the time complexity of estimating model parameters.

## CM

The CM was proposed by Wagenmakers, Ratcliff, Gomez, and Iverson (2004) as a way to assess to what extent two models are able to mimic each other's behavior. Since model complexity and the ability to mimic other models are often related, the obtained mimicry information potentially allows reducing the bias towards selecting more complex models.

The following steps are involved in the CM: First, for one of the models (say, model 1) a certain number, $N D S$, of sets of parameter values are randomly drawn from the feasible range of the model's free parameters. Second, model 1 is used to generate $N D S$ data sets employing each of the $N D S$ parameter value sets, respectively. Third, both models are fitted to each of the NDS data sets yielding NDS measures of goodness of fit (GOF, e.g., the mean squared error) for both models. Fourth, the pairwise GOF differences are computed for all datasets. By repeating these four steps for the second model (model 2), one obtains two distributions of GOF differences, one for data generated from model 1 and one for data generated from model 2.

Given a set of observations, these two distributions can be utilized to decide which of the two models provides the better account of the observations. Both models are fitted to the observations and the difference in the models' GOFs are computed. If the resulting difference is classified to more likely come from the distribution resulting from data generated from model 1 , model 1 is assumed to be more appropriate; otherwise the model 2 is assumed to be more appropriate.

Based on the results reported in Schultheis and Singhaniya (accepted), we employed a variant of the k-Nearest Neighbor algorithm $(k=10)$ for classification. The runtime complexity of the CM is $O(N D S *$ fitCost $)$.

## Simple Hold-Out

This method gauges the to-be-compared models by repeatedly splitting the set of available $n$ observations into a training and test set. For each of these splits, both models are fitted to the respective training set. The fitted models are then used to generate predictions for the data points in the test set and the corresponding prediction error is determined. Accordingly, using $I$ different splits results in $I$ prediction error values for each of the two models. The model that has the lower median prediction error is selected as the more appropriate model. The runtime complexity of the simple hold-out method is $O(I *$ fitCost $)$.

## PED

Similar to the simple hold-out the PED (van de Wiel, Berkhof, \& van Wieringen, 2009) employs $I$ splits of the original data set into training and test set to compare models. For both models the prediction error is computed for each point in the test set after fitting the models to the corresponding training set. Subsequently, pairwise differences between prediction errors for model 1 and model 2 are calculated. These signed error differences are subjected to signed rank tests to derive the probability of the observed distribution of signed ranks under the null hypothesis that the models do not differ in predictive accuracy.

Thus, the PED yields $I$ probability values. If the median of these values is below or equal to a pre-specified significance level $\alpha$, the models are assumed to be significantly different in their predictive accuracy and the model with the smaller prediction error is assumed to be the more appropriate model. In our simulations we used the Wilcoxon signed rank test with $\alpha=0.05$. The runtime complexity of the PED is $O(I *$ fitCost $)$.

## Method Properties

The procedural details of the methods described above imply a number of (differences in) crucial properties of the methods regarding model comparison.

First, the methods apply different criteria for judging the suitability of the compared models for a given data set. Both bootstrap variants, the PED, and the simple hold-out judge the models based on their ability to generalize to new data points, that is, these methods attempt to optimize what has
been called the generalization criterion (Busemeyer \& Wang, 2000). In contrast, the CM has been argued to be optimal "under the validation criterion of selecting the generating model" (Cohen et al., 2008, p. 698). Since our simulations check the methods ability to recover the generating model, they test the conjecture of (Cohen et al., 2008) or, more generally, examine to what extent methods employing different criteria perform (dis)similarly in model recovery.

Second, only the bootstrap without SE and the simple holdout method can straightforwardly be extended to the simultaneous comparison of more than two models. All other methods are (currently) restricted to comparing pairs of models.

Third, the bootstrap with SE and the PED are the only methods that explicitly take into account the statistical variability and reliability during comparison. This renders these methods potentially superior to the other methods, because statistically reliable decisions between models can be assumed to be more accurate. On the other hand this property comes with the potential disadvantage that no decision may be possible in certain situations ${ }^{1}$. Accordingly, the overall quality of the bootstrap with SE and the PED will depend on the precise tradeoff between how accurately a decision between models can be taken and the number of situations in which a decision is reached.

## Approach

Three hypothetical models of memory decay, $M 1, M 2$, and M3, were used to assess the model comparison methods. Each of these models predicts the probability of recall in dependance on the time $t$ that has passed since the to-beremembered items have been learned. The models are defined by the following formulas (see Pitt \& Myung, 2002):

$$
\begin{aligned}
& M 1:(1+t)^{-a}, a \in[0,2] \\
& M 2:(b+t)^{-a}, a \in[0,2], b \in[1,2] \\
& M 3:(1+b t)^{-a}, a \in[0,2], b \in[0,2]
\end{aligned}
$$

Note that $M 1$ is nested in both $M 2$ and $M 3$, but nesting is different in the two cases. Since, furthermore, $M 2$ and $M 3$ are not nested, the three models allowed to examine the comparison methods regarding their ability to cope with different types of nesting as well as non-nested models.

Each method was applied to all three possible pairs of models, $M 1$ vs. $M 2, M 1$ vs. $M 3$, and $M 2$ vs. $M 3$ using the following general procedure. Given one of the three models, first, a set of parameter values was randomly drawn according to a uniform distribution from the range of parameter values specified above. Second, probabilities for this set of parameter values were generated from the model. Third, these probabilities were used to randomly sample the number of successful

[^207]recalls from a binomial distribution assuming a certain number learned items $(N L)$. Fourth, this set of numbers of successful recalls was treated as if it was a set of empirical observations for which to identify the most appropriate model. Accordingly, the comparison method in question was applied as described above to the model pair and the set of observations. Fifth, which (if any) of the two compared models was found to be more appropriate was noted. This procedure was repeated $R=100$ times for each model in each model pair. Across all model pairs and methods the measure to assess model fits and prediction error was always the mean squared error and the models were fit using a variant of the Metropolis algorithm (Madras, 2002).

Following this general procedure, our simulations varied 5 factors that potentially impact the performance of the comparison methods. Besides allowing to assess the importance of each of these factors for method performance, factor variation ensured a more general view on the methods accuracy in model recovery, that is, a view that is not specific to only one particular combination of factor levels. The considered factors are tightness of fit, strength of noise, number of data points, number of samples, and split ration and are described in the following.

Tightness of fit Fitting a model to a set of observations is a specific instance of a general type of optimization problems: Find the optimal set of parameter values for the given observations. It is well known that one is rarely guaranteed to find the optimum in such optimization problems. Thus, model fits may often be suboptimal to greater or lesser extent. This raises the question how susceptible the different comparison methods are to suboptimal model fits. To investigate this, we considered 3 levels of tightness of fits by varying how thoroughly the Metropolis algorithm searches the models' parameter space. More precisely, we varied the number of sets of parameters that were sampled (called swaps) for model fitting, using swaps $=100,1000$, and 10000. Simulations looking at the rates for recovering the generating model when fitting to the probabilities directly (i.e., looking at model behavior without adding sampling noise) corroborated that these numbers of swaps realized increasingly accurate model fits.

Strength of noise Since the only noise in the data is sampling noise, the amount of noise in the data is determined exclusively by the number of learned items: The higher $N L$ is the lower is the influence of sampling noise. Accordingly, employing $N L=5,50$, and 1000 allowed to examine the methods' capability to cope with noisy data.

Number of data points The information about the process that has generated a set of data can be assumed to increase with the number of available observations in the data set. To what extent the different methods require few or many data points for performing well was explored by varying the number of data points $(N D P)$. Levels of $N D P=5,20$, and 100
were employed and the corresponding data points were generated for $t$ distributed equidistantly in the range $[0.1,8.1]$.

Number of samples All of the methods come with a parameter that controls the amount of resources that are invested for model comparison. For PED and simple holdout this parameter is the number of splits that are considered (I), for both bootstrap variants this parameter is the number of bootstrap samples $(B)$, and for the CM this parameter is the number of GOF difference samples (NDS) each GOF difference distribution consists of. By using $I=10,100,1000$, $B=100,1000$, and $N D S=100,1000$ we gauged the models resource-performance trade-offs.

Split ratio Application of the PED and the simple hold-out requires splitting the set of observations into training and test sets and the relative sizes of the two sets is potentially crucial for comparison performance. If the training set is too small, insufficient information about the generating process may be available. If the training set is too large, the danger of over fitting may arise and the test set may become too small to obtain a reliable estimate of generalization performance. In our simulations we investigated splits with $Q=0.2,0.4$, and 0.6 , where $Q$ indicates the fraction of the original observations that are used for the training set.

To assess the methods' ability to outperform less elaborate approaches to model comparison, our simulations comprise the Akaike Information Criterion (AIC, Akaike, 1973) as the sixth method and a seventh method that we term simple recovery. Following the same general procedure as described above, simple recovery compares models by only considering the GOF of each model on the given data set: The model that provides the tighter fit is assumed to be the more appropriate model. Simple recovery and AIC simulations involve the same variations of the factors tightness of fit, strength of noise, and number of data points as employed for the 5 more sophisticated methods.

## Results

To characterize the methods' performance we computed, for each method, model pair, and situation, the sum of the percentages of cases in which both (a) a clear decision between the two models of pair could be taken and (b) the actually generating model was correctly recovered. If, for example, for the model pair M1-M2, M1 was correctly recovered $90 \%$ of the time and M2 was correctly recovered $43 \%$ of the time, the performance measure was computed to be $90+43=133$. Similarly, for BSSE and PED the percentages of cases where no model could be recovered with certainty was computed as the sum of the percentages of such cases for each of the two compared models. ${ }^{2}$. From the such obtained values the first,

[^208]

Figure 1: Quartiles of performance for the three considered model pairs and the seven considered methods. $A I C=$ Akaike Information Criterion, $B S S E=$ bootstrap with standard error, SHO = simple hold-out, $C M=$ cross-fitting method, $B S=$ bootstrap, $S R=$ simple recovery,$P E D=$ PED method.
second (median), and third quartiles (and associated standard errors) were determined for each method and model pair across all situations. Figure 1 and Figure 2 display the quartiles for the different methods.

As is evident from Figure 1, there are marked performance differences between model pairs and comparison methods. As one may have expected, the nested model pairs generally prove more difficult than the non-nested model pair, with M1M3 being even more difficult than M1-M2. It is mainly in the nested pairs that the less elaborate methods, AIC and simple recovery perform worse than all of the 5 more elaborate methods. Of the 5 more elaborate methods, PED, simple hold-out, and BSSE generally outperform BS and CM. In sum, PED, simple hold-out, and BSSE tend to perform best, AIC and simple recovery perform worst, and CM and BS show intermediate performance, but are only better than AIC and simple recovery for nested model pairs. As Figure 2 shows, the superior performance of PED and BSSE comes at the cost of a substantial number of cases in which the two methods do not allow to take a clear decision for one or the other model.

Several aspects of this pattern of results seem noteworthy. In contrast to the assumption that the CM is optimal for recovering the generating model (Cohen et al., 2008), the CM performs comparatively bad. On average, the CM is only better than SR for nested models, and generally worse in avoiding misclassifications than the PED, BSSE, and the simple hold-out. In fact, given its comparative simplicity, the simple hold-out performs remarkably well. While providing a decision for $100 \%$ of the cases, these decision are correct in more than $90 \%$ of the cases on average. This set of results also provides further evidence for dissimilarity in model recovery performance depending on whether a generalization criterion or a model recovery criterion is instantiated by the employed comparison method. Comparing the simple hold-out and CM indicates performance differences depending on which criterion is used and, more interestingly, that a method using the generalization criterion can outperform a method using the recovery criterion in model recovery.

In addition to the results across all factor combinations, considering the impact each factor has on method performance yields a number of interesting insights.

Tightness of fit Across all methods, the influence of the tightness of fit (if present at all) is only considerable between loose fits $($ swaps $=100)$ and moderate to tight fits (swaps $=1000$ and 10000). In simple recovery, the tendency to select the more complex models increases with tightness of fits such that for moderate and tight fits the nesting model is selected more often even if the nested model generated the data. Except for pair M1-M3, performance of AIC increases considerably with tighter fits. In comparison, the bootstrap with SE and the CM, exhibit less (but still noticeable) susceptibility to tightness of fit in the sense that with tighter fits for nested model pairs the overall correct recovery rate increases by selectively increasing the correct recovery rate of

Figure 2: Quartiles of the number of cases for which BSSE and $P E D$ do not allow to take a decision.
the nesting model. Put differently, for loose fits, the CM and the bootstrap with SE tend to erroneously favor the simpler model; a problem that is mitigated when using tighter fits. The remaining three methods are largely insensitive to tightness of fits indicating that, for these methods, it may not be the absolute but the relative tightness of fit that matters.

Strength of noise Not surprisingly, all methods get consistently better with decreasing strength of noise. Furthermore, all methods encounter severe difficulties with the highest noise level $(N L=5)$ that leads to near chance performance for most model pairs and methods. The methods differ, however, regarding the level of noise from which they start to show good or very good performance. While the simple holdout, the bootstrap with SE and the PED achieve high accuracy already for $N L=50$, the CM and the bootstrap tend to do so only for $N L=1000$.

Number of data points Although all methods but the AIC tend to improve with an increase in the number of data points, there are marked differences with respect to the strength of the influence of this factor. The PED and the bootstrap with SE are impacted severely by the number of data points improving considerably - especially for nested models - with an increase from $N D P=5$ to $N D P=20$ as well as from $N D P=20$ to $N D P=100$ both regarding accuracy and the percentage of decision that can be made. The other four methods are much less sensitive to $N D P$ levels, but exhibit a tendency for a reduction in erroneously selecting a nested model when the data was generated from a nesting model. Interestingly, the performance of the AIC drops with increasing NDP due to an increased tendency to erroneously pick the nested model.

Number of samples Effects of increasing the number of samples are mixed across the methods. This factor has virtually no effect on the bootstrap. Yet, for the bootstrap with SE increasing the number of samples leads to a decrease in the percentage of cases in which a decision can be made and to a tendency to more often select the simpler of the two compared models. Both PED and simple hold-out perform better with increased $I$, but this trend is largely due to the difference between $I=10$ and $I=100$. Similar to the bootstrap with SE, the PED allows (slightly) fewer decision with increasing $I$. The CM exhibits a shift towards more often selecting the more complex model with increased numbers of samples.

Split ratio The split ratio has only little impact on the performance of the PED and the simple hold-out. While the number of cases that cannot be decided by the PED slightly increases with an increase in $Q$, the accuracy remains generally high. Only for comparing $M 1$ and $M 3$ do higher values of $Q$ lead to pronounced performance decrements. Similarly, the simple hold-out becomes slightly but consistently worse in correctly recovering the nested model in the two nested model pairs with an increase in $Q$.

## Conclusion

Our simulation studies revealed a number of interesting properties of the considered comparison methods. First, methods employing a generalization criterion for model comparison (e.g., simple hold-out) can outperform methods supposedly optimal for model recovery (the CM) in model recovery. Second, although all 5 considered methods can substantially improve on less elaborate approaches (as instantiated by the AIC and the simple recovery method), the less elaborate methods may perform better under certain conditions. Thus, whether the use of one of the examined methods is advantageous will depend on the precise nature of the model comparison situation at hand (e.g., how many data points are available and how noisy the data is). Third, the considered methods differ noticeably in the degree to which their performance depends on the characteristics of the comparison situation. The comparatively low quartiles of the bootstrap and the CM indicates that these methods outperform the less elaborate approaches only in comparatively few particular settings. Fourth, the highest accuracies were achieved by the PED, but this method allows decisions about which of the compared models is more appropriate only in very few cases. Furthermore, performance of the PED breaks down if only few data points are available. Fifth, despite its comparable simplicity, the simple hold-out method achieves high accuracies while allowing to select one of the models in $100 \%$ of all cases. In addition, the simple hold-out is the only method that can be easily extended to comparing more than two models.

Against this background our results suggest to employ the PED if only pairs of models have to be compared and if accuracy is more important than being able to reach a decision. The simple hold-out appears to be a good choice if more than
two models need to be compared and / or if it is important to reach a decision on which of the compared models to select.

Although this initial assessment already highlights important properties of the comparison methods, it is best viewed as a first glimpse on the methods' characteristics. Further research considering a range of different (types of) models is required to provide a more comprehensive picture of the strengths and weaknesses of available comparison methods. Besides taking up this task we intend to explore modifications of the CM, PED, and bootstrap with SE that renders them applicable to comparing more than two models in our future work.

# Rational preference shifts in multi-attribute choice: What is fair? 

Pradeep Shenoy (pshenoy@cs.washington.edu)<br>Microsoft AdCenter, Bangalore, India<br>Angela J. Yu (ajyu@ucsd.edu)<br>Department of Cognitive Science, UC San Diego, 9500 Gilman Dr. MC 0515<br>La Jolla, CA 92093 USA

#### Abstract

Humans exhibit certain systematic context-dependent preference reversals when choosing among options that vary along multiple attribute dimensions. For instance, the attraction, similarity, and compromise effects each involves a change in relative preference between two options when a third option is introduced. Previously, such effects have been attributed to irrationality or suboptimality in decision-making, or to specific architectural or dynamical constraints on cognition. We use a Bayesian model of multi-attribute choice to demonstrate that these effects naturally arise from three basic assumptions: (1) humans assess options relative to "fair market value" as inferred from prior experience and available options; (2) attributes are imperfectly substitutable, and scarce attributes are relatively more valuable; (3) uncertainty about market conditions and option values contributes to stochasticity in choice behavior. This work provides both a novel normative explanation for contextual modulation of choice behavior, and a means to predict choice as a function of past experiences and novel contexts.

Keywords: multi-attribute decision-making; preference shift; context effects; attraction effect; compromise effect; similarity effect

## Introduction

Everyday decision-making often involves choosing among options that differ in multiple attribute dimensions. For example, should you buy a house that is more spacious or one that is better located? Understanding how humans make these multi-attribute decisions, and how their choices depend on the context, is an important problem in cognitive science.

Multi-attribute decision-making is particularly challenging because there is often no universal or intrinsic way to assign relative values to the different attributes. This is especially true in contexts where the decisionmaker has limited experience (and thus significant uncertainty about market conditions), such as with big-ticket items like houses, or new technology like smart phones. Human choice behavior in multi-attribute problems exhibits certain systematic shifts due to context changes, such as when the relative preference between two options shift or even reverse when a third option, known as a decoy, is added, leading to suggestions of underlying irrationality or suboptimality (Kahneman \& Tversky, 1979; Kahneman, Slovic, \& Tversky, 1982; Tversky \& Simonson, 1993).

In the attraction effect (Fig. 1A), given two similarly preferred options, $A$ and $B$, the introduction of a third option $Z$ that is similar to $B$, but also clearly inferior to $B$ in one or both attribute dimensions, results in an increase in relative preference for $B$ over $A$ (Huber, Payne, \& Puto, 1982; Heath \& Chatterjee, 1995). In the compromise effect (Fig. 1B), when $B>A$ in one attribute and $B<A$ in another attribute, and $Z$ has the same tradeoff but is even more extreme than $B$, then $B$ becomes the "compromise" option and becomes preferred relative to $A$ (Simonson, 1989). In the similarity effect (Fig. 1C), the introduction of a third option $Z$, that is very similar and comparable to $B$ in both attribute dimensions, shifts the relative preference away from $B$ to A (Tversky, 1972).

Figure 1: Three classical contextual effects in multiattribute choice: (A) attraction effect, (B) compromise effect, (C) similarity effect. $A$ and $B$ are two equally preferable choices that differ in two attribute dimensions. The introduction of a third option $Z$ induces a preference shift between $A$ and $B$ (indicated by arrows). Solid and dashed lines illustrate model-inferred "fair value" indifference curve before and after introducing $Z$.

Two broad classes of models have previously been proposed for contextual effects in multi-attribute choice behavior: (1) normative models (Marr, 1982) that are built on behavioral constraints/goals and delineated in terms of internal beliefs and assumptions (Luce, 1959; Thurstone, 1954; Luce, 1965; Tversky, 1972; Tversky \& Simonson, 1993); (2) algorithmic or implementational models that explain behavioral phenomena as arising from specific architectural and dynamical constraints on neural processing (Busemeyer \& Townsend, 1993; Usher \& McClelland, 2004; J. S. Trueblood, 2012).

The first class of models are related to bounded rationality (Simon, 1955), but have so far been unable to explain all three contextual effects, leading to sugges-
tions that such preference shifts reflect biases or suboptimalities in human decision-making. For example, the discovery of the similarity effect invalidated Luce's early ratio-of-strength model (Luce, 1959), and other related models that follow the simple scalability principle (Tversky, 1972). Tversky proposed the elimination-byaspects model (Tversky, 1972) to explain the similarity effect, but it was invalidated by the discovery of the attraction effect, which violates the regularity principle, thus ruling out a large class of random utility models (Luce, 1965), including Thurstone's preferential choice theory (Thurstone, 1954). The compromise effect presented further complication, as no previous model could account for it, and a new context-dependent preference model (Tversky \& Simonson, 1993) was only able to account for it, along with the attraction effect, by letting slip the similarity effect (Roe, Busemeyer, \& Townsend, 2001).

The second class of models can account for all three effects, but are based on rather detailed and specific assumptions about neural dynamic and architecture, which have thus far not been verified experimentally, and whose computational provenance and consequences are unclear.

Here, we propose a novel rational account of multiattribute decision-making that explains all three contextual effects. The model is grounded in three basic, empirically motivated assumptions: (1) humans make preferential choices based on relative values anchored with respect to what is perceived "fair" in the marketplace (Ariely, 2008), which is inferred from observed data, including the set of available options (Wernerfelt, 1995; Sher \& McKenzie, 2011); (2) different attributes are imperfect substitutes for one another (Hicks, 1932), in particular one unit of a scarce attribute is more valuable than an abundant one; (3) uncertainty in posterior belief about "market conditions" contributes to stochasticity in preference on repeated presentations of the same options (see e.g., Debreu, 1958). We formalize these assumptions using a Bayesian generative model, and demonstrate that all three contextual effects are consequences of rational (Bayesian) inference of relative value, conditioned on the available options. In contrast to previous models, we view each decision as not only an expression of choice, but also as an opportunity for learning about the marketplace based on the set of options given. Thus, an individual's preference can differ in different contexts, not because of arbitrary contextdependent factors (Hsee, Zhang, Yu, \& Xi, 2004; Srivastava \& Schrater, 2012), but because of normative evolution of an individual's internal beliefs about the option landscape. Moreover, our model provides a means to predict individual and group preferences in novel contexts given past choices. In the following, we first describe the Bayesian model, followed by a comparison of simulated model behavior and empirically observed contextual ef-
fects found in the literature, and finally conclude with a discussion.

## Bayesian model of relative value inference

We begin with an intuitive explanation for contextual effects before delving into the technical details of the model. While we explain the phenomena primarily in terms of consumer decision-making here, in the Discussion we will extend the model and explanation beyond choices among consumer products.

We model presented options as being drawn from a shared landscape of options, which implies that the options are representative of the market in some sense, and are useful for inferring general market conditions. In fact, humans often use available context to infer a reference point for valuation-for instance, in the framing effect, humans evaluate the quality of an outcome differently based on whether it is described in terms of success rates or failure rates (Sher \& McKenzie, 2006). In the case of multi-attribute valuation, "fair market value" could potentially be inferred by fitting an equi-preference contour, or indifference curve (Pareto, 1927), through the presented options, where points above the line would be a "good deal", while ones below would be a "bad deal." Given the formal relationship between regression and inference (Bishop, 2006), this process is equivalent to inferring mean market value and relative attribute importance based on the samples. We first use this general intuition to explain the three effects, and subsequently present a precise generative model and inference procedure for multi-attribute choice.

In the attraction effect, $A$ and $B$ both initially lie on the inferred "fair value" indifference curve. Introducing $Z$, which is close to $B$ but clearly inferior in one or both attribute dimensions, drives down the inferred "fair value" indifference line (dashed line) near $B$, making $B$ appear to be a good deal (while $A$ is still fair, and $Z$ is worse than fair). The compromise effect arises from imperfect substitutability and diminishing marginal utility (Hicks, 1932) - e.g. the value of a small house in a good location would increase much more with a small increase in size than it would with a slight improvement in location. Thus, the indifference curves, including the fair value curve, should be strictly convex rather than linear. The compromise effect then naturally arises when $Z$ is introduced, because the convex line corresponding to "fair" passes between $B$ and $Z$, making $B$ appear to be better than fair (and $A$ fair or worse than fair). To account for the similarity effect, we adopt a stochastic decision policy that reflects posterior uncertainty about both market conditions and option values: the model samples from the joint posterior distribution over option values and chooses the maximally valued option. Because of the proximity of $B$ and $Z$ in the attribute
space, inferred values of $B$ and $Z$ are highly correlated. For each possible setting of market conditions (family of indifference curves), $B$ and $Z$ tend to be both better or worse than $A$. This gives an overall probability of choos$\operatorname{ing} A$ with $1 / 2$ probability, and choosing $B$ (and also $Z$ ) with $1 / 4$ probability.

## Model

$$
\begin{aligned}
& \mu \sim \Gamma\left(k_{\mu}, t_{\mu}\right) \\
& \gamma \sim \beta\left(a_{\gamma}, b_{\gamma}\right) \\
& \theta_{i} \sim \mathcal{N}\left(0, \sigma_{\theta}^{2}\right) \\
& v_{i} \sim \Gamma\left(k_{v}, \frac{\mu}{k_{v}}\right) \\
& o_{i} \sim \mathcal{N}\left(f\left(v_{i}, \theta_{i}, \gamma\right), \sigma_{o}^{2} \mathbf{I}\right) \\
& f\left(v_{i}, \theta_{i}, \gamma\right)=\left(v_{i}^{\frac{1+\theta_{i}}{2 \gamma}}, v_{i}^{\frac{1-\theta_{i}}{2(1-\gamma)}}\right)
\end{aligned}
$$

Figure 2: Bayesian generative model of relative value inference. Each two-attribute option $o_{i}=\left(x_{i}, y_{i}\right)$ has an underlying scalar value $v_{i}$, parameterized by $\gamma, \theta_{i}$. The value $v_{i}$ itself is generated from a prior distribution with mean $\mu$, which corresponds to "fair" value.

The critical assumptions in our model are that subjects use available options to infer about the utility function and "fair market value." We assume subjects do so by inverting a hierarchical Bayesian generative model (Fig. 2), where: (1) values $\left\{v_{i}\right\}$ for the set of options $\{i\}$ are drawn from a prior distribution with mean $\mu$, and (2) 2-d attribute values for each option, $o_{i}$, is generated from $v_{i}$ according to a common utility function and then corrupted by observation noise. For simplicity, we use the classical Cobb-Douglas utility function (Douglas, 1976), parameterized by $\gamma, v_{i}=x_{i}^{\gamma} y_{i}^{(1-\gamma)}$. While more complex utility functions can be used, for example to take into account variability in the relative scaling of the two attributes, the contextual effects are not dependent on the choice of utility function, and thus not dealt with further here. To model observation noise, we first map value into an indifference curve in the attribute space by inverting the utility function, then add Gaussian noise along the indifference curve (parameterized by $\theta_{i}$ ) and isotrophic 2-D Gaussian noise (parameterized by $\sigma_{0}$ ). We expect the main results to hold independent of the specific choices of model parameterization.

Subsequent to doing posterior inference, we assume humans choose an option by first sampling from the joint posterior $P(\mathbf{v} \mid \mathbf{o})$, and then (always) choosing the option with the highest sampled value. The computation of the posterior requires marginalizing over unceratinty about market conditions through a series of steps:

$$
P(\mathbf{v}, \mathbf{o}, \mu, \gamma)=p(\mu) p(\gamma) \Pi_{i}\left[\int_{\theta_{i}} p\left(\theta_{i}\right) P\left(v_{i} \mid \mu\right) P\left(o_{i} \mid \theta_{i}, v_{i}, \gamma\right)\right]
$$

Figure 3: Preference shifts as rational inference. (A) Model chooses $A$ and $B$ equally when there are only two options. (B) Attraction: introducing the inferior $Z$ makes $B$ more preferable to $A$ ( $Z$ is almost never chosen). (C) Compromise: introducing an extreme option $Z$ makes $B$ more preferable to $A$. (B) Similarity: introducing $Z$, highly similar to $B$, makes $B$ less preferable to $A$.

$$
P(\mathbf{v} \mid \mathbf{o}) \propto \int_{\mu, \gamma} P(\mathbf{v}, \mathbf{o}, \mu, \gamma)
$$

## Simulation details

The parameter settings for our simulations were as follows: $\left(k_{\mu}, t_{\mu}\right)=(1,100) ;\left(a_{\gamma}, b_{\gamma}\right)=(2,2) ; \sigma_{\theta}=20 ; k_{v}=$ $20 ; \sigma_{o}=2$ (see Fig. 2). The Gamma distributions were parametrized using parameters for shape ( $k_{\mu}$ ), and scale $\left(t_{\mu}\right)$, and the mean of the corresponding distribution is given by their product (e.g., $k_{\mu} \cdot t_{\mu}$ ). Accordingly, the mean of the prior distribution over $\mu$ is 100 , and the shape parameter encodes a broad uncertainty about the true value of $\mu$ (see Fig. 4).

We finely discretized each of the variables in our model to calculate the relevant posterior distributions numerically (analytical solutions do not exist). The option values used (see Fig. 1) were as follows: $A=(40,60), B=$ $(60,40)$; attraction: $Z=(30,50)$, compromise: $Z=$ $(80,20)$, similarity: $Z=(65,35)$.

## Results

## Preference shift as option-based value inference

As Fig. 3 shows, simulations of our model reproduces all three contextual effects: attraction, compromise, and similarity. In particular, the model reproduces violation of regularity in attraction effect that is also seen in human data. In all three cases, although options $A$ and $B$ are equally preferred when presented as a pair (Fig. 3A),
the presence of a third (decoy) option $Z$ changes this relative preference (Fig. 3B-D). This shift in preference depends on the relationship between the precise attribute values of the decoy relative to those of the two original two options (see Fig. 1). All three contextual effects were obtained using the same model setting, except for the position of the decoy $Z$. Thus, these contextual shifts in preference can indeed be direct consequences of normative inference about relative values, conditioned on both prior beliefs and the available options. Note that the main results hold over a wide range of parameter settings and are not sensitive to the particular parameterization of the model.

Figure 4: Posterior distributions over model variables for the compromise effect. (A) Marginal posterior distribution over what constitutes "fair" in the market, parameterized by $\mu$, before (red) and after (green) introducing Z. (B) (A, B) Marginal posterior distribution over the shape of the family of indifference curves, parameterized by $\gamma$, before (red) and after (green) introducing $Z$.

We explore the compromise effect in more detail to illustrate the inner workings of our model. The joint inference over $(\mu, \gamma)$ is reflected in the shape of the equipreference contours and the probability of each contour being "fair" (Fig. 5): colored bands represent indifference curves for the MAP estimate of $\gamma$ and a range of values of $\mu$, and the color indicates the probability of that band representing fair market value. When only options $(A, B)$ are presented (Fig. 5A), the fair market value contour passes through both $A$ and $B$; when $Z$ is introduced (Fig. 5B), the contours shift so as to make $B$ better than fair (and $A$ fair).

Next, we examine the properties of the inferred joint posterior distribution $P(\mathbf{v} \mid \mathbf{o})$, illustrated in Fig. 6. Shown in panel A are the marginal value distributions for the 3 options $A, B, Z$ in the compromise effect. Consistent with Fig. 5, the inferred value distributions show a clear ordering, with option $B$ having the highest expected value (Fig. 6B). However, the marginal distributions (panel A), and expected values (panel B) do not capture implicit correlations among inferred values induced by the shared (marginalized) variables $\mu$ and $\gamma$. In fact, our model samples from the joint posterior value distribution and selects the highest value in each sample. Fig. 6C shows the the empirical probability of each

Figure 5: Joint marketplace and value inference in the compromise effect: (A) given only $A$ and $B$ as options, (B) given $A, B, Z$. Each colored band represents an equipreference contour (indifference curve) corresponding to the MAP estimate of $\gamma$, with its color indicating the probability of its being the mean market value.

Figure 6: Value inference and sampling in compromise effect. (A) Posterior distributions over option values. (B) Mean posterior value. (C) Empirical choice distribution based on samples $(\mathrm{n}=1000)$ from the joint posterior distribution over option values.

Figure 7: Value inference and sampling in similarity effect. See Fig. 6.
option being chosen. In the joint distribution, $A$ and $Z$ are positively correlated in inferred value, and, as a result, our model strongly prefers the compromise option $B$ over $A$, stronger than would be suggested by the marginal distributions alone.

Correlations in the joint posterior value distribution is particularly important also for generating the similarity effect (Fig. 7), where the marginal distributions and mean values for $A$ and $B$ are indistinguishable from each other, but the sampled preference for $A$ is much higher, due to a strong positive correlation between the inferred values of $B$ and $Z$.

## Model predictions

Our model makes a number of experimentally testable predictions about multi-attribute choice behavior. Since presented options not only influence the immediate choice but also general beliefs about general market conditions, our model predicts systematic consequences in future choice behavior based on experienced choice history. For instance, subjects exposed to a number of choices between options generally higher in one attribute may correspondingly learn a $\gamma$ that discounts this attribute more - resulting in a smaller attraction effect for a decoy that is inferior to $B$ in this attribute dimension compared to the other. There is some evidence that subjects show such "context-dependent utility functions" (Drolet, Simonson, \& Tversky, 2000).

Another arena for experimental exploration suggested by this work is the transition among the different effects due to the precise positioning of the options in the attribute space: for instance, the "similarity" decoy in Fig. 1C could well turn into a "compromise" decoy in Fig. 1B, if it were far enough from $B$. Thus, one prediction of our model is that as the decoy $Z$ is moved away from the option $B$, while maintaining a rough tradeoff between the two attributes, the contextual effect changes from similarity effect to compromise effect. That is, if the decoy were exactly the same as $B$, preference should shift away from $B$, but as the decoy is moved further apart, preference should shift toward $B$. In an analogous manner, we expect to see a smooth transition between the similarity and attraction effects as the decoy is moved away in the orthogonal, dominated direction. Fig. 8 shows that model simulations conform to these expectations: as the decoy is moved further along nondominated (panel A) or dominated (panel B) directions, the model predicts a gradual evolutation from a similarity effect to the compromise and attraction effects, respectively.

## Discussion

We presented a normative Bayesian model for why human subjects exhibit apparently irrational choice behavior in multi-attribute decision-making. We showed that violations of the simple scalability and regularity principles need not be reflections of an irrational or suboptimal decision or valuation process, but rather rational consequences of a decision-maker who is trying to optimize choice in a relativistic system anchored to what is perceived to be fair. We used a normative, hierarchical Bayesian generative model to demonstrate how the set of options themselves can be used to infer about the landscape of available options, such as how value is distributed in the market, how the multi-dimensional observed attribute space is mapped to the scalar value representation, and the distribution of observation noise. Although the language of this paper primarily focuses on

Figure 8: Transitions in relative preference. The three effects are related to each other by the magnitude of the distance between options. (A) When a third option $Z$, initially identical to $B$, is moved away in a nondominated direction, relative preference changes from favoring $A$ (similarity effect) to favoring $B$ (compromise effect). (B) When $Z$ is moved away from $B$ in an orthogonal, dominated direction, preference changes from favoring $A$ (similarity effect) to favoring $B$ (attraction effect).
consumer decision-making, the model can be extended to a much broader range of multi-attribute choice behavior, whenever the observer has uncertainty about how to combine two attributes in order to compare the options. In future work, we plan to extend the current model to explore some non-consumer choice tasks known to exhibit context effects (Choplin \& Hummel, 2005; J. S. Trueblood, 2012; J. Trueblood, Brown, Heathcote, \& Busemeyer, n.d.).

Our approach contrasts with the class of models that explain contextual effects based on specific architectural or dynamic constraints on neural processing. One example is the decision field theory (DFT) model (Busemeyer \& Townsend, 1993), which assumes that the strength of preference for each option is driven by a noisy, accumulative input and dynamical switching of "attention" among different attribute dimensions, as well as "lateral inhibition" between the different units. A related model (J. S. Trueblood, 2012), an extension of the multiattribute linear ballistic accumulator model (Brown \& Heathcote, 2008), employs attentional switching, a contrast mechanism (related to lateral inhibition), and sensitivity to indifference/dominance. A third model, the competing accumulator model (Usher \& McClelland, 2004), assumes loss aversion in addition to attentional switching and lateral inhibition. The various overlapping and nonidentical assumptions of these process models are difficult to verify experimentally, and their computational provenance/constraints are not well understood. This is not to say that such mechanistic models are not useful. Ultimately, to understand how the brain implements multi-attribute choice, we need multiple levels of analysis (Marr, 1982) that integrate both normative and mechanistic explanations. In this vein, our work comple-
ments existing work by helping to frame and constrain mechanistic models.

Although the model presented here succinctly and rationally accounts for contextual effects in multi-attribute choice behavior, it is clearly not a complete theory of human preference choice. In particular, the simple model presented here has no means of accounting for individual differences according to taste. A natural way this arises is when people bring in different previous experiences and thus prior beliefs about the market. However, this cannot be the whole story, as any prior difference would be overwhelmed by sufficient data, and yet people who have repeated exposure to the same choices do not always converge in their preferences (e.g. office workers who eat out at the same set of neighborhood restaurants day after day). An important line of future enquiry is how individual differences in preference may arise and persist in the face of mounting, common experiences.

# Automatic and Instructed Attention in Learned Predictiveness 

Lauren T. Shone (Isho0771@uni.sydney.edu.au)<br>Evan J. Livesey (evan.livesey@sydney.edu.au)<br>School of Psychology, Brennan McCallum Building, University of Sydney, NSW 2006 AUS

#### Abstract

In novel situations, learning is biased towards information that has a degree of prior predictive utility. In human learning, this is termed the learned predictiveness effect and has proved critical in theorising about the role of attention in learning. Two experiments are reported in which the relative contribution of controlled and automatic processes to learned predictiveness are investigated. Experiment 1 showed that while learned predictiveness is susceptible to instructional manipulation, this effect is partial. Experiment 2 manipulated predictive utility and instruction orthogonally in order to test the potential involvement of automatic processes. It was found that even when cues were explicitly instructed as causal, learning was biased in favour of previously predictive over previously non-predictive cues. Interestingly, this was reversed for cues instructed as irrelevant. This suggests that learned predictiveness benefits attentional control, whereby information is both easier to attend and ignore.

Keywords: human learning, attention, controlled processing, automatic processing

## Introduction

An important question facing theories of associative learning is the nature of the relationship between learning and attention. Accordingly, many associative theories (e.g., Kruschke, 2001; Mackintosh, 1975; Pearce \& Hall, 1980) accept that stimulus selection is influenced by attentional processes. Such theories share the basic assumption that the attention devoted to a stimulus is flexible, and governed by its past utility in predicting events. Importantly, this will subsequently influence the rate at which a stimulus enters into future associations.

Evidence in favour of learned attention originates from experiments in which past predictive utility biases learning in a novel situation. A robust example, first reported by Le Pelley and McLaren (2003; see also Lochmann \& Wills, 2003), is the learned predictiveness effect. The basic experimental design used to demonstrate the effect is shown in Table 1. Participants are initially exposed to a scenario in which they are required to learn a causal relationship between cues and outcomes. Each trial consists of the presentation of a compound of two cues, leading to one of two outcomes. Critically, each compound consists of one perfectly predictive cue (represented by A - D), and one non-predictive cue ( $\mathrm{W}-\mathrm{Z}$ ). For example, A is consistently paired with the outcome O1, and therefore has perfect predictive utility. Alternatively, W has no predictive utility because it is paired equally often with both outcomes O1 and O2.

Once these relationships have been learned, a novel scenario is introduced. The same cues, in novel
combinations, are then employed in order to predict different outcomes. Importantly, although the cues are again presented in compound, this time neither component has superior predictive utility. That is, both A and W are perfect predictors as they share the same objective relationship with outcomes O3 and O4 respectively. What differs between the components of the new compounds is their status as a predictive or non-predictive cue in the initial stage of learning. Subsequent tests reveal that more is learned about the relationship between previously predictive cues and the new outcomes compared to previously non-predictive cues.

Table 1. A typical learned predictiveness design.

| Phase 1 | Phase 2 | Test |
| :---: | :---: | :---: |
| $\mathrm{AW}-\mathrm{O} 1$ | $\mathrm{AY}-\mathrm{O} 3$ | AD |
| $\mathrm{AX}-\mathrm{O} 1$ | $\mathrm{BZ}-\mathrm{O} 4$ | XY |
| $\mathrm{BW}-\mathrm{O} 2$ | $\mathrm{CW}-\mathrm{O} 4$ | BC |
| $\mathrm{BX}-\mathrm{O} 2$ | $\mathrm{DX}-\mathrm{O} 3$ | WZ |
| $\mathrm{CY}-\mathrm{O} 1$ |  |  |
| $\mathrm{CZ}-\mathrm{O} 1$ |  |  |
| $\mathrm{DY}-\mathrm{O} 2$ |  |  |
| $\mathrm{DY}-\mathrm{O} 2$ |  |  |

Note. Letters indicate individual cues. O1-O4 refer to four outcomes.

Traditionally, this bias, consistently replicated across various scenarios (see Le Pelley, 2010, for a recent review), has been interpreted to suggest that attention is modulated by the difference in predictive validity during initial stages of learning. According to this logic, attention to $\mathrm{A}-\mathrm{D}$ will be high following phase 1 and will therefore have an advantage when entering into new associations during the second phase. This effect has proved critical in theorising about the reciprocal nature of the relationship between human learning and attention.

The learned predictiveness effect is consistent with models of associative learning that assume attention changes according to mechanisms of associative competition (e.g., Mackintosh, 1975; Le Pelley, 2004; Pearce \& Mackintosh, 2010). For example, Mackintosh (1975) proposed that changes in the association between a cue and an outcome are governed by both attention paid to the cue and the discrepancy between the occurrence of the outcome and the extent to which it is already predicted on the basis of that cue, that is, the prediction error for an individual cue. Critically, attention to the cue changes according to a
comparison between its prediction error and the prediction error for other cues available at the same time. The cues with smaller individual prediction errors (i.e. those with higher predictive utility) will command more attention as learning proceeds. Higher attention, in turn, drives faster learning.

Despite its replicability, the exact nature of the learned predictiveness effect has only recently been questioned. Indeed, the concept of attention is associated with a variety of cognitive mechanisms (see Pashler, 1998; Wright \& Ward, 2008, for a review), raising the question of which processes critically characterise the effect. For example, in demonstrations of learned predictiveness there is often a high degree of conceptual similarity between scenarios. One possibility, therefore, is that the effect is governed by a simple heuristic arising from inferential reasoning. That is, it is possible that participants make the explicit assumption that the predictive utility of cues A - D will transfer across similar contexts (Mitchell, Griffiths, Seetoo, and Lovibond, 2012).

According to this explanation, learned predictiveness should be susceptible to manipulations of inferred beliefs. Indeed, Mitchell, et al., (2012) have provided evidence in support of this view. In their Experiment 2, inferences were directly manipulated across phases by way of instruction. At the onset of the second phase, participants in the continuity condition were explicitly instructed that the same cues would be relevant. Alternatively, those in the change condition were instructed the opposite, that previously predictive cues were now irrelevant. Critically, this condition revealed a complete reversal of the effect. That is, more was learned about the relationship between previously irrelevant cues and the novel outcomes. That learned predictiveness is sensitive to variations in explicit reasoning suggests a role for controlled, volitional attentional processes in explaining the effect.

However, there is evidence to suggest that the presence of the inference alone is not sufficient to produce the learned predictiveness effect. For example, Le Pelley et al. (2010a) investigated the expression of learned predictiveness adopting a procedure in which the critical relationships were embedded in text form. Interestingly, they failed to observe the effect; the attentional bias was only observed when the relevant information was presented in trial and error form across multiple trials. This is contrary to what would be expected if explicit causal attribution was the sole mechanism responsible for this bias. Similarly, related paradigms have found opposing influences of training and instruction on learned attentional responses (Le Pelley, Mitchell, \& Johnson, 2013). Taken together these findings raise the possibility that learned predictiveness reflects the operation of a combination of inferential and non-inferential processes.

As noted previously, learned predictiveness has taken an important role in theorising about learned attention. A common feature of such theories is the assumption that attentional changes are automatic in response to the
formation of associations between events (e.g., Kruschke, 2001; Le Pelley, 2004; Mackintosh, 1975; Pearce \& Mackintosh, 2010). According to this view, because associations between predictive cues and outcomes increase rapidly during phase 1 of a learned predictiveness experiment, these cues are automatically attended. Thus, previously predictive cues will capture attention at the start of phase 2, such that associations between these cues and novel outcomes are facilitated. Importantly, this process does not rely on a deliberate attempt by the individual to control attention in a biased fashion according to the nature of the phase 1 relationships.

While the results of Mitchell et al. (2012) appear to oppose this explanation, there is reason to suggest that their experimental design did not provide the conditions under which the presence of automatic processes could be adequately detected. For example, their demonstration relies on a definitive manipulation: Non-predictive cues were explicitly emphasised as important. If it is assumed that controlled attention is capable of modulating the expression of automatic processes, given the appropriate conditions, then it is possible that the manipulation was too strong, overriding the influence of automatic attention. Thus, although this manipulation demonstrates that learned predictiveness is susceptible to voluntary control via instruction, it does not test whether automatic processes also contribute to the effect under uninstructed conditions.

Further, the scenario employed, in which fictitious seeds grow different trees, potentially favours a more categorical inferential process whereby the outcome is most likely attributable to only one of the cues and not the other. This aspect of the design may have facilitated a complete reversal based on conceptual aspects of the scenario in addition to the manipulation of interest.

Therefore, the relative contribution of controlled and automatic processes to the learned predictiveness effect remains to be fully specified. The aim of the present experiments was to investigate this relationship.

## Experiment 1

Experiment 1 made use of the same instructional manipulation employed by Mitchell et al. (2012), albeit with a different cover scenario, in order to replicate their original result. The allergist scenario, employed in numerous demonstrations of learned predictiveness (e.g., Le Pelley \& McLaren, 2003) was used in which participants were asked to play the role of a doctor who must discover the allergies of a fictitious patient. The cues consisted of different foods, which predict the occurrence of various allergic reactions, serving as outcomes. At the start of phase 2, a new patient was introduced who consumed the same foods, but suffered novel reactions. As before, participants were required to discover which foods were leading to which reactions. The structure of the training phases is shown in Table 1 and reflects the standard learned predictiveness design. At the start of phase 2, one group of participants (the "same"
condition) were told that it was likely that both patients were allergic to the same foods, whereas those in the "change" condition were instructed that their two patients likely suffered from allergies to different foods.

In line with the findings of Mitchell et al. (2012), we anticipated that the bias in learning observed in learned predictiveness would proceed according to the instructions issued at the start of phase 2 training.

## Method

Participants Forty-eight University of Sydney students (27 female, 21 male; age $18-24$ ) participated in the experiment.

Apparatus and Stimuli All experiments were conducted on Apple Mac Mini computers attached to a $17-\mathrm{in}$. monitor, and programmed in PsychToolbox for Matlab (Brainard, 1997; Pelli, 1997). Foods were randomly allocated for each participant to serve as cues $\mathrm{A}-\mathrm{Z}$ in the experimental design, and consisted of: Coffee, Fish, Lemon, Cheese, Eggs, Garlic, Bread, and Peanuts. Similarly, four allergic reactions were randomly allocated to serve as the four outcomes, and were: Headache, Nausea, Rash, and Fever.

Procedure After being randomly allocated to either the same or change conditions, participants were instructed that their task was to learn which foods were causing which allergic reactions in a fictitious patient. They were told that on every trial, two foods that the patient had eaten would be presented. On being shown the foods, participants were required to predict which of two allergic reactions would occur.

Phase 1 consisted of the eight trial types shown in Table 1. Each of these was presented once in each of 16 blocks of trials. The order of trials was randomised across blocks. Each trial was followed by feedback stating whether their prediction was correct, as well as providing the actual allergic reaction experienced.

At the start of phase 2, participants were told that they now had a new patient and, as before, would be required to learn which foods were causing which allergic reactions. Those in the same condition were told that their new patient was allergic to the same foods as their previous patient, whereas those in the change condition were instructed that their new patient was allergic to different foods.

Phase 2 consisted of 16 blocks, each of which contained one of the four trial types shown in Table 1. As before, trial order was randomised within blocks and feedback was provided after each trial.

A test phase was administered immediately following phase 2. All cues were presented individually and in a randomised order throughout this phase. On each test trial, a cue would appear and participants were asked to indicate whether the cue had been paired with outcome 3 or outcome 4. This was done by making a rating on a linear analogue scale, labelled "Definitely goes with [outcome 3]" on the
left anchor, and "Definitely goes with [outcome 4]" on the right anchor.

Finally, a manipulation check was included to ensure that participants had remembered the instructions at the start of phase 2. Participants were presented with both sets of instructions and required to report which of those applied to their patient. There were no exclusions on the basis of this check.

## Results

Phase 1 For each block, accuracy was averaged across the eight compound trials to gauge acquisition. Accuracy increased consistently across training. A mixed-measures analysis of variance (ANOVA) with block (1-16) and condition (same vs. change) as factors revealed a significant main effect of block, $F(15,690)=40.1, p<.001$, but no significant effect of condition, $F<1$, and no block $\times$ group interaction, $F<1$, suggesting that the two groups learned at an equivalent rate in phase 1 .

Phase 2 A mixed-measures ANOVA examining phase 2 acquisition showed a significant effect of block, $F(15,690)$ $=44.13, p=<.001$, as well as a significant block $\times$ group interaction, $F(15,690)=2.1, p<.05$. The effect of condition did not reach significance, $F(1,46)=3.95, p=$ . 053 .

Figure 1. Learning scores for the same and change conditions for previously predictive and previously nonpredictive cues

Test data A learning score for each cue was calculated by combining accuracy for memory of the cue-outcome pairings in the test phase with the magnitude of the rating. This yielded a score out of 100 for each cue, with higher scores indicating better retention. Scores could range between 100 and -100 . Scores were averaged according to whether they were predictive ( $\mathrm{A}-\mathrm{D}$ ) or non-predictive (W -Z ) in phase 1 . These are shown for the same and change conditions in Figure 1.

Scores were subjected to a mixed-measures ANOVA with group (same vs. change) and cues (predictive vs. nonpredictive) as factors. Averaged over cue, there was no significant difference between the same and change conditions, $F<1$. Similarly, there was no effect of cue, $F<$ 1. However, as suggested by Figure 1, this resulted from a significant cue $\times$ group interaction, $F(1,46)=8.79, p<.05$.

This was further investigated with a simple effects analysis, which revealed that learning scores for predictive cues was higher than non-predictive cues in the same condition, $F(1,23)=11.51, p<.05$. The difference between predictive and non-predictive cues did not differ significantly in the change condition, $F<1$.

## Discussion

Our data provide a partial replication of Mitchell et al. (2012). While the same condition showed a standard learned predictiveness effect, this was abolished rather than reversed in the change condition. That is, there was no difference between previously predictive and previously non-predictive cues when participants were told that non-predictive cues were informative for the second phase.

Overall, a clear effect of instruction was observed making use of a scenario in which it is less likely that causal attribution is biased towards categorical reasoning. This suggests that the result of Mitchell et al. (2012) is not entirely a consequence of the conceptual structure of their scenario, further validating the influence of voluntary control on learned predictiveness.

However, it is important to note that our reversal was incomplete in the critical condition. On the basis of the current design, it is unclear why this should be the case. It is possible that the results from the change condition reflect competition between opposing inferential and automatic processes. While automatic processes would bias learning in favour of previously relevant cues, explicit inference favours irrelevant cues.

Alternatively, there may be added difficulty in the change condition. If more is learnt about the predictive cues in phase 1 , this means that they may be required in order to confirm the new object of attention, that is, the previously irrelevant cue. That is, if the explicit identity of the previously irrelevant cues is uncertain due to the fact that little learning has proceeded to these cues, then previously relevant cues may be actively used to guide responding. This is an additional process that is not necessary in the same condition.

Given that the reversal design does not allow the contribution of automatic processes to be assessed, Experiment 2 used an orthogonal manipulation of predictiveness in phase 1 and instruction to further test the relative contribution of voluntary and automatic processes.

## Experiment 2

Experiment 1 confirmed that learned predictiveness is susceptible to the manipulation of inferred beliefs. In Experiment 2, we aimed to further test the involvement of automatic processes. This was done by orthogonally manipulating the predictive status of cues in the first phase and the instructional manipulation. The design of Experiment 2 is shown in Table 2. The first phase of training was identical to that seen in Experiment 1. At the end of the initial training phase, all participants were told explicitly which foods the new patient was allergic to. However, two of those cues were previously predictive, while two were previously non-predictive. That is, they were told that the new patient was allergic to cues A and C , and X and Z .

This means that there were two cues ( A and C ) that were predictive in phase 1 , and known to cause allergies in the new patient, and two previously predictive cues ( B and D ) known not to be allergens. Similarly, of the previously nonpredictive cues, two ( Z and X ) were now known to cause allergies, and the remaining two ( Y and W ) known to be safe. The design therefore creates the condition in which an unambiguous instructional manipulation is present without removing the opportunity to observe an automatic influence of phase 1 training, if indeed it is present.

Table 2. Design of Experiment 2.

| Phase 1 | Phase 2 | Test |
| :--- | :--- | :--- |
| $\mathrm{AW}-\mathrm{O} 1$ | $\underline{\mathbf{A} Y-\mathrm{O} 3}$ | A |
| $\mathrm{AX}-\mathrm{O} 1$ | $\mathrm{~B} \underline{\mathbf{Z}}-\mathrm{O} 4$ | B |
| $\mathrm{BW}-\mathrm{O} 2$ | $\underline{\mathbf{C W}}-\mathrm{O} 5$ | C |
| $\mathrm{BX}-\mathrm{O} 2$ | $\mathrm{D} \underline{\mathbf{X}}-\mathrm{O} 6$ | D |
| $\mathrm{CY}-\mathrm{O} 1$ |  | W |
| $\mathrm{CZ}-\mathrm{O} 1$ |  | X |
| $\mathrm{DY}-\mathrm{O} 2$ |  | Y |
| $\mathrm{DY}-\mathrm{O} 2$ |  | Z |

Note. Letters indicate individual cues. Underlined letters indicate cues instructed as informative for phase 2. O1-O6 refer to six outcomes.

If, as suggested by the findings in Experiment 1, controlled processes are in operation, then a clear influence of instruction should be observed whereby more will be learned about cues $A, C, X$, and $Z$ in the second phase. However, if automatic attention favouring predictive cues is also present, then a difference should also be observed between instructed cues according to whether they were relevant ( A and C ) or irrelevant ( X and Z ) in the first phase. Given the advantage conferred by predictive utility, this predicts that more should be learned about A and C compared to X and Z .

## Method

Participants Participants comprised twenty-four University of Sydney students ( 20 female, 4 male; age $18-23$ ).

Apparatus and Stimuli Experimental stimuli remained the same as that employed in Experiment 1, with the exception that two additional allergic reactions were introduced to account for added outcomes in the design. These were Coughing and Sweating.

Procedure Phase 1 training and instructions remained identical to that used in Experiment 1. Following phase 1, participants were told that they were now observing the allergies of a new patient, but that they would be provided with a set of foods that the patient was allergic to. They were shown the names of four foods, corresponding to cues A, C, X, and Z and were informed that they would need to learn which of these corresponded to the various reactions that the patient was experiencing.

Given that foods were named explicitly, a shorter phase 2 with fewer trials per cue was employed. Participants completed four blocks, each block consisting of one of the four trial types shown in Table 2. On each trial, participants were now required to predict which of four allergic reactions would occur.

During test, each cue was displayed individually in random order. The four outcomes were displayed on screen and participants were asked to indicate which of these the cue had been paired with. This was followed by the appearance of a rating scale, asking how confident they were in their response. The left anchor was labelled "Not at all confident", and the right anchor labelled "Very confident".

Finally, the manipulation check required participants to report the instructed allergens of the second patient. Five participants were excluded, having failed to report this content, leaving 19 participants in the analysis.

## Results

Phase 1 Acquisition across blocks increased steadily for phase 1. A repeated-measures ANOVA showed a significant main effect of block on accuracy, $F(15,270)=13.01, p<$ . 01 .

Phase 2 Overall, accuracy increased during phase 2, resulting in a significant main effect of block on accuracy, $F(3,54)=12.95, p<.01$. However, acquisition varied according to whether a compound contained an instructed component that was previously predictive or an instructed component that was previously non-predictive, such that accuracy was significantly higher for the former (AY/CW higher than BZ/DX), $F(1,18)=7.25, p<.05$. The interaction was not significant, $F<1$.

Test data Accuracy scores, shown in Figure 2, were subjected to a repeated-measures ANOVA with
predictiveness (predictive vs. non-predictive) and instruction (instructed vs. ignored) as factors. This revealed a significant main effect of instruction, $F(1,18)=18.28, p<$ .01 , as well as a significant instruction $\times$ predictiveness interaction, $F(1,18)=10.6, p<.01$. The effect of predictiveness failed to reach significance, $F<1$.

A simple effects analysis investigating the interaction showed that for instructed cues, accuracy was significantly higher for previously predictive cues, $F(1,18)=5.7, p<$ .05. Interestingly, this was reversed for the remaining cues, such that accuracy was significantly higher for previously non-predictive cues, $F(1,18)=6.4, p<.05$.

Figure 2. Accuracy scores for previously predictive and previously non-predictive cues at test in Experiment 2 for the instructed and ignored conditions.

## Discussion

Consistent with the findings in Experiment 1, there was clearly an effect of instructional manipulation. However, the learned predictiveness effect was still evident amongst cues known to be allergenic. That is, more was learned about the previously predictive cues compared to previously nonpredictive cues, despite the explicit knowledge that both sets of cues were allergens. This is consistent with the involvement of automatic processes transferred from initial learning.

However, it is interesting to note that the opposite pattern emerged for cues that were not instructed as allergens, and would presumably be ignored by participants. Thus it appears that previously predictive cues were easier to ignore when known to be irrelevant. This may reflect a general benefit of prior predictive utility whereby attention is more easily directed either towards or away from stimuli in novel situations.

Alternatively, the difference in acquisition during phase 2 between compounds that contained instructed components that were previously predictive (AY and CW) and nonpredictive (BZ and DX) raises the possibility that some sort of automatic interference from phase 1 means that less is learned in general about phase 2 compounds in which participants have to attend to the previously non-predictive cue and ignore the previously predictive cue. If these
compounds were indeed more difficult to learn, despite explicit instruction, this would result in the observed lower accuracy for instructed, yet previously irrelevant cues at test.

## General Discussion

The experiments reported above suggest that a purely inferential account of learned predictiveness is insufficient to fully characterise the effect. However, it is clear that proposing an additive influence of inferential reasoning and automaticity is similarly inadequate as the results reported here suggest an interaction between the two.

For example, in phase 2 of Experiment 2, participants were given information that directly informed them which cues the patient was and was not allergic to. Even though participants could have ignored the non-causal cues completely, some learning of the cue-outcome relationships was evident. The result of interest regarding these noncausal cues was that previously predictive stimuli were learned about more poorly than previously nonpredictive stimuli. If the effects of the prior predictive history of the cues simply added or subtracted from selective attention in an automatic fashion then one would expect the opposite result for this incidental learning. That is, the predictive cues should be learned about more readily than the nonpredictive. This result suggests an interaction between control of attention and the effects of prior predictive history, which is not explained by either an inferential account nor the conventional associative account of learned predictiveness.

Accordingly, there are a growing number of studies that show that the learned predictiveness effect does not operate via the competitive associative algorithms of attentional change described by Mackintosh (1975; Le Pelley, 2004; Pearce \& Mackintosh, 2010). For instance, Le Pelley et al., (2010b) found that competition between cues in compound was not necessary for learned predictiveness to occur, and Livesey et al. (2011) found no evidence that direct comparison between predictive and nonpredictive cues affected the magnitude of learned predictiveness at all. The current study demonstrates another way in which the automatic allocation of attention appears to behave differently from model predictions. Although there appears to be a relatively automatic influence of the previous history of the cues, that influence only matches the predictions of associative learning theories for cues that are deliberately attended and not those that are deliberately ignored.

Clearly an important step in implementing attentional processes within models of human learning will require further investigations into the mechanisms responsible for biases in learning related to past predictive utility. Such biases remain to be fully specified with regards to how information is attended and ignored.

# Communication Leads to the Emergence of Sub-optimal Category Structures 

Catriona Silvey (C.A.Silvey@sms.ed.ac.uk), Simon Kirby, Kenny Smith<br>Language Evolution and Computation Research Unit, School of Philosophy, Psychology and Language Sciences, University of Edinburgh, Dugald Stewart Building, 3 Charles Street, Edinburgh, EH8 9AD, UK

#### Abstract

Words divide the world into labeled categories. Languages vary in the categories they label, sometimes to the point of making cross-cutting divisions of the same space. Previous work suggests two opposing hypotheses about how communication contributes to category emergence: 1) these spaces lack an objective shared similarity structure, and communication dynamically creates one of a number of optimally shareable category structures; 2) the category structures resulting from communication are not necessarily optimal, but diverge from a shared similarity space in language-specific ways. We had participants categorize images drawn from a continuous space in two conditions: a) non-communicative, by similarity, b) communicative, dynamically creating categories when playing a partnered communication game. The memory demands of communication lead to reliance on salient images and early conventions, resulting in non-optimal category structures compared to non-communicative participants. This supports the hypothesis that communication leads to categories that diverge non-optimally from a shared similarity space.

Keywords: communication; category structure; category emergence; language evolution

## Introduction

Words divide the world into labeled categories. Languages vary in the categories they label, with some languages making coarser, finer, or even cross-cutting distinctions relative to how other languages carve up the same space (Bowerman \& Choi, 2001; Malt, Sloman, \& Gennari, 2003). Work is ongoing to quantify and classify this variation (Majid, Jordan, \& Dunn, in progress). The mechanism by which a set of labeled categories emerges in a given language is however unclear. One hypothesis is that at least for some domains (e.g. spatial relations, containers), there is no one perceptually obvious way to divide the space into categories: there are several potential ways an individual observer could draw category boundaries (Bowerman, 2000). Some researchers have built on this idea to suggest that the process of communication itself structures a previously unstructured space, making categories that are optimally shareable between communicators (Freyd, 1983; Markman \& Makin, 1998; Steels \& Belpaeme, 2005; Voiklis \& Corter, 2012). However, cross-linguistic work by Barbara Malt and colleagues on similarity perception versus labeling shows that, while the labeled categories of different languages do indeed diverge from each other, speakers of different languages still perceive the similarities between the objects in comparable ways (Malt, Sloman, Gennari, Shi, \& Wang, 1999). This suggests that the categorization systems of different languages can in fact superimpose a range of divergent structures on a space that has a shared underlying similarity structure. These two accounts suggest radically different roles for communication in the emergence of categories.

The current experiment contributes to this debate by investigating how humans categorize a set of images designed to have unclear category boundaries. The participants categorize the images in one of two conditions: a noncommunicative condition, where solo participants divide the images into categories according to similarity, and a communicative condition, where pairs of participants play a communication game with the images. The results shed light on the effect of communication on category structure, suggesting that the categories created by communication can and do diverge from a relatively shared similarity space, even in a stimulus set designed to have ambiguous boundaries.

## Method

Participants were assigned to two conditions. In the noncommunicative condition, participants divided a continuous space of images into labeled categories on the basis of similarity. In the communicative condition, pairs of participants played a communication game using the same continuous space of images. Participants in this condition produced labeled categories via the words they used to communicate each target image in the last two rounds of the experiment. The category systems the participants produced in the two conditions were then compared.

## Stimuli

The set of images used in the experiment is shown in Figure 1. The four corner images were generated using PsychoPy software (Peirce, 2007). For each image, a random number generator assigned x and y positions for the five vertices, and the resulting shape was drawn. Morphs between these images were then generated by shifting the vertices towards each of the corners, according to a weight defined by inverse Euclidean distance (Matthews, 2009), to create a total set of 25 images. The 'objective' Euclidean distance between the images in the space may of course not correspond to perceptual similarity (see, e.g., Smith \& Heise, 1992); however, in pilot experiments, participants showed variation in where they drew the category boundaries, making these stimuli suitable for the current study.

## Labels

To control for any effects on participants' categorizations arising purely from the use of labels (Lupyan, Rakison, \& McClelland, 2007), words to label the categories were provided in both the non-communicative and communicative conditions. Lists of 25 CVCV nonsense words were generated by combining consonants and vowels randomly selected

Figure 1: The stimuli used in the study (lines thickened for clarity).
from the whole alphabet (e.g., zipi, gisa, wada). Since we expected that participants would use known crossmodal associations between attributes of words and attributes of the images in assigning category labels (e.g. voiceless stops and spikiness, Nielsen \& Rendall, 2011), we assigned the same wordlist to a yoked triple of two non-communicative participants and one communicative pair, so that in the analyses, any peculiar effects of a particular wordlist would apply equally across the conditions.

## Participants

Participants were 42 students at the University of Edinburgh (30 female, median age 23). 20 took part in the noncommunicative condition. The non-communicative experiment took 15 minutes. Participants were paid $£ 2.22$ participants (randomly assigned into 11 pairs) took part in the communicative condition. The communicative experiment took an hour. Participants were paid $£ 7$, and each member of the pair with the highest communication score was awarded a $£ 10$ Amazon voucher. One pair failed to complete the experiment within an hour and so was excluded from analyses.

## Procedure

Non-Communicative Condition Participants were presented with a randomized onscreen array of all 25 images and a set of words to label categories. To avoid cueing the participants to produce a particular number of categories, only one word was initially shown on screen: participants could reveal new words at any time, and were told that a) they could use as few or as many words as they wanted, and b) they did not have to use all the words they had revealed. Participants could reveal a new word at any stage, up to 25 words. They were instructed to label similar images with the same word and different images with different words.

Communicative Condition Participants communicated via computer terminals in separate cubicles. In a communication trial, one participant was assigned as the sender and one as the receiver. The sender was presented with a randomized onscreen array of all 25 images, one of which was selected with a red box to indicate it was the target. The sender was also presented with one initial word. The sender could reveal a new word at any stage, up to 25 words. Any words they had revealed on a previous trial remained visible on their screen for all subsequent trials. The participant was instructed to choose a word that would help the receiver pick out the target from the array of images.

Once the sender had picked a word, the receiver was presented with a randomized onscreen array of all 25 images and the word the sender had chosen. The receiver was instructed to select the image the sender had wanted to communicate.

Once the receiver selected an image, both participants were presented with a feedback screen. The feedback screen showed the word the sender had used, the target image, the image the receiver had selected, the score for the trial, and the running score for the whole experiment. The score for each trial was calculated on the basis of the inverse Euclidean distance between the target and the image the receiver selected, from a minimum of 1 up to a maximum of 15 (for correctly picking the target).

After each communication trial the sender and the receiver swapped roles. The experiment consisted of 100 communication trials divided into 4 rounds. Each round featured the 25 images as targets in a randomized order. The randomized lists were balanced such that each participant was the sender for every target image once in the first half of the experiment, and once in the second half.

The first two rounds of the experiment were not incorporated into the categorization analysis, as it was expected that at this stage a system would still be emerging. Participants' categories were therefore taken from the last two rounds of the experiment. Success scores were taken from the whole experiment.

## Dependent Variables

Number of Categories The number of categories each participant produced was recorded.

Variation in Category Size To achieve a measure of variation in category size that took the number of categories into account (since more categories would generally contain fewer images each), the number of images in each category was divided by the expected number of images in each category, if images were distributed equally. For example, if a participant had 5 categories, an equal distribution would be to place 5 images in each category: if one of their categories in fact had 10 images, this would produce a value for that category of $10 / 5=2$. The range of these values was then taken as a measure of variation in category size adjusted for the number of categories (with a minimum value of 0 in the case of perfectly balanced categories).

Category Alignment Two measures were taken to compare participants' categories and quantify their alignment. The first, the Rand index (Rand, 1971), consists of a pairwise comparison of whether participants tended to place images in the same category or different categories. The calculation produces a value bounded from 0 to 1 , where 1 is perfect alignment. The second, V-Measure (Rosenberg \& Hirschberg, 2007), is based on variation of information between the groupings, normalized to compensate for differences in number of categories. This measure also ranges from 0 to 1 where 1 is perfect alignment. Two further measures, the Variation of Information measure on which V-Measure is based (Meilă, 2003) and an adjusted version of Cramer's phi (Wills \& Mclaren, 1998) were considered, but were found to produce incongruent results when applied to groupings with divergent numbers of categories. Since the variable of interest was participants' categories rather than the words they used, the alignment measures were taken irrespective of whether participants used the same words: i.e., if two participants put the same set of images in a labeled category but used different labels, they would count as fully aligned for this category.

## Hypotheses

For the non-communicative participants, there is no particular incentive to divide the images into more or fewer categories (beyond the minimal assumption that, in being asked to sort the images, the participants are unlikely to place them all in one category). This condition therefore functions as a baseline for assessing the variability of the participants' categorization of the images without communication. The expectation is that with no strong motivation to behave in any particular way, participants' categorization performance will vary.

For the communicative participants, the pressures on their emergent categorization systems are more complex. The only way to attain a perfect communication score with this stimulus space and scoring system is to have a unique label for each image, i.e. 25 words in total, with 25 corresponding categories containing one image each. However, participants' memory constraints will likely prevent this from happening in the experiment. More generally, then, for a given number of words, the optimal strategy is to apply each word to an equal number of images in the space, in a contiguous region (Gärdenfors, 2000). Participants who converge on a system like this would maximize their possible score across all rounds of communication. Figure 2A shows an example of this kind of optimal system. When the sender uses a word corresponding to one of the categories, the receiver can adopt the strategy of picking a central member of the category, thus ensuring their response is a maximum of 1.4 Euclidean distance units (or one diagonal step) from the target. Figure 2B shows, by contrast, a non-optimal system with the same number of categories. This system is non-optimal for two reasons. 1) The number of images in each category is less balanced (one category contains only two images, while another contains ten). This means that when the sender uses the word for the bigger category, the probability of the receiver selecting

Figure 2: A) An example of a category system optimally structured for communicative success. B) A non-optimal system with the same number of categories.
an image close to the target is lower. 2) The images belonging to some categories are spread across different regions of the space and do not form contiguous regions. This raises the probability of a receiver selecting an image some distance away from the target, even if she shares this set of categories with the sender. It is worth noting that the spaces we categorize in the real world may not have this kind of smooth continuous structure, and so the regular contiguous regions of Figure 2A may be more difficult to achieve. However, in the context of this experiment, if communication does give rise to optimally structured categories, this is the kind of system we would expect to see emerging.

## Results

A linear trend ANOVA found that communicative success increased over the 4 rounds of the experiment, $F(1,9)=18.66$, $p=.002$ (Figure 3). Participants' overall success was significantly above chance, $t(9)=4.21, p=.002$.

Participants in the communicative condition used significantly more labeled categories $(M=9.95, S D=3.98)$ than participants in the non-communicative condition $(M=6$, $S D=1.37$ ), Mann-Whitney $U=60, z=-3.54, p<.001$. Communicative participants also showed significantly more variance in how many labeled categories they used, Levene's test $(1,36)=16.47, p<.001$. Pairs who communicated together, however, showed no significant difference in the number of categories they used, $t(18)=-0.38, p=.7$, showing that this effect came from differences between, rather than within, communicative pairs. Thus, even though the noncommunicative participants had less motivation to converge on a particular number of labeled categories, they were more consistent in the number they produced than the communicative participants.

Participants in the communicative condition also varied significantly more in the size of their categories, when number of categories was taken into account (category size variation as described in Methods $M=1.54, S D=0.35$, compared to non-communicative participants, $M=1.17, S D=0.4$ ). That is, images were more unevenly distributed across categories in the communicative condition, $t(38)=3.13, p<$ .005. Surprisingly for the communication-as-alignment hypothesis, communicative pairs' groupings did not align sig-

Figure 3: Average communicative success over rounds in the experiment. Dotted line shows chance. Error bars show 95\% confidence intervals.
nificantly more than non-communicative participants' (bylanguage analysis: paired-samples $t$-test $0.47<t(9)<0.63$, $p>.5$, by-subjects analysis: independent $t$-test $-0.42<$ $t(18)<0.63, p>.4)$. Neither did communicative success correlate significantly with either of the alignment measures, $r<.51, p>.14$.

To test the hypothesis that communicative participants within a pair were more aligned than communicative participants who were not paired with each other, an analysis was run comparing the alignment scores for the true pairs with alignment scores for shuffled pairs (participant 2 paired with participant 3, etc.). A similar analysis was run for the non-communicative pairs, comparing alignment of those who shared the same wordlist with those who had different wordlists. Non-communicative participants displayed equivalent levels of alignment whether or not they used the same wordlist, $t(9)<0.8, p>.58$. For communicative participants, one of the alignment measures (Rand index) tended towards being significantly higher for participants who communicated in a pair than participants who did not, $t(9)=1.88$, $p=.093$, suggesting that communicative participants were marginally more aligned within-pair than between-pair in terms of which pairs of images they categorized together. For the second alignment measure, V-Measure, no significant difference was found, $t(9)=1.22, p>.25$.

## Discussion

The results are somewhat surprising for the hypothesis that communication creates optimal structure in previously variably structured spaces. Communicative participants produced categorizations that were generally non-optimal for maximizing communicative success, as defined in Hypotheses above. This is not merely a property of how humans perceive this particular space, as shown by the contrast with the non-communicative condition, where participants' categories

Figure 4: A) A typical non-communicative participant's categories. B) A typical communicative participant's categories.
were generally more balanced in size, carving up the space in a way that would actually be more optimal by this definition. Figure 4 shows a typical example of A) a non-communicative participant's categories and B) a communicative participant's categories. It is notable that several categories in B are also non-optimal in that they cover non-contiguous regions of the space (e.g. red and yellow categories). The heatmaps in Figures 5 and 6 show more generally how communicative participants' categories were more dispersed (Figure 6) compared to non-communicative participants, who tend to clump more around certain pairings or groups to form their categories (darker regions in Figure 5).

Why did communicative participants divide up the space so differently from non-communicative participants? As mentioned in Hypotheses above, the communicative task exerts a considerable memory demand on participants: although they are presented with the full image space on each trial, they still have to remember which word applies to which image or group of images over the course of the experiment. This exerts a pressure to create a system that is optimized not just for communicative success, but also for learnability.

Aids to learnability in this experiment might include particularly salient words, images, and pairings between them, or felicitous early successes that lead to the forming of conventions. These conventions, once established, may then prove too valuable to shift in favor of more optimally structured categories. Both of these aids to learnability (salient images/words and early successes) are mentioned by participants in the post-experiment questionnaire. Typically, when asked to draw the images they remember, participants could draw from memory two to five salient images and their associated words, but were unclear on other regions of the space. Thus the memory demands of the task, and the fact that participants have to establish a system from scratch, make the salience of individual images and early established conventions important factors determining the shape of each participant's final categorization system.

The possibility that different images in the set had differing salience is also supported by the success heatmaps in Figure 7. The heatmap in Figure 7A shows which target images led to higher success scores for participants. The pattern here is at odds with Figure 7B, which shows the relative expected

Figure 5: Heatmap visualizing how often non-communicative participants placed pairs of images in the same category. Darker areas indicate pairs more often categorized together.
chance levels of success for each image: images in the middle have more low-ED neighbors, so the probability of a higher score goes up when they are the target. The fact that panels A and B differ shows that participants' success with particular images is boosted by some other factor.

Panel C shows a heatmap of this boost - darker images are those whose overall communicative success rate is highest compared to what the chance-based map in panel B would predict. The likely explanation is that these images have higher salience for participants, making them act as Schelling points between sender and receiver. The striking finding that communicative success is not correlated with overall alignment could therefore be explained by participants consolidating success on a few images, leaving other areas of the space more sparsely covered.

While Figure 7 suggests that the salience of particular images may be shared across all pairs, early conventions are

Figure 6: Heatmap visualizing how often communicative participants placed pairs of images in the same category. Darker areas indicate pairs more often categorized together.
more likely to vary between pairs due to the randomized presentation of targets. This could explain the tendency towards higher pairwise (Rand index) alignment within pairs than between pairs, as reported in the Results. Despite the low levels of alignment overall, communicative pairs' language-specific early conventions may bring them more into agreement on how they categorize specific small groups of images.

As mentioned above, the pressures on the participants in the two conditions were substantially different: participants in the non-communicative condition interacted with the stimuli more briefly and without memory constraints, as well as lacking the pressure to create more categories imposed by the communicative task. Future work could investigate how participants divide up the space non-communicatively under the same time and memory constraints as the communicative participants, thus disentangling the effects of these constraints from the effects of communication. The noncommunicative condition in this study still serves as a useful

B) Map of expected chance success rates per image. C) Difference between maps A and B. Darker images are those whose success rates are boosted highest beyond expected.
baseline, however, for participants' perceptually based divisions of the space.

The outcome of this study - that communication does not necessarily optimize category structures, but can create uneven and suboptimal structures compared to noncommunicators' division of the same space - is reflected in our experience of real language, where words vary widely in whether they specify small regions of semantic space or broad undifferentiated regions. The existence of the latter kind of word does not necessarily mean the users of the language do not perceive the differences between sub-parts of the region it covers: only that, for reasons of salience, or constraints imposed by the history and development of conventions in the language, these internal differences lack category labels. An important additional pressure in real language, not modeled in this study, is that different regions of semantic space may also have different functional importance, motivating coarser or finer-grained distinctions in different regions. However, these results show that even in the absence of functional reasons for uneven division of a space, communication can lead to the establishment of categories that may not align with noncommunicative similarity perception.

## Conclusion

Communication is not a simple process of mapping words onto pre-shared perceptual categories. Even if communicating partners agree on the underlying structure of the space they are talking about, the categories that emerge from communication can diverge in surprising ways, both from the underlying similarity space and from the category structure that would be most optimal for communicative success. Constraints on learning, salience effects, and the impact of early conventions on a language's development all contribute to shaping an emergent system of labeled categories.

# Encoding time and allocation of attention in analogical development 

Nina Simms (ninasimms@ northwestern.edu)<br>Department of Psychology, 2029 Sheridan Road<br>Evanston, IL 60202 USA

Dedre Gentner (gentner@ northwestern.edu)<br>Department of Psychology, 2029 Sheridan Road<br>Evanston, IL 60202 USA

#### Abstract

The aim of the current studies was to explore encoding time differences in objects and relations and to investigate whether these differences lead to differences in allocation of attention to object similarity. Using a match-to-sample paradigm with 5 - to 6 -year-olds and adults, we found that (1) objects were encoded faster than relations for both adults and children, and that (2) children, but not adults, preferentially allocated attention to object similarity. Ultimately, these questions are aimed at identifying the factors responsible for the development of adult-like analogical reasoning. We suggest that changes in selective attention over development may account for the pattern of results seen across these two studies.

Keywords: analogical development; relational reasoning; selective attention; encoding time

## Introduction

Reasoning by analogy is a fundamental and powerful aspect of human cognition (Gentner, Holyoak \& Kokinov, 2001). Analogical reasoning is based on relational similarity. That is, two situations are analogous if they share a common relational structure (e.g., lava lamps and plate tectonics are both characterized by a system of convection); superficial commonalities like the perceptual features of the objects involved are generally irrelevant. However, reasoning on the basis of relational similarity is not trivial. Two analogous situations may share superficial commonalities that conflict with an alignment based on relational similarity. For example, to appreciate that $1: 3$ :: 3:9, one must understand that the relationship that holds between 1 and 3 is the same relationship that holds between 3 and 9 . Based on this shared relationship, the two smaller numbers in each proportion correspond $(1 \rightarrow 3)$ and the two larger numbers correspond $(3 \rightarrow 9)$. In this case, the identity match between the two 3s must be disregarded, since this correspondence (3 $\rightarrow 3$ ) is inconsistent with the overall relational match.

Although 1:3 :: 3:9 may not seem like a particularly challenging analogy for adults, instances where relational similarity conflicts with object similarity can be very challenging for young children (Gentner, 1988; Richland, Morrison \& Holyoak, 2006) In cases like these, children will often reason on the basis of object similarity rather than relational similarity. This tendency is referred to as the object bias, but over development (with age as well as experience), a relational shift occurs whereby children
become increasingly adept at reasoning on the basis of relational rather than object similarity (Gentner \& Rattermann, 1991).

For example, Gentner and Toupin (1986) gave 6-year-old children a simple story and asked them to reenact it with new characters. They performed well when the corresponding characters were highly similar between the two stories, but performed very badly when similar characters played different roles across the two stories (the cross-mapped condition). Further studies have corroborated this finding that when relational similarity is pitted against object similarity children tend to be highly influenced by object matches and less able to attend to relational matches. For example, Richland and colleagues (2006) found the same pattern of results in a picture-matching task. The pictures depicted the same event structure, and the task was to point out correspondences based on the event patterns. When the object matches were inconsistent with the relational match, younger children were greatly impeded in choosing the correct relational match. This pattern of results, in which object similarity disrupts young children's analogical reasoning, has been found repeatedly in a variety of analogical tasks (Gentner \& Rattermann, 1991) and even across cultures (Richland, Chan, Morrison, \& Au, 2010).

The object bias is a robust and well-documented phenomenon, but a clear understanding of why it occurs is still lacking. Most accounts of analogical development that address the object bias implicitly or explicitly appeal to some processing difference (or differences) between objects and relations to explain the bias. Some of these differences include representational complexity, familiarity or fluency, salience, and automaticity. Improvements in relational reasoning over development are then explained by changes in this processing difference, and/or by improvements in some additional capacity that tempers the effects of these processing differences. For example, accounts of analogical development that emphasize the role of relational knowledge suggest that children are familiar with more object concepts than relational concepts, but as children gain more relational knowledge, and as this knowledge becomes more fluent, they become able to focus on relational similarity (Gentner, 1988, 2003). Other accounts appeal to the idea that object similarity is more salient than relational similarity, and that improvements in inhibitory control over development allow children to combat the
influence of salient object similarity when reasoning about relations (Richland et al., 2006).

Without a clear understanding of the processing differences between objects and relations, it is difficult to precisely explain the object bias and to pinpoint what changes over development to decrease this bias. Thus, the goals of the present studies are to: (1) investigate one operationalization of processing differences in objects and relations, namely encoding time; (2) explore how encoding time differences impact analogical reasoning, in particular how it affects allocation of attention; and (3) examine how these patterns change over development.

Encoding time differences are a promising potential difference to investigate for a number of reasons. First, of the many proposed processing differences between objects and relations, faster encoding of objects than relations would be predicted by - or at least consistent with - nearly all of them. Second, prior research suggests that objects are encoded faster than relations by adults (Goldstone \& Medin, 1994; Sagi, Gentner \& Lovett, 2012), and it is likely that such a difference exists for young children as well. Finally, encoding time differences may have important consequences for how analogical reasoning unfolds.

During analogical reasoning, two representations are aligned so that elements from each are placed into correspondence with one another. According to StructureMapping Theory (SMT - Gentner, 1983; and modeled by SME - Falkenhainer, Forbus \& Gentner, 1989), alignment is an incremental, multi-stage process. The mapping process begins with individual identical elements from each representation - including features, objects, and relations being placed into correspondence with one another. These initial correspondences are promiscuous; individual elements may map to multiple other elements (e.g., both cat $\rightarrow$ cat and cat $\rightarrow$ boy). In successful analogical reasoning, the final one-to-one correspondences are based upon shared relational structure (e.g., chase $\rightarrow$ chase; therefore, catchaser $\rightarrow$ boy-chaser, mouse-fleer $\rightarrow$ cat-fleer).

We hypothesize that this incremental mapping process is interleaved with encoding, which is also incremental (Lovett, Gentner \& Sagi, 2009). Pieces of the representations become available at different times, and correspondences between analogues are forged as these pieces become available. Correspondences made early in the mapping process may be particularly influential during analogical reasoning. For example, they may guide attention for further encoding and mapping (Kubose et al., 2002). Early correspondences may also be privileged if initial, incomplete mappings, rather than a full alignment, are used to make a decision (i.e., "satisficing", which young children may be especially likely to do, cf. Thibaut, French, \& Vezneva, 2010). If objects are encoded faster than relations, then object correspondences should also be found earlier, resulting in attention initially being allocated to object similarity. With a "satisficing" strategy, earlier object correspondences would also lead to object-based (rather than relation-based) reasoning.

The present studies use a match-to-sample task to explore encoding time differences between objects and relations and the impact of such differences on the allocation of attention in children and adults. In Study 1 we ask whether objects are encoded more quickly than relations (at least for the stimuli used in these studies). In Study 2 we ask whether encoding time differences predict attention to object similarity. Integrating across these studies, we then ask what might change over development to yield this pattern of results.

## Study 1

If objects are encoded faster than relations, then participants should require less time to encode a stimulus in order to find an object match and more time in order to find a relational match. Thus, this study manipulated the amount of time participants were given to encode a sample stimulus before they were asked to find either the object match or the relational match (a methodology used by Sloutsky and Yarlas, as cited by Lovett et al., 2009).

## Method

Participants Thirty-two adults and 41 5- and 6-year-olds participated in this study. Adult participants came from the undergraduate subject pool and received partial course credit for their participation, or they were recruited from the university area and given monetary compensation. Children were recruited from an existing developmental research database and given a book and t-shirt for participating.

Stimuli and Procedures This study used a match-to-sample task administered on a touchscreen laptop. Stimuli consisted of three shapes arranged in one of three patterns: ABA, AAB, or BAA (Figure 1). On each trial, participants were shown a sample stimulus, which disappeared and was replaced by two choices. All participants completed two versions of the task: object-matching, in which they had to find the stimulus with the same shapes, and relationmatching, in which they had to find the stimulus with the same pattern. In both versions, the incorrect foil did not share objects or a relational pattern with the sample. Participants selected their choice by touching it on the screen.

Within each version of the matching task, there were three sections: practice, long-encoding-time (LET) test trials, and short-encoding-time (SET) test trials. The order of version and short and long trials was fully counterbalanced. In the practice sections, participants were shown an example triad and the matching criterion was explained ("Find the one with the same shapes/pattern"). Then, participants completed several practice trials with feedback to ensure that the task instructions were clear. Practice trials were followed by a block of LET test trials or SET test trials. LET trials displayed the sample stimulus for 1000 ms . For
adults, SET trials displayed the sample stimulus for 50 ms , and for children, 150 ms .

We hypothesize that for both adults and children in this study, objects will be encoded faster than relations. Therefore, we expect high accuracy for object matching on both LET and SET trials. In contrast, we expect high accuracy for relational matching only on LET trials, in which participants have had sufficient time to encode the relational pattern in the sample; SET trials should not provide enough time to encode the relational pattern, and therefore participants should not be able to reliably select the relational match in this case. In sum, we predict a Version by Encoding Time interaction, with a larger effect of Encoding Time for relation matching.

Figure 1: Example stimuli for Studies 1 and 2.

## Results and Discussion

Results for Study 1 are shown in Figure 2.
Adults' mean proportion correct was entered into a 2(Version) x 2(Encoding Time) repeated-measures ANOVA. Overall, adults were more accurate on objectmatching than relation-matching, $F(1,31)=63.07, p<.001$, and more accurate on LET than SET trials, $F(1,31)=51.27$, $p<.001$. However, these main effects are best interpreted in light of their interaction, $F(1,31)=25.27, p<.001$. As predicted, adults showed a larger decrement from shorter encoding time for relation-matching than for objectmatching.

Children's mean proportion correct was entered into a 2(Version) $x$ 2(Encoding Time) repeated-measures ANOVA. Like adults, children were overall more accurate on object-matching than relation-matching, $F(1,40)=$ 182.97, $p<.001$, and more accurate on LET than SET trials, $F(1,40)=60.03, p<.001$. The predicted Version x Encoding Time interaction was marginally significant, $F(1,40)=3.46, p<.10$. As with adults, short encoding times were more disruptive for relation-matching than for objectmatching.

These results support the hypothesis that for both children and adults, objects are encoded faster than relations. Although this may not be true in all cases, for the stimuli used in this task, both groups needed less time to encode the object information than the relational information. These findings echo prior research suggesting that adults encode objects more quickly than relations (Goldstone \& Medin, 1994). To our knowledge, this is the first time this processing difference has been shown for children as well.

What consequences might this difference have on analogical reasoning? Assuming incremental and interleaved encoding and mapping processes (Lovett et al., 2009), information encoded early (i.e., object information) could influence the allocation of attention during alignment. Specifically, early-available object information should initially direct attention toward object similarity. This would predict that conflicting object similarity should disrupt relational matching by diverting attention to the object match, potentially leading to more errors (i.e., selecting the object match instead of the relational match) and longer latencies to correctly select the relational match (because attention to the relational match should be delayed) (Sloutsky \& von Spiegel, 2004). However, for object matching, conflicting relational matches should not disrupt accuracy or response times (RTs). In Study 2, we explore these predictions.

Figure 2: Adults' and children's match-to-sample accuracy in Study 1 by task version and encoding time.

## Study 2

If object similarity captures attention as a result of early object encoding, then the presence of conflicting object similarity on a relation-matching task should result in more errors and slower correct RTs compared to cases without conflicting object similarity. In contrast, object matching should be largely unaffected by the presence of conflicting relational similarity. However, if this asymmetrical pattern is not seen, it would suggest that object similarity is not preferentially commanding attention, despite differences in encoding time.

## Method

Participants Thirty-two adults and 37 5- and 6-year-olds participated in this study. Participants were recruited and compensated as in Study 1.

Stimuli and Procedures This study used the same basic match-to-sample task used in Study 1, with some modifications. As in Study 1, stimuli consisted of three shapes arranged in one of three patterns: ABA, AAB, or BAA (Figure 1). Also as in Study 1, all participants completed an object-matching and relation-matching version, counterbalanced for order.

There were two primary differences between the tasks used in Study 1 and Study 2. First, the encoding time manipulation was removed. In Study 2, the sample was displayed for 1500 ms on all trials. Second, another type of trial - a conflict trial - was added. On conflict trials, the foil matched the sample on the non-relevant dimension. That is, on the object-matching version, the incorrect foil was a relational match, and on the relation-matching version, the foil was an object match. These trials were interspersed with no conflict trials, where the incorrect foil did not match the sample at all (the type used in Study 1) (Figure 1).

If object similarity preferentially captures attention - one possible consequence of faster object than relation encoding - we expect participants to make more errors and respond more slowly to conflict trials than no conflict trials on the relation-matching task. However, participants should not show this difference on the object-matching task. Alternatively, if object similarity does not capture attention (despite encoding time differences), we should not see this asymmetrical pattern. In sum, a Version by Trial Type interaction would suggest preferential attention to object similarity.

## Results and Discussion

Results for Study 2 are shown in Figure 3.
Adults' mean proportion correct and RTs on correct trials were entered into separate 2(Version) x 2(Trial Type) repeated-measures ANOVAs. Adults were significantly more accurate on the object-matching version than the relation-matching version, $F(1,31)=10.92, p<.01$. This main effect of Version was modulated by an interaction with Trial Type, $F(1,31)=4.31, p<.05$. Adults showed a small but reliable decrement in performance on the relationmatching task when a conflicting object match was present, but no such difference on the object-matching task.

Consistent with faster encoding of objects than relations found in Study 1, adults showed a main effect of Version in their RTs. They made significantly faster correct responses on the object-matching task than the relation-matching task, $F(1,31)=7.94, p<.01$. However, this did not interact with Trial Type. That is, on both the object- and relationmatching versions, adults were equally fast to respond to conflict and no-conflict trials.

Parallel analyses were carried out for children's accuracy and correct RTs. Children were significantly more accurate on the object-matching version than the relation-matching version, $F(1,36)=42.09, p<.001$, and significantly more accurate on no conflict than conflict trials, $F(1,36)=10.74$, $p<.01$. These factors also interacted, $F(1,36)=15.79, p<$

Figure 3: Adults' and children's accuracy and RT data from Study 2.
.001. The effect of conflict trials was larger for the relationmatching task than the object-matching task.

Children were also faster to respond correctly on the object-matching task than the relation-matching task, $F(1,36)=11.30, p<.01$. Trial Type did not significantly interact with Version, though the data do qualitatively follow a pattern consistent with the accuracy results. Specifically, compared to no conflict trials, conflict trials showed longer latencies on the relation-matching task than the object-matching task.

Though somewhat mixed, the pattern of accuracy and RT results in Study 2 suggest a difference in adults' and children's attention to object similarity. Children's performance resembles the pattern that would be predicted if early object encoding led to preferential to object similarity. Conflicting matches led to more errors and longer RTs on the relation-matching task than the objectmatching task.

In contrast, adults' performance suggests resilience against conflicting object similarity. Conflicting object
matches did not increase response latencies on the relational matching task, and the decrement in accuracy on relational conflict trials was quite small. Altogether, the results from Study 2 suggest that encoding time differences between objects and relations may lead to preferential attention to object similarity for children but not adults.

## General Discussion

The aim of the current studies was to explore encoding time differences in objects and relations and to investigate whether these differences lead to differences in allocation of attention to object similarity. Ultimately, these questions are aimed at identifying the factors responsible for the development of adult-like analogical reasoning.

In Study 1, we found that both children and adults encoded objects faster than relations. Study 2 found a pattern of object- and relation-matching that suggested children, more than adults, preferentially allocated attention to object similarity (but see Sloutsky \& von Spiegel, 2004). Thus, we see continuity in a basic processing difference
between objects and relations, but the consequences of this difference for analogical reasoning behavior changed over development. Together, the results of Studies 1 and 2 implicate a change in an additional factor as key in explaining the difference in children's and adults' susceptibility to conflicting object similarity.

We think our results are best explained by a change in selective attention over development. Although adults encoded objects faster than relations, object similarity did not capture their attention when relational similarity was the relevant matching criterion. Thus, it seems that adults were able to selectively attend to the relational information, despite the earlier availability of object information, whereas children were not. Further work is needed to build a strong case for the role of selective attention in analogical development. However, this account is consistent with other studies of analogical reasoning in children (e.g., Thibaut, et al., 2010).

Future research will also need to explore how selective attention interacts with other factors implicated in analogical development. For example relational language has been proposed to aid relational thinking in a number of ways (Gentner, 2010). Performance on difficult analogical reasoning tasks can often be improved by providing children with language to describe the relevant relations (e.g., Loewenstein \& Gentner, 2005). With regards to selective attention, an intriguing possibility is that relational language may strengthen top-down control of attention to relational information.

## Acknowledgments

This research was funded by SILC (the Spatial Intelligence and Learning Center), an NSF Science of Learning Center, grant SBE-0541957. The authors would like to thank David Uttal, Steve Franconeri, and the Cognition and Language Group for invaluable feedback on this project. Many thanks also go to Laura Willig, Ashley Poltermann, and the RAs of the Project on Children's Thinking for their assistance in conducting this research.

#### Abstract

Screen media, such as television and videos, are a common part of young children's lives. Yet infants and toddlers have been shown to learn less effectively from screens than from interactions with another person. Using a quasi-experimental design we explored how social factors of screen media coviewing impact children's learning outcomes. We observed parents co-viewing a novel word training video with their children, then tested children for immediate and delayed word learning. We then investigated the links between parental speech during co-viewing and children's subsequent word learning. Parental speech that encouraged children to produce the novel words predicted better retention of word learning, whereas speech that focused more on the video itself rather than the content was negatively associated with learning.

Keywords: Screen media; co-viewing; word learning.

## Introduction

Screen media, such as television, videos, computers, and hand-held devices like smartphones and tablets, are an increasingly common part of young children's lives. Although the American Academy of Pediatrics recommends that children under the age of two not watch any screen media (AAP, 2010), survey data reveal that $43 \%$ of children in this age group watch TV every day (Rideout \& Hamel, 2006). This may be partly due to the recent proliferation of screen media content aimed specifically at infants and toddlers (e.g., Baby Einstein). Much of this content is presented with educational claims, including in the domain of language development (Fenstermacher et al., 2010). However, research that actually compares children's learning from screen media to their learning from face-toface interactions with another person reveals a video deficit effect (Anderson \& Pempek, 2005). That is, across varied experimental paradigms, infants and toddlers learn less effectively from a screen than from a person.

Is it possible to effectively facilitate infants' and toddlers' learning from screen media? Factors that may impact this learning include the complexity of the information on screen, whether key information is highlighted or repeated, or the presence of social cues that help children direct attention to what is important. In the work presented here we employed a quasi-experimental approach to investigate the role of a common social context for screen mediated learning: co-viewing a video with a parent. We explored the
relationship between parental behavior during active coviewing and children's learning outcomes. The results suggest meaningful links between characteristics of the screen media viewing context and children's learning of video content. Exploring the attributes and effects of coviewing is vital for guiding further research on children's screen mediated learning and applying this work in practice. In the remainder of the introduction we will briefly review the evidence for the video deficit effect in the domain of language as well as the existing research on co-viewing with young children. Many questions on this topic remain, and our approach of linking co-viewing to word learning in the moment contributes to this emerging literature.

## The Video Deficit in Language Learning

From birth, infants are constantly exposed to language, both from live and mediated sources. By manipulating whether information to be learned is presented through screen media or through face-to-face interactions, researchers have identified a video deficit effect in the domain of language development-infants and toddlers more effectively learn language from a person than from screen media. The video deficit has been demonstrated in two types of tasks in this domain: phoneme distinction and word learning.

One study took advantage of a change in phoneme discrimination that occurs in infancy. At six months of age infants can discriminate phonetic speech contrasts from their native language as well as from a non-native language to which they have never been exposed (e.g., Werker, Gilbert, Humphrey, \& Tees, 1981). However, over the first year of life, infants become attuned to distinctions between speech sounds in their native language, leading to an inability to recognize speech contrasts that do not exist in that language. Kuhl, Tsao, and Liu (2003) tested what kinds of exposure to non-native speech distinctions can prolong 9-month-old infants' ability to perceive those distinctions. These researchers found a video deficit in maintaining phonetic distinctions: infants exposed to non-native speech on video lost their sensitivity to non-native speech distinctions, whereas those exposed to live speech were still able to discriminate between non-native phonemes. In fact, infants in the video exposure group performed equivalently to a control group with no exposure; screen mediated speech led to the same outcome as no speech at all.

Another major developmental step in language acquisition is learning words. Researchers have looked at how young children learn unfamiliar or novel words from various live and screen mediated sources. In a typical word-learning task, children are shown an object and told a label for that object. To test for learning, the child is presented with an array of objects, including the trained object and distractor objects, and is asked to identify the object corresponding to the trained label. One study found a U-shaped developmental progression of the video deficit in word learning: while children between 13 and 20 months of age showed a significant deficit, younger children (aged 6 to 12 months) and older children (aged 21 to 24 months) did not show a deficit (Krcmar, 2010). Another word learning study found evidence for a video deficit among children between 15 and 24 months of age, which was actually stronger after children were exposed to a commercial video compared to a lab-created video (Krcmar, Grela, \& Lin, 2007). While the studies mentioned so far were conducted in a lab setting, another study confirmed the video deficit in word learning among 12- to 18 -month-olds exposed to a commercial video in their own homes (DeLoache et al., 2010). One study using a slightly older age group did not find any evidence for a video deficit in a word learning task among 30-montholds (O'Doherty et al., 2011). However, recent work in our lab suggests that the video deficit may persist depending on how word learning is assessed. We found that 30 - to $36-$ month-olds learned and retained one-to-one word-referent mappings from a screen, but the same children showed a video deficit in their retention of lexical categories (Sims \& Colunga, in preparation). When toddlers must generalize what they previously learned from a screen, inferring categories based on the words they learned, screen mediated learning still seems to be at a disadvantage.

In sum, studies that compare language learning from screen media to learning from a person show an early emerging video deficit effect that diminishes with age and depending on the type of task used. But why do children struggle with screen mediated learning when they can easily learn the same information in person? Some have proposed that social factors of screen media, or lack thereof, drive the video deficit effect (Richert, Robb, \& Smith, 2011). The screen mediated environment typically lacks the kind of rich social interactions and contingencies that children get when learning directly from a person. The video deficit may be rooted in the socially impoverished nature of screen media itself, particularly in the fundamentally social domain of language learning. Therefore, the social context of screen mediated learning is the focus of a related area of research, including work on co-viewing.

## Screen Media Co-Viewing

Most parents watch TV with their child either all or most of the time (Rideout \& Hamel, 2006). Parental co-viewing may provide a social context for children's screen media use. By actively co-viewing with their children, parents have opportunities to scaffold children's learning from the screen.

Most of the work linking parent-child co-viewing and children's learning from a screen has looked at slightly older age groups than studies of the video deficit effect. However, more recent research is beginning to explore how coviewing impacts infants' and toddlers' attention to and learning from screen media.

Some studies of preschoolers have experimentally tested how different types of co-viewing interactions influence children's subsequent learning. For example, one set of studies tested co-viewing in a context familiar to many young children: Sesame Street episodes. In one study, Reiser, Tessmer, and Phelps (1984) manipulated whether or not adults asked content-specific questions and provided feedback and encouragement while co-viewing segments teaching letters and numbers. Children learned the content of the video more effectively in the experimental condition compared to the control condition, in which adults did not provide any commentary. Reiser, Williamson, and Suzuki (1988) added to this result by showing that asking questions, with or without providing feedback, resulted in better learning than simply directing children's attention to the screen when educational content was being shown. Together these studies show that adult commentary and questions during co-viewing can directly facilitate children's learning from real screen media content.

Fewer studies have linked co-viewing interactions to outcome measures among infants and toddlers. Some studies have linked qualities of parental behavior or parentchild interactions to a precursor for children's screen mediated learning: attention to the screen. Results show that parents' eye-gaze to a screen modulated 12- to 21-montholds' attention to screen media (Demers, Hanson, Kirkorian, Pempek, \& Anderson, 2012). Further, sensitive and reciprocal parent-child interactions during co-viewing predicted 6- to 18 -month-olds' looking time to an infantdirected video (Fidler, Zack, \& Barr, 2010). Another study classified parental interaction styles based on co-viewing behaviors (Barr, Zack, Garcia, \& Muentener, 2008). Parents were classified into different levels of scaffolding, and these clusters of co-viewing behaviors predicted looking time and responsiveness to infant-directed videos among 12-, 15-, and 18 -month-old infants. The high-scaffolding parents tended to use verbalizations that oriented their children to the video and focused on the content therein. Together these studies show that parents who used eye gaze, high-quality, responsive interactions, and content-focused verbalizations were most effective in establishing joint attention to the screen and getting their children actively involved in coviewing.

Only one study that we are aware of has started to link observations of co-viewing to measures of learning specifically among this younger age group. In this study, parents co-viewed a video with their 12 - to 25 -month-old children that was intended to teach words (Fender, Richert, Robb, \& Wartella, 2010). The authors observed parental coviewing behaviors as well as child verbalizations, and, importantly, also asked parents which of the words in the
video their child was unfamiliar with. In this way, the authors measured learning by observing how often children produced words that they had been unfamiliar with prior to seeing the video. Parents tended to cluster into different groups depending on how much their co-viewing behavior was focused on teaching the words in the video to their children. Children produced more words that they were previously unfamiliar with when their parents had a higher teaching focus during co-viewing. Further analyses showed that these parents tended to focus specifically on the words that they knew their children were unfamiliar with. This result is particularly interesting in light of the literature on the video deficit effect in word learning. This study shows that sensitive parental scaffolding during co-viewing with infants and toddlers may be able to reduce the video deficit.

## Rationale and Predictions

In the current study, we investigated the link between parental co-viewing behavior and toddlers' word learning. Parents and their $2 \frac{1}{2}$ - to 3 -year-old children watched a video of a person teaching novel words for novel objects. Children were subsequently tested on their word learning, both immediately after watching the video and after a week-long delay. Different kinds of parental speech during co-viewing were coded, analyzed using principal component analysis, and examined as predictors of children's word learning.

This approach offers several contributions to the literature. First, by training and testing children on novel words for novel objects, we controlled for any prior knowledge or exposure children may have had to the content of the task. Second, by testing children on the content of the video, both immediately and after a delay, we were able to make direct links between parental speech during co-viewing and children's word learning and retention. Third, we included an older age group compared to most studies of the video deficit in word learning to see what behaviors impact learning once children are becoming better able to learn from a screen. Fourth, this work uses an interdisciplinary approach, drawing on methodologies from the fields of linguistics and psychology. The results will provide a first step in identifying specific co-viewing behaviors that facilitate, or possibly inhibit, word learning and retention in young children.

Based on the work reviewed above, the extent to which parents focus their speech on the key information to be learned on screen should predict children's word learning performance. Parents who are responsive and help their children focus on the content of the video should promote their children's attention to and learning from the screen. In this study that means talking about specific objects shown and novel words presented in the video. Further, parents who focus more on the novel labels being taught in the task should help children better learn the correct word-object mappings. An emphasis on the novel labels concurrent with the presentation of objects in the video should help children establish and retain these mappings.

Figure 1. a. Novel target objects taught to children in the word learning task. b. Example word learning trial.

## Method

## Participants

Fifty children were recruited for participation from the Boulder, CO area. Six subjects were excluded from analyses due to missing or inadequate co-viewing data (two children) or co-viewing speech being primarily in a language other than English (four children). Therefore, the final sample included here consisted of 44 children ( $M_{\text {age }}=32.1 \mathrm{mo}$., $S D$ $=1.3$ mo., 25 girls).

## Materials

Children were taught six novel words (elg, ife, nork, gub, $z e b$, and $l u g$ ) for six novel objects (see Figure 1a). The novel objects and words were presented in a lab-made training video of a research assistant whom the children did not meet during the study. In the video, the assistant presents one novel object at a time, placing it on a table in front of her and rotating it as she speaks. Addressing the camera directly, she labels the object in three ways: "This is a/an __. Do you see the __? This is my __." After an object is labeled, the video cuts to a 3 second still close-up image of the object. Each object is presented two times each, and thus labeled six times total, for a total video duration of 2 minutes and 50 seconds.

Two standardized vocabulary measures were used to assess language development. Children were tested on the Peabody Picture Vocabulary Test 4 (PPVT; Dunn \& Dunn, 2007), a test of receptive vocabulary. Parents were given the MacArthur-Bates Communicative Development Inventory (CDI-III; Fenson et al., 2007), a checklist on which they indicated words their children knew. Parents also completed a survey on their children's screen media use at home.

Parent-child interactions during training video co-viewing were recorded and later transcribed in ELAN (Max Planck Institute for Psycholinguistics, The Language Archive, Nijmegen, The Netherlands: http://tla.mpi.nl/tools/tlatools/elan/; Brugman \& Russel, 2004). Parental verbalizations were subsequently coded using a scheme adapted from Barr et al. (2008). We used codes from this study and also developed codes specifically related to labeling in our task (see Results section for detailed description of the included codes).

| Labels | -.179 | -.190 | -.198 |  |

## Procedure

Training At the beginning of their first visit to the lab, parents and children watched the novel word training video. Parents were encouraged to actively co-view the video with their children. The experimenter explained that the video was meant to teach some new words and that the parent could teach their child about the words in the video as they would while watching at home. The experimenter left the room for the remainder of training, and parent-child coviewing was videotaped for later analysis. When the training video had ended, the experimenter re-entered the room.
Testing Children were tested both immediately after watching the training video and again a week later. To test word learning, children were presented with pairs of trained novel objects and asked to identify one by name (e.g., "Which one is an elg?"; see Figure 1b). Each object was asked for once, for a total of six testing trials. At the end of their first visit to the lab children were given the PPVT vocabulary test.

Children were given the same word learning test at their second visit. Importantly, children were not re-trained on any of the novel words or objects at this time. Therefore, the delayed testing session captured retention of the novel words.

## Results

The first question to assess was how well children learned and retained the novel word-object mappings. Children's proportions of correct target object choices at each testing session were first compared to chance performance. Children were accurate at above-chance levels both at immediate $(M=.57, S D=.22, t(43)=2.20, p=.03)$ and delayed testing $(M=.58, S D=.20, t(43)=2.58, p=.01)$. Next, a paired t-test showed that accuracy did not differ between visits $(t<1, p>.05)$, confirming that children retained the word-object mappings they had learned initially. It is worth noting that accuracy performance at the group level was not particularly high, and yet varied a fair amount across individual subjects. This may suggest that something about the learning context of individual children influenced their accuracy in the task.

The next question was how parent speech during coviewing related to children's word learning performance. We began with two common measures of the quantity of parental speech: total word count and mean length of
utterance (MLU). These variables were entered as predictors of children's word learning outcomes at each visit in two multiple regression analyses. These measures of parental speech quantity did not explain a significant proportion of the variance in either immediate or delayed child word learning performance $\left(R^{2}<.18, F(2,43)<1, p>.05\right.$ for both models). Further, neither total word count nor MLU were significant predictors of word learning outcome at either visit $(t(41)<1.50, p>.05$ for all coefficients). Because these parent speech quantity variables did not predict learning outcome, we next explored the quality of parental speech during co-viewing.

First, to reduce the dimensionality of the qualitatively coded parent speech data, we conducted a principal component analysis (PCA). After removing several codes that were used by very few parents in the sample, eight coding categories were entered into the PCA and resulted in four components with Eigenvalues above 1.0. The first component explained $19.47 \%$ of the variance, the second $18.94 \%$, the third $18.74 \%$, and the fourth $18.01 \%$ for a total explained variance of $75.15 \%$. An orthogonal Varimax rotation was used to facilitate interpretation of the components.

The four components are shown in Table 1 with factor loadings on each included coding category. The first component included tag questions and descriptions of the items shown in the video. Tag questions, which are statements with a question appended at the end, were typically used by parents to talk about the items on screen. Many of the observed instances of tag questions were also descriptions (e.g., "it's a green lug, huh?"). This component will be referred to as describing objects because it captures parents' focus on the individual objects depicted on the screen. The next component includes label elicitation questions and confirmations, which also appeared together often in co-viewing speech. This component will be referred to as label elicitation and feedback because it captures how often parents explicitly asked children to produce labels, including giving positive feedback for doing so. The third component includes evaluations and interactive verbalizations. Parents often used evaluations to make general comments about the video or item shown on screen (e.g., "that's a cool one"), and interactive verbalizations were comments about the video itself (e.g., "it says let's see those again"). This component will be called narrating because it captures parental speech about the video and

Note. ${ }^{\dagger} p<.10 .{ }^{*} p \leq .05$.
screen viewing context more broadly. The fourth and final component includes wh- questions and explicit labeling. These codes loaded in opposite directions onto this component, so the component will be referred to as openended questions vs. explicit labeling. In the positive direction this component captures the extent to which parents provided the novel labels being taught on screen, and in the negative direction it captures the extent to which parents asked their children open-ended questions about the video (e.g., "what is that?").

Hierarchical multiple regression analyses were conducted on children's word learning outcomes at each visit. In each analysis, the independent variables were entered in two blocks. Demographic and standardized test variables were entered in the first block. These included child age in months, child gender (dummy coded), vocabulary percentile score (averaged over the CDI-III and PPVT), and average screen use per day in minutes. The second block included the four co-viewing components from the factor analysis. This method of analysis allowed for evaluating the predictive value of the co-viewing components over and above the other included variables.

Table 2 displays unstandardized and standardized regression coefficients after entry of both independent variable blocks for immediate and delayed testing. None of the included variables significantly predicted immediate word learning accuracy $\left(R^{2}=.37, F(4,43)=.68, p>.05\right.$ after entry of all independent variable blocks). Although the full model did not reach significance $\left(R^{2}=.48, F(4,43)=\right.$ 1.31, $p=.27$ ), delayed word learning accuracy was predicted by two of the independent variables entered into the regression.

Parental label elicitation and feedback was a positive predictor of learning, indicating that the more parents asked children to produce novel labels and provided positive feedback, the better children retained word-object mappings. Specifically, the model predicts that for every standard deviation increase in parents' use of label elicitations and feedback, children's delayed word learning performance should increase by 0.34 standard deviations. On the other hand, narrating was a marginally negative predictor of retained novel word learning. This suggests that parental speech that was focused on the video itself and the content only in a general way actually inhibited children's correct retention of novel word-object mappings in this task. Specifically, the model predicts that for every standard
deviation increase in parents' use of narrating speech, children should be 0.27 standard deviations worse at retaining the novel word-object mappings.

## Discussion

The results of the current study show that although toddlers as a group learned novel words from a video, certain aspects of parental speech were associated with differences in this learning. An exploratory factor analysis revealed several variables of parent speech quality that characterized the coviewing linguistic environment and that predicted children's learning outcomes. Of note, the quality of parent speech only predicted children's retention of learning. This suggests that toddlers' immediate word learning from screen media may be relatively robust, and less influenced by the co-viewing environment. Yet the retention of this information may be sensitive to parental intervention.

The first key result showed that the extent to which parents elicited labels from their children and provided feedback while watching the training video predicted children's retention of word-object mappings. Although the finding that labels during co-viewing facilitated word learning is in line with prior work and with our predictions, the specific form of this labeling is informative. Children's retention was predicted not by hearing parents label the items on screen, but by parents cuing children to produce the labels themselves and providing responsive feedback.

Another key result was that the extent of parents' narrating during co-viewing was negatively associated with children's retention of word learning. This shows that parent speech about the video itself or general, non-specific speech about what is shown on screen is not conducive to novel word retention. This result suggests a negative impact on learning due to focusing on the form rather than the content of screen media. Further, this also suggests that general evaluative speech about the content on screen is not much more informative than talking about the video itself, and both of these together may actually impede learning outcomes.

Together these results are consistent with prior work indicating that responsive behavior during co-viewing promotes children's attention to and learning from screen media. The results build on prior work by demonstrating specific co-viewing behaviors that are responsive and thus scaffold children's learning, as well as behaviors that are
linked to detrimental learning outcomes. Together they provide new insight into the role of co-viewing in learning.

The results of this study represent a first step in linking specific co-viewing behaviors to children's learning outcomes in the context of screen media. There are various ways to refine and build on this work. One future direction would be to incorporate measures of child behavior and parent-child interaction quality in the kinds of analyses presented here. The relative timing of utterances and responses between a child and parent may be particularly predictive of word learning. For example, children may learn most effectively when parents respond promptly and provide information about the item that is the focus of the child's attention in that moment. The co-viewing data collected for this study could be coded for contingencies in interactions between parents and children. This kind of analysis would also resonate with research on the social aspects of screen mediated learning (e.g., Richert et al., 2011). Although social information was not manipulated directly in video training in this study, it could be informative to test how different extents of social contingency in co-viewing link to learning outcomes.

Another future direction for this work would be to guide experimental investigations of co-viewing. The kinds of analyses presented here can be used to develop experimental manipulations of the linguistic environment surrounding screen media co-viewing. For example, the current results suggest that the type and extent of labeling during coviewing may impact learning in different ways. This could be tested by manipulating whether labels are provided to children or elicited from them and how many labels are used during co-viewing. This would allow for greater control of other characteristics of the co-viewing context, randomized assignment of children to conditions, and causal conclusions about the role of labels in screen mediated word and category learning. Similar experiments could be designed to test the effects of specific, content-focused speech compared to broad, screen-focused speech during co-viewing. Future work could also investigate co-viewing and learning outcomes from real, professionally produced child-directed media. In conclusion, the current study makes novel contributions to the emerging literature on screen mediated language learning in young children and highlights directions for future research on facilitating this learning.

# Investigating the Other-Race Effect of Germans towards Turks and Arabs using Multinomial Processing Tree Models 

Henrik Singmann (henrik.singmann@psychologie.uni-freiburg.de)<br>David Kellen (david.kellen@psychologie.uni-freiburg.de)<br>Karl Christoph Klauer (christoph.klauer@ psychologie.uni-freiburg.de)<br>Institut für Psychologie, Sozialpsychologie und Methodenlehre, Engelbergerstr. 41<br>Albert-Ludwigs-Universität Freiburg, 79085 Freiburg, Germany

#### Abstract

The other-race effect (ORE) refers to the phenomenon that recognition memory for other-race faces is worse than for ownrace faces. We investigated whether White Germans exhibited an ORE towards Turkish or Arabic faces using a multinomial processing tree model (MPT), the two-high threshold model of recognition memory with three response categories (old, skip, and new). Using an MPT enabled us to adequately disentangle memory and response processes using the Fisher information approximation, a minimum description length based measure of model complexity. Results showed that participants exhibited an ORE on the memory parameters but not on the parameters representing response processes.

Keywords: Recognition Memory; Other-Race Effect; Multinomial Processing Tree Model; Face Recognition; Minimum Description Length

## The Other-Race Effect

The other-race effect (ORE, also known as own-race effect, own-race bias, or cross-race effect; e.g., Meissner \& Brigham, 2001; Hugenberg et al., 2010) describes the phenomenon that people tend to have a recognition memory advantage for own-race faces compared to other-race faces. A typical experiment consists of two phases, the study phase and the test phase. In the study phase, participants are asked to memorize a list of faces of at least two different races (e.g., white and arabic faces). In the subsequent test phase, participants are presented with old (i.e., presented during the study phase) and new (i.e., not presented during the study phase) faces of the two races and have to decide for each face separately if it was presented during the study phase by responding either "old" or "new".

The typical data pattern observed in such an experiment is a mirror effect, namely that participants produce more hits for own-race faces than for other-race faces (i.e., $P$ ("old"|old) is higher for own-race faces) and simultaneously more falsealarms for other-race faces (i.e., $P$ ("old"|new) is higher for other-race faces). A meta-analysis by Meissner and Brigham (2001) of 39 studies with almost 5,000 participants showed $P$ (hit) was 1.4 times higher for own-race faces than for otherrace faces and $P$ (false alarm) was 1.56 times higher for otherrace faces than for own-race faces, indicating a substantial ORE.

Recent findings have qualified this overall effect. For example, in a study by Gross (2009) Asian, Black, Hispanic, and White participants performed a recognition memory experiment with Asian, Black, Hispanic, and White faces. Furthermore note that the study was performed in Southern California (USA) where the majority of the population is Hispanic
( $42 \%$ versus $38 \%$ Whites). For all participants the best performance (at least descriptively) was found for faces of the participants' own race. When analyzing participants based on their race, an interesting pattern emerged. White participants had the best performance for white faces followed by Hispanic faces followed by Asian and Black faces. Hispanic participants had the best performance for Hispanic and White faces (so no significant advantage for own-race faces) followed by Asian faces followed by Black faces. These results indicate that the ORE does not generalize to all "other-races", but its magnitude depends on which other-race is the target.

Sporer and Horry (2011) have conducted a study with a similar design that is of special importance for the current paper. Their participants were White and Turkish participants living in Germany which were tested on faces of African Americans, Turks, White Americans and White Germans. White German participants exhibited an ORE only for African-American faces, there was no reliable difference in the memory for the other three target races. Turkish participants had a comparable performance for Turkish and White German faces, which was better than the performance for White- and African-American faces.

Taken together, these results indicate that people do not display an ORE towards all other-races, rather it is an empirical question which seems to be depend on factors such as facial features of the target race (e.g., White participants in Germany did not show and ORE towards non-German White faces whereas Turks in Germany did) and also on social-cognitive factors such as the majority/minority or ingroup/outgroup status of the target race (as e.g. shown by the study of Gross, 2009). The answer to the question whether an ORE is displayed towards a specific other-race may also have severe practical implications, for example in the domain of eyewitness identification, as and ORE can lead to the wrongful accusation or conviction of innocent individuals or to an acquittal of guilty individuals.

## The Present Experiment

In this experiment we investigate whether White Germans exhibit an ORE towards people of Middle Eastern descent such as Turks and Arabs. We selected Turks and Arabs as "otherrace" as (a) the only published study we know of investigating this (Sporer \& Horry, 2011) surprisingly did not find an ORE, (b) Turks are the biggest ethnic minority in Germany (around 3 million of a 82 million population, Statistisches

Figure 1: The 2HTM for recognition memory. On the left side are the two different item types, old and new items, respectively, each represented by one tree. On the right side are the observed responses "Old", "Skip", and "New". In between are the assumed latent states with the probabilities leading to these states. $D_{o}=$ Detect an old item as old, $D_{n}=$ detect a new item as new, $g_{i}=$ guessing state.

Bundesamt, 2011), and (c) increasing prejudices towards people with Middle Eastern descent have been observed in the aftermath of the terrorist attacks on 9-11 (e.g., Morgan, Wisneski, \& Skitka, 2011).

Furthermore, our experiment employed a novel methodology that enabled us to disentangle two types of cognitive processes that contribute to performance in recognition memory, memory and response processes. According to the current state of knowledge (Meissner \& Brigham, 2001), the ORE is an effect that affects both memory and response processes. However, in the next part of this manuscript we will argue that the usual employed methodology of disentangling memory and response processes is flawed and offer an alternative.

## Measuring Recognition Memory Performance

It is generally agreed upon that there are at least two different kinds of cognitive processes that contribute to an observed pair of $P($ hit $)$ and $P$ (false alarm) in a recognition memory experiment (Snodgrass \& Corwin, 1988): memory processes (e.g., how good the memory for the studied items is) and response processes (e.g., the tendency to respond with "old" instead of "new"). For example, better memory for the studied items should increase $P$ (hit) but decrease $P$ (false alarm), whereas differences in the response tendencies should affect $P($ hit $)$ and $P($ false alarm $)$ in the same direction.

So far, the study of the ORE has relied on simple performance indices such as $d^{\prime}$ or $A^{\prime}$ (see Macmillan \& Creelman, 2005) to measure the aforementioned processes. Based on these indices Meissner and Brigham (2001) concluded that the ORE is mainly a memory effect and that there are also
differences in response bias (i.e., participants are more inclined to respond with "old" for other race faces) which are considerably smaller than the effect for memory processes.

However, the ability of these measures to accurately characterize an individual's performance is known to be quite limited, as they make simplifying assumptions (e.g., homoscedasticity of the evidence distributions) which, if violated, seriously compromise any conclusions drawn from the analysis (see Verde, Macmillan, \& Rotello, 2006). In particular, differences in memory and response tendencies tend to be grossly confounded. Unfortunately the data usually gathered does not allow to test these assumptions, encouraging the use of measurement models which are based on richer data sets.

A model that has been extensively used in the literature is the Two-High-Threshold Model (2HTM; Snodgrass \& Corwin, 1988). The 2HTM assumes that studied and non-studied items at test can be in either a detection or uncertainty state: When an item is detected its true status (studied or nonstudied) is known, and a correct response is invariably given. On the contrary, when an item is not detected, it is in an uncertainty state where no information regarding its true status is available, leading to a response based on guessing. The 2HTM can be represented as a multinomial processing tree (MPT; Riefer \& Batchelder, 1988), as depicted in Figure 1.

Figure 1 describes the 2 HTM for a recognition-memory task, which we have enriched by introducing a third response option "skip" in addition to "old" and "new". The studied items can be detected with probability $D_{o}$, which is assumed to invariably lead to response "old". In the absence of detection (which occurs with probability $1-D_{o}$ ), the individual merely guesses, responding "old", "skip", or "new" with probabilities $g_{1},\left(1-g_{1}\right)\left(1-g_{2}\right)$, and $\left(1-g_{1}\right) g_{2}$ respectively. Non-studied items can be detected with probability $D_{n}$, invariably leading to response "new" and in the absence of detection (which occurs with probability $1-D_{n}$ ) the individual guesses using the above-stated probabilities. Parameters $D_{o}$ and $D_{n}$ attempt to capture memory retrieval processes as well as memory-based metacognitive judgments (e.g., Strack \& Bless, 1994), while $g_{1}$ and $g_{2}$ capture response tendencies.

The advantages of using this model are threefold: First, the 2HTM is a simple yet validated model (e.g., Bröder, Kellen, Schütz, \& Rohrmeier, in press; Snodgrass \& Corwin, 1988) that is used as a building block in more complex measurement models (e.g., Klauer \& Kellen, 2010). Second, the use of 2HTM allows for different independent parameter estimates for German and Turkish face-stimuli, while other popular measurement models based on Signal Detection Theory (Macmillan \& Creelman, 2005) suffer from identifiability issues that compromise their use (see Wickens \& Hirshman, 2000). Third, the 2HTM is a member of the MPT model class, a class for which model selection under the Minimum Description Length principle is well documented and available (Singmann \& Kellen, in press; Wu, Myung, \& Batchelder, 2010). The latter point is discussed in greater detail below.

## Model Selection in the MPT Model Class: A Minimum Description Length Approach

One of the advantages when employing an analysis based on cognitive models is that model parameters capture entities of primary interest such as the probability with which a certain cognitive state is reached (e.g., the probability of remembering a face). A direct consequence of this is that psychological hypothesis directly correspond to relationships among model parameters. For example, the absence of an ORE corresponds to the identity of parameters for German and Arabic faces. Hence, in our analysis different versions of the MPT model described above are used corresponding to different hypothesis (e.g., no ORE, an ORE only based on memory processes, etc.). To establish which hypothesis is the most plausible given the experimental result therefore entails an assessment of the performance of the different models, a process known as model selection.

Model selection requires a weighting between the ability of the model to account for the observed data (via goodness-offit statistics) and the ability of the model to account for data in general (model complexity or flexibility), as more flexible models provide a better fit to data a priori (Roberts \& Pashler, 2000). The established goal is to find the model with the best trade-off between fit and flexibility, with different methods and approaches being proposed in the literature (e.g., Vanderkerckhove, Matzke, \& Wagenmakers, submitted).

One prominent approach in model selection is based on the Minimum Description Length principle (MDL; Grünwald, 2007). According to the MDL approach, both models and data are understood as codes that can be compressed. The goal of MDL is to assess models in terms of their ability to compress data. The greater the compression, the better the account of the underlying regularities that are present in the data. One of the indices emerging from the MDL principle is the Fisher Information Approximation (FIA), which combines a model's goodness of fit with model-flexibility penalties. Specifically, FIA takes the number of parameters and the sample size into account, but additionally contains a term that accounts for the flexibility of the model due to its functional form by integrating over the determinant of the Fisher information matrix of the model for a sample of size 1 (see Wu et al., 2010). An algorithm that computes FIA for members of the MPT model class was developed by Wu et al. (2010), and made available in an open-source package by Singmann and Kellen (in press).

While common model-selection indices such as AIC and BIC (Burnham \& Anderson, 2002) use the number of free parameters as a proxy for the relative flexibility of a model, FIA is able to capture the model's ability to account for data in general. Because of this MDL indices such as FIA usually outperform AIC and BIC (and null-hypothesis testing) when attempting to identify the most suitable model (e.g., Klauer \& Kellen, 2011).

One further advantage of FIA is the ability to incorporate order restrictions being imposed on the parameters (e.g.,
$D_{o} \geq D_{n}$ ), allowing for the testing of informative hypotheses (Kellen, Klauer, \& Bröder, in press). This means that one can restrict the flexibility of the models to patterns that are theoretically plausible, and directly test whether this flexibility is sufficient to account for the observed data.

## Methods

## Participants

A total of 42 White German psychology students (mean age $=21.4$ years, $S D=2.7$ ) participated in the experiment for partial fulfillment of course credits.

## Materials

The pictures were taken from publicly accessible websites of sports team of lower leagues (mostly soccer teams) from Central European countries (e.g., Germany, Belgium), Turkey, and Middle Eastern countries. In total we gathered 123 White and 125 Turkish/Arabic pictures (henceforth we will refer to these as Arabic pictures). We digitally removed the background and eye-catching features and colorized the shirts uniformly black. The pictures were then pretested in an online study on four 7-point scales: two ethnicity dimensions (German/Central European and Turkish/Arabic), distinctiveness ("How easy it is to spot the face in a crowd?", Valentine \& Bruce, 1986), and valence (positive to negative). We obtained a mean of 20.6 ratings per picture. The ethnicity dimensions were subtracted from each other to form a racial extremity score (i.e., German minus Turkish rating for White pictures and vice versa for Arabic pictures).

Based on the pretest data we selected 100 pictures from each category (avoiding extreme ratings on any dimension) that were comparable (albeit significantly different) in their ratings. On the racial extremity dimension the Arabic pictures were somewhat less extreme than the White pictures, 3.7 versus 4.6 . On the distinctiveness and valence dimension ratings were comparable, 3.5 versus 3.0 and 4.3 versus 4.6, respectively. Additionally, we randomly selected another 10 pictures from the remaining pictures to serve as primacy and recency items in the study phase. More details on the pretest can be found here: http://www.psychologie.unifreiburg.de/Members/singmann/pubs/cogsci13supp

## Procedure

Participants were tested individually. They were informed that they were to take part in a memory experiment consisting of two study phases in which they had to memorize a set of faces and a subsequent test phase. No reference was made to race or related concepts. In the first study phase, 50 White and 50 Arabic faces (randomly selected) were presented in random order (plus 5 primacy faces at the beginning and 5 recency faces at the end) each for 2 seconds with a 0.5 seconds inter-trial interval (ITI). To increase memory for the pictures, the study phase was repeated with the same items (plus primacy and recency items) presented in a new random order. Directly after the second study phase, participants were introduced to the test phase in which they had to
judge for each of 200 faces ( 50 White old, 50 White new, 50 Arabic old, and 50 Arabic new) whether or not it was presented during the study phase by selecting one of three options: "old" ["altes Gesicht"], "skip" ["überspringen"], or "new" ["neues Gesicht"]. We implemented a 0.5 seconds ITI in the test phase.

## Results

## Response Proportions

Table 1 presents the response proportions obtained for White and Arabic faces and $p$-values of $t$ tests comparing those (without controlling for multiple testing). As can be seen, we did not find a mirror effect. Rather, we found slightly higher proportions of hits and higher proportions of false alarms for the Arabic faces. Additionally, we found differences in the use of the "skip" option in that participants used "skip" more often for Arabic than for White new faces.

## MPT Analysis

All analyses were performed using MPTinR (Singmann \& Kellen, in press).

The Unrestricted Model. We fitted the unrestricted 2HTM model to each individual dataset separately using the maximum likelihood method. The model seemed to provide a good fit to the data (as the unrestricted model was saturated we couldn't formally test this). Of the 42 participants only 6 participants had a $G^{2}>1$, of those only two participants had a $G^{2}>2$ (3.70 and 4.95). The summed $G^{2}$ was 19.19.

The mean parameter estimates and the underlying distributions plus additional information are depicted in Figure 2. As can be seen, there were no big differences for parameters $D_{o}$, $g_{1}$, and $g_{2}$. Only $D_{n}$ showed a difference in the expected direction, $D_{n}$ was smaller for Arabic than for White faces. This results was also supported by significance testing (Table 2), only for $D_{n}$ did the parameters for White and Arabic faces differ. Somewhat unexpectedly, $D_{o}$ tended to be slightly higher for Arabic faces than for White faces, although this result did not reach significance.
Model Selection. To test for the existence of an ORE we fitted eight models implementing different sets of parameter

Table 1: Mean Response Proportions (SD)

|  | White faces | Arabic faces | $p$ |
| ---: | :---: | :---: | :--- |
| $P($ hit $)$ | $.67(.16)$ | $.71(.14)$ | .06 |
| $P\left(\right.$ skip $\left._{\text {old }}\right)$ | $.07(.08)$ | $.07(.09)$ | .66 |
| $P($ miss $)$ | $.26(.16)$ | $.21(.12)$ | .03 |
| $P($ fa $)$ | $.16(.11)$ | $.27(.17)$ | $<.001$ |
| $P\left(\right.$ skip $\left._{\text {new }}\right)$ | $.09(.12)$ | $.13(.13)$ | .01 |
| $P(\mathrm{cr})$ | $.75(.16)$ | $.60(.19)$ | $<.001$ |

Note. Column $p$ contains $p$-values from paired $t$ tests comparing response proportions for White and Arabic faces. $P(\mathrm{fa})=P($ false alarm $) ; P(\mathrm{cr})=P($ correct rejection $)$.

Table 2: Mean parameter values (SD) of model without parameter restrictions

| parameter | White | Arabic | $p$ |
| ---: | :---: | :---: | :---: |
| $D_{o}$ | $.45(.23)$ | $.50(.23)$ | .10 |
| $D_{n}$ | $.53(.28)$ | $.24(.23)$ | $<.001$ |
| $g_{1}$ | $.39(.22)$ | $.38(.22)$ | .79 |
| $g_{2}$ | $.78(.24)$ | $.74(.25)$ | .09 |

Note. Column $p$ contains $p$-values of paired permutation tests comparing parameters across races using 100.000 bootstrap samples (Hothorn et al., 2006). p-values of paired $t$ tests are identical up to the second decimal (up to the fourth decimal for $p<.001$ ).
restrictions and furthermore calculated the FIA for each of those models using 200,000 Monte Carlo samples (see Table 3 for the results). The different models correspond to the different hypothesis regarding the nature of the ORE we could capture with the 2 HTM . The first model is the model without any parameter restrictions reflecting the possibility that an ORE is driven by both differences in memory processes and differences in response tendencies. In models two to four, only memory parameters (i.e., $D_{o}$ and $D_{n}$ ) were restricted to be equal across the races, but response tendencies were allowed to vary. Model five only assumes differences in the memory parameters but no differences in the guessing parameters. Models six to eight implement different versions of a memory ORE with the guessing parameters restricted. Note that for all but the first model we implemented an inequality restriction on the memory parameters so that $D_{o}$ and $D_{n}$ for White faces were equal or larger than those for Arabic faces (unless they were restricted to be equal).

The model with the best performance was model 6 (Ta-

| 6 | $D_{o}, g$ | 126 | 210.97 | $<.001$ | $\mathbf{4 5 4 . 4 6}$ | 16 |
| 7 | $D_{n}, g$ | 126 | 356.87 | $<.001$ | 527.66 | 3 |
| 8 | $D_{o}, D_{n}, g$ | 168 | 385.13 | $<.001$ | 504.25 | 14 |

Note. The results are summed across participants. The lowest FIA value is printed in bold. Column "best" contains the number of times each model provided the best performance (using FIA as the criterion). If not restricted, $D_{o}$ and $D_{n}$ are inequality restricted to be equal or larger for German faces than for Arabic faces (except for the "none" model in which all parameters are free).

Figure 2: Violin plots (Hintze \& Nelson, 1998) of the parameter estimates for the unrestricted 2HTM. The outer area depicts the density of each variable. The boxplot depicts the first, the second (i.e., the median), and the third quartile and the area 1.5 times the interquartile range outside those values. The mean is depicted as a $\times$.
ble 4) with $D_{o}$ and the $g$ parameters restricted across races and the only differences being $D_{n \text { White }} \geq D_{n A r a b i c}$ (this model also had the lowest FIA value in an analysis without the inequality restrictions on the memory parameters), indicating that we found a memory based ORE. This model did not only have the lowest FIA value, but also provided the best FIA performance for the largest number of participants (16 of 42 participants).

Inspecting the best performing models per individual datasets revealed a surprising spread. Each model (with the exception of the unrestricted model) provided the best performance for at least one dataset. Furthermore, the model assuming no ORE (model 8) provided the best fit for 14 participants, indicating that quite a substantial subgroup did not show an ORE.

## Discussion

The goal of this experiment was to investigate whether White Germans exhibit an ORE towards people of Middle Eastern descent such as Turks or Arabs. In contrast to the only other published study we know of investigating this (Sporer \& Horry, 2011), we indeed found evidence for an ORE of our participants. More specifically, the analysis using the 2HTM

Table 4: Mean parameter values (SD) of best performing model with parameters $D_{o}$ and $g$ restricted

| parameter | White | Arabic | $p$ |
| ---: | :---: | :---: | :---: |
| $D_{o}$ | $.50(.23)$ |  |  |
| $D_{n}$ | $.52(.24)$ | $.23(.24)$ | $<.001$ |
| $g_{1}$ | $.35(.18)$ |  |  |
| $g_{2}$ | $.76(.23)$ |  |  |

Note. See Table 2.
revealed that the majority of the participants were less able to detect the correct status of new items for Turkish and Arabic faces (i.e., lower $D_{n}$ ) than for White faces, hence our ORE was a pure memory effect. There were no reliable differences on the other memory parameter (i.e., $D_{o}$ ) nor on the response bias parameters (i.e., $g$ ). Additionally, our analysis revealed that not all participants exhibit an ORE. In fact, although most of the participants did show this effect, 14 of 42 participants did not show any ORE. This latter finding may in part be responsible for the failure of Sporer and Horry to find an ORE towards Turks as their analysis strategy might have not have been as powerful as ours, as it may have suffered from problems of the employed performance index $A^{\prime}$ (see also below).

When looking at the response proportions only, we did not find the expected mirror effect (higher hit rate for own-race faces and higher false alarm rate for other-race faces; Meissner \& Brigham, 2001) which is the usual data pattern in the ORE. One possible explanation for this is that our decision to enrich the data base by introducing a "skip" option may have hidden the mirror effect. Alternatively, the mirror effect, which is usually found in studies when the other-race is Black, could be absent for Arabic faces. Future research should try to disentangle these two explanations. The absence of the mirror effects also indicates that, although we did find an ORE, our finding regarding the underlying processes may not simply generalize to different own- or other-races.

Enriching the data base by introducing the "skip" option and thereby allowing to employ a fully identified two-high threshold multinomial processing tree model, has proven to be a useful tool in investigating the ORE. It not only overcomes limitations of the often-used performance indices such as $d^{\prime}$ or $A^{\prime}$ (Verde et al., 2006), it is also able to overcome identifiability issues when using two different stimuli classes (i.e., White and Arabic faces) in a signal-detection framework
(Wickens \& Hirshman, 2000). We hope that this new tool may help in answering some of the open questions regarding the ORE (see Hugenberg et al., 2010).

The adopted model selection strategy was also successful in uncovering interesting individual differences. Theories of ORE have highlighted that differences in ORE can be explained by social-cognitive variables such as attitudes towards other-races (Hugenberg et a., 2010). Combining our methodology with relevant individual differences measures within the MPT framework, such as the new MPT model for the implicit association test (IAT; F. Meissner and Rothermund, in press), could therefore be fruitful.

## Acknowledgments

We thank Alina Arnhold, Felicitas Flade, and Hannah Kammüller for their help in collecting the data and Jasmyn Touchstone and Johannes Falck for preparing the stimuli.

# Semantics: Intuition, Experiment or Illusion? 

Peter Slezak (p.slezak@unsw.edu.au)<br>Department of Philosophy, School of Humanities<br>University of New South Wales, Sydney NSW 2052 Australia

#### Abstract

Externalist theories in natural language semantics have become the orthodoxy since Kripke is widely thought to have refuted descriptive theories involving internal cognitive representation of meaning. This shift may be seen in developments in philosophy of language of the 1970s - the direct reference "revolution against Frege" (Wettstein 2004, 66). Almog (2005, 493) writes of the "uprising against Frege's doctrines" that "spread like fire" based on the work of Kripke, Donnellan, Putnam and Kaplan. However, I consider Fodor's (2004) heretical thought that something has gone "awfully wrong" in this philosophical consensus, perhaps confirming Chomsky's (1992) view that the whole field of philosophical semantics is "utterly wrongheaded" and "crazy" by virtue of its non-naturalist assumptions and "methodological dualism." I suggest that the externalist orthodoxy is a kind of cognitive illusion seen elsewhere in philosophy and cognitive science.

Keywords: semantics; externalism; meaning; intuition.

## Externalist Orthodoxy

Externalism is widely acknowledged to be the orthodoxy in the theory of mental content and psychological states. However, despite its subjective force, externalism may be undermined by attending to its aetiology and showing how the intuitions evoked arise from deceptive mechanisms. Instead of defending internalism directly, we may ask: Why does externalism seem so convincing? This is a cognitive science of biases and illusions among philosophers.

Kripke (1972) is regarded as having "ushered in a new era in philosophy" (Soames 2005, 1) by refuting a widely held descriptive conception of proper names. In the philosophy of language, this was part of the 1970s direct reference "revolution against Frege" (Wettstein 2004, 66). Frege held that something about the speaker's cognitive state must explain the difference between sentences such as "Hesperus is Phosphorus" and "Hesperus is Hesperus." The first is cognitively significant but the second is knowable $a$ priori as necessarily true, even though the substituted terms are co-referential. However, Kripke's externalist doctrine of "rigid designators" has become the orthodoxy - essentially the view of J.S. Mill that proper names have no meaning other than the name's denotation, and a name refers to the same individual in any possible situation.

In Putnam's slogan, the externalist orthodoxy holds that "meanings ain't in the head" since mental content is individuated by referents in the world. This view rests on intuitions elicited by thought-experiments such as Putnam's (1975) famous Twin Earth story, characterized as "a sort of paradigm in the philosophies of language and mind" (Segal

2000, 24). On another planet, Twin Earth, the only difference is that the clear, potable liquid in rivers and lakes has chemical structure XYZ rather than $\mathrm{H}_{2} \mathrm{O}$. An atom-foratom replica of an Earth person might have identical internal psychological/brain states and yet not have the same waterthoughts since Twin Earth thoughts are about XYZ. Also influential has been Kripke's (1979) puzzle about Pierre who believes both that Londres est jolie and also that London is ugly, not realizing that London is the same city as Londres. Kripke says "I know of no answer" to the question "Does Pierre, or does he not, believe that London is pretty?" Kripke regards the puzzle as comparable to the Liar Paradox (1979, 904). On this point, Salmon (2011, 236) endorses Kripke's "sound methodology" quoting Tarski's classic discussion of the Liar antinomy and its intellectual challenge.

Kripke's "primary moral" is that "the puzzle is a puzzle" (1979) and he insists that it can not be resolved by redescribing the problem, but this conception is open to challenge. A re-description need not avoid the problem but rather it may show how a pseudo-problem arises. After all, the indeterminacy of Pierre's belief about London is not like the contradictory state of Shrödinger's cat or the quantum wave/particle duality. To be sure, in another case, restating Zeno's paradox of Achilles and the Tortoise (e.g. with a distance/time graph) is to sidestep the puzzle rather than solving it since the re-description doesn't expose the flaw in Zeno's reasoning. Kripke is right to say that talk of 'what is really going on' doesn't answer his original question, but it does show clearly what's wrong with the original question and why the puzzle isn't a puzzle, after all. With Kripke, we can point out that "No answer has yet been given" to the question of whether Lois Lane loves Clark Kent, but we understand why.

Or, seeing the Necker Cube on two different occasions, Pierre might not recognize it as the same geometrical figure. Adapting Kripke's (1979) words, we may ask "Does Pierre, or does he not, believe that the Figure (not the shape satisfying such-and-such descriptions, but the Figure) is facing upwards to the left? No answer has yet been given." Fodor $(2008,76)$ pointedly asks "But why on earth should we suppose that the question [concerning Pierre] has a definite right answer when it's phrased that way? And, once one sees why it doesn't, why does it matter that it doesn't?" However, while sharing Fodor's dismissive attitude, we may go further to ask why the puzzle should have such a firm grip on philosophical imagination.

Thus, Devitt $(1984,385)$ has made a salutary distinction: "Thoughts are one thing, their ascription another." Devitt
warns "it is a common practice ... to use 'belief', for example, where what one means to refer to is belief ascription" (1984, 389). The failure to respect Devitt's distinction is to blame for Kripke's puzzle in which we seem forced to describe the hapless Frenchman as holding contradictory beliefs about London. The relevance of Devitt's distinction should be clear: "a difference in sorts of thought ascription does not entail a difference in the sorts of thought object ascribed" (1984, 389). In this case, the question concerning Pierre's belief about London involves thought ascription about the thing itself or de re, using our own reference, like Putnam's thought ascriptions about $\mathrm{H}_{2} \mathrm{O}$ and XYZ. The intuition that we can be induced to share is simply the idea that we can ascribe de re beliefs from our own perspective independently of the beliefs of the subject in question. Brandom $(1994,503)$ explains, "expressions that occur within the scope of the 'that' [in de dicto contexts] serve to specify how things are represented by the one to whom the belief is ascribed."

## Little Choice?

Significantly, Kripke (1972, 42) acknowledges that he was led by his "natural intuition" to his view of proper names and that there could not be "more conclusive evidence one can have about anything, ultimately speaking." However, Farkas (2003) characterizes the "deeply rooted" intuitions as "baffling" and a "vexatious problem" that "poses a serious challenge for any attempts to give an internalist analysis." Accordingly, we may ask why philosophers feel that the "intuitive responses to a certain kind of thought-experiment appear to leave them little choice," as Boghossian (1998, 273) puts it. Fodor (1987a) has noted that the Twin-Earth Problem is not a problem but "just a handful of intuitions together with a commentary on some immediate implications of accepting them" (1987a, 208). Significantly, he says: "it is very plausible that all these intuitions hang together. The question is: What on earth do they hang on?" (Fodor 1987, 202). I offer an answer that gains a distinctive, if not decisive, strength from the fact that the intuitions in this domain "hang on" the same biases and illusions to be seen operating elsewhere throughout cognitive science.

## Giving Intuitions a Bad Name

In different guises, under such headings as 'conceptual analysis' (Jackson 1998) or 'conceivability' (Chalmers 2002), intuitions have played a central role in philosophy (DePaul \& Ramsey eds. 1998). Hintikka (1999, 127) suggested intuitions "came into fashion in philosophy" as philosophers' attempted to "get on the bandwagon of transformational grammar" that they took to provide a methodological model for research into cognition. Hintikka (1999, 127,8) specifically cites Kripke's (1972) Naming and Necessity as an influential case in point, suggesting "Unfortunately" his doctrines are "apt to give intuitions a bad name." Even a sympathetic account by Hughes (2004) makes a damaging admission: He confesses "blindness" to Dummett's (1973) alternative reading of key sentences but
takes "comfort" from the fact that the same defect is very widespread among philosophers. However, the Müller-Lyer illusion is very widespread too. As Sosa $(2001,26)$ notes, the phenomenon of ambiguity is widespread in the English language and the "shiftiness" of linguistic constructions containing modal expressions is akin to lexical ambiguity of words such as "bank." Closer are the structural ambiguities familiar to linguists and the basis for jokes such as Groucho Marx's remark: "One morning I shot an elephant in my pajamas." Failure to appreciate the humour through blindness to the ambiguity is a psychological defect rather than theoretical criticism.

Contrary to Hintikka (1999, 132), Chomsky's use of intuitions in linguistics has nothing to do with being a "selfacknowledged Cartesian" or innate ideas. Nevertheless, Hintikka (1999, 133) correctly notes, in contrast to linguists' use of intuition, "philosophers' intuitions do not pertain to the supposed faculty of intuition itself but to the truths about which this faculty is supposed to provide knowledge." For an egregious example, Bealer $(1998,202)$ argues that intuitions have a "strong modal tie to the truth" which he suggests "is a philosophical (conceptual) thesis not open to empirical confirmation or refutation." In the same vein, Chalmers (2002) challenges the systematic scientific picture asking "Does Conceivability Entail Possibility?" However, we need not agree that "Philosophical intuition is epistemologically useless" (Cummins 1998, 125). If philosophers' intuitions are taken properly on the model of generative grammar, they may be seen as psychological evidence rather than intimations of truth. The PutnamKripke intuitions might be explained like the Müller-Lyer illusion as deceptive in spite of its subjective force.

## Omniscient Philosopher-Narrator

The model for this kind of inquiry into intuitive judgements is the 'heuristics and biases' program of Tversky and Kahneman (1974). This work has demonstrated the systematic unreliability of compelling intuitions resulting in a wide range of cognitive illusions to which we are prone. Seen from this perspective, I suggest externalist theories of reference involve a generic pseudo-explanatory mistake that is not confined to any one domain. For example, Chomsky has explained the need for a fully explicit grammar that avoids the unwitting dependence on the linguistic knowledge of the theorist. Of course, the potential for this error is not unique to linguistic explanation and its very seductiveness means we should expect to find it elsewhere. Generally, it seems difficult to avoid invoking internal representations which have their meaning because we, as theorists, can understand them. This has been the charge against pictorial theories of imagery by Pylyshyn (2003) and was precisely anticipated by Descartes. In this case external representations are taken as a model for internal representations and, therefore, relying on the theorist's intelligence and invoking the notorious homunculus. Chomsky (1962) notes that a grammar may produce the illusion of explanatory completeness, but in fact have
"serious limitations so far as linguistic science is concerned" because the success of the grammar depends on being "paired with an intelligent and comprehending reader." Chomsky explains: "Reliance on the reader's intelligence is so commonplace that is significance may be easily overlooked" (Chomsky 1962, 528). In a different guise of interest here, the theorist posits mental representations based on his own knowledge of the truth rather than the subject's beliefs. In this case, philosophical intuitions arise from tacitly adopting the perspective of an invisible narrator - the illusion of the omniscient story-teller, the literary device that Mario Vargas Llosa (1975) aptly refers to as the "philosopher-narrator."

## Residue of Commonsense

Pietroski (2003) suggests that despite a considerable literature on reference, "no one has shown that names do bear any interesting and theoretically tractable relation to their bearers." If he is correct, we are owed an explanation of how so many philosophers could have been so misguided. Chomsky characterizes the commonsense conception of semantics as a kind of illusion and points to the kind of diagnostic, aetiological concern I wish to pursue: "Here, I think, philosophers and linguists and others who are in the modern intellectual tradition are caught in a kind of trap, namely, the trap that assumes that there is a reference relation" $(2012,28)$. That is, "there is no wordthing relations." This is undoubtedly a shocking remark that flies in the face of the most obvious, taken-for-granted facts about language. Of course, that's just the point. Chomsky suggests that we may suffer from a "residue of commonsense," some deeply persuasive, but illegitimate, "distorting" picture of the world (see also Egan 1999, 188). Word-thing relations are "mythical" by contrast with the question of "how the person's mental representations enter into articulation and perception" $(1996,23)$, but this is syntax. Chomsky $(2000,148)$ suggests that we can have no intuitions about such questions as whether an identical replica of ourselves uses the word "water" to refer to something, XYZ, which is not $\mathrm{H}_{2} \mathrm{O}$ because the key terms such as "extension" and "reference" are technical inventions. In the same way, it would be pointless to explore our intuitions about "tensors" or "undecidability." However, there can be no doubt that certain intuitions may be consistently induced in philosophers and others by the notorious thought experiments. These are not random in the way that intuitions about tensors might be among the uninitiated. The vast philosophical literature attests to the existence of systematic, robust and widely shared intuitions that are at the heart of externalism.

## Who Cares What the Mayans Think?

Recently, the question has been illuminated from a new angle by empirical inquiries into the cross-cultural variation in intuitions on which philosophers have relied (Machery et al., 2004). These studies have challenged the universality of the evidence on which philosophical puzzles have relied.

For example, Segal $(2004,339)$ says "we should not trust those intuitions" because Putnam and Kripke "mistakenly think that their intuitions are 'ours', that they are representative of those of all sensible, reflective humans" (2004, 340). Segal reports studies "designed to tap relevant twin-Earth intuitions among tribespeople" such as the Mayans of the Yucatan in Mexico. The data are mixed, but Segal says "surely these data ... should be given considerably more weight than Putnam's intuitions about Oscar's "water" concept and Kripke's intuitions about medieval "unicorn" concepts (Segal 2004, 343). In the same vein, Machery et al. (2004, B7) found that "Chinese subjects tended to have descriptivist intuitions, while Westerners tended to have Kripkean ones" and these data suggest "significant philosophical conclusions." The authors conclude:

#### Abstract

We find it wildly implausible that the semantic intuitions of the narrow cross-section of humanity who are Western academic philosophers are a more reliable indicator of the correct theory of reference ... than the differing semantic intuitions of other cultural or linguistic groups. (2004, B9)

## Competence or Incompetence?

Devitt (2011) rejects the challenge of cross-cultural evidence to semantic theory because they tested the wrong subjects. The intuitions of ordinary folk are unreliable by comparison with intuitions of "experts," namely, "metaphysicians and other philosophers." However, we need not accept philosophers' intuitions as authoritative divinations to treat them, instead, as diagnostic evidence of illusion among those who suffer from it - data for the development of a theory of 'tacit knowledge' or "competence" (i.e. incompetence).

The point has been missed in the ongoing controversy about empirical inquiries into intuitions. Recently, Nagel (2012) has argued that epistemic intuitions do not, after all, vary in ways that pose a challenge, but Stich (2012) has defended such research and its threat to philosophical reliance on intuition. He cites evidence that even the MüllerLyer visual illusion is not universally shared among all human cultures. Kalahari San foragers apparently do not judge the familiar lines as differing in length. So what? Devitt, Stich and Nagel miss the point that it remains a matter of psychological interest to explain why we do suffer from the illusion. The only difference with the case of philosophical intuitions is that we don't take our visual perceptions as veridical.

That is, it is no help to be told that someone else doesn't share your puzzlement. Who cares what the Mayans or Chinese think? Their failure to be puzzled doesn't help resolve our problems. If I am the only one who is guilty of confirmation bias or base rate neglect, I need diagnosis and a cure, not anthropology. Even if it is parochial to Western departments of analytic philosophy, the central problem remains for Kripke and those who do, as a matter of fact, share the intuitions in question. Moreover, the anthropological evidence of cross-cultural variation does not
illuminate the fundamental question because, even if the Kripke-Putnam intuitions were universally shared, their credentials are not thereby established as guides to scientific or metaphysical claims.

## Who is in the Know?

Putnam $(1975,11)$ explains that internally identical "water" thoughts are said to have different meaning on Earth and Twin-Earth, although the chemistry of H 2 O or XYZ may never be discovered by people on either planet. That is, externalism depends on intuitions arising from the theorist's knowing the truth. Indeed, defending externalism, Burge (1988) confirms this diagnosis saying "We take up a perspective on ourselves from the outside." The conception of an "Omniscient Observer" is explicitly embraced as unproblematic by Donnellan (1974), a perspective Kaplan (2012, 156), too, has endorsed as "description from above." This is an understanding "in which one surveys another's thought" from a point of view "independent of whether the subject's thought corresponds to reality." These are remarkable confirmations of my diagnosis of the illusion of the "philosopher-narrators" omniscience.
In Crane's (1996) useful phrase, the question of who is "in the know" is central to untangling the intuitions at the heart of puzzles concerning externalism. Crane's question recalls Putnam's $(1981,50)$ question "From whose point of view is the story being told?" The invisibility of our own role and our own knowledge creates the illusion that it is the relational fact about how the world really is that determines the thought or belief in question. As Crane $(1996,293)$ notes, "the Twin Earth cases are meant to demonstrate that the world itself can, as it were, fix the meanings of some of our words." Crane's apt characterization captures the paranormal or clairvoyant conception of meanings which somehow link the mind directly with its objects in the world.

## Philosophers, autistics \& three year olds

Burge $(2012,119)$ recently explains the nature of de re belief in terms that are suggestive of other philosophical problems: "One can have a de re belief that is successfully referential and meets all other conditions on being de re, which nevertheless fails to count as knowledge." Consider the case in which someone is looking at a chair which he can see in a certain position apparently in the next room. However, he doesn't notice that he is looking at a large mirror and, therefore, sees the reflection of a chair that is actually nearer to him in the same room. As it happens, there is an identical chair in the next room behind the mirror, exactly where the reflection appears to be. It is evident that this circumstance is precisely Burge's scenario of de re belief and it is also exactly the Gettier (1963) case of justified, true belief that doesn't count as knowledge. Burge doesn't mention Gettier, but these parallels suggest the Problem has a wider interest beyond the epistemological issues it has been directly concerned with. Accordingly, it is interesting to notice Fodor's comment about the semantics
of mental representations applies to Gettier too: "we need it [broad or externally individuated content] to make sense of the fact that thoughts have the truth conditions that they do" (1994, 50). As if describing the Gettier Problem, in an entirely different context, Fodor gives a diagnosis that is apt for this puzzle:

It is, to put the point starkly, the heart of externalism that semantics isn't part of psychology. The content of your thoughts (/utterances), unlike for example, the syntax of your thoughts (/utterances), does not supervene on your mental processes. (Fodor 1994, 38)

In the Gettier case, too, the wide contents of your thoughts construed transparently as knowledge do not supervene on your mental processes, being merely justified beliefs. Fodor had made the same point where he said "truth, reference and the rest of the semantic notions aren't psychological categories" $(1980,253)$.

In response to the semantic orthodoxy, Farkas' (2003) argues that "external features are important only if they are incorporated into the internal cognitive or experiential perspective of cognizers." Schantz, too, explains, "As far as psychological explanation is concerned, what counts is how the world is internally represented as being, not how the world really is (2004, 23; emphasis added)." This is essentially the formula with which Fodor (1998, 20) characterized externalism, the view that "what you are thinking depends on what world you're in." This diagnosis of externalist semantic intuitions is precisely appropriate to the notorious Gettier (1963) Problem. In Chisholm's (1966) classical version, the subject sees a sheep-like bush and acquires a perceptual belief "There is a sheep in the field." Although this belief is justified by the evidence, it is true only by accident because, unbeknownst to him, there is a sheep elsewhere in the field. The classical criteria for knowledge - justified, true belief - appear to be met, but the belief does not count as knowledge. Hetherington (2012) has recently given an analysis of "Gettiered beliefs", being cases in which "truth remains essential." His diagnosis is that philosophers' intuitions are evidence of their "being infallibilists, without realizing this about themselves." This seems to be another way of making my point about puzzles that arise from the "narrator's" omniscience. Putnam's Twin Earth example, too, is a case in which mental content is ascribed to someone on the basis of truths that are not represented internally by the subject just as in the Gettier Problem.

Schantz' prescription for psychological explanation what counts is how the world is internally represented as being, not how the world really is - is apt also for capturing the mistaken "theory of mind" in a different domain. We see a striking analogue known to clinical psychologists in the Wimmer and Perner (1983) "false belief" task: Autistics and three year-olds ascribe beliefs to others based on their own knowledge of the truth rather than on the other's justified beliefs. Switching the candy when the character isn't looking in the experiments of Wimmer and Perner is
analogous to Gettier's substitution of bushes for sheep, or Fodor's substitution of shrews for mice in cases of misrepresentation. Putnam's substitution of XYZ for $\mathrm{H}_{2} \mathrm{O}$, like Dretske's (1986) disoriented microbes, are various ways that have been devised to make 'the world go wrong.' The truth-making facts are unconnected with the grounds for belief which are known only to the philosopher-narrator. By ascribing beliefs in this way, it appears that philosophers make the same mistake that autistics commit and children grow out of by the age of four. Ralph's belief about Ortcutt (Quine 1960) just like Twin Oscar's thoughts about water (Putnam 1975) and Pierre's thoughts of London (Kripke 1979) are essentially ascriptions of belief based on the philosophers' knowledge of the truth (see Slezak 2011).

## Obscurantist Intentional Magic

"Object-dependent" referential thoughts called de re are taken to be "singular thoughts" about a particular object or person that the speaker has in mind. This is the strong intuition expressed by Brian C. Smith that symbols somehow "reach out and touch someone" (1987, 215). Kripke has placed these issues in his framework of 'rigid designators' that denote the same individual in all 'possible worlds.' However, Stalnaker (2003) emphasizes that Kripke's claims rest on intuitive grounds, and poses a revealing question: "Doesn't this presuppose that the same individuals can be found in different possible worlds? Searle (1969, 93), too, argues that if an expression has no descriptive content as Kripke and 'direct reference' theorists claim, "then there could be no way of establishing a connection between the expression and the object." He asks "What makes this expression refer to that object?" Kripke's preferred answer is that a chain of historical, causal, connections back to a baptismal event fixes the reference. However, this account utterly fails to explain how a particular individual acquires the competent use of a name. The point is precisely analogous to Putnam's $(1967,18)$ attempt to rebut Chomsky's "innateness" claims by citing the common historical origin of all human languages. But this response fails to address the problem of language acquisition - the question of how each individual child must accomplish the task of becoming a competent speaker. The common origin of all human languages is irrelevant to this question, just as the supposed historical-causal chain is irrelevant to an individual's understanding and use of proper names. Stalnaker $(2003,178)$ captures the problem aptly, speaking of the only alternative to descriptive accounts which seems to be "some kind of obscurantist intentional magic." In Searle's $(1969,87)$ suggestive words, the idea that we can mean or intend a particular object and not another inclines us to think "that it is a movement of the soul." In the same vein, Putnam (1981) suggests that externalist intuitions are a "magical theory of reference" that assumes occult "noetic rays" connecting words with their referents. Indeed, these referential intuitions are suggestive of widely held, compelling misconceptions concerning visual perception that are thought to involve emanations
from the eyes - the so-called "extramission theory of perception" maintained by early Greek philosophers. Remarkably, following Piaget, Winer et al. (2002) report evidence that belief in extramission remains widespread, deeply ingrained and resistant to educational efforts. I don't mean to suggest that such theories are literally believed by philosophers, but the compelling conceptions are very suggestive of intuitions underlying the most widely held externalist semantic theories.

#### Abstract

In order to interact with the world, people must be able to predict how it will unfold in the future, and these predictions must be updated regularly in light of new information. Here we study how the mind updates these predictions over time. Participants were asked to make ongoing predictions about the destination of a simulated ball moving on a 2 D bumper table. We modeled these decisions by assuming people simulate the world forward under uncertainty. This model fit participants' behavior well overall, suggesting that people continuously update their physical simulations to inform their decisions. In some specific scenarios participants' behavior is not fit well by the simulation based model in a manner suggesting that in certain cases people may be using qualitative, rather than simulation-based, physical reasoning.

Keywords: intuitive physics; forward simulation

## Introduction

Changing lanes while driving seems like a simple and ordinary task - millions of people do it everyday. But to do so safely requires sophisticated predictions. Drivers must judge where their own car and those around it will be during the lane change, and, crucially, they must update these predictions with new information: if a car in the adjacent lane accelerates, a driver may abort her lane change to avoid a collision.

This scenario demonstrates how people typically plan their actions: prediction is updated as new information is gathered. Research spanning decades has investigated how people predict future object movement while objects are hidden (Faisal \& Wolpert, 2009; Rosenbaum, 1975; Runeson, 1975; Smith \& Vul, 2013; Téglás et al., 2011), but in most natural cases, observers continue to see objects while updating their predictions. In this study we investigate how people change their instantaneous predictions about objects over time: are ongoing predictions the result of online simulation?

Recent research provides evidence that people use 'Noisy Newtonian' models of physics to simulate the world (Sanborn, Mansinghka, \& Griffiths, 2013): peoples' internal physical models are based on correct assumptions about physics, but uncertainties in object position, movement, and latent variables can cause biases and variability in prediction. This framework has been used to predict peoples' judgments about the stability of a tower of blocks (Hamrick, Battaglia, \& Tenenbaum, 2011), the movement of hidden objects (Smith \& Vul, 2013), and even judgments about physical causality (Gerstenberg, Goodman, Lagnado, \& Tenenbaum, 2012). These works, however, solicited predictions at single instances in time. In this paper, we
investigate whether a model that assumes faithful physics under uncertainty is also consistent with how peoples' predictions evolve over time. We show that people's decisions are often consistent with online forward simulation, but we also find that people can use qualitative reasoning about the world (e.g., Forbus, 1994) when this is more informative than simulations.

## Experiment

We asked participants to play a game in which they make predictions about the path of a ball bouncing around a computerized table. The ball can reach one of two targets on the table, and participants earn points for predicting which target it reaches first. Crucially, they make this prediction continuously throughout the trial, earning points while predicting the correct target but losing points while predicting the incorrect target. In this way, we could capture how uncertainty (decisions whether to choose a target) and choices (which target) evolved over the course of each trial.

## Methods

Sixty-six UC San Diego undergraduates participated in this experiment for course credit. ${ }^{1}$

On each trial, participants saw a ball moving around a 'table' on the computer screen that contained blocks and both a red and a green target. The ball bounced perfectly elastically off of the edge of the table and blocks, ending when the ball reached one of the two targets. While the trial progressed, participants were asked to predict whether the ball would hit the red target or the green target first, indicating their guess by holding down either the ' $z$ ' or the ' $m$ ' key (each key counterbalanced for red and green between participants). If they were unsure, participants could press neither key, and if their prediction changed midtrial, they were encouraged to switch keys. Holding down a key would fill a bar of the associated color, and at the end of the trial, the score would be determined by the difference between the proportion of time the keys for each target were held down:
(1) Score $=20+100 *($ Prop $($ Correct $)-\operatorname{Prop}($ Incorrect $))$

After each trial, participants were notified of their score and could continue to the next trial by pressing the spacebar.

Participants were each given the same 400 trials in a random order. Of these, 370 trials were randomly generated, and 30 were designed to consider various extreme scenarios.

[^209]Of special note in the hand-crafted trials are five trials in which the configuration of the walls made it impossible for the ball to ever reach one of the two targets; these are called the 'qualitative' trials as they were meant to differentiate between simulation-based intuitive physics and a qualitative assessment of the table configuration.

Each trial lasted between 2.0 s and 10.2 s . Target colors were randomly swapped for each trial to avoid color bias effects. ${ }^{2}$ Responses were polled and recorded once every tenth of a second.

Figure 1: Illustration of an ongoing trial. Participants would see the ball travel along the dotted line and would predict green or red during its motion (neither blue line was visible).

## Results

We analyzed participants' aggregate performance across trials via their total score (eq. 1). Participants showed low variability in their average trial scores (mean $=56.0$, $\mathrm{sd}=$ 5.1) and scores for each trial were very consistent across participants (split half correlation, $r=0.96$ ).

We investigated whether there were surface-level features of trials that make them more or less difficult. Here we use average score as a proxy for difficulty; high scores indicated that most participants could accurately predict the path of the ball easily (and early), while low scores indicated uncertainty and mis-prediction.

The features we considered as possible predictors included: (1) trial duration, (2) the number of blocks on the table, (3) the number bounces before the ball hit the target, (4) the initial deviation of the ball's path from a horizontal or vertical direction, (5) the proportion of the table clear of walls or targets, (6) the ratio of the area of the correct target to the incorrect target, (7) the ratio of the average distance of the ball to the correct target versus the incorrect target, and (8) the closest the ball ever was to the incorrect target.

We found four predictive features: trials were easier when their trajectory was on average closer to the final target, involved fewer bounces, when the initial motion was along a cardinal direction, and when the ball never approached the incorrect target. These four predictors together explained $31.9 \%$ of the variance in scores across trials.

[^210]Table 1: Predictors of trial difficulty. Partial correlation is correlation between predictor and trial score accounting for all other predictors.

| Predictor | $r$ | $\mathrm{r}_{\text {partial }}$ |
| :--- | ---: | ---: |
| (7) Distance ratio | -0.51 | -0.24 |
| (3) Bounces | -0.25 | -0.19 |
| (4) Direction deviation | -0.21 | -0.14 |
| (8) Nearness to incorrect | 0.42 | 0.09 |

Although, aggregate metrics of ball trajectory accounted for some of the variation in difficulty across trial, such an analysis fails to capture the rich predictions individuals make over time and how those change in light of the details of a given table configuration and ball trajectory.

To further delve into how people make online physical predictions and explain why some of these features might make trials more difficult, we compared human behavior to predictions made via stochastic physical reasoning.

## Physical Prediction Model

## Description

The model we used to predict behavior on this task has two parts: the physical simulator, which provides possible paths that the ball can take, and the decision policy, which uses the output of the physical simulations to decide which target to choose (if either).

Physical simulator The part of the model that simulates the trajectory of the ball is based in large part on the model of Smith \& Vul (2013). This model assumes that people base their physical models on real physics but must incorporate uncertainty about the world into their physical judgments.

This model captures two sources of uncertainty: 1) perceptual uncertainty arises from the noisiness of inferring the position and movement of objects, and 2) dynamic uncertainty is uncertainty about the roughness and elastic properties of the table and walls that could cause the ball's path to deviate from idealized Newtonian physics over time.

The physical simulator produces 500 simulation paths ${ }^{3}$ every tenth of a second for each trial to replicate the polling frequency in the experiment. These simulation paths were produced using the same uncertainty parameters and fits as Smith \& Vul (2013). ${ }^{4}$ Each path terminates when the simulated ball reaches either the red or the green target, or when 10 seconds of simulated time has passed. ${ }^{5}$

[^211]The physical simulator outputs a set of proportions: how many paths reached the green target, how many reached the red target, and how many did not reach a target within the maximum simulation time ('uncertain' paths).

Decision policy The decision policy takes the output of the physical simulator and assigns belief to two decisions: 1) is there sufficient certainty about which target the ball will hit to offer any guess at all? (analogous to participants' decision whether or not to press any button at all), and if so, 2) which target should be guessed?

The decision of whether any prediction should be made is based on the proportion of simulation paths that reached either target. These are combined and fit with two parameters: a parameter $\alpha$ representing a Luce choice softmax weighting, and a parameter $\gamma$ to capture a bias towards making any guess at all:

$$
\begin{equation*}
P(\text { Any })=\frac{\text { Sim }(\text { Red or Green })^{\alpha}+\gamma}{\text { Sim }(\text { Red or Green })^{\alpha}+\text { Sim }(\text { Uncertain })^{\alpha}+\gamma} \tag{2}
\end{equation*}
$$

Conditioned on the decision to make any guess at all, the decision whether to guess red or green is based on the relative proportion of simulated paths that reached each color target. Here, there is a single Luce choice soft-max weighting parameter ( $\beta$ ), but because experimental trial colors were randomized, we assumed no bias:

$$
\begin{equation*}
P(\text { Red } \mid \text { Any })=\frac{\operatorname{Sim}(\text { Red })^{\beta}}{\operatorname{Sim}(\text { Red })^{\beta}+\operatorname{Sim}(\text { Green })^{\beta}} \tag{3}
\end{equation*}
$$

Finally, we assume there is a decision offset: people cannot immediately use simulation information, but instead must take time to process it, come to a decision, and move their hand to push a button. Thus we fit a single parameter $t$ to determine how long the model should wait to use simulation information. ${ }^{6}$

These four parameters were optimized to fit the empirical data at each polling time point for each trial. At each point, we created a vector of the empirical probabilities of pressing each of the two keys at time point i of trial $\mathrm{j}:\left[\operatorname{prop}(\operatorname{Red})_{i j}\right.$, $\left.\operatorname{prop}(\text { Green })_{i j}\right]$. We then calculated a similar vector of model predictions: $\left[P(\text { Red })_{i j}, P(\text { Green })_{i j}\right]$. The parameters were fit to minimize the total Euclidean distance between these points over all time points of all trials:
(4) $\sum_{j} \sum_{i} \sqrt{\left(\text { prop }(\text { Red })_{i j}-p(\text { Red })_{i j}\right)^{2}+\left(\text { prop }(\text { Green })_{i j}-p(\text { Green })_{i j}\right)^{2}}$

## Model performance

How do predictions change over time? Participants often changed their decisions as trials progressed, either from uncertain to certain or one color to the other. We first ask whether we can capture changes in participants' predictions over time. We compared model decision probabilities to the distribution of participants' choices at each time point: what

[^212]proportion of participants guessed the ball would end in the red target or the green target, or were too uncertain to offer a guess. Although there were differences in individual predictions, we believe aggregation is appropriate given the low variability in total scores and high consistency within trials (split half correlation, $\mathrm{r}=0.96$ ).

Figure 2: Joint histogram of model (x-axis) and human (yaxis) decisions. (Top) The probability of making any guess (pushing a button). (Bottom) The probability of choosing 'red' given a decision. Colors indicate log-frequency of time points in each bucket, with hotter colors indicating more observations. Observations along the diagonal indicate the model is accurately capturing the exact proportions of participants making decisions.

If people make decisions based on similar uncertainty and decision policies to those of the model, then the model should be able to predict both (a) when people make any decision and (b) which choice they make (red or green) when they do. Figure 2 shows the correlation between model predictions and participants' behavior. In the top panel, we see that participants' decisions whether to push either button are well predicted by the model ( $\mathrm{r}=0.84$ ): at most time points either our model believes that no guess should be made and nearly no participants offer a guess
(bottom-left), or our model believes that a guess should definitely be made and nearly all participants offer a guess (top-right). Moreover, even when participants are not unanimous in their decision to offer a guess, the model captures the variation in the proportion of people making guesses. In the bottom panel, we see that the choice people make (red or green) at time points when they do offer a guess, is well explained by the model $(r=0.92)$ : again much of the time participants are nearly unanimous in their choice of one of the targets, as is the model. But again the model also captures the gradations in beliefs when participants are split on which target to choose

What makes trials difficult? We also wanted to know if we could better explain what makes trials easier or harder. To do so, we calculated the average model score for each trial in an equivalent way to participants' scores:
(5) ModelScore $=20+100 * \sum_{t}\left(P(\text { correct })_{t}-P(\text { incorrect })_{t}\right)$

The model predicts the difficulty of the trials better $\left(\mathrm{R}^{2}=\right.$ 0.675 ; see Figure 3) than using superficial trial features, as we first investigated $\left(\mathrm{R}^{2}=0.319\right)$. It is noteworthy that our model was never explicitly informed about how the trial would unfold, which characteristics should make a trial more difficult, or even how scoring works; nor was the model fit to capture trial scores. Instead simply by considering variations in moment-by-moment physical predictions, we could capture variation in trial difficulty.

Figure 3: Modeled versus empirical trial scores. Each point represents a single trial, where bars are $95 \%$ confidence intervals on empirical scores.

There remains reliable variability in participants' average scores that is not explained by the model. To investigate what might be causing this, we again predicted participants’ scores on each trial, using the same features that we had before, but physical model's score included as a predictor. With the model score added, no new features became significant predictors (indicating that the model is unbiased with respect to those features), and two features - the number of bounces and the smallest distance to the incorrect target - were no longer good predictors (indicating that the model accounts for these difficulties well). Two features did remain though: the deviation of the path from the horizontal or vertical, and the ratio of the average distance of the ball
to each of the targets. Including these two predictors did provide a statistically significantly better fit $(F(2,393)=12.9$, $p<0.001$ ), but only explained slightly more variability in participants' scores $\left(\mathrm{R}^{2}=0.695\right)$.

The remaining feature predictors inform us about what aspects of human cognition the model is not capturing. First, the model does not capture the additional difficulty introduced when the ball is traveling at an angle. The physical model assumes that directions of movement are equally difficult to simulate, but this indicates that people may find it difficult to predict the path of objects travelling at an angle, in the same way people have difficulty discriminating oblique motion (Matthews \& Quin, 1999). The ratio of the distances between the targets also remains as a predictor, but the correlation is attenuated as compared to the relationship without the model predictions, perhaps suggesting that there is a bias to believe the ball will hit the nearer target beyond simulations.

Table 2: Predictors of trial difficult including the physical model. Partial correlation is correlation between predictor and trial score after all other predictors have been included. Prior partial correlation is partial correlation of prediction not including the physical model (see Table 1)

| Predictor | $r$ | $\mathrm{r}_{\text {partial }}$ | Prior $\mathrm{r}_{\text {partial }}$ |
| :--- | ---: | ---: | ---: |
| Physical model | 0.82 | 0.65 | $\mathrm{~N} / \mathrm{A}$ |
| (4) Direction deviation | -0.21 | -0.17 | -0.14 |
| (7) Distance ratio | -0.51 | -0.15 | -0.24 |

Why do human and model predictions differ? Participants' predictions were overall consistent with the model, but this fit varied by trial. To explain how people might be consistent with or deviate from simulation using noisy physics, we investigated how well the model fit empirical data on each trial. Our metric of trial fit was the average deviation between participants' decisions and model predictions over the trial, similar to eq. 4:
(6) Dev $_{j}=\sum_{i} \sqrt{\left(\text { prop }(\text { Red })_{i j}-p(\text { Red })_{i j}\right)^{2}+\left(\text { prop }(\text { Green })_{i j}-p\left(\text { Green }_{i j}\right)^{2}\right.} / t_{j}$

Figure 4: Model deviation from empirical decisions as a function of trial difficulty.

Well-fit trials had lower average deviations, whereas poor fits were characterized by high deviation. As can be seen in

Figure 4, the model predicted participants' decisions better on trials that the participants found easy, with a slight reduction in performance as the trials became more difficult.

Many of the highest scoring and best fitting trials were straightforward, as people quickly decided on the correct target, and the model captured this behavior. We first review two trials with average model fit (the green points, Figure 4) to discuss the strengths of the model, then review where the model deviates from human performance: two trials that people find difficult but the model does not (the purple points), and the five 'qualitative' trials that the model finds difficult but people do not (the red points). Information on all other trials can be found online at experiments.evullab.org/physovertime/trials.html

Figure 5: (Left) Image of average fitting trials. Numbers represent the time in seconds when the ball passes that point. (Right) Associated proportion of red, green, or undecided decisions by participants (top) or the model (bottom). Time on the x -axis is matched to the associated point in the trial diagram. The model tends to capture human behavior, erring only in confidence (top trial) or timing (bottom trial).

Moderately difficult trials were those in which the correct target was not immediately obvious, requiring participants to either resolve their belief over time (see Figure 5-top), or change their beliefs when more information arrived (see Figure 5-bottom). The model predicted these types of decisions well, typically erring only in either the amount of uncertainty or the timing of decision changes. This suggests that in aggregate, the model captures the way that people resolve uncertainty: certainty increases as the ball travels or when people see the outcome of a bounce.

There were also trials that participants did poorly on that the model did not fit well. These were typically trials where (a) the ball was traveling at a steep angle, and (b) small changes in the perceived layout of the table could cause a difference in the ending target. For instance, the top trial in Figure 6 was the trial for which the model performed the worst. Here, if the wall just below the green target were
slightly larger, the ball would miss that target and hit red. The model assumes perfect knowledge of the table, but it is likely that people have uncertainty about the area of the bumpers and target-areas as well - uncertainty that the model does not have.

Figure 6: Image of trial path (left) and associated empirical and model predictions (right) for difficult, poor-fitting trials. Slight changes in the layout of the table would have significant consequences for both trials, which the model does not capture.

We also specifically created 'qualitative' trials in which one target was difficult for the ball to get to, but the other was unreachable (see Figure 7). These trials comprised a large portion of the trials that the model found difficult but participants found easy. If participants are deciding between the two targets based solely on the output of a physical simulator, then they should show large amounts of uncertainty until near the end of the trial. On the other hand, if people can qualitatively analyze the structure of the table and determine that one target is unreachable, then they should quickly show high confidence for the possible but unlikely target. On these trials, participants tended to be much more confident than model predictions starting early in the trial, suggesting that they were performing a qualitative, topological analysis of the possible trajectories and outcomes on the table.

## Discussion

In this study we demonstrated that human online predictions about the world can be well captured by a model that continually simulates the world forward using noisy physical principles. This physical simulation model could better predict which trials were easy and which were difficult than a simple analysis of trial features. Likewise, it well predicted how often people would decide on one of the two target, and which target they would decide on. Together, these results suggest that people are performing forward physical simulation online as the trial unfolds.

Furthermore, we found aspects of human behavior that the model missed, for instance difficulty with balls traveling at oblique angles or uncertainty about the state of the table. These factors are consistent with a forward simulation model, and suggest refinements to our knowledge of how people simulate object movement.

The qualitative trials, on the other hand, are inconsistent with a pure simulation account. On these trials, simulations would have difficulty reaching the incorrect target, and thus pure simulation would predict uncertainty throughout the trial, as our model does. Instead, people quickly grow certain, reasoning that if the ball cannot reach one target, it must eventually reach the other. This suggests that people may use qualitative spatial reasoning (e.g. Forbus, 1994)

Figure 7: Image of trial path (left) and associated empirical and model predictions (right) for qualitative trials.
Participants can quickly discover that the ball cannot reach one of the two targets and select the other, but the model must use simulations to make this determination.
when it provides a clear answer about their environment, but otherwise use simulations to reason about the future. Further investigation is required to understand how and when people decide to switch between modes of prediction.

Finally, our model made predictions by generating a new set of simulated paths at each time step. However, people probably conserve computation and only slightly update a single set of simulations at each time step (e.g., using a particle filtering algorithm). Details of the exact prediction algorithm are a fruitful area for future research.

We can predict the future state of the world and integrate new information to make better predictions. This study suggests these predictions often come from continuously updating our vision of how the world will unfold, but also leaves tantalizing clues that we can overlay our simulations with qualitative reasoning about our environment as well.

# Linguistic structure is an evolutionary trade-off between simplicity and expressivity 

Kenny Smith (kenny@ling.ed.ac.uk), Monica Tamariz \& Simon Kirby<br>Language Evolution and Computation Research Unit, School of Philosophy, Psychology \& Language Sciences, University of Edinburgh, Dugald Stewart Building, 3 Charles Street, Edinburgh, EH8 9AD, UK

#### Abstract

Language exhibits structure: a species-unique system for expressing complex meanings using complex forms. We present a review of modelling and experimental literature on the evolution of structure which suggests that structure is a cultural adaptation in response to pressure for expressivity (arising during communication) and compressibility (arising during learning), and test this hypothesis using a new Bayesian iterated learning model. We conclude that linguistic structure can and should be explained as a consequence of cultural evolution in response to these two pressures.

Keywords: language; structure; cultural evolution; learning; communication

## Introduction

Human language is unique among the communication systems of the natural world in that it is exhibits a rich combinatorial and compositional structure: language provides a generative system for productively combining meaningless elements (e.g. speech sounds) to form meaning-bearing units (morphemes), which are further recombined to yield complex units (phrases) whose meaning is derived in a predictable manner from the meaning of their component parts and their manner of composition. This allows us massive expressive potential: at least at a first approximation, anything you can think you can express in language. No other species has a communication system providing anything approaching this expressive power: why do humans?

One explanation for the presence of structure ${ }^{1}$ in human language appeals to biological evolution under natural selection (Pinker \& Bloom, 1990): language is fundamentally a biological trait, being underpinned by some innate languagespecific apparatus; the ability to communicate propositions which a structured language provides is adaptive, since it facilitates social interaction and ultimately increases fitness; therefore, structure in language represents a biological adaptation to facilitate communication. A second account explains structure in language as a consequence of cultural, rather than biological, evolution (Christiansen \& Chater, 2008). Rather than language structure reflecting an evolved domain-specific learning apparatus, the idea is that languages have adapted over repeated episodes of learning and production (a process sometimes called iterated learning) in response to weaker, domain-general constraints arising from the biases of language learners. We have previously termed this evolutionary process cultural selection for learnability (Brighton, Kirby, \& Smith, 2005). A range of models and experiments show

[^213]that cultural selection for learnability leads to the evolution of structure, under certain assumptions about the nature of transmission and the biases of language learners. Under a strong interpretation of this account, language's function for communication could be seen as an epiphenomenon: structured language provides a powerful medium for communication, but language structure is not 'for' communication.

Here we present a new model of iterated learning, motivated by recent experimental work, which goes some way to reconcile these two viewpoints. We draw from the biological account the insight that the alignment between language's apparent function as a system for expressing propositions and its structure, tailor-made for just such a purpose, is unlikely to be a fortuitous coincidence. We draw from cultural evolutionary account two insights: 1) biological evolution is not the only evolutionary process which might act to shape language: cultural evolution, a necessary consequence of the fact that language is socially learned, is a second such mechanism; 2) selection for learnability will impact on language during its transmission. This model suggests that structure arises from cultural evolution when language is under pressure to be expressive and learnable: pressure for expressivity arises from language use in communication, language learning by naive individuals introduces a pressure for simplicity arising from domain-general preferences for compressibility in learning. Crucially, both must be in play: pressure for expressivity or simplicity alone does not lead to structure. Structure in language is a linguistic adaptation, not a biological adaptation, in response to competing pressures for expressivity and learnability (Kirby, Cornish, \& Smith, 2008; Steels, 2012).

## Cultural evolution of structure: previous work

Models of the cultural evolution of linguistic structure typically emphasise the role of learnability constraints in driving the evolution of compositionality. Specifically, language is under pressure to be compressible: to allow the formation of compressed mental representations, i.e. simple grammars. This pressure for compressibility is inherent in learning (Chater \& Vitanyi, 2003), and can be amplified by other constraints acting on language transmission (e.g. the mismatch between the infinite expressivity of languages and the finite set of data from which such languages must be learned). Learning and transmission therefore favour languages which admit to compressed representations, i.e. which permit generalisations. Recursive compositionality is one such generalisation (e.g. Steels, 1998; Kirby, 2002; Brighton, Smith, \& Kirby, 2005), and therefore represents an adaptation by lan-
guage in response to pressures inherent in transmission and learning. However, compressibility is not the only constraint on learnability in these models: they typically include some learner bias in favour of languages which embody a one-toone mapping between meaning and form (which happen to be communicatively functional mappings), e.g. by implementing indirect (Kirby, 2002) or direct (Steels, 1998) competition between meanings which map to a single form. Brighton, Smith, and Kirby (2005) show that, if this bias against one-toone mappings is absent, the pressure for compressibility acting in isolation leads to degenerate, not structured, languages, where all meanings map to a single maximally-ambiguous form. While this might suggest that such a one-to-one bias would be adaptive, Smith (2004) shows that such a bias is unlikely to evolve for its (eventual) communicative payoff, and concludes that the one-to-one bias must be a product of domain-general cognitive biases. Again, this suggests that the utility of language for communication might be a side-effect of learnability pressures alone.

Diffusion-chain experiments with adult human participants have also been used to investigate the impact of cultural selection for learnability. Kirby et al. (2008) report two experiments in which participants are trained on a miniature language which provides labels for objects (coloured moving shapes, e.g. a red square bouncing), and are then prompted to produce labels for a further set of objects. Participants are organised into a diffusion chain, such that the labels produced by the $n$th participant in a given chain provide the training data for participant $n+1$ in that chain. The first participant in each chain is trained on a unstructured holistic system, where each object is associated with a unique random label (and therefore shared elements of meaning do not map to shared components of form).

Across two experiments, Kirby et al. (2008) show that languages change as a result of their transmission to be more learnable: the languages produced later in a chain of transmission are learnt with greater accuracy. In their Experiment 1 , this is achieved by the languages becoming simple: the languages lose distinctions. In the most extreme case, this results in a degenerate language in which all objects (with one exception) are associated with a single, highly-ambiguous label. Simplification facilitates learning at the expense of expressivity: while the initial holistic languages have high expressive potential, the languages which ultimately emerge allow only a few contrasts between objects to be signalled linguistically. However, there is no pressure for expressivity in this experiment: the language is under pressure to be learnable, but given the lack of a communicative task, under very little pressure to provide distinct labels for distinct objects.

In their Experiment 2, an artificial pressure for expressivity was introduced: homonyms (labels paired with multiple objects) were eliminated during the process of sampling from the $n$th participant's productions to yield the training data for participant $n+1$. As in Experiment 1, the languages became more learnable, but this was achieved by the development of
compositional structure: colour, shape and motion came to be encoded in separate 'morphemes' of multi-morphemic words. These structured languages are both learnable and expressive, allowing all distinctions between objects to be encoded linguistically.

Garrod, Fay, Lee, Oberlander, and MacLeod (2007) present a task in which participants are required to communicate a set of pre-specified concepts using drawings. Participants who repeatedly play the game together develop an expressive system of symbol-like graphical representations to communicate these concepts. This system of communication is holistic: each symbol is an idiosyncratic, stand-alone entity. Theisen-White, Kirby, and Oberlander (2011) present a modified version of this paradigm, integrating the dyadic context for communication with the diffusion-chain method from Kirby et al. (2008). An initial pair play a variant of the communication game from Garrod et al., using a modified set of concepts designed to provide a basis for systematic structure (e.g., teacher, school, teaching; firefighter, fire station, fire-fighting). The drawings produced by that pair during communication are then observed by a fresh pair of participants, who go on to communicate together, and so on. The system of communication is therefore under pressure to be both expressive (communicatively functional) and learnable (by the naive individuals during the observation phase). Theisen-White et al. find that the sets of drawings become more structured over these chains of transmission: the drawings develop component parts which refer to the domain (e.g. teaching, fire-fighting) and the category (e.g. person, building, activity).

These experimental results are therefore consistent with the modelling literature reviewed above and suggest a three-way contrast: pressure for compressibility alone results in degenerate languages (Kirby et al., 2008, Experiment 1); pressure for expressivity but not learnability (Garrod et al., 2007) leads to holistic systems; pressure for expressivity (from artificial filtering or, better, communication) leads to structure (Kirby et al., 2008; Theisen-White et al., 2011). However, no one model or experimental paradigm completely decouples learnability and expressivity: below, we present a model which does this, and which demonstrates this link between expressivity, learnablity and structure more conclusively.

## The model

We model individuals as rational learners who infer a distribution over possible languages (meaning-form mappings), and use those languages to communicate. Learners have a (parameterised) prior preference for simple, compressible languages, and during interaction a (parameterised) tendency to avoid utterances which are ambiguous in context.

## Model of languages

A language consists of a system for expressing meanings using forms. We consider the simplest possible meanings and forms which are nonetheless capable of evidencing systematic structure: meanings are vectors of length $v$, where each
element in the vector takes one of $w$ possible values. Similarly, forms are of length $l$, where each character is drawn from some alphabet $\Sigma$. We take $v=w=l=|\Sigma|=2$, which yields a set of meanings $\mathcal{M}=\{00,01,10,11\}$ and a set of forms $\mathcal{F}=\{a a, a b, b a, b b\}$. This gives a space of 256 possible languages, including degenerate, compositional and holistic mappings: see Table 1 for examples. ${ }^{2}$

## Hypotheses

Learners infer a distribution over languages: the space of hypotheses is therefore the space of possible distributions over all 256 languages. ${ }^{3}$ Following Burkett and Griffiths (2010), we use a Dirichlet process prior (Ferguson, 1973), characterised by concentration parameter $\alpha$ and base distribution $G_{0}$. The parameter $\alpha$ determines how many languages feature in this distribution: low alpha (we use $\alpha=0.1$ ) corresponds to an a priori belief that the majority of the probability mass will be on a single language. The base distribution is a distribution over languages, and would be the prior if learners only considered single-language hypotheses.

Our base distribution encodes a preference for simplicity, operationalised as a preference for languages whose description is compressible. Intuitively, degenerate languages permit more compressed descriptions than compositional languages; holistic languages are, by definition, incompressible. The prior used in Kirby, Dowman, and Griffiths (2007) captures this intuition: it assigns higher probability to languages in which fewer forms are used to convey a given set of meanings. We simply apply this metric both over the full set of meanings and specific feature values (see Appendix). This prior splits the space of 256 possible languages into 12 language classes, based on the number of forms in the language and the regularity with which feature of meaning are mapped to components of form: the priors for individual languages are depicted in Fig. 1, with example languages from some pertinent classes in Table 1. The prior yields the desired ranking of languages: more compressible languages (i.e. with fewer forms) are preferred, but within those languages with a given number of forms, there is a preference for languages which consistently map feature values in the meaning to a single character in the corresponding position in the form.

## Likelihood

We sample a form $f$ from the distribution $P(f \mid h, C, t)$, which specifies the probability of $f$ given hypothesis $h$, a context of utterance (a set of meanings) $C$, and topic $t \in C$, which the speaker attempts to discriminate from the other meanings

[^214]Table 1: Example languages from three important classes.

|  | Form |  |  |
| :---: | :---: | :---: | :---: |
| Meaning | degenerate | holistic | compositional |
| 00 | aa | aa | aa |
| 01 | aa | ba | ab |
| 10 | aa | ab | ba |
| 11 | aa | bb | bb |

Figure 1: Probability in $G_{0}$ for individual languages in each class, arranged by number of distinct forms, and (within a given number of forms) increasing compressibility. Annotations give the number of languages per class, all of which have equal prior probability.
in $C$. $P(f \mid h, C, t)=P(l \mid h) \cdot P(f \mid l, C, t)$ : we simply sample a language $l$ from the speaker's hypothesis, then given that language and the context, sample an utterance. We include a parameterisable preference to avoid ambiguity during this latter step, following the model of pragmatics provided by Frank and Goodman (2012). Assuming some small probability of error on production $\varepsilon$ :

$$
P(f \mid l, C, t) \propto \begin{cases}\left(\frac{1}{a}\right)^{\gamma}(1-\varepsilon) & \text { if } t \text { is mapped to } f \text { in } l \\ \frac{\varepsilon}{|S|-1} & \text { if } t \text { is not mapped to } f \text { in } l\end{cases}
$$

where we normalise over all possible forms from $\mathcal{F}$. $a$ is ambiguity, the number of meanings in $C$ that map to form $f$ in $l$, and $\gamma$ specifies the extent to which utterances which are ambiguous in context are penalised. If $a=1$ ( $f$ is unambiguous in this context) and/or $\gamma=0$ then this yields a model of production where the 'correct' form is produced with probability $1-\varepsilon$. However, when $\gamma>0$ and $f$ is ambiguous in context (i.e. $a>1$ ), then the 'correct' mapping from $t$ to $f$ is less likely to be produced, and the remaining probability mass is spread equally over the other possible forms. Therefore, $\gamma>0$ introduces a penalty for languages whose utterances are ambiguous in context. We use $\varepsilon=0.05,|C|=3$, and vary $\gamma$.

## Inference

Exact inference over this hypothesis space in intractable: instead, following Burkett and Griffiths (2010), we use a Gibbs
sampler based on the Chinese Restaurant Process to sample a hypothesis direct from the posterior. As described below, learners acquire an expanding set of observed utterances during their lifetime: we run the inference over the most recent $r=80$ observations, in order to improve simulation runtimes.

## Transmission in populations

Following the experimental methods employed by TheisenWhite et al. (2011) and Garrod et al. (2007), we compare two types of population: in chains, simulated agents are organised into pairs, are trained on data produced by the previous pair (see below), and then interact, producing data which the next generation in the chain (a new, naive pair of simulated individuals) are trained on. In dyads exactly the same regime of training and interaction is observed. However, naive individuals are not introduced at each generation: rather, the same individuals are trained on their own productions from the previous phase of interaction. ${ }^{4}$ The contrast between chains and dyads allows us to manipulate the pressure for learnability: in chains, where naive individuals are introduced at every generation, the pressure for learnability (i.e. the influence of the prior preference for simplicity) is likely to be relatively strong. In dyads, in contrast, there is only one episode of transmission to naive individuals (at generation 1), and consequently the pressure for simplicity arising from the prior is substantially diminished.
Training During training, the pair are presented with a shared set of 20 form-meaning pairs, produced by the preceding pair during interaction or (for the first generation only) a shared set of 20 form-meaning pairs generated from a randomly-selected fully-expressive holistic language (this initialisation with holistic languages is inspired by the experimental work discussed above). This data is added to each agent's memory (which will be empty for individuals in chains), and then a hypothesis is sampled from the posterior.
Interaction After training, the pair interact for 40 rounds. At each round of interaction, one individual acts as teacher and the other as learner. The teacher is prompted with a randomly-selected context and topic, and samples a form from their hypothesis. The learner adds the observed form-meaning-context triple to its memory, and samples an updated hypothesis. The roles of teacher and learner then switch, and a new round is played.
Transmission The 20 form-meaning pairs produced by one randomly-selected member of the pair at generation $n$ is used

[^215]as the training data for the pair at generation $n+1 .{ }^{5}$

## Results

The results (Fig. 2) match the predictions of our hypothesis, and are consistent with the experimental results described above. When there is pressure for learnability arising from transmission to naive individuals, but no pressure for expressivity (achieved by using the chain population model and setting $\gamma$ for interaction to 0 ), the final distribution is dominated by degenerate languages, as in Kirby et al. (2008), Experiment 1. Note that this preference for degenerate languages is even stronger than that seen in the prior: given the parameters of the model, in particular the low concentration parameter for the Dirichlet process prior, this exaggeration of the prior is as predicted by Burkett and Griffiths (2010). In contrast, in the condition where there is expressivity pressure but little pressure for learnability (dyads, $\gamma=3$ ), the initial holistic languages, (expressive but not compressible) persist. Members of the dyad constantly replenish their own evidence that the language is holistic: consequently, the initial holistic language is locked in. This matches the experimental results obtained for dyads (Garrod et al., 2007): due to the lack of transmission to new individuals, there is little pressure for compressibility to counteract lock-in and expressivity requirements during interaction, and structure does not emerge. Note also that this result holds despite the fact that we set a fairly low memory limit for individuals $(r=80)$. Finally, when there is pressure for both learnability and expressivity (chains, $\gamma=3$ ), we see structured languages emerge: the final distribution is dominated by a priori unlikely expressive languages, but among these it is the a priori most likely languages, the compositional languages, that dominate. Again, this matches our hypothesis and the experimental data from Theisen-White et al. (2011).

## Discussion

Our model shows that pressure for expressivity or simplicity alone does not lead to the emergence of structure: only when both pressures are at play does structure emerge. Furthermore, only cultural evolution is required for structure: we can explain why language is structured without recourse to invoking an evolved, domain-specific faculty of language.

As well as corresponding closely with existing modelling and experimental data, these findings make sense of the distribution of structure in the communication systems of nonhuman animals. Many small but expressive communication systems exist in nature, a classic example being alarm calling systems, which allow the discrimination of several referents (predators), but do so using vocalisations which are holistic and unlearned (Fitch, 2000). Learned vocal communication systems are witnessed in many species of bird, as well as being patchily distributed among mammals (Fitch, 2000): strik-

[^216]Learnability, no expressivity

Expressivity, no learnability

## Learnability and expressivity

Figure 2: Time courses (left: mean probability of each language class in the last sampled hypothesis of each individual in multiple chains/dyads) and final distributions (right: mean probability as in time courses, averaged over the final 50 generations of those same simulation runs). When learnability is the only pressure (top: average of 20 simulation runs), degenerate languages dominate the final distribution. When expressivity is the only pressure (middle: 50 runs), the original expressive but holistic languages are preserved. When both pressures are at play (bottom: 50 runs), expressive but compositionally-structured languages emerge.
ingly, song, the classic example of (combinatorial, not compositional) structure in animal communication, occurs in precisely these species, whose communication system is under cultural selection to be learnable but expressive. This is entirely consistent with the predictions of our model, although we would suggest that the expressivity pressures inherent in communication in these species must be rather different from the expressivity pressure in language, with a focus on signalling e.g. individual quality, rather than communicating propositions.

## Conclusions

The results from our model support the hypothesis drawn from our review of the modelling and experimental literature on the evolution of communication systems: structure emerges when a system of communication is under pressure to be both expressive (due to communicative interaction) and simple (due to domain-general preferences for compressibility imposed during language learning). Crucially, both these pressures must be in play: pressure for expressivity or simplicity alone does not lead to structure. Linguistic structure therefore can and should be explained as a consequence of cultural evolution: structure in language is a linguistic adaptation, not a biological adaptation, and it is an adaptation in response to competing pressures for expressivity and learnability inherent in language transmission and use.

## Appendix

For a given set of forms $F$ (where members of the set are either complete forms, e.g. $a a$, or partially-specified forms, e.g. $\quad a *$, indicating a string-initial $a$ ) and a set of meanings $M$, we can count the number of mappings in a language for which forms from $F$ are associated with meanings from $M$ : we denote this quantity $n(M, F)$. For instance, $n(\{00,10,11,10\}, a a)=4$ for the degenerate language in Table 1 , since the form $a a$ is associated with all 4 of these meanings, but 1 for the compositional and holistic languages; $n(0 *, a *)=2$ for the degenerate and compositional languages but 1 for the holistic language, since there is only a single mapping where meaning-initial 0 maps to form-initial a. Our base probability for language $l$ characterised is then:

$$
G_{0}(l) \propto P(l, \mathcal{M}, \mathcal{F}) . \prod_{m \in\{0 *, 1 *\}} P(l, m,\{a *, b *\}) \cdot \prod_{m \in\{* 0, * 1\}} P(l, m,\{* a, * b\})
$$

where we normalise over all possible languages and $P(l, M, F)$ is the prior from Kirby et al. (2007),

$$
P(l, M, F)=\frac{\Gamma(|F| \sigma)}{\Gamma(\sigma)^{|F|} \Gamma(m+|F| \sigma)} \prod_{f \in F} \Gamma(n(M, f)+\sigma)
$$

where $\Gamma(x)=(x-1)$ ! and $m$ is the number of meanings from $\mathscr{M}$ that unify with $M$. The parameters $\sigma$ determines the strength of the preference for simplicity: low $\sigma$ (we use $\sigma=1$, the lowest possible value) strengthens the preference for more compressible languages, higher $\sigma$ leads to a weaker preference for such languages.

# Modelling the Supervisory System and Frontal Dysfunction: An Architecturally Grounded Model of the Wisconsin Card Sorting Task

#### Abstract

We present a model of the Wisconsin Card Sorting Test, a classical neuropsychological test frequently used to assess deficits in executive functioning. The model is grounded in a cognitive architecture based on the Supervisory System theory of Norman and Shallice (1986) and evaluated against data from control subjects and several groups of neurological patients as reported by Stuss et al. (2000). The model is able to account for control performance across a range of dependent measures. When damaged in theoretically motivated ways it is also able to capture the behaviour of the different patient groups. Specifically, the model supports the association by Shallice et al. (2008) of the function of tasksetting to left lateral prefrontal cortex, of the function of attentiveness to inferior medial prefrontal cortex, and of the function of monitoring to right lateral prefrontal cortex. The implication of these results for the supervisory system architecture and the localisation of function within prefrontal cortex are discussed.

Keywords: Cognitive architecture; Supervisory system; Wisconsin card sorting task; Frontal dysfunction.

## Introduction

Several theories of the organisation of cognitive processes have been proposed over the last 25 years. These cognitive architectures generally comprise complex production systems, and normally have their roots in behaviours in specific cognitive domains (e.g., problem solving, as in, Soar: Newell, 1990; associative memory, as in ACT-R: Anderson, 2007; or immediate response tasks as in EPIC: Meyer \& Kieras, 1997). While such architectures have been highly successful at accounting for a range of behavioural effects, they are not well suited to modelling the behaviour of neurological patients with focal brain damage. This is largely because it is unclear how the functional components of such architectures might be impaired without causing complete breakdown of the system. The cognitive architecture sketched by Norman and Shallice (1986) and elaborated by Shallice et al. (2008), in contrast, provides a modular view of cognition in which functional components may operate more or less efficiently, and hence neurological deficits might be more directly accounted for.

The Norman/Shallice theory draws a primary distinction between routine behaviour, which is generated by a lower level scheduling system - Contention Scheduling - and nonroutine behaviour, which is effected by a higher level system - Supervisory System. This higher level system operates indirectly on behaviour by modulating the functioning of Contention Scheduling. When initially
described (Norman \& Shallice, 1986), the situations requiring Supervisory System input were clearly enumerated but the subsystem's functioning was specified only in abstract terms. Those functions include what have since come to be known as executive functions such as tasksetting, monitoring and working memory maintenance.

In a somewhat separate line of work, Shallice, Stuss and colleagues (e.g. Stuss et al., 2000; Shallice et al., 2008) have attempted to account for the deficits of several groups of patients with focal frontal lobe lesions in terms of deficits affecting specific executive functions which, they argue, are effected by different regions of the prefrontal cortex. Thus, the deficits of patients with left lateral prefrontal lesions across a range of tasks are interpreted as reflecting impaired task-setting, while the deficits of right lateral prefrontal patients are interpreted as reflecting impaired monitoring. Similarly, the deficits of patients with focal lesions affecting inferior medial prefrontal regions are interpreted as reflecting an impaired ability to sustain attention to a task, while the deficits of patients with focal lesions affecting superior medial prefrontal cortex are interpreted as reflecting an impairment in "energisation", i.e., mobilisation of cognitive resources, corresponding phenomenologically to cognitive effort.

Shallice et al. (2008) relate the four executive functions discussed in the previous paragraph to the Supervisory System, with a specific focus to how the two accounts relate within a simple task-switching study. However these authors provide only an informal characterisation of the functions. They do not provide a precise computational instantiation of the ideas. The goal of this paper is to provide and evaluate such an instantiation. More specifically we present a computational account of the heterarchical organisation of the Supervisory System. The account is grounded in a model of a specific task - the Wisconsin Card Sorting Test (WCST). This widely used test of executive function provides multiple dependent measures that are sensitive to frontal lobe damage (Milner, 1963). We report simulations of the behaviour of control subjects and of four patient groups, comparing our results with those of Stuss et al. (2000), who tested patients and controls on the task.

The following sections briefly discuss the cognitive architecture in which the model is framed, the Wisconsin card sorting test and the neuropsychological group study that provides the target data. Following this, we present the model itself, the methodology for modelling control and

Figure 1: The proposed functional organisation of the Supervisory System architecture. Hexagonal boxes represent processes while rounded rectangles represent buffers or storage systems. Arrows show hypothesised connectivity between components.
patient performance, and the respective simulation results. We conclude by considering the implications of this work for the computational specification of the Supervisory System and more generally for the functional organisation of higher cognition.

## The Supervisory System Architecture

The Supervisory System proposed by Shallice, Stuss and colleagues (e.g., Shallice et al., 2008) is a heterarchical system comprising, amongst other things, four core subprocesses: task-setting, active monitoring, energisation and attentiveness. The evidence for this organisation is drawn from neuropsychological case studies where the nature of deficits exhibited by frontal patients show subtle differences based on the lesion location. For example, the impairment exhibited by left prefrontal patients may be understood as resulting from inefficient task strategy formation while right prefrontal patients make errors that suggest poor ability to monitor internal and external events. The deficits of inferior medial prefrontal patients may stem from a characteristic lack of attention while superior medial prefrontal patients exhibit a longer $(30 \%)$ start up delay in task execution compared to other groups (for a review, see Shallice \& Cooper, 2011).

The cognitive architecture of the model described in this paper is derived from the Contention Scheduling / Supervisory System theory and is depicted in figure 1. Processing within the Contention Scheduling components of architecture is as follows: perceptual input enters Sensory Stores. Potential responses are generated from this by Apply Set subject to application of the current stimulus-response mapping set. These responses are passed to a Response Buffer before being generated as actions. The Generate Response process also maintains Forward Model, which represents the anticipated sensory feedback of the system's actions. The Supervisory System modulates the behaviour
of Contention Scheduling by two key processes: a) Monitoring, which compares sensory feedback with anticipated sensory feedback and rejects the current stimulus-response mapping if there is a mismatch (i.e., an unanticipated sensory input) by clearing Current Set, and b) Task Setting, which sets a stimulus-response mapping when Current Set is empty. Two other supervisory processes, Attentiveness and Active Maintenance, work to counteract decay which is assumed to operate on elements within Current Set and Working Memory. With the exception of Energisation, the model adequately represents all other subprocesses of the Supervisory System theory.

## The Wisconsin Card Sorting Test

## The Task

In order to evaluate the Supervisory System architecture we consider its application to a specific task: the Wisconsin Card Sorting Test (WCST). The WCST exists in various forms. The version simulated here is the 64A version used by Stuss et al. (2000). In this version of the task, subjects are required to sort a deck of cards, 64 in total presented one at a time, into four groups. Each card has a picture of a specific shape in variable numbers and colours (e.g., one red triangle or four blue squares; see figure 2). Four "target" cards, differing with respect to the number, colour and shape of items they depict, are provided and subjects are required to place each successive card from the main deck under one of the four target cards. In the 64A version, subjects are informed of the three possible sorting criteria - sort by colour, sort by number or sort by shape - prior to the test. After each card is sorted, the subject is given feedback. Based on the feedback, the subject should attempt to infer the correct sorting rule and use it for subsequent sorts. Once the subject correctly sorts 10 cards consecutively, the experimenter changes the rule without warning. The ideal

Figure 2: The Wisconsin Card Sorting Test, after two cards have been sorted according to the colour of their symbols and as a third card (two blue triangles) is presented for sorting.
subject will detect this and select a new rule, based on the feedback after each sorting attempt.

Neurologically healthy subjects have little difficulty in this task. However patients with frontal lesions are prone to perform poorly, frequently showing incapacity to change the rule when the feedback is negative, i.e. they tend to 'persevere', but also showing 'set loss' errors, where they appear to correctly infer a rule, but fail to follow that rule for ten consecutive sorting trials, even with positive feedback.

## Neuropsychological Evidence

The motivation behind choosing the WCST for evaluation of the supervisory system architecture over other executive tasks is the availability of detailed empirical data published by Stuss et al. (2000) on patients categorised with focal lesions on the four brain regions of theoretical interest. The empirical study carried out by Stuss et al. (2000) tested seven groups of subjects. Four groups had focal frontal lesions on left/right dorsolateral prefrontal cortex (LDL/RDL), superior medial (SM) and inferior medial (IM) prefrontal regions. The fifth and the sixth patient groups had lesions affecting left/right non-frontal brain regions and the seventh group comprised neurologically healthy subjects. The subjects were tested on three versions of WCST: 128, 64 A and 64B. In the 128 version, subjects were not provided any instructions on how to perform the test. In 64A version, subjects were informed of the three possible sorting criteria beforehand, while in 64B version subjects were also alerted when the rule was about to change. In each case, the errors made by subjects were classified into four categories: perseveration of preceding category (PPC: an incorrect response that matches the preceding sorting criterion), perseveration of preceding response (PPR: an incorrect response that matches exactly the features on the preceding trial), set-loss (an incorrect response following
three or more consecutively correct responses) and other errors. Patients with frontal lesions, compared to those with non-frontal lesions and controls, exhibited more PPC, PPR and set-loss errors. The error patterns exhibited by the different frontal groups revealed subtle differences. For example, in the 64A condition, all frontal groups except IM showed significantly more PPC and PPR errors than controls. In contrast, the IM group made significantly more set-loss errors than patients from other frontal groups.

## Modelling the WCST

## Model Assumptions and Description

The model discussed here is an elaboration of the heterarchical Supervisory System theory (figure 1), with its components configured for the WCST 64A condition of the empirical study by Stuss et al. (2000). Consider first the three buffers and two processes that make up Contention Scheduling. When a card is to be sorted, a propositional representation of the card appears in Sensory Stores. Apply Set then consults Current Set for a representation of the current sorting rule (e.g., sort by colour) and uses this in conjunction with the representation in Sensory Stores (e.g., two blue triangles) to generate a putative response (e.g., place the card on the right-most pile) which is stored in Response Buffer. Generate Response then produces the actual response (storing a copy in Working Memory), together with a representation of the anticipated consequences of the response - the Forward Model. (In the current implementation Forward Model is ignored, since the anticipated consequence of any action is positive feedback.)

Processing within the Contention Scheduling components is modulated by the Supervisory System components. First, Monitoring may detect negative feedback in the sensory store (or more generally, a mismatch between the contents of Forward Model and Sensory Store). In such situations, Monitoring will clear Current Set (on the assumption that the current sorting rule is inappropriate). Second, Task Setting may generate a putative sorting rule and place a representation of that rule in Current Set. This occurs when Current Set is empty (e.g., because the representation of the previous sorting rule in Current Set has either decayed or been explicitly deleted by Monitoring). Generation of a putative sorting rule depends on the contents of Sensory Buffer and recent responses stored in Working Memory.

Elements in the two supervisory buffers (Current Set and Working Memory) have activation values that decay over time. If the activation values fall below a threshold, the buffer contents cannot be accessed. The supervisory processes of Attentiveness and Active Maintenance work in direct opposition to decay, exciting buffer elements so as to prevent their loss

The model's behaviour may be summarised as follows: At the beginning of the task, the first sorting schema is generated at random from among the three possible schemas: sort-by-colour, sort-by-number and sort-by-form. When a card is presented, the Contention Scheduler sorts

Table 1: Parameters of the model.

| Parameter | Range | Description |
| :--- | ---: | :--- |
| Monitoring $_{\text {exogenous }}$ | $0-1$ | If impaired, feedback is not acted upon |
| Monitoring $_{\text {endogenous }}$ | $0-1$ | If impaired, drop in attention is not monitored |
| Taskset $_{\text {none }}$ | $0-1$ | If impaired, unable to switch strategy | Taskset $_{\text {random }}$ Attentiveness ${ }_{\text {persistence }}$ If impaired, unable to produce efficient strategy, a random strategy is chosen

the card according to the sorting criterion stored in Current Set. Feedback is monitored by Monitoring, a supervisory process that clears Current Set in the event of negative feedback. When Current Set is empty, Task Setting is invoked. This process accesses Working Memory to gather details of previous unsuccessful sorting attempts (if any can be recalled) and generates a new potential sorting rule that has not been recently used. If there is more than one possible choice of rule consistent with current evidence, Task Setting chooses at random from the available choices.

The model is implemented in the C programming language. In order to ensure their independent nature, the supervisory sub-processes and Contention Scheduling are implemented as separate 'threads'. Results are scored according to the criteria followed by Stuss et al. (2000).

## Behaviour of the Model

The model's behaviour is dependent on a number of parameters, which essentially determine the efficiency of processing of the various sub-processes. Table 1 provides a brief description of what these parameters represent and the range of values they can take. There are essentially two types of parameters: activation-related parameters (thresholds, activation persistence and activation boost parameters) and efficiency-related parameters. The latter specify the probability of a subsystem functioning. For instance, a value of 0.10 for Monitoring exogenous specifies that monitoring is active roughly $10 \%$ of the time. The remaining $90 \%$ of the time, the process does not function.

All parameters have optimal or ideal values. Thus, when all efficiency parameters are set to 1.00 , activation boost rates are set to the reciprocals of corresponding persistence rates (so that maintenance exactly counteracts decay), and thresholds are set to 0.5 , the model sorts optimally, correctly sorting approximately 56 out of 64 cards, achieving 5 categories (i.e., correctly sorting 10 cards according to 5 different rules) and making errors only when it is attempting to discover a rule following negative feedback.

## Modelling Control Performance

When neurologically healthy subjects attempt the WCST they generally do not perform at the optimal level. Thus the control subjects of Stuss et al. (2000) achieved on average 3.9 categories, made occasional perseverative errors, where they continued sorting by a rule even given negative feedback, and also occasionally produced set-loss errors, where they appeared to correctly infer the sorting rule, only to forget it even though the feedback was positive (see figure 3, right-most bars). In order to model control performance, normally distributed random noise was added to activation values of Working Memory and Current Set elements, the persistence of activation values was decreased, and the efficiency of supervisory processes was decreased. Systematic exploration yielded performance similar to controls when these parameters were set as follows: noise standard deviation $=0.05$; Monitoring exogenous $=$ Monitoring $_{\text {endogenous }}=$ Taskset $_{\text {none }}=$ Taskset $_{\text {random }}=0.90$; Memory $_{\text {persistence }}=0.70$; and Attentiveness ${ }_{\text {persistence }}=0.76$. With these values, the model generates perseveration and set-loss errors at rates comparable to those of the control subjects of Stuss et al. (2000) - see figure 3. The values indicate that control performance can be modelled by introducing slight imperfections to the Supervisory System.

## Modelling Frontal Dysfunction

Based on the arguments of Shallice et al. (2008), we associate exogenous monitoring (Monitoring ${ }_{\text {exogenous }}$ ), task setting ( Taskset $_{\text {none }}$ ) and attentiveness (Attentiveness ${ }_{\text {persistence }}$ ) with right dorsolateral, left dorsolateral and inferior medial prefrontal patients respectively. Although endogenous monitoring (Monitoring endogenous ) and task random setting (Taskset ${ }_{\text {random }}$ ) are important elements of monitoring and task setting processes, analysis of the model's behaviour revealed that they do not contribute significantly to the dependent measures and hence they have been excluded from the analysis of frontal dysfunction. Moreover we do

Figure 3: Model performance versus that of the patients of Stuss et al. (2000). Error bars represent one standard error from the mean.
not attempt to account for the behaviour of the superior medial prefrontal patients as the model does not have an explicit representation of the energisation process.

We adopt the methodological approach of modelling patient performance by reducing the efficiency of the process held to be impaired in the corresponding patient group. Specifically, we adjust the relevant parameter so that the model accurately captures the mean number of categories achieved by each set of patients in the Stuss et al. study ( 0.6 categories for RDL patients, 1.3 categories for LDL patients and 2.6 categories for IM patients), and then compare the model's behaviour on the three dependent measures described above (PPC, PPR and set-loss errors).

Thus an impairment level of 0.00 in Monitoring exogenous,, 0.10 in Taskset ${ }_{\text {none }}$, and 0.74 in Attentiveness ${ }_{\text {persistence }}$ produced a mean category measure comparable to RDL, LDL and IM patients respectively. When setting these parameters to model the impairments of the three patient groups, all other parameters were fixed at the levels used to simulate control subjects. Simulation data on three dependent measures PPC, PPR and set-loss errors - for each patient category obtained in this way and averaged over 10 runs of the model is shown in figure 3, plotted against the corresponding patient data published by Stuss et al.

## General Discussion

As shown in figure 3, the model of WCST behaviour, embedded within the broader Supervisory System / Contention Scheduling architecture, is able to provide a good account of control subject behaviour across four dependent measures: categories obtained, PPC errors, PPR errors and set-loss errors. This provides support - albeit weak support - both for the Supervisory System / Contention Scheduling architecture and for the model of WCST within it. However, equally important for the current work is the behaviour of the model when damaged and its relation to that of neurological patients. When damaged in theoretically motivated ways, the model reproduces several key features of the behaviour of neurological patients. Most critically, an impairment of exogenous monitoring leads to elevated levels of PPC and PPR errors, as seen in right dorsolateral prefrontal patients. An impairment of task setting leads to a similar error profile, as seen in left dorsolateral prefrontal patients. Finally, an impairment of attentiveness leads to elevated set loss errors, as seen in patients with inferior medial prefrontal lesions. This provides further support for both the model and the association of these supervisory functions with the different regions of prefrontal cortex.

The results must be interpreted with caution, however. First, the model performs similarly with impairments to either exogenous monitoring or task setting. While this is consistent with patient behaviour, it supports an argument originally made by Stuss et al. (2000) that the erroneous behaviour of their right dorsolateral and left dorsolateral groups, whilst qualitatively and quantitatively similar, may in fact be due to different functional impairments. The model demonstrates that the WCST is unable to discriminate between these functional impairments (at least with respect to PPC and PPR errors), and that empirical studies of the two patient groups on other, more discriminating, tasks is necessary if one is to make the argument that the functions of (exogenous) monitoring and task setting are indeed supported by different regions of prefrontal cortex.

The reverse side of this argument, however, derives from the fact that inferior medial patients produce elevated numbers of set-loss errors but not of PPC or PPR errors. This pattern of behaviour is produced by an impairment to the effectiveness of the attentiveness sub-process. Thus the
model supports the treatment of 'attentiveness' as a functionally and structurally distinct sub-process, as well as the 'impaired attentiveness' account of inferior medial prefrontal patient performance.

A second caution regarding the results concerns the rate of set-loss errors in simulation of RDL patient performance, which is lower than that seen in patient behaviour. This is in part because the model must sort a minimum number of consecutively presented cards correctly (and hence demonstrate that it is following a rule) before an error can be counted as a set-loss error. With severe impairments in the model, this is rare. Hence the opportunity for set loss errors is rare. We have simulated the RDL patient group by setting Monitoring ${ }_{\text {exogenous }}$ to 0.00 in order to match performance on the number of categories correctly sorted. Perhaps this level of impairment is too severe. This is an issue to be addressed in future work.

The issue of severity relates to the methodology employed in simulating patient behaviour. Patient performance was modelled by choosing one parameter value to match the number of categories achieved by the model to that of the relevant patient group. This does not take account of the heterogeneity of each patient group - not all patients were equally severely impaired - and a more appropriate methodology would be one that attempted to match the varying severity of individual patients, rather than of each group as a whole. This is an issue for further research, though in the absence of individual subject data, a plausible strategy may be to sample different levels of severity, as used by Cooper et al. (2005) in modelling the action errors of neurological patients.

Two more general questions concern the nature of supervisory processes and the Contention Scheduling / Supervisory System architecture within which the WCST model is embedded. Considering first the architectural issue, the model demonstrates that the functional decomposition of Contention Scheduling and the Supervisory System is able to support behaviour on a complex task, and so the Contention Scheduling / Supervisory System architecture provides a viable alternative to production system architectures such as ACT-R, Soar and EPIC. At the same time, the architecture remains relatively underspecified and substantial elaboration of the architecture and its subcomponents (e.g., through application to other tasks) is required before it can be fully compared with these alternatives.

With regard to the nature of supervisory processes, many theorists appear to assume, at least implicitly, a distinction between supervisory and non-supervisory processes. There is, however, some debate about whether the supervisory system is most appropriately viewed as a unitary system (e.g., Duncan, 2010) or as functionally heterogeneous (e.g., Stuss, \& Benson, 1986; Shallice, \& Cooper, 2011), and whether prefrontal cortex is better viewed as functionally hierarchical (e.g., Badre, 2008) or functionally heterarchical (Shallice \& Burgess, 1996; Shallice et al., 2008). The model described in this paper substantiates the theoretical stand of

Shallice and colleagues, but again further work is required. A possible extension to the present model is to generalise it to other executive tasks such as Tower of Hanoi, Tower of London, Stroop test etc. Applying the architecture to other executive tasks will allow for better validation of the theoretical hypotheses, which are not adequately and independently assessed by WCST.

#### Abstract

A recent paper by Lev-Ari and Keysar (2010) reported that the processing fluency associated with non-native speech causes non-native speakers to sound less credible. The authors found that the same trivia statements were rated as less truthful when spoken by a non-native speaker of English. The present paper reports the results of three studies that attempted to replicate the findings of Lev-Ari and Keysar (2010) by focusing on processing fluency manipulations other than accent. Although we used virtually the same methodology as Lev-Ari and Keysar (2010), we failed to replicate the key finding that foreign-accented speech is less credible than native-accented speech. The implications of this finding is discussed.

Keywords: fluency, foreign accent, credibility.

## Introduction

The U.S. Census Bureau (2010) reported that 38.5 million people (around $12.5 \%$ of the nation's population) have as mother tongue a language other than English. The increasing number of non-native speakers of English in the U.S. suggests that a significant amount of daily interactions involve a non-native speaker communicating in English with some sort of foreign accent.

The social psychological literature on language attitudes has documented considerable amount of evidence showing that, compared to their nonstandard, accented counterparts, listeners evaluate standard, non-accented speakers more favorably across different traits, such as competence, status, intelligence, confidence, guilt and success (Ryan \& Giles, 1982).

It is not entirely clear which cognitive mechanisms underlie this phenomenon. There is research suggesting that accent serves as a signal for the speakers' social group and that any negative attitude towards non-native speakers is caused by in-group biases and not by the accent itself. Alternatively, there is research showing an individual's actions and attitudes towards others are heavily dependent on how that person processes the information provided by them. The subjective ease with which individuals process incoming information influences them in a variety of cognitive tasks and domains (Gilbert, 1991; Schwarz, 2004; Alter \& Oppenheimer, 2009) such as estimates of familiarity (Jacoby \& Whitehouse, 1989), clarity (Whittlesea, Jacoby, \& Girard, 1990), riskiness (Song \& Schwarz, 2009), location and abstractness (Alter \& Oppenheimer, 2008), truthfulness (Reber \& Schwarz, 1999;

Unkelbach, 2007), liking (Winkielman \& Cacioppo, 2001) and even confidence (Koriat, 1993). Thus, one plausible hypothesis is that the negative impressions and judgments towards non-native speakers are triggered by the difficulty associated with processing accented speech.

A recent paper by Lev-Ari and Keysar (2010) directly explored this possibility. They asked native speakers of English to listen to a series of trivia statements such as Ants don't sleep and then indicate the degree of veracity of each statement. Participants listened to statements spoken by both native and non-native speakers of American English. The accented speech varied in terms of the degree: either mildly or heavily accented. They found that the statements spoken by non-native speakers were reliably rated as less truthful compared to the same statements spoken by native speakers.

The authors argued that their findings could not be explained in terms of stereotypes of prejudice signaled by the accent because participants were told that the non-native speakers were only reciting statements provided by a native speaker, and therefore were not displaying their own knowledge. Based on these findings, Lev-Ari and Keysar (2010) claimed that people misattribute the processing difficulty associated with non-native accented speech with the level of credibility they attribute to the content of the speech.

We began this project with the aim of exploring this issue further. The core idea is that if processing fluency influences people's judgments of the veracity of statements, then other manipulations of the speech signal such as adding background noise would also influence judgments of truth. We hoped to explore this issue both for statements of the kind used by Lev-Ari and Keysar (2010) as well as other kinds of judgments like consumer preference judgments. To presage our results, though, we were unable to replicate the initial findings.

This paper reports results for 3 studies. Study 1 explored the claim that inducing processing difficulty with mechanisms other than foreign accent (i.e., white background noise - Study 1a - and speech babble noise - Study 1b) affects judgments of truth. Studies 2 and 3 are attempts to replicate the findings of Lev-Ari and Keysar (2010). In Study 2, we asked participants to judge the truthfulness of trivia statements spoken by native and non-native speakers of English. In Study 3 we explore whether accent influences participant's
perception of the price of a product.

## Study 1

Study 1 investigated the claim that inducing processing difficulty with mechanisms other than foreign accent affects judgments of truth.

## Study 1a

Participants Twenty-six native speakers of English participated in Study 1a. Participants were undergraduate students at The University of Texas at Austin and participated for course credit.

Materials A female native English speaker recorded 70 trivia statements such as $A$ rat can last longer without water than a camel in a sound-attenuated booth. To obtain equivalent overall amplitude level for all statements, the sound files were equated for RMS amplitude. Each sound file was mixed with white noise at a four different Sound-to-Noise Ratios (SNR): level 0 corresponded to +17 dB SNR ( 68 dB of speech and 51 dB of noise), level 1 corresponded to +12 dB SNR, level 2 to +6 dB SNR and level 3 to 0 dB SNR. In the SNR notation used in this paper, the smaller the dB SNR, the louder the background noise. The mixed files were presented to participants using E-prime 2.0.

Procedure Study 1a used a within-subject design. Each participant heard all 70 trivia statements (48 experimental ones and 22 fillers) randomly mixed with one of three levels of noise (level 0, level 1 and level 2). Participants sat in front of a computer screen with headphones and were asked to indicate the truthfulness of each statement, using a scale between 0 (definitely false) and 10 (definitely true). Participants were also asked to rate whether they knew for a fact that the statement was true.

Manipulation Check To ensure that the noise manipulation made the trivia statements more difficult to process, a different group of 24 participants were asked to listen and rate the degree of difficulty to understand the statements. Each participant heard 25 randomly selected statements (five for each level of noise: no noise, level 0, level 1, level 2 and level 3).

Manipulation Check Results A one-way repeated measures ANOVA, with the difficulty level as dependent variable and noise level as independent variable, revealed a statistically reliable main effect of noise, $F(4,80)=60.59$, $p<.0001, \eta^{2}=.75$, suggesting that the overall distribution of the mean perceived difficulty across the five different noise levels significantly differed from each other. Post-hoc Bonferroni-corrected $t$-tests showed that, except for the level 0 vs. level 1 comparison, all other pairwise comparisons reliably differed from each other, $p^{\prime} s<0.05$.

Truthfulness Ratings Results and Discussion Because we wanted to avoid participants suspicion about the noise ma-
nipulation, we decided to present participants only with statements mixed with some level of noise, excluding therefore the sentences with no noise. Also, because the difficulty ratings for level 3 noise was extremely high ( $M=8.30, S D=1.89$ ), we decided to exclude this level, to avoid the possibility that participants would simply be unable to hear the statements completely.

To verify whether white noise affected the truthfulness ratings of the trivia statements, we ran a one-way repeatedmeasures ANOVA, with the truthfulness ratings as the dependent variable and the noise levels as the independent variable. Contrary to what we expected, the mean truthfulness ratings were very similar across all three different levels of white noise. The ANOVA showed that the means did not differ reliably from each other, $F(2,50)=.81, p=.45$.

The pattern of results suggests that the presence of white noise in speech does not affect judgments about the content of the speech. These findings go against the robust literature that shows that processing fluency affects cognitive judgments. On the other hand, because the overall truthfulness ratings across all levels of noise was $M=4.80(S D=2.85)$, one might claim that participants were just not engaging properly in the task, given that, in general, people are not used to hearing speech against this particular type of noise. In fact, Kozou et al. (2005) shows that speech competitors have a different effects on speech recognition and performance compared to non-speech competitors, such as white noise. Study 1 b addresses this point by presenting the statements against a speech competitor (i.e., babble speech) which is more common in people's environments and is found to affect speech differently than white noise (Kozou et al., 2005).

## Study 1b

Participants Twelve native speakers of English participated in Study 1b. Again, participants were undergraduate students of Psychology enrolled in a The University of Texas at Austin and participated for course credit. None of the participants from Study 1a participated in Study 1b.

Materials The materials were the same as in Study 1b, however, each sound file was mixed with speech babble noise at the same four different SNR's $(+17 \mathrm{~dB},+12 \mathrm{~dB},+6 \mathrm{~dB}$ and 0 dB ). Similarly to Study 1a, the mixed files were presented to participants using E-prime 2.0. The procedure was identical to Study 1a.

Manipulation Check As we did for Study 1a, a different group of 21 participants listened and rated the degree of difficulty to understand the statements. The procedure for the manipulation check was identical to Study 1a.

Manipulation Check Results A one-way repeated measures ANOVA showed a statistically significant main effect of noise, $F(4,80)=41.14, p<.0001, \eta^{2}=.67$. Slightly
different from what was found for Study 1a, post-hoc Bonferroni-corrected $t$-tests revealed that, level 3 significantly differed from all other levels ( $p^{\prime} s<0.009$ ). However, level 0 , level 1 and level 2 did not differ significantly from each other.

Truthfulness Ratings Results and Discussion Similarly to the findings from Study 1a, the mean truthfulness ratings did not differ significantly across all three different babble noise levels, $F(2,22)=.14, p=.86$. Although, the results for Study 1a and Study 1b suggest that noise (both white and speech babble) does not influence judgments of truth, one might claim that the failure to show differences in truthfulness ratings in Study 1b is easily explained by the fact that the various levels of noise were not perceived as different in terms of difficulty. To address this point, we re-ran Study 1b, but this time with different levels of SNR's. This time, level 0 corresponded to +8 dB SNR , level 1 corresponded to +2 dB SNR, level 2 to 0dB SNR and level 3 to -2dB SNR (negative SNR means that noise signal is louder than the speech signal). Using the same manipulation check procedure as before, 17 participants were asked to rate the degree of difficulty associated with listening the statements. A one-way repeated measures ANOVA showed a significant main effect of noise, $F(4,64)=45.21, p<.0001, \eta^{2}=.74$. Post-hoc Bonferronicorrected $t$-tests revealed that, except for the pairs level 1 vs . level 2 and level 2 vs. level 3, all other levels reliably differed from each other, $p^{\prime} s<0.05$.

For the truthfulness ratings of this novel noise level manipulation, a group of 13 native speakers of English were asked to rate the degree of truthfulness of the statements (procedure identical as before). Once again, the speech babble noise did not influence the judgments of truth, $F(2,24)=0.43, p=n s$. More importantly, the pairwise combinations that did differ in terms of difficulty level (i.e., level 0 vs. level 1, level 0 vs. level 3 and level 1 vs. level 3) did not show any reliable difference in terms of truthfulness ratings.

The results of Study 1a and 1b combined suggest that neither white noise nor speech babble noise seem to influence judgments of truth. More broadly, processing fluency associated with these auditory stimuli does not affect judgments about the content of the sentences. These findings go directly against Lev-Ari and Keysar (2010)'s claim that processing fluency associated with understanding foreignaccented speech directly influences judgments of truth. Study 2 and Study 3 are direct attempts to replicate Lev-Ari and Keysar (2010)'s findings with foreign-accented speech.

## Study 2

Participants Sixty-five native speakers of English participated in Study 2. Participants were undergraduate students at The University of Texas at Austin and participated for course credit. None of the participants from the previous studies participated in this one.

Materials A female native English speaker, two female native speakers of Brazilian-Portuguese and two female native speakers of Korean recorded the same 70 trivia statements used in the previous studies. As before, all sound files were equated for RMS amplitude. To ensure that the speech was perceived as accented, a separate pool of 28 participants rated the degree of foreign-accentedness of the statements (both the native and non-native speech). A repeated-measures ANOVA showed a main effect of language, that is, both the BrazilianPortuguese and the Korean speech were perceived as significantly more accented than the native speech, $F(2,54)=307.6$, $p<0.001, \eta^{2}=.91$. Brazilian-Portuguese and Korean did not differ from each other, although the Brazilian speakers were perceived as slightly more accented.

Procedures To test for the effect of accent on credibility judgments, participants sat in front of a computer and listened to 48 trivia statements in English. Sixteen of these statements were spoken by a native speaker of Brazilian-Portuguese, 16 by a native speaker of Korean and 16 by the native English speaker. All statements were recited in English. After listening to each statement, participants were asked to indicate how truthful they thought the statements were. For this, they used a Likert scale ranging from 1 (definitely false) to 10 (definitely true). Each participant heard additional 20 fillers statements read by two additional native speakers of English.

Results and Discussion To investigate the effect of foreign accent on the judgments of truth, we ran a repeated-measures one-way ANOVA, with language (accented vs. native) as independent variable and the truthfulness rating as the dependent variable. Our results failed to replicate the findings reported by Lev-Ari and Keysar (2010). There was no reliable main effect of language on the truthfulness ratings, $F(2,128)=.18, p=.83$ (Figure 1). Contrary to what Lev-Ari and Keysar (2010) claimed, although the foreign speech is perceived as accented relative to the native speech, the accent did not change people's perceptions of truthfulness. However, the main claim of Lev-Ari and Keysar (2010) is that the difficulty associated with foreign-accented speech, and not necessarily the accent itself, is what drives the misattribution effect. It is reasonable to assume that although the foreign speech is accented, it might not necessarily be difficult to understand. On top of that, it might be that given that the content of the trivia statements are too opaque, participants in our study just did not engage in the task properly.

To further explore these points, we ran Study 3 using a more engaging decision-making task. We also assessed the level of difficulty on top of the level of accentedness for the non-native speakers. Study 3 used a design similar to (Shah \& Oppenheimer, 2007) who showed that people weigh fluent information more heavily than they weigh disfluent information. Using a similar design, we hypothesized that if accented speech is indeeed more difficult to process (i.e., dis-

Figure 1: Credibility ratings as a function of accent.
fluent) compared to native speech, participants would weight consumer reviews provided by non-native speakers less heavily than the same review provided by a native speaker.

## Study 3

Participants Sixty native speakers of English participated in Study 3. Participants were undergraduate students of psychology at The University of Texas at Austin and participated in exchange for course credit. None of the participants in Study 3 participated in the previous studies.
Materials Three female native speakers of English and three female non-native speakers of English (a BrazilianPortuguese speaker, an Iranian speaker and a Korean speaker) recorded both positive and negative reviews for six different products. To obtain equivalent overall amplitude levels for all recordings across the two speakers, the sound files were equated for RMS amplitude.
Difficulty and Accentedness Manipulation Check To ensure that the non-native speech was indeed perceived as more difficult to understand, a different group of 24 participants rated the degree of difficulty of the reviews. Each participant randomly heard a review for each of the six products. Three of these reviews were positive and three were negative. Three were from a native speaker and three were from a nonnative speaker (one for each non-native language). Participants rated the level of difficulty using a Likert scale ranging from 1 (easy) to 7 (difficult).

A repeated-measures two-way ANOVA, with language

Figure 2: Accentedness and Difficulty
(native vs. non-native) and valence (positive vs. negative) as independent variable and the difficulty ratings as dependent variables, revealed a reliable main effect of language, $F(1,22)$ $=91.51, p<0.001, \eta^{2}=.98$, but no statistically significant main effect of valence or language $x$ valence interaction. Notably, the main effect of language suggests that the non-native speech was perceived as reliably more difficult ( $M=3.54, S D$ $=1.66)$ than the native counterpart $(M=1.05, S D=0.23)$.

The same participants were also asked to rate how accented they perceived the reviews to be. Similarly to the results for the difficulty ratings, a repeated-measures two-way ANOVA, with language (native vs. non-native) and valence (positive vs. negative) as independent variable and the accent ratings as dependent variables, showed only a statistically significant main effect of language, $F(1,22)=260.5, p<0.001, \eta^{2}=$ .92 , suggesting that the non-native speech was perceived as significantly more accented ( $M=4.86, S D=1.44$ ) than the native counterpart ( $M=1.04, S D=0.2$ ). Overall, the pattern shows that the more accented, the more difficult to understand (see Figure 2).

Procedures Study 3 used a 2 (valence: positive vs. negative) X 2 (language: native vs. foreign) fully within-subject design. Each participant completed a total of 12 trials (six fillers and six experimental trials) that were presented to them in random order. Three of the trials were negative reviews and three were positive reviews. Language was also balanced per participant: three native speakers and three non-native speakers.

In each trial, participants were presented with a series of specifications about a product (e.g., this camera has 14.0 megapixels of resolution). The specifications were presented in the written format and were the same across conditions. After reading a product specifications they listened to a consumer review about the product. After listening to each review, participants were asked to estimate how much they

Figure 3: Price Estimates as a function of Accent and Valence
think the product should cost. For each product, participants were given a range or prices to estimate from.
Results and Discussion As the price intervals were different for each product, we standardized the estimates to be amounts between 0 and 1 . To investigate whether valence and language affected the prices estimates, we ran a repeatedmeasures two-way ANOVA with valence and language as independent variables and the standardized price estimate as dependent variable. We found a reliable main effect of valence, $F(1,58)=22.64, p<.001, \eta^{2}=.28$, suggesting that participants were indeed attentive to the content of the reviews, providing higher price estimates for the positive reviews ( $M=$ $.44, S D=.28$ ) than for the negative reviews ( $M=.17, S D$ $=.20$ ). However, no reliable main effect of language or interaction of language and valence were found (see Figure 3). Again, this pattern of results suggests that processing fluency associated with processing foreign accented speech does not affect cognitive judgments such as price estimation, $F(1,58)$ $=.14, p=.71$.

## General Discussion

In the present paper, we ran three studies to further explore the idea that the difficulty associated with foreignaccented speech affects cognitive judgments Lev-Ari and Keysar (2010). In both Studies 1a and 1b, the presence of noise made the statements significantly harder to understand than the statements spoken in quiet. This finding is consonant with several studies showing that processing speech in adverse conditions imposes an extra cognitive burden on listeners (Lane, 1962; Munro, 1998). Yet, this manipulation did not affect participants' judgments of truth.

For Study 2, even though the non-native speech was perceived as accented, they did not affect judgments of truth. This result is consonant with other research showing no rela-
tionship between degree of accent and credibility (De Meo, Vitale, Pettorino, \& Martin, 2011).

In Study 3, although the reviews spoken by non-native speakers were perceived as accented and difficult, they did not influence participants' price estimations. Taken together, these findings fail to support the claim that the processing difficulty associated with understanding non-native accented speech influences cognitive judgments.

The lack of effect of accent on cognitive judgment can be explained in terms of the kinds of masking (energetic versus informational) that accent and background noise causes to the speech signal. Energetic masking (also known as perceptual masking) occurs when there is a degradation of the acoustic signal in shared spectro-temporal regions. Because the energy of a speech signal is concentrated in a few spectrotemporal regions of high informational value, if masking takes place in other regions, little impact on speech processing will be observed (Cooke, 2006). On the other hand, informational masking (also known as conceptual masking) occurs when there is a reduction of speech intelligibility even after any energetic masking has been accounted for (Cooke, 2006). Generally, informational masking refers to distractions that directly competes with the listener's attentional resources when processing the speech (e.g., the presence of an unrelated task.)

Studies on speech processing and speech segmentation (Mattys, White, \& Melhorn, 2005; Mattys, Carroll, Li, \& Chan, 2010) have demonstrated that depending on the type of masking (energetic or informational), people will attend to different cues to process and segment the speech. Energetic masking (e.g. white noise) tends to favor the listener's reliance on lexical-semantic information whereas informational masking tends to favor the listener's reliance on sub-lexical, acoustic information. Related to our current findings, it might be that the presence of white noise (i.e., energetic masking) made our participants focus closely on the conceptual aspect of the message other than the acoustic features. Therefore, instead of producing a metacognitive feeling of disfluency, the presence of the white noise made it easier for people to focus on the declarative information of the speech.

Another alternative is linked to the evidence that listeners normalize accented speech before engaging in any sort of conceptual processing with the content of the speech (Lahiri \& Marslen-Wilson, 1991; Floccia, Goslin, Girard, \& Konopczynski, 2006). According to this view, the acoustic signal is cleaned of all distortions and deviant information and a "clean" signal is processed instead. This normalization process happens after short periods of exposure to accented speech. In fact, there is evidence that after sufficient information on the accent is gathered, comprehension strategies return to baseline levels (Floccia et al., 2006), making people less tuned to the acoustic properties of the signal. It is possible that the participants in our study normalized the accented speech after a short period of exposure and then neglected to attend to sub-lexical acoustic features of the speech.

## Conclusion

Our findings suggest that (Lev-Ari \& Keysar, 2010) findings might have been a case of a false positive. Although scientists always aim at publishing accurate and replicable effects, errors are inevitable (Simmons, Nelson, \& Simonsohn, 2011). In fact, the standard alpha level widely adopted in science (i.e., $5 \%$ ) means that about $5 \%$ of the time, when scientists look for an effect that is not there, they will find a statistically significant difference. The only way to spot such Type I Errors is by reducing the publication bias (Pashler \& Wagenmakers, 2012), that is, by giving more space in the literature for publications attempting to replicate previous findings. In that sense, replications and failures to replicate effects play an important role in the scientific arena (Makel, Plucker, \& Hegarty, 2012). The present paper contributes to the growing body of research interested in unvailing and understanding more systematically psychological phenomena.

# Picture-Word Interference with Masked and Visible Distractors: Different Types of Semantic Relatedness Inhibit Lexical Selection 

Katharina Spalek (katharina.spalek@staff.hu-berlin.de)<br>Department of German Language and Linguistics, Humboldt-University Berlin, Unter den Linden 6, 10099 Berlin, Germany

Markus F. Damian (m.damian@bristol.ac.uk)<br>University of Bristol, School of Experimental Psychology, 12a Priory Road, Bristol BS8 1TU, United Kingdom

#### Abstract

One question in word production is how the presence of a semantically related word affects the naming process. It has been suggested that semantic effects in picture-word interference tasks are a net result of both inhibitory and facilitatory processes that take place at different processing levels. Finkbeiner and Caramazza (2006) argued that masking distractor words removes the inhibitory component, leaving only lexical facilitation. We investigated this claim by comparing different types of semantic relationship categorical relatedness, associative relatedness, and a combination of both - in picture-word interference with masked and visible distractors. We observed inhibitory effects in all conditions. In the visible condition, semantic category coordinates exerted the strongest inhibition, while in the masked condition, associatively related distractors interfered most. These findings are not easily reconciled with previous findings on polarity shifts of semantic effects with masked distractors. We discuss how all present findings could be explained within the same framework.

Keywords: lexical access, competition, response exclusion, picture-word interference, unconscious access

## Introduction

In the last decade, models of speech production that assume a competitive process of lexical selection (e.g., Levelt, Roelofs, \& Meyer, 1999) have been subjected to strong and sometimes heated criticism and equally passionate defense (see, e.g., Spalek, Damian, \& Bölte, 2012, for a summary of the arguments). The majority of empirical findings for (and against) the assumption of competitive lexical selection comes from experiments using the picture-word interference paradigm (e.g., Rosinski, 1977): Participants have to name pictures presented on the screen. Pictures are presented together with to-be-ignored distractor words (either in written or in spoken form). An often-repeated finding is that participants' responses are slower when the distractor word belongs to the same semantic category (e.g., fruit) as the target word (e.g., Schriefers, Meyer, \& Levelt, 1990) than when it belongs to an unrelated category. This has been taken as evidence for lexical competition: Target and distractor word are connected at the conceptual level through a common category node and prime each other. This results in two strongly activated representations, making the selection of the target representation more difficult and hence, more time-consuming (e.g., Roelofs, 1992).

An alternative explanation for the effects observed in the picture-word interference paradigm has been formulated in the so-called response exclusion hypothesis (e.g., Mahon et al., 2007): There is no competition between the lexical entries of a target word (the picture name) and a coactivated competitor (the distractor word). Interference arises at a later, post-lexical, processing level: Before a word can be pronounced, it occupies a single-channel output buffer. If the element in the buffer is the target word, it can be articulated; if it is the distractor, it has to be removed from the buffer before the target can enter the buffer and, eventually, be produced. According to Mahon and colleagues, the buffer knows about basic semantic properties of its entries. A word which is relevant to the experimental (or communicative) goal is more difficult to remove from the buffer than a word that is irrelevant to the task. Therefore, if the task is to name the picture of an animal, for example "dog", a distractor like "mouse" will be more difficult to remove from the buffer than a distractor like "pear".

The idea that interference occurs at a post-lexical processing level has received some support from findings with masked distractor presentation in picture-word interference studies: Finkbeiner and Caramazza (2006) had participants name pictures with visible distractors, replicating the semantic interference effect. When they presented the same stimuli but masked distractors such that participants weren't consciously aware of the distractors' identity, the semantic inhibition effect turned into a strong and reliable facilitation effect. Finkbeiner and Caramazza argue that the unconscious presentation prevented the distractor word from occupying the response buffer. Therefore, no competition effect was observed. However, the distractor words were still active enough to prime semantically related items in the mental lexicon, causing a net effect of facilitation. The finding that masking a distractor word turns inhibition into facilitation has been replicated by Dhooge and Hartsuiker (2010).

As noted by several researchers (e.g., LaHeij, Dirkx, \& Kramer, 1990), studies on semantic inhibition effects usually do not report the degree of association between target and distractor word. Pairs such as cat and dog and cat and horse are both related because they belong to the category animals. However, cat and $d o g$ are also associatively related because they often co-occur in the
language, and if people are asked to freely associate words in response to cat, dog is often one of the first associates produced. Finkbeiner and Caramazza (2006) don't provide a list of their materials, but Dhooge and Hartsuiker (2010) do. Perusal of their Appendix shows that they used categorically related picture-distractor pairs that were only weakly associated (e.g., spoon - knife; monkey - bear), but also pairs that were strongly associated (lion - tiger; apple pear), and, most critically, pairs that can be thought of as part-whole-relationships (farm - shed; pot - lid). The last type of relationship has been shown to cause facilitatory effects even in visible picture-word interference paradigms (Costa et al., 2005). While the data pattern observed by Dhooge and Hartsuiker is clear cut and shows a 15 ms interference effect in visible naming and a 12 ms facilitation effect in masked naming, it is possible that different items are responsible for the effects observed in visible and masked naming: If the inhibition observed with visible distractors is driven by the categorically related items, then a manipulation that makes them less salient competitors might allow the facilitation caused by the associated and part-whole relations to come to the fore.

In order to investigate this possibility, we used three different types of semantic relationship in our study, categorically related target-distractor pairs, associatively related target-distractor pairs, and categorically and associatively related (in the following: combined) targetdistractor pairs. Crucially, unlike in the study by Dhooge and Hartsuiker (2010), the categorically related items never were in a part-whole relationship, and strongly and weakly associated pairs were distributed across two different conditions. Before turning to our study, we will briefly review the literature on the effects of categorically and associatively related context words in picture naming.

Studies investigating categorical and associative relationships at SOA 0 (with written distractors) mainly found an effect of the former: Lupker (1979) used categorically related distractors and associatively related distractors in a picture-word interference study. He found that while the former caused interference, the latter had no effect. In a second experiment, he used distractors that were either categorically related or categorically and associatively related. He found that the inhibitory effect was exactly the same for both types of distractors. He concluded that categorical relatedness inhibits word production, and that this effect is not modulated by the association strength of the two category coordinates.

A study by LaHeij, Dirkx, and Kramer (1990) provides a different finding: They selected categorically related targetdistractor pairs that were either highly associated or weakly associated and used these items in a picture-word interference paradigm with different SOAs. At SOA 0, they observed inhibition for weakly associated category coordinates but not for highly associated ones. They argue that in the case of highly associated category coordinates the inhibitory effect is offset by an associative priming effect.

Investigating the time-course of these effects more closely, Alario, Segui, and Ferrand (2000) carried out an experiment on picture naming primed by pre-exposed words (in essence a picture-word interference paradigm with negative SOA). They discovered that associatively related words facilitate picture naming, but only if they are presented around 200 ms before picture onset. By contrast, categorically related words inhibit picture naming, but only if they are presented 100 ms (or less) before picture onset. So, it seems that associative relationships prime a target word whereas categorical relationships compete with a target word. However, these two mechanisms also seem to have a different time-course.

In contrast to the findings by Alario et al. (2000), Abdel Rahman and Melinger (2007) observed inhibition with categorically related distractor words and facilitation with associatively related distractor words with the same timecourse. In their study, spoken distractor words were presented 150 ms before the target pictures.

To sum up, the findings on associative distractor words in picture-word interference, while somewhat inconsistent, support the assumption that an associative relation between target and distractor facilitates target naming.

Given the observation that there is a facilitatory component to both associative and categorical distractors and that masking a distractor enhances the facilitatory component, we wanted to investigate how masking affects picture naming with categorically related, associatively related, and combined distractors. Participants named the pictures both with visible distractors and with masked distractors. For visible distractor presentation we predict an interference effect for categorically related distractor words. For associatively related distractor words, we expect to see either a facilitatory effect or a null effect. Finally, for combined items, we expect to see either an effect of equal size as for the categorically related items (as Lupker, 1979, did) or an attenuation of the effect as in LaHeij et al. (1990).

If masking the distractor effectively prevents it from entering a response buffer, no inhibitory effects are expected in the masked condition. Instead, categorically related and associatively related distractors should yield facilitation which should be greatest for combined distractors.

A second aim of the study was to address a concern formulated by Kouider and Dupoux (2004). They question whether previous studies on unconscious priming truly presented words in a subliminal manner, and argue that participants are typically at least partially aware of a masked stimulus and that this partial awareness causes the priming effect. We carried out a lexical decision task on the distractor words after the picture naming study. Distractors were masked in the same way as during the picture naming study. Assessing participants’ performance in the lexical decision task gave us a tool to investigate in how much (partial) awareness of the distractors modulated the effects.

## Method

## Participants

Forty-eight native speakers of German (thirty-five women) were recruited from the participant database of the Institute of Psychology at the Humboldt-University Berlin. Their mean age was 24.2 years. Participants received monetary compensation for their participation.

## Materials

Twenty pictures of animals and objects were chosen as targets. For each of the pictures (e.g., picture LEMON), three distractor words were selected: a semantically related word (i.e., a category coordinate, e.g., kiwi), an associatively related word (i.e., a word from a different category, e.g., vitamin), and a semantically and associatively related word (e.g., orange). Distractor words were matched on length and frequency. The associative relation was determined pre-hoc by the intuitions of two native speakers of German and backed up post-hoc by associative relatedness ratings of the participants. Participants were asked to rate the strength of the association of two words on a scale from 1 (not associated) to 7 (very strongly associated). The categorically related items had an association strength of 2.93, the associatively related items an association strength of 4.00, and the combined items had an association strength of 5.57. As intended, the categorically related items were less strongly associated than both the associatively related items $(t(19)=4.09, p<.001)$ and the combined items $(t(19)=$ 4.62, $p<.001$ ). What was not intended was that the association strength was also higher for combined items than for associatively related items $(t(19)=11.92, p<.001)$.

We created three unrelated conditions by recombining the related distractors with different pictures. Therefore, in each of the three conditions (categorically related, associatively related, combined), the same pictures and the same words were used in both the related and the unrelated condition.

Each participant saw a target word in all six conditions (three critical conditions and three control conditions). A different randomization was created for each participant to avoid order effects.

For the lexical decision task (see below), 20 non-words were created by using existing words and replacing one or two letters. These letter changes could occur in any position in the word. Care was taken to change each position equally often. Non-words were matched in length to the word targets.

## Procedure

Participants carried out three different tasks: the pictureword interference study, a lexical decision task and a questionnaire. Order of presentation for the picture-word interference studies (visible vs. masked) was counterbalanced across participants. The questionnaire contained all related target-distractor pairs. Participants were asked to indicate how strong the association between
the two concepts is, using a scale from 1 (not associated) to 7 (strongly associated). The experiments were programmed and run with Presentation (NeuroBehavioral Systems).

Visible Distractor Presentation. Participants were instructed to name the pictures on the screen and to ignore the superimposed distractor words. A trial started with a fixation cross that was presented for 500 ms . The word was presented centered on the screen for 53 ms . Picture and word were presented together for 2000 ms . Participants' responses triggered a VoiceKey and were recorded.

Delayed Distractor Presentation Participants were instructed to name the pictures on the screen and to ignore the superimposed distractor words. A trial started with a forward mask (\#\#\#\#\#\#\#\#\#\#) that was presented for 500 ms . The word was presented centered on the screen for 53 ms . It was replaced by the picture and a non-pronounceable mask consisting of a string of 10 consonants presented in the same location as the distractor word. The use of a consonant string as a backward mask was motivated by Finkbeiner and Caramazza (2006) who refer to findings having shown its particular effectiveness in eliminating phonological priming effects. Picture and mask were presented together for 2000 ms. Participants' responses triggered a VoiceKey and were recorded.

Lexical Decision Task A forward mask (\#\#\#\#\#\#\#\#\#\#) was presented for 500 ms centered on the screen. It was followed by a letter string that was presented for 53 ms . The letter string was replaced by the same mask as in the masked picture-word interference paradigm. The mask stayed in place until the participant had made a response. Participants were instructed to decide whether the briefly presented word had been an existing word of their language or not. They were encouraged to make a guess if they felt they had not seen a word at all. The results of the lexical decision task will not be analysed in the present paper, we merely used participants' overall accuracy in order to split the group in a "high-recognition" and a "low-recognition" group (see below).

## Results

We carried out an ANOVA on the mean reaction times and error rates with the within-subject and within-item factors Type of Relationship (Categorical, Associative, Combined) and Relatedness (Related vs. Unrelated).

Table 1 presents the mean reaction times and error rates in the visible distractor condition. Table 2 presents these measurements in the masked distractor condition.

In the visible condition, for the reaction times, the effect of Type of Relationship was highly significant $\left(F_{1}(2,94)=\right.$ 16.61, $\mathrm{MSE}=433, p<.001 ; F_{2}(2,38)=5.31, \mathrm{MSE}=537, p$ $<.01)$, as was the effect of Relatedness $\left(F_{1}(1,47)=17.54\right.$, MSE $=412, p<.001 ; F_{2}(1,19)=6.75$, MSE $\left.=498, p<.05\right)$, showing faster reaction times for unrelated distractors than
for related distractors. The interaction of the two factors was not significant (both Fs $<1$ ).

For the error rates, the effect of Type of Relationship was not significant $\left(F_{1}(2,94)=1.57\right.$, MSE $=0.04, p=.21, F_{2}<$ 1). The effect of Relatedness was marginally significant with slightly higher error rates for related distractors $\left(F_{1}(1,47)=3.65, \mathrm{MSE}=0.05, p=.06, F_{2}(1,19)=1.82, p=\right.$ .19). The interaction was not significant (both $F$ s $<1$ ).

Table 1: Reaction times and error rates (in brackets) in the visible condition.

|  | Categorical | Combined | Associative |
| :--- | :--- | :--- | :--- |
| Related | $646(1.5)$ | $631(1.8)$ | $625(1.5)$ |
| Control | $631(0.7)$ | $622(1.5)$ | $619(0.9)$ |
| Effect | $15(0.8)$ | $9(0.3)$ | $6(0.6)$ |

Table 2: Reaction times and error rates (in brackets) in the masked condition.

|  | Categorical | Combined | Associative |
| :--- | :--- | :--- | :--- |
| Related | $622(1.1)$ | $613(0.5)$ | $615(0.7)$ |
| Control | $616(0.5)$ | $610(0.4)$ | $608(0.6)$ |
| Effect | $6(0.6)$ | $3(0.1)$ | $7(0.1)$ |

In the masked condition, for the reaction times, the effect of Type of Relationship was significant $\left(F_{1}(2,94)=4.05\right.$, $\left.\operatorname{MSE}=414, p<.05 ; F_{2}(2,38)=4.62, \mathrm{MSE}=166, p<.05\right)$, as was the effect of Relatedness $\left(F_{1}(1,47)=6.96\right.$, MSE $=$ 297, $\left.p<.05 ; F_{2}(1,19)=6.00, \mathrm{MSE}=137, p<.05\right)$, again showing inhibition for related distractors. The interaction of the two factors was not significant (both Fs < 1).

For the error rates, the effect of Type of Relationship was not significant $\left(F_{1}(2,94)=1.44\right.$, MSE $=0.02, p=.24, F_{2}<$ 1). The effect of Relatedness was significant by items $\left(F_{1}(1,47)=1.54, \mathrm{MSE}=0.03, p=.22, F_{2}(1,19)=4.75\right.$, MSE $=0.004, p<.05$ ). The interaction was not significant $\left(F_{1}(2,94)=1.04, \mathrm{MSE}=0.02, p=.36, F_{2}(2,38)=2.02\right.$, MSE $=0.004, p=.15)$.

In order to investigate if the masking manipulation affected the critical effects, we pooled the data of both experiments and carried out an ANOVA with the factors Experiment, Type of Relationship, and Relatedness. We observed a significant effect of Experiment with faster reaction times for masked distractors $\left(F_{1}(1,47)=5.43\right.$, MSE $\left.=5877, p<.05, F_{2}(1,19)=17.61, \mathrm{MSE}=772, p<.001\right)$. The factors Type of Relationship $\left(F_{1}(2,94)=19.01\right.$, MSE $=$ 406, $p<.001, F_{2}(2,38)=7.51$, $\left.\mathrm{MSE}=426, p<.001\right)$, and Relatedness $\left(F_{1}(1,47)=21.37\right.$, MSE $=398, p<.001$, $F_{2}(1,19)=12.25$, MSE $\left.=306, p<.01\right)$ also had a significant effect. Importantly, we observed a marginally significant interaction of Experiment and Type of Relationship by participants $\left(F_{1}(2,94)=2.62, \mathrm{MSE}=442, p=.08, F_{2}(2,38)\right.$ $=1.52$, $\mathrm{MSE}=277, p=.23$ ).

Because the interaction, albeit rather weak, suggests that the effects for the different types of relationship might differ
in the visible and in the masked condition, we carried out paired $t$-tests for all three types of relationship in the two visibility conditions.

In the visible condition, the only reliable inhibition effect (by participants) was observed with categorically related distractors, $t_{1}(47)=2.76, p<.01, t_{2}(19)=1.92, p=.07$. In the combined condition, there was only a trend by participants, $t_{1}(47)=1.97, p=.054 ; t_{2}(19)=1.47, p=.16$. Finally, the effect for the associatively related condition was not significant, $t_{1}(47)=1.63, p=.11, t_{2}(19)=1.04, p=.31$.

In the masked condition, the pattern was reversed : The categorical relatedness effect was not significant, $t_{1}(47)=$ $1.50, p=.14, t_{2}(19)=1.47, p=.16$, and neither was the combined effect, both $t \mathrm{~s}<1$. By contrast, the associative relatedness effect was significant by participants $\left(t_{1}(47)=\right.$ 2.33, $p<.05$ ) and approached significance by items ( $t_{2}$ (19) $=1.83, p=.08$ ).

Finally, we split the subjects in two groups, based on their accuracy in the masked lexical decision task. We used a median split, with the "low-recognition group" being correct on $49 \%-73 \%$ of all trials and the "high-recognition group" being correct on $73 \%-93 \%$ of all trials. We reanalyzed the data set with the additional between-subjects variable "Recognition" (high vs. low). There was no main effect of recognition (both $F s<1$ ) and no higher-level interactions of Type of Relationship and Relatedness with Recognition (all ps > .20). Even though the ANOVA showed that Recognition did not affect the data pattern, we present the descriptive data for the high- and low-recognition group in the masked condition in Tables 3 and 4.

Table 3: Results for the high-recognition group in the masked condition

|  | Categorical | Combined | Associative |
| :--- | :--- | :--- | :--- |
| Related | 621 | 609 | 615 |
| Control | 617 | 610 | 609 |
| Effect | 4 | -1 | 6 |

Table 4: Results for the low-recognition group in the masked condition

|  | Categorical | Combined | Associative |
| :--- | :--- | :--- | :--- |
| Related | 622 | 616 | 616 |
| Control | 615 | 609 | 607 |
| Effect | 7 | 7 | 9 |

The descriptive data show that, if anything, those participants who recognized the masked distractors less well showed the stronger inhibitory effects in the picture-word interference study.

## Discussion

Overall, we found inhibitory effects of semantically related distractors in both masked and visible distractor presentation in a picture-word interference paradigm.

The findings for the visible distractor presentation are in line with many previous findings. We observed semantic interference. The lack of a significant interaction between Type of Relationship and Relatedness suggests that the effect was equally strong for all types of relationship. The post-hoc $t$-tests, by contrast, hint at a possible difference: The interference is strongest for categorically related distractors and statistically absent for associatively related distractors, with categorically and associatively related distractors patterning in-between. This finding is generally in accordance with the result obtained by LaHeij et al. (1990).

The observation that interference persists for masked distractors is at odds with the two previous studies (Dhooge \& Hartsuiker, 2010; Finkbeiner \& Caramazza, 2006) discussed in the Introduction. Ignoring for the moment the issue of how different types of semantic relationship might affect the results and simply focussing on the categorical condition, the results do not indicate the predicted polarity reversal from inhibitory (visible) to facilitatory (masked) effects. At a general level, our data show that the polarity reversal for semantic effects dependent on distractor visibility is less universal than suggested by the previous studies.

A possibility is that in our "masked" experiment, the specific masking procedure was not exactly identical to the previous studies in terms of distractor visibility. Although an effort was made to keep all relevant parameters (e.g., distractor duration, backward mask, etc.) as similar as possible, relatively minor variations in, e.g., contrast or display size could potentially affect distractor visibility. It is also the case that our study used a different language from the original studies (English and Dutch), and that words perhaps had slightly different properties. For instance, German words tend to be longer on average than English words, therefore, the amount of information that can be extracted from a word presented under masked conditions might differ among languages. Hence, perhaps our masked distractors were either too heavily masked, or not masked well enough. The first scenario - masking of distractors was too stringent - is refuted by the simple fact that we did observe a significant effect of relatedness in that experiment. Could it therefore be that our distractors were not masked well enough, i.e., that they acted in the same way as visible distractors, and hence induced similar inhibitory effects? The strongest argument against this possibility comes from the comparison of participants who recognized more words during the visibility test with those who recognized fewer words. If the inhibition effect observed in the masked condition is due to the fact that participants recognized the masked distractors too well, then the inhibitory effect should be strongest for those participants who recognized the distractors the best. Contrary to this prediction, there was no significant difference in the data pattern for "good" and "poor" recognizers; indeed, descriptively the inhibitory effect was larger for the "poor" than the "good" recognizers. This
renders it unlikely that heavier masking (or perhaps, a reduction in distractor duration) would have resulted in the predicted facilitatory effect of semantic relatedness.

While we cannot say at this point which differences in the experimental procedure have caused the differences in results, it is clear that the semantic facilitation effect with masked distractors is much more susceptible to such procedural differences than the semantic inhibition effect with visible distractors. Therefore, caution is needed when using this effect for theory-building and it is necessary to better understand the experimental conditions that allow for a polarity shift.

A second important finding is that while inhibition occurred in both presentation conditions and was not statistically modulated by the exact type of semantic relationship, there were still some crucial differences. In the visible condition, the categorically related condition caused the greatest inhibition, whereas in the masked condition, the associatively related condition caused the greatest inhibition. Explanations for this pattern remain at present speculative. One possible scenario derived from earlier work on such relationships (Alario et al., 2000; La Heij et al., 1990) is that associative pairings represent direct interlexical links, perhaps at a "peripheral" level (i.e., the orthographic or phonological lexicon). If so, it is conceivable that links at such "shallow" processing levels would be more dominant with masked distractor presentation, compared to visible distractors whose effect might emerge more clearly at "deeper" (i.e., lexicalsemantic or conceptual) processing levels. To our knowledge, our study represents the first attempt to address the possible dependency of effects of various types of semantic relationships on distractor visibility, and more research is clearly needed.

From a broader perspective, our data, combined with the earlier studies in the literature reporting a polarity reversal, contest the assumption that the inhibitory component in speech selection is binary in the sense that either a distractor will enter the competition or not. Rather, inhibition and facilitation can be relatively stronger or weaker, modulating the net outcome. Roelofs, Piai, and Schriefers (2011) suggest that masking a distractor word results in this word receiving a smaller weight in the competition process. Such a mechanism, depending on the magnitude of the weight change, could accommodate the entire continuum of effects. That is, for clearly visible distractors, the distractor will receive a high competition weight, resulting in an inhibitory effect. As visibility decreases, the competition weight will decrease, too, reducing the inhibitory component of the effect. With a very low competition weight, the facilitatory component of the effect (i.e., the target is primed by the distractor) will result in a facilitation effect. The challenge for future experiments would then be to precisely predict the size of the competition weights in different contexts. The response exclusion hypothesis is less able to explain such a smooth transition from inhibition to facilitation. Intermediate effects could be explained by the response
exclusion hypothesis as an experimental artifact, if either facilitation or inhibition is observed on a trial-by-trial basis (i.e., if a participant observes a word in a given trial, it will enter the buffer and interfere, if (s)he does not observe a word in a different trial, it will not enter the buffer and therefore, facilitation will result). While the sum of trial-bytrial inhibition and facilitation might result in anything from facilitation to inhibition, too, this explanation is refuted by our finding that, numerically at least, the inhibition effects in masked distractor presentation were larger for those participants, who perceived the masked words less well.

In conclusion, previous studies have reported a polarity reversal of semantic effects in picture-word interference tasks, such that clearly visible distractors which are semantically related to the picture name generate interference, whereas visual masking of such distractors results in facilitation. This pattern was taken as supporting different loci of the facilitatory and interfering components. In our own experiments we were unable to replicate this polarity reversal; instead, our findings suggest that significant semantic interference can prevail even under masked conditions, but that the precise pattern might depend on the exact form of semantic relationship between distractor and target.

## Acknowledgments

The research presented in this paper was supported by DFGgrant SP1126/4-1 to KS. We thank Julia Knoepke and Carsten Schliewe for their help in programming the experiment and Julia Knoepke for testing the participants.

# Implications of Polychronous Neuronal Groups for the Nature of Mental Representations 

William Benjamin St. Clair (wst.clair@ucmerced.edu) David C. Noelle (dnoelle@ucmerced.edu)<br>Cognitive and Information Sciences<br>University of California, Merced<br>5200 North Lake Road; Merced, CA 95343 USA

#### Abstract

How are concepts represented in the human mind? Vector space representations based on the instantaneous firing rates of neurons have been used with great success. However, there is growing evidence, both empirical and computational, that relevant information is encoded in spatiotemporal patterns of spikes called polychronous neuronal groups (PNGs). In this paper, we consider the philosophical implications of PNG representations with regard to their temporal extension, grounding, compositionality, and similarity. We suggest that the temporally extended nature of PNGs implies that conceptual-level dynamics may only be coherent at coarse time scales. We introduce the notion of PNG trigger sets as a way to ground the meaning of PNG representations, and we discuss potential approachs to compositionality. Finally, we identify the open problem of how to define an appropriate similarity metric for PNG-based mental representations.

Keywords: Philosophy of Cognitive Science; Neuroscience; Representation; Dynamical Systems.

## Introduction

How are concepts represented in the human mind? One highly productive approach to this question has involved the application of a continuous dynamical systems perspective to the problem (Spivey, 2008). From this perspective, the currently active concepts of a cognitive system (or subsystem) are jointly encoded as a point in a high dimensional vector space (Churchland, 1989). Nearby points in this space, according to some distance metric, are seen as representing similar conceptual states, allowing regions and manifolds within this space to capture more general concepts or categories (Gärdenfors, 2000). The evolution of mental states over time becomes a trajectory in this vector space (Yoshimi, 2012), driven by mechanistic cognitive processes (Churchland, 1996).

This vector space approach to conceptual representation has many strengths. It supports accounts of the biological basis of cognition by viewing the dimensions of the vector space as the activity of neural units, such as their firing rates, offering a framework for mapping from the physical state space of the brain to the conceptual state space of the mind (Spivey, 2008). The approach provides a straightforward way to discuss the cognitive state of a system at any instant in time, as well as how those states change over time. Issues surrounding the grounding of representations are well addressed from the perspective of conceptual role semantics (Greenberg \& Harman, 2006), with the "meaning" of a representation being a function of the inputs that activate it and the other representations that it produces through causal relationships,
eventually making causal contact with the world through sensory and motor processes. When using the vector space approach, these cognitive processes are well described in neurocomputational terms, with nearby points in a vector space tending to produce similar results when presented to models of downstream neural circuits. While the vector space approach has been criticized as lacking support for compositional and structured conceptual representations (Fodor \& Pylyshyn, 1988), and there continues to be extensive work on addressing this critique (Gayler \& Levy, 2011), highly promising approaches to compositionality have been proposed, making use of vector space operations of superposition, convolution, and sparse coding (Smolensky, 1990; Plate, 2003; OReilly, Bhattacharyya, Howard, \& Ketz, 2011). In general, the vector space approach to conceptual representation has been very productive.

Past challenges to the vector space approach have come from above: from more abstract and symbolic characterizations of cognitive content and cognitive processing. More recently, a challenge has arisen from below: from insights into the neural coding of information (Rieke, Warland, Steveninck, \& Bialek, 1999). There is increasing empirical evidence that, in at least some neural systems, relevant information is encoded in the spatiotemporal pattern of discrete action potentials, or spikes, produced by neurons in a given nucleus (Rolston, Wagenaar, \& Potter, 2007; Madhavan, Chao, \& Potter, 2007; Pasquale et al., 2008). While information, in some cases, may be carried by synchronous or coherent firing of neurons (Fries et al., 2005), computational considerations have suggested that content may frequently be encoded in complex asynchronous patterns of spikes (Izhikevich, 2006). These complex spike patterns have been called polychronous neuronal groups (PNGs). The PNG approach to representation differs substantially from the vector space approach. A PNG is a temporally extended pattern of discrete spiking events over a collection of neurons, and it is not clear how such a pattern could be mapped to a point in a continuous vector space so as to preserve relevant aspects of similarity between representations. In the vector space approach, temporally extended trajectories capture dynamic changes in cognitive content, while the PNG account encodes individual conceptual states in such trajectories. A PNG need not be oscillatory, so it does not make sense to extract features like frequency or phase to map a PNG into a vector space. In some important ways, the PNG approach is fundamentally
different than the vector space approach.
It may be tempting to view the vector space account as supervening on the PNG account, with PNGs implementing vector space states at some lower level of analysis. In this brief article, we argue that such a view either is untenable, with no mapping from the complexities of PNG representations to points in a vector space being possible, or, at least, is in dire need of an explanation of how such a reduction might be accomplished. Specifically, we raise four problematic issues that arise when shifting from a vector space approach to a PNG approach: (1) Temporal Extension - If conceptual representations involve temporally extended PNGs, to what degree can a conceptual state be said to be active at a particular instant or actively maintained over an interval? How does the use of the PNG framework change the characterization of the evolution of conceptual states over time? (2) Grounding - If conceptual role semantics is to be used to understand the "meaning" of a PNG representation, what are the biologically realistic causal mechanisms that link PNGs in an inferential cascade? (3) Compositionality - Does the PNG approach fare better or worse than the vector space approach in accommodating compositional or structured representations? (4) Similarity - Is there a distance measure for PNG representations that could be used to capture conceptual similarity while reflecting the way in which downstream neural circuits would naturally generalize across disparate PNGs?

Each of these four issues is elaborated in the following sections, and preliminary insights into how these issues could be addressed are provided. The goal is to highlight how the PNG approach challenges the prevailing vector space account of mental representation, while offering some clues concerning how this challenge might be met.

We begin by offering a review of PNG representations, providing a foundation for exploring each of the four issues that we find problematic. We then conclude with a brief discussion of open questions in this domain.

## Polychronous Neuronal Groups

Polychronous Neuronal Groups (PNGs) have been proposed as a possible unit of representation in the human brain (Izhikevich, 2006). A PNG is a reproducible, timelocked, spatiotemporal spike-timing pattern over a collection of neurons. They are reproducible in the sense that the sequence of spike times tends to replay when the input conditions experienced by the neural network are repeated. They are time-locked in the sense that, once the PNG begins, the times between the spikes within the spiking pattern are the same whenever the PNG is triggered. They are spatiotemporal in the sense that they are defined in terms of a specific set of neurons that participate in the pattern (spatial) as well as the specific times at which spikes appear in the pattern (temporal). PNGs spontaneously emerge in spiking neural networks that incorporate variance in the amount of time it takes for an action potential to reach its receiving neurons (conductance delays), and they are reinforced by mechanisms of spike
timing dependent plasticity (STDP) (Izhikevich, 2006).
To understand the information-bearing properties of PNGs, it is important to understand how they are generated and propagated. An individual neuron remains at its resting potential until it receives, or "observes", a sufficient number of spikes in a short enough period of time, at which point this coincident input causes the neuron to generate an action potential of its own. This action potential is then, in turn, observed by the neurons to which this neuron projects. However, since it takes time for action potentials to propagate down axonal connections, there is a delay between when a spike is generated and when it is received. For example, in the cat brain, this delay can be as short as 0.1 ms , or as long as 44 ms (Swadlow, 1992). Since a cortical neuron may project to anywhere between 1,000 and 10,000 other neurons, a single action potential will be received at many different times. Thus, spikes that are synchronized on generation will not necessarily be synchronized on their receipt.

Typically, a single input spike is insufficient to drive the receiving neuron to fire an action potential, and the membrane potential of such a neuron is constantly decaying toward its resting potential. Within just a few milliseconds after receiving a single spike, the membrane potential of a neuron will return to its equilibrium state, removing the electrical effects of the spike (Cessac, Paugam-Moisy, Viéville, et al., 2010). This highlights the need for synchrony in the arrival of spikes to initiate firing, but it is important to remember that spikes that are synchronized at the time of receipt will not necessarily be synchronized at the time of their initiation, due to variance in conductance delays.

Figure 1: A small neural network with time delays.

Consider the network portrayed in Figure 1. If neurons $a$, $b$, and $c$ spike at the same time, Time 0 , those spikes will be received by neuron $x$ at Times 1,5 , and 9 , respectively, and those same spikes will be received by neuron $y$ at Times 8 , 5 , and 1 , respectively. In this case, neither $x$ nor $y$ receive the coincident spikes needed to fire. The difference in arrival times are caused by differences in axonal propagation times. If, instead, neurons $a, b$, and $c$ spike at Times 8,4 , and 0 , respectively, neuron $x$ will receive all three of these spikes at Time 9, potentially allowing the cell to fire. In contrast, neuron $y$ would receive the three spikes at Times 16, 9, and

1 , respectively, providing it with no coincident spikes to drive an action potential. Alternatively, if neurons $a, b$, and $c$ fire in the reverse order, neuron $y$ will may spike, while neuron $x$ will remain silent. Thus, the effects of spikes from neurons $a$, $b$, and $c$ on the firing of neurons $x$ and $y$ is critically dependent on the timing of the spikes.

In larger, more connected, networks, like those found in mammalian brains, a particular stimulus will cause a chain reaction of spikes over time. This group of neurons firing with precise timing is what forms a corresponding PNG. Importantly, PNG patterns can be strengthened with repetition, with the strengthening well explained by spike timing dependent plasticity (STDP) (Izhikevich, 2006). Synapses that exhibit STDP are strengthened whenever the post-synaptic neuron fires just after it receives evidence of a pre-synaptic spike. Conversely, whenever the post-synaptic neuron fires just before it receives evidence of a pre-synaptic spike, then the synapse is weakened (Dan, Poo, et al., 2004). Thus, as a PNG unfolds, STDP strengthens the synapses participating in the PNG's generation and weakens the synapses that were active but did not facilitate the firing of neurons participating in the PNG. Thus, every time a particular PNG unfolds, and hence becomes strengthened via the mechanism of STDP, it becomes easier for that PNG to be reproduced.

To restate, a PNG is a reproducible, time-locked, spatiotemporal spike-timing pattern. A PNG is reproducible in the sense that, when the neurons participating in a PNG are stimulated in a similar way, the PNG will unfold in a similar way. Furthermore, each reproduction causes a PNG to become more stable through STDP, making the PNG increasingly robust to timing noise (i.e., some input spikes may be omitted or added without substantially effecting the generation of the PNG). A PNG is time-locked due to the fact that the conductance delays between the participating neurons are fixed by the anatomy of the network. A PNG is spatiotemporal in the sense that it necessarily occurs at many times (polychronous) and involves many neurons. Once stabilized via STDP, subtle variations in spike timing due to noise do not lead to unpredictablely different PNGs, but generate a member of a family of related PNGs (Izhikevich, 2006). Also, it is important to note that many PNGs may be simultaneously active in a common neural network without interacting, due to the low probability that two arbitrary PNGs will overlap substantially in their precise spike times. In addition to these properties, PNGs also minimize redundancy through the weakening of synapses via STDP, and they are more energy efficient than vector space representations that depend on neural firing rate (Levy \& Baxter, 1996). It is also interesting to note that the "small world" connectivity structure of the mammalian brain gives rise to stable PNGs much more readily than networks of neurons that are connected uniformly at random (Sporns \& Zwi, 2004; Vertes \& Duke, 2010).

Since their introduction, PNGs have been utilized extensively in computational neuroscience models of cognitive information processing. The intricate dynamics of PNGs have
been used in combination with models of NMDA receptors and neurotransmitter reuptake to produce a promising account of working memory function (Szatmáry \& Izhikevich, 2011). PNGs have been incorporated into a formal account of the dopamine system in order to produce a candidate model of neural reinforcement learning that addresses the problem of temporally distal reward (Izhikevich, 2007). In addition to their use in computational neuroscience models, empirical evidence for PNGs has been reported, with reproducible, time-locked, spatiotemporal patterns of spikes being observed in cortical slices (Rolston et al., 2007). It is clear that PNGs show great promise as a form of representation in the brain.

As this review of PNGs shows, the information carried by a PNG in a neural network is critically dependent on the timing of individual action potentials. This contrasts with vector space accounts of mental representation which map vector space dimensions onto the instantaneous firing rates of neurons. The PNG approach highlights the way in which individual spike times can carry information, with spiking rates lacking sufficient spatiotemporal detail to discriminate between different representational states. It is this shift that gives rise to a number of potential problems with viewing PNGs as the foundation of mental representation.

## Temporally Extended Representations

## The Challenge

In vector space representation schemes that make contact with biology, each dimension corresponds to the instantaneous activity of a neural element, such as the instantaneous firing rate of a neuron. This provides us with a natural way to capture the mental state of the agent at any given point in time. The active maintenance of a conceptual state involves a relative lack of change in these firing rates, and the evolution of mental states over time are captured in trajectories through the vector space.

In contrast, the PNG approach inherently involves temporally extended representations. A PNG is a spatiotemporal pattern of spikes. If mental representations are to be associated with PNGs, to what degree can any concept be seen as active at any given instant? Can a representation be actively maintained over time if the physical substrate of the representation is changing over time? How does the use of the PNG framework change the characterization of the evolution of conceptual states over time?

## Addressing the Challenge

While some philosophical work may be needed to fully appreciate the nature of temporally extended mental representations, we do not see this challenge as insurmountable.

The activation level of a particular PNG at an arbitrary point in time, in the midst of a sequence of spikes, does not have a clear definition. We can identify, however, the degree to which recently produced spikes match portions of a PNG, as well as the propensity for the neural network to continue
with the production of further spikes in the PNG. Thus, the notion of the activation of a concept is only coherent at time scales that match the time scale of the PNG. For example, if the PNG $\pi$ refers to a 30 ms long spike sequence, it may be asked if, over the last $30 \mathrm{~ms}, \pi$ appeared. For that same $\pi$, it may also be asked at what times over the last $60 \mathrm{~ms} \pi$ was present. In this way, activation of a mental state represented by a PNG only makes sense at relatively coarse time scales in comparison to the time scales used for common vector space representations. The PNG approach does not admit to a coherent sense of a truly instantaneous mental state.

The mental state encoded by a PNG may be actively maintained for a period of time longer than the duration of the spike sequence that makes up the PNG. For example, PNG models of working memory have involved the repeated activation of a PNG, with the spike pattern being sequentially reinitiated, allowing it to persist for arbitrarily long periods, as needed (Szatmáry \& Izhikevich, 2011). Once again, this notion of active maintenance is limited to a time scale corresponding to the temporal length of the PNG, but the PNG approach does not rule out the possibility of persisting in a mental state for a longer period of time.

## Grounding Of Representations

## The Challenge

The symbol grounding problem highlights the need for representational schemes to provide some account of the meaning of mental representations (Harnad, 1990). Understanding in an ungrounded representational system is analogous to the content of a dictionary, defining words in an ultimately circular fashion, in terms of other words. It has been argued that this problem can be overcome by grounding internal representations in reflections of the world, mediated by iconic representations associated with direct sensations (Harnad, 1990). Similarly, the meaning of an internal representation can be seen as arising from the role it plays in a cognitive inferential process, as described by the theory of conceptual role semantics, with causal and inferential chains eventually connecting to the world through sensation and action (Greenberg \& Harman, 2006).

In the vector space approach, representations may be grounded in the causal processes in which they participate, both in terms of inputs that give rise to a representation (eventually leading back to iconic representations) and the effects of that representation on downstream neural circuits. These causal relationships can be characterized in terms of functional mappings between vector spaces. For example, if the transduction of sensory information from the world directly results in a pattern of neural firing rates, this pattern corresponds to a point in a sensory vector space, and neural circuits can be seen as mapping this point to corresponding points in the vector spaces for other neural populations, encoding the corresponding conceptual content. In this way, the mappings implemented by neurocomputational mechanisms ground internal representations.

The activation of a PNG and the downstream effects of the initiation of a PNG are mechanistically and computationally quite different than standard neurocomputational mechanisms that can be easily cast as functions between vector spaces. Given this difference in the causal structure of PNGs, how can PNG representations be grounded?

## Addressing the Challenge

We assert that the PNG approach to mental representation requires only a slightly different understanding of the nature of the relevant causal relationships. Rather than being characterized as functional mappings between vector spaces, we posit that the causal relationships between PNGs are best described in terms of trigger sets. Let us first consider the definition of a $\sigma$-triggered polychronous neuronal group.

Definition A $\sigma$-triggered polychronous group refers to the set of neurons that can be activated by a chain reaction whenever trigger neurons $N_{k}(1 \leq k \leq \sigma)$ fire according to the timing pattern $t_{k}(1 \leq k \leq \sigma)$, where $\sigma$ is the size of the stimulus required to trigger the PNG (Martinez \& PaugamMoisy, 2009).

Here, we recognize that a given PNG can have more than one stimulus trigger. This distinction motivates the definition of a trigger set.

Definition For a given PNG $\pi$, its trigger set, $\tau_{\pi}$, is the set of spike-time patterns that trigger the existence of $\pi$. Each spike-time pattern in the trigger set of $\pi$ will give rise to $\pi$ when presented in the absence of interfering spikes.

Note that each element of a trigger set may be a PNG or a portion of a PNG. Thus, the presence of a PNG spike-time pattern may trigger, or help trigger, other PNGs. The set of PNGs that have the potential of being triggered by a given PNG can form the core of a formal characterization of the causally grounded meaning, $\mu_{\pi}$, of that PNG.

Definition If a PNG, $\pi_{0}$, is seen as a set of spikes (with each spike indexed by the identity of the spiking neuron and the time of the spike), and $\mathbb{P}$ is the set of all possible PNGs in the neural network, then the meaning of $\pi_{0}$, called $\mu_{\pi_{0}}$, is defined as the set of PNGs whose trigger set, $\tau_{\pi}$, contains an element with a nonempty intersection with $\pi_{0}$, or

$$
\mu_{\pi_{0}}=\left\{\pi: \pi \in \mathbb{P}, \exists \pi_{t} \in \tau_{\pi}, \pi_{t} \cap \pi_{0} \neq \emptyset\right\} .
$$

By this definition, $\mu_{\pi_{0}}$ includes any PNG for which $\pi_{0}$ contributes some spikes that may contribute to the triggering of the PNG. Thus, $\mu_{\pi_{0}}$ includes PNGs that may only be triggered by $\pi_{0}$ in the context of other spike-time patterns. In this way, the meaning of a PNG is context sensitive. While constrained by the network's topology, the size of $\mu_{\pi_{0}}$ may be very large.

These definitions describe the causal relationships between PNGs, providing the basis for a conceptual role semantics approach to symbol grounding in the PNG framework. PNGs
triggered by sensory neurons can be considered iconic representations, as can PNGs that trigger motor responses. PNGs triggered by other neurons in a network form internal representations that are ultimately grounded in these iconic representations through the causal connections of their trigger sets.

## Compositionality Of Representations

## The Challenge

A representation that exhibits compositionality, simply put, is one where "the meaning of a compound expression is a function of the meanings of its parts" (Janssen, 1996). In the vector space approach, compositional representations have historically been difficult to capture (Fodor \& Pylyshyn, 1988), but progress has been made (Van Gelder, 1990; Gayler \& Levy, 2011). The most common solutions involve either representational components being maintained in subspaces of a parent vector space, or components being superimposed or convolved to form compound representations like tensor product codes, holographic reduced representations, or sparse codes (Smolensky, 1990; Plate, 2003; OReilly et al., 2011).

Do PNG representations suffer from the same problems of compositionality as vector space representations? Are current approaches to compositionality in the vector space framework also appropriate for PNG representations? How might compositionality be captured in PNG representations?

## Addressing the Challenge

The PNG approach offers two ways to capture compositional representations that are impossible, or at least of limited utility, in the vector space approach. These two methods include sequential concatenation of PNG component representations and the superposition of PNG components.

A PNG representation might be seen as being composed of subsequences of spikes, giving rise to representations at multiple time scales. In essence, a PNG may be seen as containing many smaller PNGs within it, or, inversely, it may be a part of a sequence of other PNGs. Consider the meaning of a particular PNG, $\mu_{\pi_{0}}$. If a PNG $\pi_{1} \in \mu_{\pi_{0}}$ has an element of its trigger set, $\tau_{\pi_{1}}$, contained completely within $\pi_{0}$, then $\pi_{0}$ will reliably trigger $\pi_{1}$, in the absense of interfering spikes. Note that $\mu_{\pi_{0}} \neq \mu_{\pi_{1}}$, so these two PNGs do not have the same meaning. These two PNGs may be combined by simple concatenation, producing a new PNG, $\pi_{2}=\pi_{0} \cup \pi_{1}$. Importantly, the meaning of this compound representation, $\mu_{\pi_{2}}$, is a simple function of the meanings of its parts: $\mu_{\pi_{2}}=\mu_{\pi_{0}} \cup \mu_{\pi_{1}}$. (Note that this is the case even if $\pi_{0}$ does not reliably trigger $\pi_{1}$.)

An alternative approach to compositionality involves directly superimposing PNGs over the same time interval. Since spikes may be sparse over time, the probability of superposition producing interference between PNGs is relatively small. In this way, the composition of PNG representations may simply involve the simultaneous activation of the component PNGs.

## Similarity Of Representations

## The Challenge

Distances in a vector space have been fruitfully used to capture dissimilarity between representations, providing a useful mechanism for generalization. Common distance metrics, like inner-product distance (related to angular distance), are tightly related to the kinds of functional mappings between vector spaces that are are easily implemented by neural circuits. How might similarity between representations be captured in the PNG approach?

## Addressing the Challenge

We see this as an important open question. There are many existing metrics for evaluating the similarity of spike trains (Victor \& Purpura, 1996; Naud, Gerhard, Mensi, \& Gerstner, 2011). Developing a good similarity metric has proven difficult, however, as spike sequences are inherently non-Euclidian (Aronov \& Victor, 2004). The metrics that have been presented focus on comparing spike trains generated by a single neuron, recorded over many trials. Current approaches make the assumption that the significance of a spike can be treated as independent from other spikes produced in the same neural network. Because of these and other issues, existing similarity metrics for comparing groups of spike trains do not predict well whether two PNGs will have a similar effect on downstream neurons.

It is our suspicion that similarity metrics based on trigger sets may overcome some of the obstacles described here. Determining a meaningful similarity metric for PNG representations is a focus of our future work.

## Conclusions and Future Work

Ongoing work in computational neuroscience is uncovering the powerful capabilities of polychronous neuronal groups, and empirical studies are starting to find evidence for this kind of encoding in biological neural circuits. If PNGs emerge as a dominant means of representation in the brain, the vector space account of conceptual states will need to be reconsidered. While many of the strengths of the vector space account appear to transfer, with some modifications, to the PNG framework, there remain challenges for viewing complex spike patterns as conceptual representations. Perhaps the most substantial challenge faced by the PNG approach to conceptual representation involves the nature of representational similarity in this framework. This is the primary focus of our ongoing research program.

Much philosophical work has been done in order to clarify how the vector space account of mental representation provides a bridge between brain processes and cognitive processes. If further neuroscientific investigations suggest that polychronous neuronal groups carry conceptual content in at least some brain systems, similar work will need to be pursued for this representational framework. By highlighting several potentially problematic issues with PNG representations, and sketching promising solutions for some of these
issues, we hope to have helped launch this philosophical effort.

## Acknowledgments

# Testing theories of skill learning using a very large sample of online game players 

Tom Stafford (t.stafford@sheffield.ac.uk)<br>Department of Psychology, University of Sheffield Western Bank, Sheffield, S10 2TP, UK

Michael Dewar (michael.dewar@nytimes.com)<br>The New York Times R\&D Lab, 620 Eighth Avenue<br>New York, NY 10018, USA

#### Abstract

We analyse data from a very large $(n=854064)$ sample of players of an online game involving rapid perception, decisionmaking and motor responding. This data set allows us to connect full details of training history with measures of performance, for participants who are engaged for a sustained amount of time in effortful practice. We show that lawful relations exist between practice amount and subsequent performance, and between practice spacing and subsequent performance. This confirms results long established in the literature on skill acquisition. Additionally, we show that higher initial variation in performance is linked to subsequent higher performance, a result we link to the exploration-exploitation tradeoff from the computational framework of reinforcement learning. We discuss the benefits and opportunities of behavioural datasets with very large sample sizes and suggest that this approach could be particularly fecund for studies of skill acquisition.

Keywords: skill acquisition; learning; game.

## Introduction

The investigation of skill learning suffers from a dilemma. One horn of the dilemma is this: experts in real-world skills can be brought into the lab and their performance tested, but it is difficult to reliably recover comprehensive details of their training. This makes it impossible to be certain of exactly how features of the history of their practice are related to the skilled performance you can observe. The other horn of the dilemma is this: you can test different training regimes rigorously, but you are restricted to measuring performance on trivial or unnatural skills, and often without extended training of the order that experts in complex real-world skills engage in.

Computer games offer a partial resolution to this dilemma. Even simple computer games are not trivial in terms of the cognitive abilities which they test. In fact, these abilities are often the staples of cognitive science: perception, decision making and motor responses. Computer game playing is a real-world skill in which many people choose to become expert, devoting hundreds of hours of practice. Unlike most skills, computer games allow a potential record every action in the history of that practice - allowing for the first time detailed investigation of the connection between features of practice and level of final performance. This is what the current investigation sets out to do. We take detailed records of practice activity from an online game and relate amount of practice and features of practice to levels of eventual performance. In doing this we are able to confirm and quan-
tify established findings from experimental studies of learning. In addition we provide a confirmation of a recent result based on the theoretical framework of reinforcement learning (Stafford et al., 2012). Use of online games to collect very large samples offers a new method for the investigation of skill acquisition, we argue, and the work here showcases just some of the possibilities opened up by this approach.

## Practice amount and spacing

We first consider two well established results against which we will validate our data set as a model of skill acquisition: the effects of practice amount and of practice spacing on performance. Studies of learning have shown a lawful relation between practice amount and performance. If performance is gauged in terms of some measure of efficiency (e.g. time taken to make cigars by experienced cigar manufacturers Crossman, 1959), then it is possible to express the relation between practice extent and performance in a power law of learning (Newell \& Rosenbloom, 1981; Ritter \& Schooler, 2001).

For practical reasons studies of the effect of extensive practice have typically looked at different learners possessing differing amounts of practice rather than the same learners at different stages (i.e. cross-sectional rather than longitudinal designs). Experimental studies of learning which do follow learners longitudinally have predominantly focussed on labbased tasks which can be mastered in one or a small number of sessions (although there are, of course, honourable exceptions such as the work looking at the automatisation of visual search performance (e.g. Neisser, Novick, \& Lazar, 1963; Czerwinski, Lightfoot, \& Shiffrin, 1992).

Highlighting the importance of practice quantity in skill development, Ericsson and colleagues stress that the highest levels of performance are never reached without an amount of practice on the order of ten thousand hours (Ericsson, 2006; Ericsson, Krampe, \& Tesch-Rmer, 1993). Additionally, they report that the nature of that practice matters - effortful, directed, 'deliberate' practice is what distinguishes elite performers, even among those who appear to have performed similar quantities of practice.

Experimental studies of learning have focussed on another factor which defines the nature of practice - spacing. The distributed practice effect denotes the finding that if time devoted to practice is separated out rather than massed, or if the spacing is larger rather than smaller, retention improves
(Cepeda, Pashler, Vul, Wixted, \& Rohrer, 2006; Delaney, Verkoeijen, \& Spirgel, 2010). The distributed practice effect is surely one of the most solid findings in learning and memory research. It holds for both motor skill and declarative learning (Adams, 1987). Due to the limitations of experimental methods there is a dearth of evidence on longer spacing intervals (Cepeda et al., 2006), a dearth which we hope the present study offers a method of addressing.

Next we review an area where the approach adopted in this paper affords particular traction for looking at how the history of skill acquisition affects performance.

## Exploration versus exploitation

The computational framework of reinforcement learning (Sutton \& Barto, 1998), outlines a fundamental trade off in decision making: every decision forces us to choose between taking the action which we estimate will yield the best long term consequence (highest 'value'), or trying out an action of unknown or less certain value. This is known as the 'exploration-exploitation dilemma'. Every choice is an opportunity to receive the outcome from only one action, and so also to update our estimate of the value of only one option. Too much exploitation leads an agent to rely on suboptimal actions, seldom discovering better valued actions. Too much exploration, on the other hand, leads to an agent wasting time exploring the space of actions without garnering the reward of frequently choosing the highest known-valued action. The implications for skill learning are that non-maximising performance during early practice may allow superior subsequent performance. Indeed we might even expect that 'expert learners' would adopt an early exploration strategy in order to maximise final performance.

We have already found evidence for this in humans and rats using an experimental task (Stafford et al., 2012). There is other evidence that variability in practice conditions can aid final performance (Roller, Cohen, Kimball, \& Bloomberg, 2001), as well as generating benefits in learning which crosstask (Seidler, 2004) (which has been termed 'structural learning' by some). This is somewhat in tension with accounts which emphasise the need for transfer-specificity in skilled performance (e.g. Logan, 1988). There is not a direct contradiction, merely we are emphasising the benefit of training off the to-be-tested skill.

## Method

Game designers Preloaded produced a game for the Wellcome Trust called 'Axon', which can be played here http://axon.wellcomeapps.com/. They inserted tracking code which recorded a machine identity each time the game was loaded and kept track of the score and date and time of play. The game was played over 3.5 million times in the first few months of release (Batho, 2012).
The game involved guiding a neuron from connection to connection, through rapid mouse clicks on potential targets. A screenshot can be seen in Figure 1 (see figure caption for
description of game dynamics). Cognitively the game involved little strategic planning, testing rapid perceptual decision making and motor responses.

Figure 1: Screenshot of the game Axon. Players control the axonal branching of the white neuron. At each point, possible synaptic contacts (the other dots) are those within the zone of expansion (the larger transparent circle), which shrinks rapidly after each new contact is made. Non-player neurons (in red here) compete for these synaptic opportunities. Score is total branch length in micrometers (shown bottom left).

The analysis was approved by the University of Sheffield, Department of Psychology Ethics Sub- Committee, and carried out in accordance with the University and British Psychological Society (BPS) ethics guidelines. The data was collected incidentally and so did not require any change the behaviour of game players, nor impact on their experience. No information on the players, beyond their game scores, was collected and so the data set was effectively anonymised at the point of collection. For these reasons the institutional review board waived the need for written informed consent from the participants.

Because the data we record is indexed by machine identity, which is derived from the web browser used to access the game, it is not possible to guarantee that a single individual is responsible for all the scores recorded against an single identity. Nor is it possible to guarantee that a single individual is responsible for only one set of scores. These uncertainties add noise to our analysis, but the data set is large enough to accommodate this. It is not clear what, if any systematic distortions these caveats would introduce. For the remainder of this paper we will use the term 'player(s)' to refer to the set of scores associated with a single machine identity.

The data was extracted from Google Analytics using a Python library by Clint Ecker (2009). Data from between 14th of March and 13th of May 2012 was downloaded and compiled into the source data set for the analyses presented here. This data set comprised a total number of 854064 players. Most played only a small num-
ber of times (the modal number of plays is 1 ), but some played up to 1000 times. The data and code for producing the analysis and plots presented here are available from https://github.com/tomstafford/axongame.

## Results

## Practice amount

On average, scores are higher with each consecutive play for up to 100 plays (Figure 2). At around 80 plays the levels of variation between scores, combined with the drop off of number of players reaching that number of attempts, begin to be seen in the loss of the smooth curve and larger error bars.

Figure 2: Average score for each play attempt. Standard errors shown (n.b. some error bars not visible at this scale).

Taking only those who played more than 9 times ( $n=$ 45672), we can calculate a 'high score' for each players (i.e. the highest score they achieved, irrespective of which play it occurred on). The criterion of 9 or more plays for subset selection is arbitrary, an attempt to balance size of subset (which drops with a higher criterion) against likelihood that practice effects will be reliable (which should be greater for higher criterion values). For this, and all other analyses presented in this paper, the results are not contingent on the particular values used to divide up the data (i.e. here we get similar results if greater than $8,10,5$ or 20 plays are used as the criterion. To confirm this we invite interested readers to run the analysis with altered parameters themselves, by visiting the data and analysis code repository referenced above).

From this subset players are then grouped into 5 groups based on the percentile ranking of their high score, and the average score is calculated for each attempt for all players in each percentile group. This shows that the difference between higher and lower scorers is not merely the amount of practice. The difference in average score is present from the very first plays (Figure 3).

Figure 3: Average score against attempt number for different groupings according to maximum score. Standard errors shown.

## Practice spacing

Taking only those who played more than nine times, we divide players into percentile groups according to their highest score, regardless of on which play it was obtained. We also calculate the separation in time between their first and last play. The result shows a clear upward trend (Figure 4, red dots), with players who score most highly spreading their first and last plays further apart. This is unsurprising, however, since even if there was no relation between practice and scoring, and scores were simply random on each attempt, those players who played had more attempts would tend to collect higher scores and have first and last attempts which were more separated in time. We use bootstrapping to estimate confidence intervals as if this were the case. Keeping the number of players and the number and time of the attempts constant, we generate 2000 simulated datasets, sampling with replacement at random from the total record of all scores for all players. The observed data falls below this bootstrap data for low maximum score percentiles and above for high maximum score percentiles, suggesting that the scores really are distributed non-randomly and according to the spread in time of participant's plays (Figure 4).
It is possible to interrogate this result further by a finer slicing of the data. Taking only players who played more than 14 times $(\mathrm{n}=21575)$, we calculate the spread in time between the first play (or second play where this data was missing) and their tenth play (or ninth, where this data was missing). We also identify their best score on plays 11 to 15. We then divide them into two groups, those who played their first ten times within a 24 hour period ("goers"), and those who split their first ten plays over more than 24 hours ("resters"). Resting between first and tenth plays appears to have a benefit on your subsequent performance (Figure

Figure 4: Players graded according to their maximum score percentile against the delay between their first and last plays. Standard errors shown.
5). The difference between the groups is highly significant $(t(20354)=6.219, p<0.00001)$, albeit for a small effect size (Cohen's d $=0.11$ ).

## Exploration versus exploitation

The variance of scores for each player in the first five plays was calculated, and this statistic for each player ranked and so percentile groups created. The same was done for the average on plays six to ten. Plotting one against the other we see a clear correlation - with higher early variance associated with higher subsequent performance (Figure 6, the very high number of individuals made a scatterplot impractical at this scale, so we present a heatmap).

The Pearsons's $r$ correlation coefficient was 0.59 and significantly different from zero at a high probability ( $p<$ 0.0001 ). Randomising the scores for each attempt within the structure of the number of players and the number of attempts per players, it is possible to generate a bootstrap data set which gives a confidence interval for this correlation - in other words, answers the question "to what extent is a correlation between high early variance and high late scoring inherent in the distribution of scores and the structure of how players accumulate scores from that overall distribution". These bootstrapped confidence intervals, at the $95 \%$ level were 0.009 to -0.009 . Thus we can conclude with a high degree of confidence that the correlation is both significantly different from zero and not a trivial consequence of the distribution of scores. Instead, the correlation results from the particular way individual player's early scores are related to their later scores.

## Discussion

These results confirm, but also quantify, results from experimental psychology regarding the effects of practice quantity

Figure 5: Average maximum score following first ten plays, for those who group their first ten plays within one day ('goers') and for those who split their first ten plays over two or more days ('resters'). Standard errors shown.
and quality on performance. As players practice their average score improves. Dividing the players into percentile groups according to high scores appears to show that practice alone does not allow most players to achieve the highest scores. The best players have an advantage from the very first plays. This advantage is consolidated with practice, in that not only do they score more on their first plays, but their rate of improvement is faster. This is in marked contrast to some popular (e.g. Gladwell, 2008) and academic (e.g. Ericsson et al., 1993) accounts of high performance which have denigrated the importance of talent with respect to practice. We regard this result as provisional. It needs to be replicated with another data set so we can assess if it generalises to other skills. Replication would also assuage worries that some specific confound of the present data set has produced the result. For example, we have no way of controlling for the prior game experience or hardware set-up of the players of the Axon game. It is possible that it a certain amount game experience is required for individuals to get high learning rates with this specific game (we thank an anonymous reviewer for pointing out this potential 'thresholding of performance improvement by prior experience' confound).

The analysis of practice spacing confirms the wisdom from experimental studies of learning and memory that distributed practice is better than massed practice. It remains to be seen if there is an optimal amount of spacing, as has been reported for semantic knowledge (Cepeda, Vul, Rohrer, Wixted, \& Pashler, 2008), or an optimal timing of spacing (Goedert \& Miller, 2008).

The exploration-exploitation result confirms a preliminary result from a recent experimental study (Stafford et al., 2012). Although bootstrapping confirms that this finding is

Figure 6: Heatmap made from scatterplot of variance of scores on first five plays versus average score on plays six to ten.
not an incidental result of the distribution of scores, it still isn't clear if the level of exploration (operationalised as score variance on early plays) per se causes the higher level of performance ('exploitation', characterised as score average on later plays). It is doubtful that low scoring attempts in themselves cause higher subsequent performance. Rather low scores may be the impetus for players to shift their playing style or tactics in ways which unlock higher subsequent performance (similar to the postulated freeing and freezing of degrees of freedom which have been thought to characterise changes in motor skill (Berthouze \& Lungarella, 2004; Bernstein, 1967). The ultimate test exactly if and how early exploration affects subsequent performance will be to intervene to make players explore and see how this affects later scores. In other domains there have been suggestions that introducing guided mistakes or deliberate failure into early training may have benefits for overall performance (something for which there is some evidence: Lorenzet, Salas, \& Tannenbaum, 2005).

## Games

Games are a great opportunity for the cognitive science of learning. They provide participants in high numbers who are engaged willing to undertake extensive practice. Games can provide large amounts of detail on training conditions and actions, in ways that other paradigms cannot. In the future it may even be possible to introduce experimental manipulations into engaging games through partnership with games designers.

## 'Big Data'

The method of study adopted here means we lose experimental control over the factors involved in learning. However,
advantages stem from the very large sample size we are able to collect. Some of the emphasis on the importance of experimental control in cognitive science is due to the loss of statistic power than can result from uncontrolled measurement. With large sample sizes, loss of statistical power is not an issue. We need only concern ourselves with the ways in which lack of experimental control introduces systematic confounds into our data set. As well as large statistical power, very large sample sizes mean we can interrogate data in new ways. One of these is 'slicing' by which we mean identifying individuals who meet certain conditions and comparing within that group. This is a substitute for the conventional experimental method of creating individuals that meet certain conditions in low numbers. In experimental design you control potential confounds in advance (by attempting to remove them). With slicing you attempt to account for potential confounds post hoc by selecting multiple different sub-datasets, each of which controls statistically for a potential confound - and thus by a process of elimination gathering support for your hypothesised causal variables. This is a less powerful method than experimental control, but it does offer some advantages.

Bootstrapping provides a way of testing observed patterns against sophisticated null hypotheses. Both bootstrapping and slicing are illustrated in this paper in the analysis of spacing effects.

Two modern crises of psychology are the apparent low replicability of effects (Pashler \& Wagenmakers, 2012) and the use of inappropriate statistics (Wagenmakers, Wetzels, Borsboom, \& Maas, 2011; Simmons, Nelson, \& Simonsohn, 2011). Very large sample sizes can side-step both of these. With a large enough sample size you do not need to use inappropriate statistical techniques - small effects are easy to find. Furthermore, you have enough data to use techniques such as cross validation to guard against false-positives.

Analysed in detail, very large data sets provide an observational playground in which we can not just detect effects, but compare the size of different effects against each other. For example, in the present data set it can be seen that the benefit of 24 hours spacing is about 3000 points (Figure 5). This is comparable to about 5 plays, in the $10-15$ play range (Figure 2), or equivalent to an extra $50 \%$ practice at this stage of experience.

Obviously, nothing will replace the controlled experiment in terms of causal inference. For hypothesis testing the controlled experiment must remain the the gold-standard. However, there is space within the scope of investigation for studies with purposes other than theory-driven hypothesis testing (Rozin, 2009). This paper has focussed on characterising the data and confirming effects discovered in traditional controlled experiments. We believe the approach illustrated here can be complementary to experimental studies, and has the potential to open up new avenues for investigation in the study of skill acquisition.

## Acknowledgements

Thanks to Tony Barnes for an introduction, to Phil Stuart, Charles Batho and Cameron Yule at Preloaded, to the Wellcome Trust for allowing the data from their game to passed to us, to Stuart Wilson for help with python, Ashvin Shah for discussion of reinforcement learning and four anonymous reviewers. Special thanks to Edith Mary Cameron, whose late arrival and post-birth disposition allowed TS to carry out the bulk of the analysis and writing for this paper.

#### Abstract

Instruction often employs visual representations to support deep understanding. However, students' prior misconceptions may override the meaning in these scaffolds. We investigate fraction bars, a common representation intended to promote sense-making. Our prior work found that students often did not use the fraction bars effectively. This difficulty factors assessment compares four scaffold types: pictures only, two forms of pictures with numbers, and numbers only, to assess which interpretation steps were difficult. On equivalence items, students performed equally well with all scaffolds that included pictures, but worse with the numbers-only scaffold, indicating that fraction bars improved scores for equivalence. However, including numbers with the pictures decreased performance for fraction addition. Although students demonstrated competence with fraction bars in fraction equivalence, they did not transfer this knowledge to addition. These results suggest caution in designing and teaching representations for sense-making.

Keywords: graphical representation; fraction addition; symbolic fractions.

Many researchers strive to identify ways to support deep understanding, as it is thought to promote robust and adaptable learning. One strategy has been to use multiple representations, particularly ones that connect to students' prior knowledge and aid sense-making. However, there is little data on what representations will make sense to the students. Singapore textbooks and the NCTM standards, for example, advocate using concrete visual representations in mathematics as a bridge to more formal, abstract thinking (NCTM, 2013; Leinwand \& Ginsburg 2007). But, perhaps we should question the benefits of these representations (Rittle-Johnson \& Koedginer, 2001; Booth \& Koedinger, 2012): Are they actually easy entry points for students?

Our tutors for $5^{\text {th }}$ graders aim to support sensemaking by providing conceptual representations as feedback, a strategy that appears effective with adults (Mathan \& Koedinger, 2005; Nathan, 1998). In our fraction-addition tutor interfaces, equally-divided rectangles, or fraction bars, provide immediate feedback by dynamically
showing the fractions that students enter numerically. We hypothesized that fraction bars would be a more intuitive representation than symbolic fractions, and having students input symbolic fractions and get feedback from fraction bars would prompt thinking on how the two representations were related. Also, we thought it would show students that the common mistake of adding both numerators and denominators was incorrect. We termed this feedback grounded feedback because it was grounded in student's prior knowledge, and grounded an unfamiliar representation (fraction symbols) in a more intuitive one (fraction bars). An initial think aloud study showed promise. The $5^{\text {th }}$ grade participants seemed to understand what the fraction bars meant, and used them to find and correct fractionaddition errors (Stampfer, Long, Aleven, \& Koedinger, 2011). An experimental study found learning benefits with a fraction bar tutor (interface in Figure 1) (Stampfer \& Koedinger 2012). This tutor does not indicate explicitly if an individual step is right, but students cannot advance to the next problem until all steps have been solved correctly.

Although students learned from the tutor (improved from pre-test to post-test), process measures show incorrect interpretations of the fraction bars. Students often indicated they were done solving the problems even though the fraction bars did not line up. They clicked the "done" button on the tutor screen an average of about 2.5 times per problem (rather than the one necessary click). This finding revealed that one of our key assumptions about this form of grounded feedback for these students was not fully satisfied. It appeared that the fraction bar representations of addition were not as meaningful to all students as the think-aloud results suggested. Thus, we were led to investigate more deeply the cognitive

Figure 1: Fraction Addition Tutor. Top row of fractions and fraction bars are given, second row reflects students' inputs, typed in the boxes at the bottom. Text hints appear below when requested.
mechanisms required for processing these representations and, in particular, to attempt to identify the sticking points where student processing deviates from expectation. This difficulty factors assessment (cf., Koedinger, Alibali, \& Nathan, 2008) examines how students understand fraction bars in the context of the fractions they represent; if this process changes depending on the topic (addition vs. equivalence); and how each processing step affects performance.

## Difficulty Factors: Pictures and Numbers

Using a theoretical cognitive task analysis, we identified three likely skills needed to understand the fraction bar representations for fraction addition: 1) equal areas represent equal amounts; 2) the rectangular bars represent the symbolic fractions written above or below them; 3) if two shaded areas are equal, the fractions they represent are equal. We developed matched test items intended to isolate those skills (Figures 2-5). Fraction addition items presented a fully solved problem and students indicated whether it was solved correctly (true or false). Fraction equivalence items presented two fractions and students indicated if the first fraction was bigger than, equivalent to, or smaller than the second fraction. The four question presentations are intended to isolate the skills needed to make sense of the tutor interface in Figure 1. The pictures format (Figure 2) assesses if students know that the shaded rectangles use area to represent quantity, such that two rectangles with equal-sized

Figure 2: Pictures. Does area equal quantity?

Compare, then circle the correct answer
a) $\frac{1}{3}$ is bigger than $\frac{8}{19}$
b) $\frac{1}{3}$ is equivalent to $\frac{8}{19}$

True or False: $\frac{2}{11}+\frac{1}{2}=\frac{15}{22}$

Circle the correct answer: True False
c) $\frac{1}{3}$ is smaller than $\frac{8}{19}$

Figure 5: Numbers-Only Control. Can students evaluate solved problems?
shaded areas represent equal quantities. Pictures-and-numbers items (Figure 3) include fraction symbols with the fraction bars, to test if students can understand the fraction bars as representations of fractions. Half-pictures-and-numbers items (Figure 4) also include both fraction bars and fraction symbols, but only presents the fraction bars as the hint at the top of the problem. This determines if students can find the relationship between the two fraction bars, map that relationship to the symbolic fractions represented, and then select the relationship that the symbolic fractions have to each other. Numbers-only (Figure 5) provides a baseline for how well students can evaluate the equivalence and addition problems without fraction bars. Another pair of questions gives a baseline for translating a single fraction bar to a fraction symbol (e.g., when shown a rectangle divided in 5 parts with 3 of them shaded, the student should write $3 / 5$ ).

## Methods and Participants

155 fifth grade students from a local public school participated in this study during their normal school day. They were given 20 minutes for a 30item assessment. The school tracked these classes, with 57 students in the highest track, 61 in the middle track and 37 in the lowest track.
Each test included 8 equivalence items and 8 addition items (one correctly solved and one incorrectly solved for each scaffold type). All addends in these items had unlike denominators. The sums in the incorrect addition items followed the popular misconception of adding both numerators and both denominators. Tests also included two single fraction bar items, one with numbers for how many pieces were shaded and how many total. Item presentations were counterbalanced with the specific numbers in the problems to avoid confounding. Item order was determined randomly and half of the tests were given with the order reversed. Questions were scored as 1 if correct and 0 otherwise.

## Results: Scaffold Type Affects Performance

Scores on the single-fraction-bar items were near perfect ( $94 \%$ correct). Figure 6 shows the mean scores for the equivalence and addition items by

Figure 6: Mean scores (max. 1) on equivalence and addition items
scaffold type. Mean scores on the fraction equivalence items were high, with 81-83\% correct for all scaffold types with pictures, and $50 \%$ for the numbers-only presentation. Equivalence items offered three options (bigger, equivalent, or smaller) so even the numbers-only score is well above $1 / 3$ chance. Mean scores on the fraction addition items were lower ( $21 \%$ to $79 \%$ ). These scores steadily decreased as the saliency of the numbers increased. Lower-than-chance results indicate that instead of guessing randomly on the more difficult scaffolds, students answered based on a systematic misconception. Blank answers were scored as 0 and they could reduce performance below the 50\% chance rate. However, students were no more likely to skip the numbers-only addition items than the other addition items that included numbers (numbersonly addition was skipped 13 times, while half-pictures-and-numbers and pictures-and-numbers were skipped 14 times each).
There is a strong interaction effect between question type and scaffold type. We ran an ANOVA on the item scores: 3 (class tracking level: high, middle, low) x 4 (scaffold type: pictures, pictures and numbers, half pictures and numbers, numbers only) x 2 (item: equivalence or addition) with repeated measures for the scaffold type and item. With the Huynh-Feldt correction (since sphericity could not be assumed), results showed significant within-subjects effects for scaffold type and item, and a significant scaffold
by item interaction (all $\mathrm{p}<.0005$ ). Results also showed significant between-subjects effects for class tracking level, with parameter estimates indicating that higher-tracked students got higher scores.

The patterns in figure 6 suggest that all scaffold types with pictures have a similar effect for equivalence, but each scaffold type has a different effect for addition. To verify these hypotheses statistically, we ran separate ANOVAs on each tracking level for equivalence and addition scores, with scaffold type as a fixed factor and student as a random factor. For each of those analyses on the equivalence scores, scaffold was significant ( $\mathrm{p}<.0005$ ) and post-hoc Tukey tests showed that the numbers-only scaffold was significantly different from the other three ( $\mathrm{p}<.0005$ ). For each of those analysis on the addition scores, scaffold was again significant ( $\mathrm{p}<.0005$ ). Tukey tests for the middle track show significant differences among all scaffold types ( $\mathrm{p}<.01$ ). The lowest track did not have significant differences between half-pictures-and-numbers and numbers-only, likely a floor effect. The highest track did not have significant differences between pictures and pictures-and-numbers, likely a ceiling effect.

Figure 6 also suggests that addition with the pictures-only scaffold is no more difficult than equivalence with the pictures-only scaffold. To test this, we ran an ANOVA on the item scores for the pictures-only scaffold: 3 (class tracking level: high, middle, low) x 2 (item: equivalence or addition) with repeated measures for item. Results showed no significant difference for scores on the two question types ( $p=.2$ with the Huynh-Feldt correction). Subsequent ANOVAs on each of the other scaffold types showed significant differences for scores on the two question types (all p<. 0005 with the Huynh-Feldt correction).

Finally, we examined the effect of spatial reasoning on scores. One may hypothesize that when pictures are present, students would be more accurate when there is a large disparity in the area of the quantities being compared. To test this hypothesis, we calculated a disparity measure for each question where the two fractions were not equivalent or the two addends did not equal the sum. For the equivalence items, the disparity is
the absolute value of the first fraction minus the second fraction. For the addition items, the disparity is the true sum of the addends minus the sum in the question. We ran separate ANOVAs for each question type, with scaffold type and disparity as fixed factors and student ID as a random factor. For both addition and equivalence, between-subject main effects were significant for scaffold type and student ID ( $\mathrm{p}<.0005$ ) but not for disparity ( $p=.141$ for addition, $p=.888$ for equivalence), and there was no scaffold*disparity interaction ( $\mathrm{p}=.257$ for addition, $\mathrm{p}=.136$ for equivalence). This indicates that disparity did not affect scores, and the effect of disparity did not change with scaffold type. Additionally, the equivalence questions all had smaller disparities than the addition questions (means: . 06 for equivalence, .39 for addition), yet the equivalence questions were as easy or easier, further evidence that disparity did not affect scores.

## Discussion: Fraction Bar Skills are Context-Based

Students were at ceiling for writing the symbolic fraction represented by a single fraction bar. Students were quite good at comparing two fractions and indicating if the first was greater than, equivalent to, or smaller than the second. Further, scores on these equivalence items were equally high for all scaffold types that included pictures.

On the equivalence items, students demonstrate competence with the three skills identified in the cognitive task analysis: equal areas represent equal quantities (pictures), the bars represent fractions (pictures and numbers), the relationship between the bars maps to the relationship between the fractions they represent (half pictures and numbers). Students were likely not solving these equivalence problems with the numbers alone, since numbers-only performance is much lower.

Surprisingly, these skills are not consistently demonstrated with fraction addition. Pictures-only scores are just as high with addition as they are with equivalence, indicating that the knowledge that equal areas represent equal quantities does transfer to addition. However, performance decreases steadily across pictures-and-numbers and half-pictures-and-numbers, suggesting
difficulty both with understanding the bars in the context of fractions and mapping the relationship between the fraction bars to the relationship between the fraction symbols. Yet, the bars still increase performance above the numbers-only control (which has worse-than-chance scores).

We hypothesize that the temptation of the incorrect add-both-numerators-and-denominators strategy overrides the area-as-quantity reasoning that students demonstrate when the numbers are not shown. A cognitive-load hypothesis may predict that fraction symbols are distracting because they visually clutter the problem. In that case, scores with half pictures and numbers should be higher than pictures and numbers, since there is less information and less visual clutter. Yet, scores decrease, indicating that performance is not correlated with cognitive load.

Byrnes and Wasik (1991) discuss a theory that conceptual knowledge will prevent students from making certain procedural errors. In this theory, a "self-critic" (our name), evaluates procedural outcomes for conceptual errors. For example, if a student adds $3 / 4$ and $1 / 7$ and gets $4 / 11$, their "self-critic" may reason that $4 / 11$ cannot be right because it is less than half while $3 / 4$ is greater. With the picture scaffolds, these steps are easier instead of numeric mental operations, students can compare the fraction bars. Scores on the equivalence and the pictures-only addition items demonstrate students' skill in comparing fraction bars, yet they still seem to not use their "critic" on the fraction addition items with numbers.

Interestingly, Byrnes and Wasik argue against the self-critic theory, claiming that conceptual and procedural knowledge are not activated simultaneously in problem solving. Further, conceptual knowledge may precede procedural skill, so in some stages of learning conceptual knowledge would not be correlated with procedural performance. Instead, procedural skills improve through proper discrimination and generalization. To test these theories, they compared three instructional techniques for LCD fraction addition. One was procedural, and stressed that "you can't add fractions the way you add ordinary numbers." The other techniques added conceptually-based instruction (one with
paper fraction bars) to that procedural instruction. Results showed that the conceptual methods did not improve learning above the purely procedural one. These findings suggest that aiding discrimination will improve procedural skill, and that skill is not enhanced further with brief conceptual instruction. These findings and the results from the fraction equivalence items suggest that students will not benefit from more conceptual instruction on fraction bars, even though they performed poorly on fraction addition items with fraction bars. Instead, they may benefit from support for separating whole-number and fraction addition. Alternatively, students may benefit from practice and support in invoking their "self-critic." However, these critics may be stifled by a misconception unrelated to fractions: the meaning of the equals sign.

McNeil et al. (2006) found that $6^{\text {th }}-8^{\text {th }}$ grade students looking at a problem such as $3+4=7$ were more likely to interpret the equals sign to mean 'write answer here' than 'both sides are equivalent.' Perhaps this misinterpretation of the equals sign in equations with operations interfered with students' internal "critic" in the addition items. Even when the pictures show the sum to be smaller than one of the addends, the student may not realize that the two sides of the equal sign are supposed to be equivalent. A "critic" that interprets " $=$ " as 'write output of procedure here' may simply verify that the add-both-numerators-and-denominators strategy was executed well. In other words, the presence of numbers may not only prompt over-generalization of whole-number addition, but also interfere with students' interpretation of the equals sign and thus throw off the "critic."

## Conclusion

These data imply that the usefulness of the fraction bar scaffold is dependent on the topic for which it is employed, and the specific combination of images and numbers. When naming fractions represented by individual fraction bars and solving equivalence problems with fraction bars, students were equally proficient whether the numeric symbols were present or not. However, for fraction addition, the
fraction symbols were detrimental. The picturesonly addition problems may invite reasoning based on conceptual understanding (the sum of two areas cannot be smaller than either addend), while the presence of fraction symbols may invite procedural problem solving that is initially divorced from the underlying concepts.

This DFA study suggests that students' difficulty with dynamic fraction bars in a tutoring system was due to the specific addition context. More broadly, it suggests caution in the design and use of conceptual scaffolds for math problems. Students may demonstrate proficiency with a scaffold in one domain without being able to transfer those skills, even to a closely related domain. Procedural misconceptions may override the conceptual reasoning these scaffolds attempt to induce. Perhaps students need instruction to support their "self-critics" in checking procedural outcomes against conceptual knowledge. Or, perhaps students require certain domain-specific knowledge before their "self-critics" are triggered. Our future work with fraction bars will explore the effect of metacognitive "self-critic" training and domain-specific instruction on the meaning of the equals sign.

# The Importance of Nouns in Text Processing 

Lauren M. Stuart, Julia M. Taylor, and Victor Raskin (\{lstuart, jtaylor1, vraskin\}@ purdue.edu)<br>Purdue University, 656 Oval Drive<br>West Lafayette, IN 47907-2086 USA

#### Abstract

In the area of computational processing of natural language texts, advances toward simpler yet more accurate models of meaning are desirable. As syntax is a major component of semantic analysis, we explore how a long-term institutional bias towards the verb as the main determiner of syntactic (and semantic) structure may underserve some kinds of information. We introduce an analysis paradigm that restores the noun to some importance in syntactic analysis. A noundriven syntax representation has been developed and evaluated, and implications of its use in further processing and in better modeling of natural language meaning are investigated.

Keywords: Linguistics, Language Understanding, HumanComputer Interaction, Representation, Syntax, Semantics

## Introduction

Text interpretation by computers is highly desirable and arguably necessary as we continue to produce and analyze text. One major benefit to the improvement of natural language understanding (NLU) for text is more intuitive natural interaction with highly structured or, conversely, loosely associated, large stores of information.

Text processing may proceed sequentially, on the assumption that only full (or major) analysis of the surfaceward structure yields the next deepest structure, where deepest structure is some formulation of the text's meaning, possibly applicable to other meanings of other texts, and the surface structure is the written or spoken input for a computer. This linear process encourages the development of incremental processing modules; that is, given some intermediate representation of something going on in the text, the module will produce a further refined model according to its internal rules and heuristics. For an example, take a phonetic processor that processes speech data and outputs a series of symbols for use in phonological and morphological analysis.

The process does not have to be linear; an alternative approach may parallelize the different analyses to some degree, even to the maximum possible (for instance, we cannot process any syntactic data if it has not yet been furnished). In this approach, iterations of processing may "clear up" a map of the sentence's interpretation (meaning) incrementally. Easy or simple rule applications start the process and such selections provide feedback for further selections in those areas of the map that are not yet clear, for some threshold of "clear" that is dependent upon the form and eventual use of the data.

Linear or not, any processing of a text from its surface form to some model of its meaning relies on various stages
of language processing. We wish to explore how a bias in one of these stages, and its correction, affects processing in another.

## Sentence Processing

As a sentence is analyzed, much importance is given to the verb(s): modal verbs modify the main verb; noun phrases participate as subjects or objects; any noun phrase not directly related to the verb may be a complement of a preposition, which is itself associated with the verb or a noun phrase, or of some other clause or phrase whose meaning props up the meaning of the verb (the event said to be encoded in this particular sentence) and whose place or expression in the syntactic structure of the sentence is as much (or more) dictated by the verb as the head of the phrase. Nouns generally remain building blocks of arguments to be fed into a verb.

Figure 1: Representation of a phrase structure parse from Berkeley Parser

Figure 2: Representation of a dependency parse from Stanford Typed Dependencies

In syntactic representations, this privileging of the verb is typically expressed as a shorter distance between the root of the tree and the main verb; some representations go so far as to shorten the paths to the other verbs in the sentence. See Figure 1 for a constituency tree representation, and note the comparative height of the verb and its nouns. Then see

Figure 2 for a dependency tree, noting how the removal of some phrase structure also removes some steps to access any particular word, but verbs are still comparatively close to the root and can be accessed from one another. This reveals an intuition that a sentence is primarily "about" its verb and that composition of multiple sentences is "about" lining up the verbs together.

In the process of computational understanding of natural language, a computer may be given a syntax tree from which to construct a meaningful model of the events and objects that the sentence describes (with "meaningful", here, determined by the eventual use to which the model will be put: are we looking for frequencies of events? a reconstruction of the actions of one particular object? similarities in locations, origins, or attributes of events or objects?). Then, to maintain the appropriate interpretation of meaningfulness, the distance of a particular word or word category from the root of the sentence must correlate to its need, or incorporation, in the construction of this model. Given syntax trees that are verb-centered, it is most efficient to construct verb-centered semantic representations. Processing may not need to be sequential (as in, phonological then morphological then syntactic then semantic), but we will leave that possibility alone for right now.

A mapping may be observed between simple sentences and logical expressions in first-order predicate logic: The images show a landscape can be formulated as a function show() with the arguments images and landscape. The proposition show(images, landscape) is held to be equivalent to the sentence - that is, if it is tested for a binary truth value, it evaluates to "true" in all the situations in which the sentence from which it comes would be considered true. More complex statements can be generated using such rules as well, e.g., show(images, landscape) \& is_on(landscape, Mars). By mapping natural language sentences to this restricted logical form, we arrive at a sort of semantic notation that is easier, somehow, for a computer to use. Its close resemblance to the syntax of many programming languages suggests that, if only we can translate all sentences into such expressions, we can execute the program obtained by concatenation (in accordance with rules for coordination, negation, etc.) of these expressions and thereby arrive at some truth value for the sentences taken together. We may not just want an answer (true or false) but a model of the meaning in the text; tweaking the execution of these formulae may allow us to build that model.

However, first-order predicate logic is not entirely adequate. Luuk (2009) extends the mapping to a less strict system and theorizes about the possible evolution of argument-like concepts (nouns) before predicate-like concepts (verbs, among others).

Still, all of this analysis is predicated on the idea that the verb (or the event it describes) is the central element of analysis, from which all other considerations flow. However, there are some natural and regular instances in
which the verb is no help, or possibly even absent. Take a copular sentence: The Curiosity is the Mars rover. While the existential senses of is are large and have many implications, they are only manageable when knocked down to the scope of is the Mars rover. In practice, the verb in this sentence is demoted to purely technical predicate status and the predicative nominal elevated in its place. Now we are to analyze a noun phrase as a predicate; there is plenty of precedent, as we can talk about noun-expressed events taking arguments structured similarly to those their verbexpressed counterparts accept. Compare We celebrated the launch today with The celebration of the launch was today.

However, the question must be asked: why is our analysis so verb-centered, and to such a degree that we must postulate verbs, i.e., essentially to create dummy verbs, where there are none?

## Towards a Noun-Driven Paradigm

We propose an alternative, perhaps complementary analysis paradigm: center the noun. Such a paradigm might include analysis of concepts as informational objects - for events to be frames - and events as actions somehow intrinsic or controlled by the objects they involve. This paradigm may open up a world of gains in processing different flavors of information sources, particularly those that have been traditionally managed by computers, with different degrees of naturalness in the language used to interact with them. A noun-driven paradigm may then boost ease of interaction with these sources via natural language understanding by simply not introducing an unneeded event structure for analysis.

To this effect, we have proposed a noun-driven syntax representation (Stuart, 2012). It inherits from the class of dependency grammars by formulating syntax rules as directed binary relationships between nodes. For instance, a preposition may be eliminated entirely and encoded in the syntactic tree as a directed relation, carrying the meaning of the preposition, between the elements it used to connect. For an example, see Figure 3.

Figure 3: Prepositional collapse in Stanford Typed Dependencies Output

There may be tradeoffs between dependency grammars and constituency grammars - Nivre (2006) considered the tradeoffs favorable - but some may be more important in
the noun-driven paradigm (for instance: should it perhaps be the noun-phrase-driven paradigm?) and only further investigation will reveal these.

A noun-driven representation has been developed, starting in Stuart, et al. (2012a) and Stuart, et al. (2012b). The structure links all nouns from the root, so a parallelized meaning-scaffolding program may have several starting points and begin to converge upon an intermediate structure (towards a model of meaning) as it traverses the nodes held in common between noun-rooted subsets. The corresponding parallelization applied to verb-driven dependency grammar representations does not result in the same gains: there are typically two noun phrases to every verb phrase in English (Baker, 2005). The number of nouns relative to verbs only gets larger when we consider noun chains ("crater rim"-see also Taylor et al 2010, 2012) and prepositional phrases (the objects of which are always noun phrases).

The number of prepositional phrases also contributes to the complexity of syntactic analysis. Some prepositional phrases have ambiguity in attachment; some may attach somewhere in syntactic analysis but be restricted from that attachment during more meaning-directed evaluation. Consider The images show a landscape on Mars vs. The images show a landscape of Mars. In the first, on may attach to both show (the event of showing could occur on Mars) and to landscape (the landscape is specifically one on Mars). In the second, of may only attach to landscape, but can sometimes attach to other verbs (as a particle, for instance, in to think of), so the evaluation of the attachment as valid may take several steps of analysis. Multiple prepositions can also attach to the same elements; as they all will have noun-phrase objects, the centering of the noun phrase in analysis hikes the prepositional phrase up in the hierarchy of importance as well.

## Implications for Semantic Processing

The "object-oriented" nature of noun-driven syntax may also align sufficiently well with object-oriented semantic languages to collaborate easily in parallelized processing, allowing groups of objects at certain "stages" to be swapped out with "higher-stage" interpretations or representations of them.

Take the sentence introduced before: "The images show a landscape" and its partial processing, as shown in Figures 2 and 3. In the latter, "show" has been tagged as a noun rather than a verb. Possibly these are candidates with the highest confidence due to internal simplicity, some rules about sentence formation, the topic of the information, or from previously-mentioned information: "the images" likely refers to some set of images that have already been introduced. In a pass that has produced some semantic or intermediate representations for parts of the map-the intermediate conclusions made in the other parts of the sentence contribute to analysis of the other parts. Analogously, in a greedy meaning algorithm, the subsets of
the sentence which are simplest to compute or represent drive the interpretation of the rest of the sentence.

As in many syntactic analysis algorithms, "steps" of processing can be reverted (or previous states saved) to enable backtracking or the output of multiple best candidates if appropriate. The processing shown in Figures 4 and 5 presupposes object-oriented semantic-processing modeling. For those systems with event-oriented semantic processing, verb-driven syntactic approaches (linear or parallel) are just as useful.

Figure 4: Processing steps when "show" tagged as a verb

Figure 5: Processing steps when "show" tagged as a noun
Regardless of whether the semantic modeling used in process is object-oriented, event-oriented, or some hybrid, we find it prudent to also consider the possible object- or event-biased information sources. Suppose we have an encyclopedia article about the geographical features of Mars. While many sentences will perhaps explain the dates and methods of discovery of certain facts about Mars and its geography, we can expect a large amount of discussion on the features themselves, their attributes, positions, and the larger classes to which they belong. In the example sentence A peak sits to the south of the crater rim, we receive information that there is some peak (perhaps in a larger range of mountains) somewhere south of a crater that has been (we hope) previously introduced. This is position information; the verb is sit but if it were for some reason left out of the sentence or replaced with is, is located, or is situated, we would still get the gist.

Consider, then, a general article about geography, the content of which an NLU system will have to make use of in order to understand the instantiations (in the Mars geography article) of types and classes described in the general article. We can expect some events here: various geographers may have contributed to the development of some concepts. However, we argue that the most useful part of the article (again, for understanding something about the features of Mars) is that part which defines the types, attributes, and relative locations of geographical features. This area of the article is likely to be strongly nouncentered: positions, lists of items, and weak verbs may
dominate. (A volcanic crater is a circular depression in the ground.) This is not to say that the verb-driven paradigm is useless in a very noun-dominated information space. However, a verb-driven syntactic analysis may waste some resources by trying to identify and promote predicates. As well, a verb-driven semantic analysis may find that most of its "events" are existential and not temporally-bounded instances of some action.

Now consider some more rigidly-defined information spaces. The most rigid might be the company relational database, which strictly encodes lists of relationships between objects - Li et al. (2008) developed an engineering ontology and lexicon for processing natural language search queries, in a supply chain application, to just such a database, which also included information in unstructured (that is, natural language) descriptive documents. The user queries (and therefore the ontology) emphasize parts' shapes, materials, purposes, and origins. Such domains are fundamentally concerned with objects and how they are related to each other. The "translation" from machinereadable language to natural language must rely heavily on nouns, adjectives, quantities, and the relationships and attributes of semantic concepts representing "things" rather than "happenings". The basic semantic structure of the information is already there: the database schema gives us relations by which to connect the objects (event instances, object-parts, etc.) that are its subject.

Take now, for example, a computer program written in some programming language. Improvement of NLU also underwrites the improvement of translation between natural language and programming languages (for instance, in specifying and evaluating privacy constraints, as in Brodie et al. (2006)). The language itself does not need to be conceived of as object-oriented (Java, C++) because a reductive view of a computer program is that of an informational object which takes informational objects as inputs and gives more information objects as outputs. The transformations that these input objects undergo are events, the transformations may be affected partially or wholly by some qualities of the objects to which they are applied. This is a strength of inheritance and polymorphism in those object-oriented languages: one prototypical "event" can be expressed in terms of the classes of objects to which it is applied, and many events are specific, intrinsic, and unique to a (class of) informational object (data structure). Thus, "translation" of the event relies ultimately upon the objects involved; that is, Object.do() is specified at least in part by the implementation of the class Object. Even in a language that is not specifically object-oriented, the specific actions undertaken in the execution of the method process(thing) depend on the content or nature of the object thing.

Finally, consider the sentence "Airborne geomagnetic surveys showed a strange pattern of symmetrical magnetic reversals on opposite sides." Our main verb here is "show", but the important events (the act of surveying, and the occurrence of magnetic reversal) appear in noun form, and some important attributes appear as adjectives and a
prepositional phrase. Verb-centered processing (purely syntactic or as a step towards semantic processing) prioritizes "show"; it stands in for a fuller explanation that investigating scientists learned about the reversals by reviewing data from the surveys, and thus does have some importance (for instance in auditing the assertion "Many magnetic reversals have occurred", as one question could be "How do we know that?"). In an article about the scientific process, its many forms, and its contribution to knowledge, this is a salient detail. However, in reading an article about the geomagnetic history of the earth, we may be much more interested in the apparent occurrence of magnetic reversals, and the source of the data analyzed in order to reach that conclusion.

## Experimental Evaluation

Stuart et al. (2012b) began evaluating the performance of the noun-driven syntax in a small query context: assuming that most queries to syntax trees take the form of traversing the tree to or from a certain node or a node of a certain category, the node's depth is used as a rough measure of accessibility for further analysis. The initial experiment was carried out by hand and in comparison with outputs from Stanford Dependencies, Stanford PCFG, and Berkeley parsers. The dataset consisted of only 30 sentences; the noun-driven syntax representation performed at least as well, or better, than the dependency grammar trees, and both much better than the phrase-structure trees. As well, the dependency and noun-driven trees were evaluated from a parallelized perspective.

A larger experiment used 600 sentences, chosen from six different articles, each of which fell under one of three categories. The categories - "noun-heavy", "verb-heavy", and "neither" - attempted to capture a meaning-motivated difference in syntax between information sources, as well as to test intra-category variance to a degree. The performance of the noun-driven syntax was compared to that of a developed hybrid phrase structure representation - the latter considerably "flattened" phrase structures. Direct comparison with a dependency parser's output could not be obtained for this larger experiment due to technical difficulties, but it is planned for the future.

The noun-driven representation was generated by a phrase-structure parser integrated with Ontological Semantics Technology (OST), a natural language understanding framework under current development (Taylor et al., 2012). The parser used a partial lexicon - a set of word entries with associated syntactic information, intended eventually to include semantic, morphological, and phonological information useful for word sense disambiguation and construction of semantic meaning representations. The parser used a modified chart-parsing algorithm, similar to that presented in Allen (1987) but organized around heads of phrases rather than building phrase structure from left to right. The parser generated parses in phrase-structure representations then converted those to noun-driven trees. An example representation of the
output appears below in Figure 6; compare with Figures 1 and 2.

Figure 6: Representation of a noun-driven dependency parse
A testing program counted the depths for each word in the word categories of interest (determiner, noun, verb, adverb, preposition, adjective). One metric for appropriateness of the categories is in measuring the ratio of nouns to verbs; this data is shown in Table 1. A "fingerprint" for each of the subcategories (counts by word class) appears in Figure 4; note some similarity within each of the categories. However, these findings are complicated by unknown effects of style (the two "noun-heavy" articles were from Wikipedia, the two "neither" articles from the New York Times website, and the last two from Safety.gov and a recipe book, respectively), though there may be an association between style and subject matter that does uphold the categorization. As well, these results do not distinguish between parses with differing levels of correctness or acceptability; work in progress does mark parses on a spectrum from non-grammaticality to candidacy as the parse most compatible (with some semantic processing) with the rest of the article.

Figure 7: Word class counts per parse, by subcategory

| Table 1: Noun/Verb Ratios |  |
| :--- | :---: |
| Sentence subcategory(article subject) | N/V |
| Neutral 1 (Mars Rover) | 3.82 |
| Neutral 2 (2012 Election) | 3.65 |
| Noun-heavy 1 (Plate Tectonics) | 4.82 |
| Noun-heavy 2 (Mathematics professions) | 5.23 |
| Verb-heavy 1 (Safety Tips) | 3.59 |
| Verb-heavy 2 (Recipes) | 4.56 |

A sample of 64 sentences, randomly selected from the 600 , was tested for parser correctness and accuracy - the
distinction arises from a difference between transforming a string of grammar symbols into all possible syntactically correct parses of the symbols, regardless of their content, and obtaining the correct parse, as the syntax parser has no ability to determine which of the correct strings of symbols is actually completely grammatically correct. This is a result of an inexpressive tag set and a lack of semantic parsing integration. For the 64 -set, in 6 cases were the correct parses not included in the output; this was due to a lexicon gap, verb particles not correctly accounted for, or an oversight in vetting the data set for conformance to the limited grammar template that the parser was designed.
For the 600 sentences, some measures were taken of possible syntactic ambiguity: if for one sentence the parser turned out more than one parse and could be counted on (according to an interpretation of the outcome of the 64 -set results, which is not entirely dependable) to be correct, if enthusiastic, in its determination of good syntactic parses, then the sentence was determined to carry syntactic ambiguity. Of the 600,241 sentences were given only 1 parse; an equal number had 2.16 sentences had 10 or more different parses turned out; some of these were due to prepositional phrase attachment ambiguity, and some to possibilities that, for instance, the form of a verb in the $3^{\text {rd }}$ person-present-singular is identical to that of a plural noun, or vice versa.

Table 2: Depth Counts for Nouns

|  | Noun-Driven |  |  | Phrase-Structure |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Group | Average | Min | Max | Average | Min | Max |  |
| All | 1 | 1 | 1 | 3.38 | 2 | 9 |  |
| Neutral 1 | 1 | 1 | 1 | 3.29 | 2 | 9 |  |
| Neutral 2 | 1 | 1 | 1 | 3.34 | 2 | 8 |  |
| Noun-heavy 1 | 1 | 1 | 1 | 3.48 | 2 | 9 |  |
| Noun-heavy 2 | 1 | 1 | 1 | 3.66 | 2 | 9 |  |
| Verb-heavy 1 | 1 | 1 | 1 | 3.27 | 2 | 8 |  |
| Verb-heavy 2 | 1 | 1 | 1 | 2.98 | 2 | 7 |  |

Table 3: Depth Counts for Verbs

|  | Noun-Driven |  | Phrase-Structure |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| Group | Average | Min | Max | Average | Min | Max |
| All | 2 | 2 | 2 | 2 | 2 | 2 |
| Neutral 1 | 2 | 2 | 2 | 2 | 2 | 2 |
| Neutral 2 | 2 | 2 | 2 | 2 | 2 | 2 |
| Noun-heavy 1 | 2 | 2 | 2 | 2 | 2 | 2 |
| Noun-heavy 2 | 2 | 2 | 2 | 2 | 2 | 2 |
| Verb-heavy 1 | 2 | 2 | 2 | 2 | 2 | 2 |
| Verb-heavy 2 | 2 | 2 | 2 | 2 | 2 | 2 |

Table 4: Depth Counts for Prepositions

|  | Noun-Driven |  | Phrase-Structure |  |  |  |
| :--- | :---: | ---: | :---: | :---: | :---: | :---: |
| Group | Average | Min | Max | Average | Min | Max |
| All | 2.38 | 2 | 3 | 3.60 | 2 | 8 |
| Neutral 1 | 2.40 | 2 | 3 | 3.58 | 2 | 8 |
| Neutral 2 | 2.47 | 2 | 3 | 3.68 | 2 | 7 |
| Noun-heavy 1 | 2.34 | 2 | 3 | 3.69 | 2 | 8 |
| Noun-heavy 2 | 2.33 | 2 | 3 | 3.59 | 2 | 8 |
| Verb-heavy 1 | 2.56 | 2 | 3 | 3.64 | 2 | 7 |
| Verb-heavy 2 | 2.32 | 2 | 3 | 3.26 | 2 | 6 |

Tables 2 and 3 show results for depth counts between the two syntax representations evaluated, over the 600 -sentence set, for the two main categories, noun and verb. We include the depth counts for prepositions as well (Table 4) because of the complexity that prepositional phrases add to syntactic structure.

Examination of these tables reveals that, even when compared with a "flatter" (verb-driven) phrase structure syntax representation, the noun-driven representation does at least as well, if not better. Notice as well that in the phrase-structure trees, nouns have a wider range of "float" because, while a single noun may be the subject and thus be found in a shallower position, prepositional phrases and noun-chaining bury nouns further.

Preliminary results from further evaluation also reveal data that may be usable for characteristic profiles of prepositional attachment. As well, we may investigate whether the addition of some phrase structure features to the dependency-like representation would provide better information for prepositional attachment and other local operations influenced by concepts or structure use.

## Conclusion

If computational processing of information is (even sometimes) object-centered, then an object-centered approach aligns with it. Given that we have started at the syntax level, and that most objects (as well as some events) are typically expressed as nouns, the noun-driven syntax representation, and an eventual development of a parsing approach, begins the building of a noun/object-centered paradigm for the analysis of natural language text.

There are information spaces that are not so noun-biased, or even further verb-biased - with the full field of verbdriven syntactic and semantic analysis, these will not be left behind. A dual analysis, using both perspectives, may produce some gains in efficiency and effectiveness.

#### Abstract

The Cognitive Reflection Test (CRT) was devised to measure the inhibition of heuristic responses to favour analytic ones. Toplak, West and Stanovich (2011) demonstrated that the CRT was a powerful predictor of heuristics and biases task performance - proposing it as a metric of the cognitive miserliness central to dual process theories of thinking. This thesis was examined using reasoning response-times, normative responses from two reasoning tasks and working memory capacity (WMC) to predict individual differences in performance on the CRT. These data offered limited support for the view of miserliness as the primary factor in the CRT. The strongest predictor of CRT in both experiments was WMC. It is argued that while cognitive miserliness has been implicated in CRT performance, participants must also possess the requisite WMC and mindware to successfully complete it. Therefore, the psychological and psychometric properties of the CRT require continued study.

Keywords: Cognitive Reflection Test, Heuristics and Biases, Dual-process Theory, Belief-bias, Matching-bias, Reasoning, Cognitive Misers.

## Introduction

Dual-process theories of reasoning and judgment dissociate fast and frugal 'snap' judgments from slow, effortful and methodical analyses (e.g., De Neys, 2012; Evans, 2007; Stanovich, 2004) with the latter being viewed as being more likely to lead to normatively sanctioned answers in a variety of reasoning tasks. These contrasting processes are captured by heuristic-analytic tasks that involve a conflict between these processes (see Kahneman, 2011 for a recent review) and are referred to as Type 1 (heuristic) and Type 2 (analytic) (e.g., Evans, 2011).

Frederick (2005) devised the Cognitive Reflection Test (CRT) to examine the ability of participants to resist intuitive, tempting answers in favour of deeper, more analytic ones. By way of illustration, an example item from the CRT is "A bat and a ball cost $\$ 1.10$ in total. The bat costs $\$ 1$ more than the ball. How much does the ball cost?"

Most participants respond that the answer is 10 cents; however, a slower and more analytic approach to the problem reveals the correct answer to be 5 cents.
The CRT has been a spectacular success, attracting more than 100 citations in 2012 alone (Scopus). This may be in part due to the ease of administration; with only three items and no requirement for expensive equipment, the practical advantages are considerable. There have, moreover, been numerous correlates of the CRT demonstrated, from a wide range of tasks in the heuristics and biases literature (Toplak et al., 2011) to risk aversion and SAT scores (Frederick, 2005). Its publication was also timely as it coincided with the recent boom in dual process theories of thinking and reasoning (e.g., De Neys, 2012; Evans, 2007; Stanovich, 1999). The CRT and its items have been adopted as a testbed for the predictions of these theories (BourgeoisGironde, \& Vanderhenst, 2009; Campitelli \& Labollita, 2010; De Neys, Rossi, \& Houdé, 2013; Toplak et al., 2011). Bourgeois-Gironde and Vanderhenst (2009) have also highlighted the advantage that the CRT offers in terms of testing dual process predictions against arithmetic norms rather than the more controversial normative standards in logic or probability (see Elqayam \& Evans, 2011).
Toplak et al. (2011) presented perhaps the most comprehensive examination of the CRT, demonstrating considerable evidence for it as a predictor of non-normative responses to a battery of heuristics and biases tasks (each explicable) by dual process theories. Based on their findings Toplak et al. argued that the CRT predicts variance in rational thinking independently of intelligence, executive function and thinking dispositions, and that this variance is not insubstantial. Furthermore, Toplak et al. advance the CRT as a promising metric to tap into "What Intelligence Tests Miss" (Stanovich, 2009a) by accounting for rational thinking tendencies that are not captured by standard IQ tests (Stanovich suggests Dysrationalia as a term for people with higher IQ scores who fail on heuristics and biases tasks because they lack these thinking tendencies).

Stanovich (2009b) describes these rational thinking tendencies in a rational thinking taxonomy. Important categories for the CRT include, cognitive miserliness - the well-documented tendency to expend as little cognitive effort as is necessary to complete a task (first coined by Fiske \& Taylor, 1984); and, 'mindware gaps' - whereby the necessary cognitive rules, strategies, or belief systems are lacking, corrupted or are not applied.

Moreover, De Neys, Rossi, and Houdé (2013) presented evidence in support of cognitive miserliness as an explanation of performance on the CRT, based on confidence ratings that demonstrated diminished confidence ratings for participants who give the '10 cents' response to the 'Bat and Ball' question. De Neys et al. argue that even though the participants had an intuitive sense of the correct response they still responded incorrectly. They explicitly argue that their data indicate that, while they appear to be cognitive misers, participants are not offering erroneous responses in blissful ignorance.

In further support of this position, Campitelli and Labollita (2010) investigated how individual differences in cognitive reflection impacted on decision-making. They argue that cognitive reflection is indicative of a thinking disposition related to Baron's (1988) proposals about Actively Open Minded Thinking. This thinking tendency is an obvious contrast with cognitive miserliness. Active Open Minded Thinking is associated with enhanced performance on a range of heuristics and biases tasks including the generation of alternatives and belief based reasoning tasks (Stanovich \& West, 1999).

It would appear that the case for the CRT as a measure of cognitive miserliness is compelling. However, Thompson et al., (in press), examined the CRT as part of a paper testing the influence of perceptual fluency (Alter, Oppenheimer, Epley \& Eyre, 2007) and answer fluency in priming deliberative thinking (Thompson, Prowse Turner, \& Pennycook, 2011). They demonstrated that a degraded presentation of the CRT slowed participants down (conducive to analytic thinking and the converse of cognitive miserliness), but that this failed to facilitate correct responses among all but the most cognitively able participants (those in the uppermost quartile for IQ). These data suggest that increased response times to the CRT which potentially ameliorate cognitive miserliness by encouraging greater cognitive effort - are not universally beneficial. These data, moreover, suggest that there is an important role for cognitive capacity (or working memory) in gaining the benefits of slower Type 2 processing.

In studies of syllogistic reasoning, response-times are predictive of normative responding, but this is not universal across problem types (Stupple, Ball, Evans and KamalSmith, 2011). Stupple, et al. demonstrated that inflated response times predicted normative responding where there were conflicts of belief and logic, and that this effect on normative responding was particularly associated with response times for invalid-believable problem types.

Further support for the utility of response times as a predictor of normative responding in tasks with a dual process conflict was reported by Stupple Ball and Ellis (2013), who created a heuristic-analytic conflict using matched and non-matched surface features in syllogistic reasoning problems (Stupple \& Waterhouse, 2009). Stupple et al. (2013) noted that increased response times for invalid matching problems in a syllogistic reasoning task were associated with an increase in the overall normative responding. In contrast, increased response-times for valid non-matching problems were associated with decreased normative responding. These data demonstrate that it is not just the avoidance of miserliness that is important, but also that being sensitive to normative responses, perhaps by possessing the required mindware is important ${ }^{1}$. In short, a successful use of cognitive resources requires possession of the right mindware or the application of a sound strategy to be successful. Increased time deriving a response may indicate that Type 2 processing has occurred, but it is a fallacy to assume that the correct or normative answer will follow. A slow, effortful, but erroneous process cannot be characterized as the response of a miserly participant.

It is, nonetheless, argued that response times are vital to unpacking the predictions of dual process theories and that willingness to engage in time-consuming Type 2 processing on a syllogistic reasoning task should be predictive of willingness to engage in such processing on the CRT. A disposition to devote cognitive resources to a task coupled with the right mindware, however, may not be enough to find the correct answer if a participant has insufficient cognitive resource to reach the correct or normatively sanctioned conclusion.

Working memory capacity (WMC) has been shown to be important to reasoning performance, and to the process of analytic thinking (Bacon, Handley, Dennis \& Newstead, 2008; Copeland, \& Radvansky, 2004). Working Memory is, moreover, central to measures of intelligence (e.g., Kyllonen \& Christal, 1990). Frederick (2005) makes sound arguments to differentiate the CRT from intelligence measures, but there is yet to be a detailed examination of the importance of WMC in solving the CRT. Detecting the error in the heuristic response to the CRT is arguably only the first step towards solving the problems in the CRT. Working out the correct response is likely to involve working memory demand, for example, when participants consider the candidate values for the ball and then concurrently calculate the total value of the bat and the ball. This argument is supported by the finding from Thompson et al. (in press) that Type 2 processing may only benefit the most cognitively able (and by implication the highest WMC) participants on the CRT. Toplak et al. (2011) argue that the items on the CRT are not insight problems (see Gilhooly \& Murphy, 2005) - which do not incur significant working memory load - and are instead analytic problems, which do.

[^217]Toplak et al. (2011) also acknowledge the influence of WMC and examine the role of CRT in predicting performance on heuristics and biases tasks, with the influence of WMC factored out. The focus here is instead upon the extent that WMC is predictive of the CRT in conjunction with Cognitive Miserliness, and sensitivity to normative considerations.

Mean response-times to syllogistic reasoning problems were used as an index of cognitive miserliness, a logic index (e.g., Stupple et al., 2013) was calculated to generate a measure of normative responding and a composite working memory score derived from Operation Span, Symmetry Span and Reading Span measures (Unsworth et al., 2005) was used as a measure of working memory capacity.

It is argued that Toplak et al.'s (2011) miserliness account of the CRT predicts that participants who devote the longest times to solving syllogisms would also be those who were most successful in solving CRT items. It was predicted that this would be the strongest predictor of CRT performance and the first factor included in the regression model by the stepwise procedure. It was also predicted that normative sensitivities and WMC would be significant predictors of CRT performance, but that these would account for less variance in CRT performance than the miserliness measure.

## Method Experiment 1

Design Predictor variables were generated from the working memory span tasks (Unsworth et al., 2005) and the beliefbias reasoning task. Mean response-times to belief bias problems were calculated to generate an index of miserliness; acceptance rates for belief bias problems were used to generate a logic index. The dependent variable was the score on the CRT.
Participants Sixty-five undergraduates from the University of Derby, aged 18-45, were recruited via opportunity sampling. Participants had no training in formal logic and had not previously studied the psychology of reasoning or encountered the CRT. Each received a voucher (value £5) for participating.
Materials and procedure Participants received 16 target syllogisms counterbalanced for figure and mood. Belieforiented contents were those employed by Stupple and Ball (2008). There were equal numbers of valid and invalid problems, and believable and unbelievable conclusions.

Logic index was calculated by adding acceptance rates for Valid Believable and Valid Unbelievable problems and subtracting total acceptance rate for Invalid Believable and Invalid Unbelievable problems (Valid Believable + Valid Unbelievable - Invalid Believable - Invalid Unbelievable).

Syllogisms and instructions were presented with Authorware 6.5 on a PC. Problems were counterbalanced, with contents rotated through them. WMC was measured using three complex span tasks (Unsworth et al., 2005) in EPrime Version 2.0. These consisted of Automated Operation Span, Automated Symmetry Span and Automated Reading Span (see Unsworth et al., 2005 for details). The three
measures of working memory capacity were combined to form a composite working memory score (Bartlett, 1937), derived from the three absolute span scores (defined as the sum of all sets of items that are recalled without error, Unsworth et al, 2005). The CRT was a pen and paper task.

## Results Experiment 1

A Stepwise Multiple Regression tested the relative predictive strength of response-times and logic index in a belief-bias reasoning task and WMC for performance on the CRT. The Mean CRT score for the sample in Experiment 2 was 1.32 ( $\mathrm{SD}=1.11$ ) which is well within the range described by Frederick (2005) ${ }^{2}$.

Data indicated that WMC reliably accounted for $27 \%$ of the variability in CRT scores with participants with higher WMC scores performing better on the CRT than those with lower scores. Surprisingly, no further steps in the regression analysis significantly increased the variance accounted for as neither the Logic index nor the Response times were reliable predictors. Response-times demonstrated a nonsignificant correlation with CRT scores close to zero.

Table 1: Stepwise Regression Analysis of Working Memory Capacity, Logic index and Reasoning Responsetimes for Belief Bias problems as predictors of the CRT
Predictors

| Model 1 | $\mathrm{R}^{2}=.28, \mathrm{R}_{\text {add }}^{2}=.27$ |
| :--- | :--- |
|  | $\mathrm{~F}(1,64)=24.87, \mathrm{p}<.001$ |
| WMC | $\beta=.529, \mathrm{p}<.001$ |

Excluded
Logic index $\quad \beta=.156, p=.146$
Response-times $\beta=.052, p=.641$
Durbin Watson= 1.72, VIFs ranged from 1.01 to 1.08

## Interim Discussion

These findings were contrary to the expectation as there was no reliable relationship shown for response times to syllogistic reasoning problems. Moreover, the variance explained by the composite measure of WMC was by far the most substantial predictor.
These results were surprising and may be specific to the syllogistic reasoning task employed. While there are similarities between belief bias problems and the CRT, in that some items may require the inhibition of an initial heuristic response, it is not the case that the CRT involves belief inhibition per se. A second experiment utilizing the same methodology, but employing an alternative set of reasoning problems (Roberts, 2005) that are also known to induce a heuristic-analytic conflict - the matching bias problems used by Stupple et al. (2013), was conducted.

[^218]Consistent with the CRT these matching problems feature conclusions, which are tempting to endorse, or reject based on their surface features. For example, in the case of the second item in the CRT: "If it takes 5 machines 5 minutes to make 5 widgets, how long would it take 100 machines to make 100 widgets? $\qquad$ minutes?" The most frequent erroneous response is 100 minutes, whereby participants may be matching their answer to the surface features of the problem. Similarly, performance on matching-bias syllogisms requires the inhibition of an inclination to respond based on whether surface features of conclusions and premises match, (and possessing the mindware to eliminate a double negation). It was hypothesized that (1) working memory capacity would again be a significant predictor of CRT scores, and, (2) that logic index and response times would predict CRT scores. However, these predictions were made with reduced confidence in the light of the findings from Experiment 1.

## Method Experiment 2

Design Response times and conclusion acceptance rates from the matching bias reasoning task were used as predictors and the three Working Memory Span measures (Operation span, Reading span and Symmetry span (Unsworth et al., 2005) were again used to derive a composite WMC score. The dependent variable was the CRT scores.
Participants Forty-nine undergraduates from the University of Derby aged 18-45 were recruited via opportunity sampling. Participants had no training in formal logic and had not previously studied the psychology of reasoning or encountered the CRT. Each received a voucher (value $£ 5$ ) for participation.
Materials and Procedure Sixteen one-model syllogisms were presented. Conclusions either matched the premises (premises and conclusions were traditional affirmative or both were double negated), or were not matched with the premises - traditional affirmative premises were presented with double negated conclusions or double negated premises were presented with traditional affirmative conclusions. For non-conflict problems, analytic and heuristic strategies produced the same response, whereas for conflict problems analytic and heuristic matching strategies were in competition. Syllogism content involved combinations of professions and pastimes. These were rotated through the different problems. Reasoning problems, WMC measures and the CRT were administered identically to Experiment 1.

## Results Experiment 2

The Mean CRT score for the sample in Experiment 2 was 1.12 ( $\mathrm{SD}=1.14$ ) which is well within the range described by Frederick (2005), although for this experiment it was below the overall average reported by Frederick (2005).

A Stepwise Multiple Regression was conducted to test the relative predictive strength of response-times, and logic in a
matching bias reasoning task and WMC for performance on the CRT. Data indicated that WMC reliably accounted for $23 \%$ of the variability in CRT scores in the first model, with participants with higher composite WMC scores demonstrating better performance on the CRT than those with lower scores. In a second model, the variance explained increased to $34 \%$ with the addition of the Logic index predictor. As with the first experiment, responsetimes did not reliably account for variance in CRT scores. More surprising, was the fact that the response-times correlated negatively (albeit unreliably) with CRT scores in the opposite direction to that predicted.

Table 2: Stepwise Regression Analysis of Working Memory Capacity, Logic index and Reasoning Responsetimes for Matching Bias problems as predictors of the CRT

| Predictors |  |
| :--- | :--- |
| Model 1 | $\mathrm{R}^{2}=.245, \mathrm{R}_{\text {adj }}^{2}=.229$ |
|  | $\mathrm{~F}(1,48)=15.54, \mathrm{p}=.001$, |
| WMC | $\beta=.495, \mathrm{p}<.001$ |
|  |  |
| Model 2 | $\mathrm{R}^{2}=.365, \mathrm{R}_{\text {adj }}^{2}=.338$ |
|  | $\mathrm{~F}(2,47)=13.52, \mathrm{p}=.001$, |
|  | F change, $\mathrm{p}=.004$ |
| WMC | $\beta=.426, \mathrm{p}=.001$ |
| Logic index | $\beta=.354, \mathrm{p}=.004$ |
|  |  |
| Excluded | $\beta=-.149, \mathrm{p}=.203$ |
| Response-times |  |

Durbin Watson=1.70, VIF $=1.04$

## Discussion

The experiments presented here tested the relative contributions of Response times to reasoning tasks (as an index of cognitive miserliness), Logic Index (as a measure of sensitivity to normative responses) and WMC to predicting variance in the CRT. Consistent with predictions, WMC was a reliable predictor of performance on the CRT in both experiments - and was a substantially stronger predictor than expected. Moreover, the unexpected null finding for response times, suggested that if the CRT is conceptualized as a measure of cognitive miserliness then it might not convincingly generalize beyond the arithmetic based problems to standard dual processing tasks such as belief bias or matching bias syllogisms. If the CRT is a general measure of cognitive miserliness then those participants responding primarily with the Type 2 answers to the CRT should engage in more Type 2 processing on syllogistic reasoning tasks as indexed by increased response times. These data suggest that this was not reliably the case.

WMC correlating most strongly with performance on the CRT is somewhat problematic for the use of the test as a measure of miserliness. Individuals with lower WMC may expend a great deal of effort in attempting to solve heuristic-
analytic problems, but lack the capacity to maintain their representation of, for example, possible ball costs relative to the bat as they work through the alternatives. Participants with higher WMC may find the cognitive costs less expensive and, thus be more willing to pay them ${ }^{3}$.

Cognitive miserliness could be argued to be relative to the cognitive resource of the participant. A participant with a high WMC who provides heuristic responses to the CRT would be categorized appropriately as a cognitive miser as they had the necessary cognitive resources, but chose not to apply them to the task. In contrast, a participant with lower WMC who devotes considerable time and effort, but arrives at a heuristic answer would be inappropriately described as miserly (perhaps they could be considered cognitive wastrels instead). It may be that those participants with greater WMC can engage in the deliberative thought required to avoid the heuristic response with relatively less effort when compared to those with lesser WMC. This reduced cognitive cost may become affordable to the participants with more miserly tendencies, but who also have ample working memory resources available ${ }^{4}$.

De Neys et al. (2013) suggest that participants are aware of the incongruity of answering 10 cents to the bat and ball question, but often fail to engage the deliberative processing required for the correct ' 5 cents' answer. We would add to this claim that while cognitive miserliness is almost certainly a factor, our data indicate that, for a proportion of participants at least, they may not have the cognitive resources to pursue their metacognitive uncertainty about their intuitive response. Alternatively, the intuitive response may offer a cognitive escape hatch, if processing demands are too great (cf. Quayle \& Ball, 2000). Similarly, with regard to Thompson et al.'s (in press) findings - that only the most able participants benefitted from the Type 2 processing that dis-fluent stimuli encouraged in terms of the accuracy of their responding demonstrating that increased response times may be important to success on the CRT, but they are not sufficient. Further investigation is required to understand the nuanced interplay between miserliness and cognitive ability/working memory capacity on the CRT.

It was notable that there was not a reliable relationship between normative responding in a belief bias task with performance on the CRT, but that normative responding on the matching bias task was a highly reliable predictor of CRT performance. A possible account of the discrepancy between studies could be based on the manner in which the heuristic-analytic conflict is resolved. Optimal performance

[^219]on belief bias problems requires an ability to inhibit belief driven responses while searching for alternative models (Stupple et al., 2011), whereas the matching bias problems required an explicit awareness of the logic of double negatives - such that errors could be characterized as the result of missing or corrupted 'mindware' (Stanovich, 2009b). This difference in the source of the heuristicanalytic conflict could potentially account for the discrepancy between problem types. This further contrasts with the proposal of the CRT as an index of cognitive miserliness. The absence of the appropriate mindware for double negations among those participants who score lowest on the CRT would appear to indicate a lack of an understanding of logic or rule based thinking, rather than, an unwillingness to engage in the requisite cognitive effort. This is inconsistent with the arguments from Toplak et al. (2011), who suggest that knowledge gaps represent a major class of reasoning error but that: "The potency of the CRT as a predictor of performance on heuristics-and-biases tasks certainly does not derive from its ability to assess knowledge gaps, because it clearly does no such thing." (Toplak et al, 2011, p. 1284). The variance in CRT scores explained by normative responding to matching-bias syllogisms cannot reasonably be claimed as a causal link, but suggests an association between possessing the necessary cognitive rules or strategies for detecting matching bias conflicts and the heuristic-analytic conflicts that are implicated in success on the CRT. We would argue that examination of the CRT as an index of conflict detection also warrants further investigation.

Therefore, it is advocated that self-report measures such as the Need for Cognition (Cacioppo \& Petty, 1982) or Rational-Experiential Inventory (Epstein, 1994) continue to be used alongside the CRT to quantify the subjective experience of miserliness. This subjective experience is likely to co-vary with cognitive capacity - relative to the task demands. The CRT as an index of cognitive miserliness presupposes a degree of equality in our cognitive wealth. Self-report measures may supplement the CRT by offering insight into the experience of how effortful the task was and by quantifying self-perceptions of cognitive miserliness.

Nonetheless, we agree with Toplak et al. (2011) that the CRT captures variability in performance on heuristics and biases tasks that are not captured by IQ tests and the CRT remains a promising measure to explore in this regard. What remains clear from these data is that explaining the psychological properties of the CRT is not a simple task, and while it is undoubtedly an influential task that will remain popular among dual process theorists, the precise nature of its psychometric and psychological properties require continued study.

#### Abstract

In current theories of word reading the structure and operations of the phonological buffer are quite underspecified. We investigated this issue by running a reading aloud experiment in Italian. We adopted a priming paradigm, with three-syllabic words as primes and targets and we jointly manipulated two effects ascribed to the stage of phonological and phonetic encoding, that is stress priming and syllable frequency. Target words varying for the frequency of their initial syllable were preceded by words congruent or incongruent for the stress pattern. The results showed an interaction between syllable frequency and stress prime, with the stress congruency effect larger for the targets with low-frequency first syllable. This result suggests that, in reading aloud, stress assignment and syllable computation have a tight time dynamics in the phonological output buffer, and that the process at the level of phonology-to-phonetic interface operates interactively.

Keywords: Lexical stress; syllable frequency; phonological-to-phonetic interface; phonological buffer; reading aloud.

## Introduction

Reading aloud requires the execution of multiple operations, e.g., perceiving the stimulus, converting the printed information in a speech signal, and articulating the word's sounds, taking into account both segmental (e.g., sounds) and suprasegmental (e.g., stress) information. While many reading studies have investigated the operations involved in word recognition, the phonological encoding of a word and its phonetic realization have received less attention. The same happens with computational models of reading aloud: They usually implement in a detailed way the procedures readers use to recognize words, but they are less specific about those phenomena related to the production stages (see, e.g., Coltheart, Rastle, Perry, Langdon, \& Ziegler, 2001), and the very few that have attempted to implement procedures for stress assignment differ in the solutions they propose (see, e.g., Arciuli, Monaghan, \& Seva, 2010; Perry, Ziegler, \& Zorzi, 2010; Rastle \& Coltheart, 2000; Sibley, Kello, \& Seidenberg, 2010).

The investigation of the production stage of reading aloud can benefit from the speech production literature, as it has been argued that speech production and reading aloud may share the last stages of processing, specifically the phonological and phonetic encoding of the word (Roelofs, 2004). In the model developed by Levelt and colleagues (Levelt, Roelofs, \& Meyer, 1999) it is assumed that during
phonological encoding speakers retrieve in parallel the segmental material and the metrical structure - number of syllables and word's stress pattern - and combine them into the phonological word (see also Roelofs \& Meyer, 1998). At this point, the phonological word is phonetically encoded and it is then translated into its phonetic realization.

A detailed architecture of the phonological and phonetic encoding, however, has never been proposed by any model of word reading and how the reading system converts abstract phonological information into phonetic representations is still an open issue. An effort in this direction has been done by Perry and colleagues (2010): In their CDP++ model of reading, at the level of phonological output buffer, the authors implement a double process analogous to the one proposed for word production, with two different loci for stress and phonemes activation. In particular, the model presents stress-output nodes, i.e. nodes specifying the position of the stress within the lexical string. Such nodes are activated autonomously from the segmental information, although full processing of the latter is conditional upon the former: Articulation of the word phonemes cannot be initiated until the word stress has been fully determined. However, despite the improvement of the phonological output buffer, nothing is said about how segmental and suprasegmental information are assembled together, and how the selected phonological information is converted into a phonetic representation.

Recent empirical data that can help to better understand how the phonological and phonetic encoding work within the reading system. Some studies run in Italian (Colombo \& Zevin, 2009; Sulpizio, Boureux, Burani, Deguchi, \& Colombo, 2012a; Sulpizio, Job, \& Burani, 2012b), support the view that metrical and segmental information are autonomously involved in planning and assembling an utterance, both when stress is sub-lexically computed (Colombo \& Zevin, 2009; Sulpizio et al., 2012a) or lexically retrieved (Sulpizio et al., 2012b). In particular, the latter study showed an effect of stress position priming for segmentally different prime-target pairs. Specifically, readers are faster in reading a word when it is preceded by a word with the same stress, e.g., TESsera (card) - BUfala (hoax), than when in is preceded by a word with a different stress, e.g. cuGIno (cousin) - BUfala (hoax) ${ }^{1}$. The pattern was interpreted as showing that stress priming affects the

[^220]stage of phonological word encoding in the phonological buffer.

An effect that has also been ascribed to the later stages of reading aloud is that of syllable frequency. Researches in different languages have shown that participants are faster in producing a word that starts with a high-frequency syllable than one with a low-frequency syllable (see, e.g, for Dutch: Cholin, Levelt, \& Schiller, 2006; English: Cholin, Dell, \& Levelt, 2011; French: Laganaro \& Alario, 2006; Italian: Sulpizio \& Job, 2010; Spanish: Carreiras \& Perea, 2004) and there is consensus on the claim that such effect is attributed to the phonetic encoding, when readers convert the abstract phonological word into abstract motor programs.

Jointly considering the effects of stress assignment and of syllable frequency in reading aloud may allow us to better articulate the operations involved in the phonological-to-phonetics interface, the rather neglected and oversimplified component of reading models. Both stress priming and syllable frequency are assumed to affect the latest stages of reading process, when readers (a) spell out segmental and metrical information and (b) plan the articulation of the word, with syllable frequency affecting the word's phonetic encoding (Carreiras, Mechelli, \& Price, 2006; Laganaro \& Alario, 2006). Thus, an additive pattern of syllable frequency and stress priming would be consistent with the proposal of two separate consecutive stages for the two effects, or with the assumption of a threshold of activation for one component before the other may start its computations (Perry et al., 2010): In such a view, word phonetic encoding can start only after the processing of stress assignment ends, with the consequence that a delay in the computation of stress would affect the phonetic encoder independently from how fast its content might be computed. Differently, an interaction between syllable frequency and stress priming would suggest that both the effects may concurrently affect the same stage of processing, i.e. the phonological-to-phonetic interface. If this is the case, it would suggest that: a) there is no reason to postulate a threshold setting the timing of either segmental or suprasegmental activation; b) the mapping of the phonological word into phonetic codes may occur through an interactive process.

## Experiment

Three-syllabic Italian words were used as stimuli as stress position for these words is not always predictable. Indeed, Italian three-syllabic words have two main stress patterns (Thornton, Iacobini, \& Burani, 1997): Antepenultimate stress (i.e., the first syllable bears stress, e.g., TAvolo 'table'), and penultimate stress (i.e., the second syllable bears stress, e.g., coLOre 'color'). Although their distribution differs - $80 \%$ of three-syllable words bear penultimate stress and $18 \%$ bear antepenultimate stress ${ }^{2}-$

[^221]the two patterns are lexically stored within the phonological lexicon and the asymmetry does not affect lexical reading (Paizi, Zoccolotti, \& Burani, 2011).

By jointly manipulating stress priming and syllable frequency we aimed at investigating the operations involved in the phonological-to-phonetic interface that take place during the later stages of word reading. Specifically, if stress priming and syllable frequency originate at two separate stages of processing or the former is governed by a threshold mechanism, then the stress priming effect should be of similar size for both words starting with a high- and words staring with a low-frequency syllable. Differently, if stress priming and syllable frequency may concurrently affect the phonological-to-phonetic interface, an interaction between the two effects should be expected.

## Method

## Participants

Twenty-four students (14 male, mean age: 24, sd: 3.8) of the University of Trento. They were all Italian native speakers and they had normal or corrected-to-normal vision. They received credit course for their participation.

## Materials and Design

Four sets of three-syllabic words were used as targets. The sets were selected by combining two variables: Frequency of the first syllable (high or low) and stress pattern (penultimate or antepenultimate). Each set was composed of 22 low-frequency words selected from the CoLFIS database (Bertinetto et al., 2005). Stimuli were matched on length in letters, orthographic neighborhood size, orthographic neighbors' summed frequency, frequency of the second and third syllable, mean bigram frequency, orthographic complexity, initial phoneme (Table 1), and had a stress neighborhood composed mainly of stress friends (Burani \& Arduino, 2004).

Table 1. Summary statistics: means (and standard deviations) for the three-syllabic target words.

|  | First Syllable Frequency |  |  |  |
| :--- | :---: | :---: | :---: | :---: |
|  | High |  | Low |  |
|  | Pen. | Antep. | Pen. | Antep. |
| stress | stress | Stress | Stress |  |
| First Syllable | 690 | 720 | 28 | 41 |
| Frequency | $(561)$ | $(505)$ | $(25)$ | $(30)$ |
| Second+third | 1588 | 1711 | 2088 | 2228 |
| Syllable | $(847)$ | $(809)$ | $(919)$ | $(769)$ |
| Frequency |  |  |  |  |
| Word frequency | 4.5 | 6.5 | 7.1 | 6.05 |
|  | $(4.9)$ | $(11.2)$ | $(12)$ | $(7.3)$ |
| Length in letters | 7 | 6.8 | 7.1 | 7 |
|  | $(0.6)$ | $(0.4)$ | $(0.3)$ | $(0.2)$ |
| Mean Bigram | 11.6 | 11.5 | 11.4 | 11.5 |
| frequency | $(0.2)$ | $(0.2)$ | $(0.2)$ | $(0.4)$ |
| N of orthographic | 1 | 1 | 1.1 | 1 |
| neighbors | $(1.2)$ | $(1.1)$ | $(0.9)$ | $(1)$ |

| Neighbors' | 4.7 | 8.1 | 2.1 | 6 |
| :--- | :---: | :---: | :---: | :---: |
| summed frequency | $(9.9)$ | $(22.9)$ | $(2.8)$ | $(14.9)$ |

Note: Pen. = penultimate stress; Antep. $=$ antepenultimate stress; syllable frequency measures are calculated out of 1 milion occurrences (Stella \& Job, 2001); word frequency measures are calculated out of 1 million occurrences (Bertinetto et al., 2005); mean bigram frequency is $\log$ transformed on the basis of the natural logarithm.

Targets were pre-tested to ensure that none of the initial syllables was a probabilistic orthographic cue for stress (Arciuli, Monaghan, \& Ševa, 2010). Thus, syllable frequency was not expected to interact with word's stress pattern. To further rule out such possibility, we ran a pilot experiment asking 18 university students to read aloud all targets. Stimuli appeared in capital letters in the center of the screen, after a fixation cross displayed for 400 ms . Each stimulus remained on the screen until the participant began to read or for a maximum of 1500 ms . The presentation order was randomized between participants. Mean RTs for correct responses were submitted to a 2 (high- vs. lowfrequency syllable) x 2 (penultimate vs. antepenultimate stress) ANOVA. The analysis showed an effect of syllable frequency $\left(F_{1}(1,17)=22.19, M S E=1246, p<.01 ; F_{2}(1,84)\right.$ $=17.29, M S E=2033, p<.01$ ), with faster reaction time for words with a high-frequency syllable. Neither stress type $\left(F_{l}(1,17)=1.60, M S E=246 ; F_{2}<1\right)$ nor the interaction were significant $\left(F_{l}(1,17)=3.60, M S E=217 ; F_{2}<1\right)$. No effect was significant in the analysis of errors (4.8\%). Results of the pilot experiment suggest that targets' first syllables are not preferentially associated with a certain stress pattern, as suggested by the absence of a syllable frequency by stress type interaction.

Two sets of 44 high frequency three-syllabic words were used as primes. One set included penultimate stress words and the other antepenultimate stress words, all selected from CoLFIS (Bertinetto et al., 2005). The two sets were matched on: Length in letters, orthographic neighborhood size, orthographic neighbors' summed frequency, mean bigram frequency, and initial phoneme (Table 2). Primes were paired with target words in such a way that neither semantic relation nor orthographic overlapping existed between prime and target. Targets were divided between the two prime stress conditions (congruent and incongruent) and each prime word was paired with both a congruent (e.g., niPOte 'nephew' - laSAgna 'lasagna') and an incongruent stress target (e.g., niPOte 'nephew' - MUscolo 'muscle').

Table 2. Summary statistics: means (and standard deviations) for the three-syllabic prime words.

|  | Stress Type |  |
| :--- | :---: | :---: |
|  | Pen. | Antep. |
| Word frequency | 216 | 228 |
|  | $(118)$ | $(127)$ |
| Length in letters | 6.9 | 6.7 |
|  | $(0.7)$ | $(0.7)$ |

| Mean Bigram frequency | 11.5 | 11.4 |
| :--- | :---: | :---: |
|  | $(0.4)$ | $(0.3)$ |
| N of orthographic neighbours | 1.9 | 1.8 |
|  | $(1.7)$ | $(1.4)$ |
| Neighbors' summed frequency | 51.5 | 52.6 |
|  | $(68.7)$ | $(65.1)$ |

Note: Pen. = penultimate stress; Antep. = antepenultimate stress; syllable Word frequency measures are calculated out of 1 million occurrences (Bertinetto et al., 2005); mean bigram frequency is log transformed on the basis of the natural logarithm.

The Experiment had a 2 (congruent $v s$. incongruent stress pattern) x 2 (high- $v s$. low-syllable frequency) design. Following the procedure adopted by Sulpizio and colleagues (2012b), prime-target pairs were divided in 4 pure blocks (prime and target sharing the stress pattern $\&$ target with a high-frequency initial syllable; prime and target sharing the stress pattern \& target with a low-frequency initial syllable; prime and target with different stress patterns \& target with a high-frequency initial syllable; prime and target with different stress patterns \& target with a low-frequency initial syllable). Furthermore, in each block, half of the targets had penultimate stress and half had antepenultimate stress, and in no case prime and target shared the initial phoneme. The order of stimuli was randomized within blocks and block order was counterbalanced across participants. Primes and targets were paired in such a way that for half of the participants a target was in a congruent stress condition (prime and target having same stress), and for the other half the same target was presented in the incongruent stress position (prime and target having different stress).

## Apparatus and procedure

Participants were tested individually. They were instructed to read the targets as quickly and accurately as possible. Each trial started with a fixation cross, centered on the screen, for 400 ms . The prime was then presented in lowercase letters just above the center of the screen for 86 ms and it was followed by a 86 ms blank; then, the target stimulus was displayed in upper-case letters just below the center of the screen. The target remained on the screen until the participant began to read it or for a maximum of 1500 ms . The inter-stimulus interval was 1500 ms . A practice session with 8 trials preceded the experiment. Naming times were recorded by means of E-Prime software. The experimenter noted the naming errors.

## Results

Responses shorter than 250 ms or longer than 1500 ms ( $2.4 \%$ of all data points) were excluded from the analyses. Naming errors, including both phonemic and stress errors, summed to $2.7 \%$ of all data points and were not analyzed. Results are reported in Figure 1.

A $2 \times 2$ analysis of variance with syllable frequency (high- vs. low-frequency syllable) and condition (congruent vs. incongruent stress) was conducted on the reaction times (RTs) of correct responses. The factors were within
participants $\left(F_{1}\right)$ and between items $\left(F_{2}\right)$. The main effect of condition was significant, with congruent target words read faster than incongruent target words $\left(F_{1}(1,23)=10.49\right.$, $M S E=3771, p<.01, \eta^{2}=.27 ; F_{2}(1,176)=51.49, M S E=$ 1558, $p<.001, \eta^{2}=.23$ ). The main effect of syllable frequency was also significant, showing that targets with an initial high-frequency syllable were read faster than targets with a low-frequency syllable $\left(F_{1}(1,23)=8.73, M S E=995\right.$, $p<.01, \eta^{2}=.31 ; F_{2}(1,176)=10.24, M S E=1558, p<.01$, $\left.\eta^{2}=.15\right)$. Finally, there was a significant interaction between congruency condition and syllable frequency, $\left(F_{1}(1,23)=\right.$ $4.39, M S E=675, p<.05, \eta^{2}=.16 ; F_{2}(1,176)=4.26, M S E=$ $\left.1558, p<.05, \eta^{2}=.12\right)$ : LSD post-hoc comparisons showed that the 55 ms stress priming effect ( $\mathrm{p}<.005, \eta^{2}=.31$ ) for targets with a low-frequency initial syllable was significantly different from the 31 ms effect ( $\mathrm{p}<.05, \eta^{2}=$. 23 ) for the targets with a high-frequency initial syllable.

Figure 1. Reaction times and percentage of errors by condition

The results of the present experiment are clear. Word targets preceded by stress-congruent primes were read faster than targets preceded by stress-incongruent primes. Moreover, words with a high-frequency first syllable were read faster than words with a low-frequency first syllable. Finally, the priming effect was larger for targets with a lowfrequency first syllable than for those with a high-frequency first syllable.

## Discussion

The main finding of our study is that syllable frequency and stress priming interact: Reading times are longer to incongruent prime-target stress pairs for both high- and lowfrequency syllable targets, but for the latter the difference is larger than for the former. Thus, syllable frequency modulates the impact of stress priming. The findings allow us to better understand some aspects of the mechanics of phonological and phonetic encoding during reading. They also provide hints on the relative timing of the operations underlying stress retrieval and word articulation in reading aloud.

The effect of syllable frequency has been generally
ascribed to the phonetic encoding level by assuming that speakers are facilitated in articulating those syllables they produce frequently. Specifically, Levelt et al. (1999) argue that high-frequency syllables can be retrieved from a mental syllabary, while low-frequency syllables are assembled using the phonological word as input. The assumption of a mental syllabary has been accepted by most of the reading literature which reported effects of syllable frequency in word and pseuwdoword reading tasks (Carreiras \& Perea, 2004; Carreiras et al., 2006; Laganaro \& Alario, 2006; Perea \& Carreiras, 1998; Sulpizio \& Job, 2010). Thus, also in word reading, the effect of syllable frequency can be located at the stage of phonetic encoding, that is in the phonological output buffer.

The effect of stress priming has been ascribed to mechanisms operating at the level of the phonological buffer (Sulpizio et al. 2012b; see also Colombo \& Zevin, 2009; Sulpizio et al., 2012a). In such a view, the preactivation of metrical information by a prime word would affect the component of the phonological buffer responsible for metrical encoding by affecting the timing of the operations the system performs to retrieve and assign the correct stress pattern to the target word.

The interaction we report suggests that syllable frequency and stress assignment may affect a common locus, and that such locus is the phonological output buffer, where the phonological word is phonetically encoded and thus realized. One might argue - contra Levelt at al. (1999) - that syllable frequency may affect reading during the orthography-to-phonology conversion. If that were the case, the syllable frequency effect would have emerged only in the congruent stress condition; in the incongruent stress condition, in fact, the time needed to account for the stress mismatch would have delayed the assembling of segmental and metrical information, with the result of allowing enough time for fully computing low-frequency syllables. This being the case, the syllable frequency effect would have been greatly reduced or even annulled. This is not the case, and our results support the proposal that syllable frequency effect arises at the phonetic encoding (Levelt et al., 1999).

The difference in speed of processing between high- and low-frequency first syllables for congruent and incongruent stress targets seems to be the critical factor in the pattern we obtained and the interaction suggests that, at the level of phonology-to-phonetic interface, words with a highfrequency initial syllable are less prone to interference from the stress mismatch. Although the present data do not allow us to finely specify the nature of such interaction - that is, it is hard to establish whether the nature of the stress priming effect is facilitatory or an inhibitory - a possible interpretation of our finding can still be sketched by referring to the different procedures for syllabification of high- and low-frequency syllables. According to the mental syllabary theory (Levelt et al.'s, 1999), the former are retrieved from the repertoire of syllables while for the latter a composition from their constituent phonemes is postulated. The syllable stored in the repertoire are used to
drive the motor programs, that is they allow the speakers to map the abstract phonological syllabic representations into phonetic packages, which are still partially abstract representations of the to-be-performed articulatory gestures, and each syllable can thus be still prone to be articulated in different ways (e.g., with longer or shorter duration, with more or less force, or with different kinds of pitch modulation; Levelt, 1989). Therefore, in case of a stimulus with a high-frequency first syllable, the reading system may start the phonological-to-phonetic mapping by processing the segmental information up to the syllable repertoire and independently of how fast the computation of the suprasegmental information occurs; then, as soon as the stress system determines the correct stress pattern the activated phonetic syllable is specified in terms of stress. In such a view, the phonetic code retrieval of a high-frequency syllable is weakly affected by the prime computation as the former can proceed independently from the latter. Thus, for words starting with a high-frequency syllable, the difference between targets in the congruent- and incongruent-stress prime condition would be only due to the different timing required for the specification of the correct stress pattern of the target in the two conditions.

A different process, however, can be postulated for words starting with low-frequency syllables as they do not have a stored representation in the syllabary and are thus assembled on-line. As a consequence, to map the abstract phonological constituents of a syllabic unit into a corresponding phonetic-detailed representation, the reading system needs all the relevant information - the phonemes and the specification of stress (i.e., if the syllable is either stressed or unstressed) - to be both in the phonological output buffer, as a partial or incomplete activation of either segmental or suprasegmental information would make the buffer unable to assemble a well-formed phonetic unit. In such a view, the large priming effect reported for lowfrequency syllables may emerge because, for such stimuli, the operations of stress assignment and phonetic syllable computation are sequential. The implication of such assumption is that the time required to assemble a lowfrequency syllable is a function of the time required to correctly assign the stress pattern to the word, as the latter can speed up or delay the initiation of phonetic encoding of the former.

The CDP++ model of reading (Perry et al., 2010), which was recently implemented for English bisyllables, explicitly assumes that the start of articulation is conditional to stress retrieval, and thus may be used to frame our interpretation of the pattern of results. In the Perry et al.'s (2010) model, the phonological output buffer includes two distinct mechanisms for segmental and suprasegmental computation, i.e., phonological output nodes and stress output nodes, with the latter nodes being responsible for stress assignment. This is consistent with our claim that the locus of the interaction is the phonological output buffer. However, the functional architecture of the model seems to be still underspecified to be able to fully account for our
results since in the model the timing of the operations in the phonological output buffer is such that only after the relevant stress pattern has been activated the word constituent phonemes, structured in their syllabic constituents, can be overtly articulated. Such architecture would predict an additive effect of stress assignment and syllabification, with the consequence that a delay in the processing of stress assignment should equally affect both word with a high-frequency first syllable and words with a low-frequency first syllable. Although our data support the view that stress assignment is essential for articulation to take place, they also suggest different procedures for highand low-frequency syllables, i.e. an interactive process at the level of phonology-to-phonetic interface (for a similar proposal, see Perret, Schneider, Dayer, \& Laganaro, 2012).

To conclude, our findings show that words with an initial low-frequency syllable are more strongly affected by manipulation of incongruent stress priming than words with a high-frequency initial syllable. This is the first evidence showing that, in word reading, the processes of stress assignment and syllable computation may interact within the phonological output buffer. The finding is consistent with the view that the phonological buffer acts as the locus of phonological-to-phonetics interface, where the abstract phonological word is converted into its phonetic representation, and where stress and syllable information may interact.

#### Abstract

Two prominent approaches to describing how people make decisions between risky options are algebraic models and heuristics. The two approaches are based on fundamentally different algorithms and are thus usually treated as antithetical, suggesting that they may be incommensurable. Using cumulative prospect theory (CPT; Tversky \& Kahneman, 1992) as an illustrative case of an algebraic model, we demonstrate how algebraic models and heuristics can mutually inform each other. Specifically, we highlight that CPT describes decisions in terms of psychophysical characteristics, such as diminishing sensitivity to probabilities, and we show that this holds even when the underlying process is heuristic in nature. Our results suggest that algebraic models and heuristics might offer complementary rather than rival modeling frameworks and highlight the potential role of heuristic principles in information processing for prominent descriptive constructs in risky choice.

Keywords: cumulative prospect theory; probability sensitivity; computational modeling; heuristics; risky choice.

## Introduction

How can risky decision making-in which people have to choose between options offering different outcomes with certain probabilities-best be modeled? Two prominent approaches in decision research are algebraic models and heuristics (e.g., Brandstätter, Gigerenzer, \& Hertwig, 2006; Payne, 1973; Payne, Bettman, \& Johnson, 1993). Algebraic models follow the principle of expectation maximization and use an algorithm that integrates (some function of) probability and outcome information multiplicatively to describe people's risky choices. Arguably the most prominent model in this tradition is cumulative prospect theory (CPT; Tversky \& Kahneman, 1992). According to CPT, options are evaluated independently of each other. The model invokes psychophysical constructs such as probability sensitivity and loss aversion to account for characteristic phenomena in choice, and quantifies them using adjustable parameters. Heuristics, by contrast, are based on simple principles of information processing, such as
sequential and limited search, dimensional comparison, and aspiration levels; in contrast to algebraic models, heuristics often go without integrating information, and ignore part of the information (e.g., Payne et al., 1993; Thorngate, 1980). Models of heuristics for risky choice include the semiorder rule (Luce, 1956), the similarity heuristic (Leland, 1994; Rubinstein, 1988), elimination-by-aspects (Tversky, 1972), and the priority heuristic (Brandstätter et al., 2006).

Algebraic models and heuristics are often treated as antithetical (e.g., Brandstätter et al., 2006; Payne, 1973; Svenson, 1979). As pointed out by Lopes (1995), however, this opposition may be unnecessary: "Some models focus on the algebraic pattern of people's risk preferences, others on the content of their choice processes [models of heuristics]. Although one might suppose that these two kinds of accounts are alternate ways of describing the same thing-indeed, that one kind of model might eventually be reducible to the other-the approaches have tended to be disjoint" (p. 177). To date, however, the relationship between algebraic models and heuristics has yet to be elaborated.

To close that gap, we use CPT (Tversky \& Kahneman, 1992) as an illustrative case highlighting that algebraic models offer a tool for describing characteristics of the decision process in psychophysical terms; here, we focus on the sensitivity to differences in probabilities. We argue that diminished sensitivity to probability information-as captured in CPT's weighting functions-can result from lexicographic and noncompensatory processing of heuristics. As such, CPT may offer a useful framework to represent heuristic decision making in terms of established constructs such as sensitivity to probability information. Conversely, as heuristics are explicit with regard to the informationprocessing steps underlying a decision, elaborating the relationship between heuristics and CPT might contribute to a better understanding of the cognitive mechanisms potentially underlying the characteristic shapes of CPT's weighting and value functions (cf. Hogarth \& Einhorn, 1990). Overall, we thus suggest that the relationship between the algebraic and heuristic models of risky choice is complementary rather than adversarial.

In the following, we first briefly describe CPT's parametric framework and how its weighting functions reflect sensitivity to probability information. Second, we elaborate for one specific heuristic, the priority heuristic (Brandstätter et al., 2006), how heuristic choices may be reflected in CPT's parameters. Specifically, we take advantage of the fact that the degree to which the priority heuristic attends to probability information depends on the choice environment; using computer simulations, we examine how this translates into differences in CPT's weighting function.

## Probability Sensitivity in CPT

CPT assumes that decisions are made to maximize expected return. More specifically, choices between risky options are based on a person's subjective valuation of these options and then maximization. In CPT, the overall valuation $V$ of an option $A$ is defined as
$V(A)=\sum_{j=1}^{k} v\left(x_{j}\right) \pi_{j}^{-}+\sum_{i=k+1}^{n} v\left(x_{i}\right) \pi_{i}^{+}$.
$v(x)$ is the value function, describing how an objective outcome $x$ is translated into a subjective value, and $\pi^{+}$ $\left(\pi^{-}\right)$is the weight given to a positive (negative) outcome $x$ (Tversky \& Kahneman, 1992) and depends on the probability of the outcome.

CPT assumes a rank-dependent transformation of the outcomes' probabilities into decision weights. Specifically, with outcomes $x_{I} \leq \ldots \leq x_{k} \leq 0 \leq x_{k+1} \leq \ldots \leq$ $x_{n}$, the weight $\pi^{+}\left(\pi^{-}\right)$given to a positive (negative) outcome $x$ is the difference between the probability of receiving an outcome at least as good (bad) as $x$ and the probability of receiving an outcome better (worse) than $x$ :
$\pi_{i}^{+}=w^{+}\left(p_{i}+\ldots+p_{n}\right)-w^{+}\left(p_{i+1}+\ldots+p_{n}\right)$ for $k<i<n$
$\pi_{j}^{-}=w-\left(p_{1}+\ldots+p_{j}\right)-w-\left(p_{1}+\ldots+p_{j-1}\right)$ for $1<j \leq k$.
$w^{+}$and $w^{-}$are the probability weighting functions for gains and losses, respectively. They are assumed to have an inverse S-shaped curvature. Different types of weighting functions have been proposed (for an overview, see Stott, 2006). We use the following twoparameter version that separates the curvature of the weighting function from its elevation (e.g., Goldstein \& Einhorn, 1987; Gonzalez \& Wu, 1999):
$w^{+}(p)=\frac{\delta^{+} p^{\gamma^{+}}}{\delta^{+} p^{\gamma^{+}}+(1-p)^{\gamma^{+}}}$.
$w^{-}(p)=\frac{\delta^{-} p^{\gamma^{-}}}{\delta^{-} p^{\gamma^{-}}+(1-p)^{\gamma^{-}}}$
The parameters $\gamma^{+}$and $\gamma^{-}$(both varying between 0 and 1) govern the amount of curvature of the function in the gain and loss domains, respectively, and indicate how sensitive decisions are to differences in probabilities (with smaller values of $\gamma<1$ resulting in more S-shaped weighting functions, reflecting lower sensitivity to
differences in probabilities). The elevation of the weighting functions for gains and losses is controlled by the parameters $\delta^{+}$and $\delta^{-}$(both $>0$ ), respectively.

CPT has repeatedly been shown to be highly successful in describing risky choices between monetary gamble problems (e.g., Glöckner \& Pachur, 2012; but see Birnbaum, 2004; Brandstätter et al., 2006). As a description of the underlying cognitive process, however, CPT's implied algebraic calculus and its commitment to a multiplicative framework have not been unchallenged (e.g., Brandstätter et al., 2006; Lopes, 1995). One such challenge has been put forth by proponents of heuristics. We turn to this modeling approach next.

## Probability Sensitivity Resulting From Heuristic Information Processing

In contrast to the integrative approach of CPT, heuristics often ignore part of the information and do not integrate information. They are based on simple principles of information processing, such as sequential and limited search, dimensional comparison, and aspiration levels (e.g., Payne et al., 1993; Thorngate, 1980). Lexicographic strategies, for instance, proceed through several dimensions sequentially and stop at the first dimension that enables a decision to be made (Fishburn, 1974; Gigerenzer, Todd, \& the ABC Research Group, 1999; Thorngate, 1980). The priority heuristic (Brandstätter et al., 2006), which is related to lexicographic semi-orders (Luce, 1956; Tversky, 1969), belongs to this class. Its architecture is based on established principles of bounded rationality (e.g., Simon, 1955), such as sequential search, stopping rules, and aspiration levels, and it assumes that probabilities and outcomes are compared between gambles, rather than integrated within gambles (as assumed by CPT). For choices between two-outcome gambles involving gains, the priority heuristic entails the following steps:

1. Priority rule. Go through dimensions in the order of minimum gain, probability of minimum gain, and maximum gain.
2. Stopping rule. Stop examination if the minimum gains differ by $1 / 10$ (or more) of the maximum gain; otherwise, stop examination if probabilities differ by $1 / 10$ (or more) of the probability scale.
3. Decision rule. Choose the gamble with the more attractive gain (probability).
(For losses, "gains" are replaced by "losses"; for mixed gambles, "gains" are replaced by "outcomes.")

Due to its stopping rule, the priority heuristic considers probability information depending on the structure of a gamble problem. The heuristic first examines the (minimum) outcomes of the gambles. If this reason discriminates, then probabilities will not be examined. If, however, the outcomes fail to discriminate, probabilities will be examined. That is, the priority heuristic attends to probability information only when the minimum outcomes do not differ. The heuristic's
sensitivity to probability information is thus dependent on the structure of the choice environment.

## Heuristics' Probability Sensitivity as Captured in CPT's Parametric Framework

These two approaches to model risky choice-CPT and heuristics-are based on fundamentally different algorithms. Whereas CPT considers all outcome and all probability information, the priority heuristic considers the reasons sequentially, and stops information search as soon as a reason discriminates. Moreover, although CPT may be a relatively flexible model due to its several adjustable parameters (e.g., Gonzalez \& Wu, 1999), it still has important constraints: both the value and the weighting function are restricted to be monotonic, the value function is concave for gains and convex for losses, and the weighting function is constrained to have an inverse S-shaped curvature. Can CPT, given these constraints and given its starkly different algorithmic structure, nevertheless accommodate choices generated by the priority heuristic and accurately reflect the degree to which the heuristic attends to probability information?

In addressing this question, we strive to contribute to a better understanding of the relationship between algebraic models and heuristics. One crucial aspect of our argument is that diminished sensitivity to probability information may be due not only to psychophysical regularities in magnitude evaluation, but also to the limited attention that a heuristic devotes to probabilities. More specifically, the weighting function's $\gamma$ parameter (Equation 3), which reflects sensitivity to probabilities, should differ systematically as a function of whether the heuristic makes a choice based on the first reason (outcome) or the second reason (probability). The less frequently the priority heuristic considers probabilities in a set of gamble problems, the lower the resulting value of the $\gamma$ parameter should be. Slovic and Lichtenstein (1968) made a similar proposal more than 40 years ago, suggesting that "increases [in] the saliency of the money dimensions and decreases [in] the relative importance of the probabilities" should lead to "relatively flat [i.e., more strongly S-shaped] subjective probability functions" (p. 16). Next, we test this suggestion using a computer simulation.

## Computer Simulation

We created three sets of two-outcome gamble problems, each including 180 randomly generated problems with similar expected values: 60 gain, 60 loss, and 60 mixed problems (cf. Rieskamp, 2008). Across the three sets, we varied the percentage of problems in which the minimum gains (losses) discriminated between the gambles (i.e., that differed by at least $10 \%$ of the highest gain or loss). In the first set, the minimum gains (losses) discriminated in $75 \%$ of the cases, and the priority heuristic therefore only proceeded to the second reason-the probability of the minimum gains (losses)-in $25 \%$ of the cases; in the
second set, the minimum gains (losses) discriminated in $50 \%$ of the gamble problems, and the heuristic therefore proceeded to the probability information in the remaining $50 \%$ of the cases; in the third set, the minimum gains (losses) differed in only $25 \%$ of the cases, and the heuristic therefore proceeded to the probabilities in $75 \%$ of the cases. The gambles were constructed such that if the heuristic proceeded to the probability information, this reason always discriminated. We predicted that CPT's probability sensitivity parameter $\gamma$ fitted to the priority heuristic's choices would increase across the problem sets.

We simulated the choices of the priority heuristic in all three problem sets and subsequently fitted CPT's weighting functions and value functions, respectively, to these choices, separately for each set. Our implementation of CPT had six adjustable parameters: $\alpha$ $(=\beta)$ and $\lambda$ for the value function, $\gamma, \delta^{+}$and $\delta^{-}$for the weighting function, and $\varphi$ for the choice rule necessary to derive predicted choice probabilities (see below). ${ }^{1}$ To reflect CPT's main assumptions (e.g., an inversely Sshaped probability weighting function, a concave value function for gains, and a convex value function for losses; see Tversky \& Kahneman, 1992), in the parameter estimation procedure the parameter values were restricted as follows (see Rieskamp, 2008): $0<\alpha \leq 1 ; 0<\lambda \leq 5 ; 0<$ $\gamma \leq 1 ; 0<\delta^{ \pm} \leq 4 ; 0<\varphi \leq 5$. The deviation between CPT's predictions and the heuristic's choices was quantified using the likelihood measure $G^{2}$ (e.g., Sokal \& Rohlf, 1994), with a smaller $G^{2}$ indicating a better fit:

$$
\begin{equation*}
G^{2}=-2 \sum_{i=1}^{N} \ln \left[f_{i}(y \mid \theta)\right] \tag{4}
\end{equation*}
$$

where $N$ refers to the total number of choices, and $f(\mathrm{y} \mid \theta)$ refers to the probability with which CPT, given a particular set of parameter values $\theta$, predicts an individual choice $y$. If gamble A was chosen, then $f(\mathrm{y} \mid \theta)$ $=p_{i}(\mathrm{~A}, \mathrm{~B})$, where $p_{i}(\mathrm{~A}, \mathrm{~B})$ is the predicted probability that gamble A is chosen over gamble B ; if gamble B was chosen, then $f(\mathrm{y} \mid \theta)=1-p_{i}(\mathrm{~A}, \mathrm{~B})$. To determine $p_{i}(\mathrm{~A}, \mathrm{~B})$, we applied an exponential version of Luce's (1956) choice rule (also known as softmax):

$$
\begin{equation*}
p_{i}(A, B)=\frac{e^{\varphi V(A)}}{e^{\varphi V(A)}+e^{\varphi V(B)}}, \tag{5}
\end{equation*}
$$

where $V(\mathrm{~A})$ and $V(\mathrm{~B})$ represent the subjective valuation of the gambles A and B according to CPT, and $\varphi>0$ specifies how sensitively the predicted choice probability reacts to differences between the gambles' subjective valuations $V(\mathrm{~A})$ and $V(\mathrm{~B})$, with higher values indicating higher sensitivity. In the fitting procedure, we first

[^222]Table 1: Parameter estimates obtained when fitting CPT to the choices of the priority heuristic where the decision was made on the first reason (minimum gain/loss) in $25 \%, 50 \%$, or $75 \%$ of the cases, respectively, and on the second reason (probability of the minimum gain/loss) otherwise.

| \% <br> Decisions <br> on first <br> reason | $\gamma$ | $\delta^{+}$ | $\delta^{-}$ | $\alpha$ | $\lambda$ | $\varphi$ | $G^{2}$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $75 \%$ | 0.32 | 0.01 | 0.15 | 1.0 | 2.06 | 0.34 | 84.25 |
| $50 \%$ | 0.50 | 0.05 | 0.49 | 1.0 | 1.30 | 0.15 | 153.45 |

Note. $G^{2}$ assuming random choice is 249.53 .
implemented a grid search to identify the parameter values that minimize $G^{2}$; the 20 best-fitting combinations of grid values were then used as starting points for subsequent optimization using the simplex method (Nelder \& Mead, 1965), as implemented in MATLAB.

## Results

Table 1 shows the best-fitting CPT parameters when fitted to the simulated choices of the priority heuristic in gamble problems where the decision was made on the minimum gain (loss) in $75 \%, 50 \%$, or $25 \%$ of the cases, respectively, and on the probability of the minimum gain (loss) otherwise. As can be seen-and as predicted-the probability sensitivity parameter $\gamma$ increased across the sets; it was lowest in the set where the priority heuristic decided on the first reason (minimum outcome) in the majority of cases and it was highest in the set where the heuristic decided on the second reason (probability of the minimum outcome) in the majority of cases. In other
words, CPT accurately reflected the different degrees to which the priority heuristic attended to probability information across the three sets.

Panels A and B of Figure 1 plot the weighting functions based on the best-fitting parameters, separately for the gain and loss domains. Irrespective of domain, for choices that only considered probabilities in $25 \%$ of the cases, the weighting function was most strongly Sshaped, indicating low sensitivity to probability information; for choices that considered probabilities in half of the cases, it was comparatively less S-shaped; and for choices that considered probabilities in $75 \%$ of the cases, it was least S-shaped. (Note that the differences in shapes of the weighting function between the gain and loss domains were due to differences in the elevation parameters; i.e., $\delta^{+}$and $\delta^{-}$).

The best-fitting parameter values of the priority heuristic's choices in the three problem sets are summarized in the parameter profiles in Panel C in Figure 1.

Interestingly, CPT did not fit equally well to the choices across the three problem sets (see $G^{2}$ in Table 1). Specifically, the fit was best when most choices (75\%) were made on the first reason, worsened when $50 \%$ considered probabilities, and improved again when only $25 \%$ of the choices were made on the first reason. CPT is thus apparently better able to fit choice sets where a substantial proportion of choices stop examination on the same reason than when choices are based on different reasons (as in the $50 \%$ choice set).

## Discussion

CPT models decisions based on a compensatory algorithm where outcomes and probabilities are integrated multiplicatively and summed up separately within each option. The priority heuristic, in contrast, models decisions based on sequential information

Figure 1: Panels A (gains) and B (losses) plot the weighting functions obtained when fitting cumulative prospect theory to the choices of the priority heuristic in gambles where the decision was made on the minimum gain (loss) in $75 \%$, $50 \%$, or $25 \%$, respectively, and on the probability of the minimum gain (loss) otherwise. Panel C shows the parameter profiles of CPT's value and weighting function parameters fitted to the choices of the priority heuristic in the three gamble sets (as the parameters differed in their scale, they were normalized for this graph; for the exact parameter values, see Table 1).
processing and compares outcomes and probabilities between the options. Despite these stark differences, our result is that CPT is able to represent choices generated by the priority heuristic in a psychologically meaningful manner: the weighting function's curvature reflects differences in the heuristic's sensitivity to probability information between the three choice environments that differed in how frequently choices were decided based on the probability dimension.

Taken together, our results thus demonstrate that although CPT is based on a different algorithmic architecture than heuristics, its parametric framework might offer a useful tool for characterizing heuristic processes in terms of prominent descriptive constructs such as probability sensitivity (for a discussion of other constructs of CPT , such as risk aversion, loss aversion, and outcome sensitivity, see Suter, Pachur, \& Hertwig, 2013a). Conversely, the integration of the two approaches might enable hypotheses to be derived about the processes generating the characteristic shapes of CPT's functions.

Our finding that specific values of CPT's $\gamma$ parameter can reflect the processing steps of a lexicographic heuristic-that is, whether probability information was called upon or not-has important implications for the use of CPT in empirical investigations of risky choice: CPT's parameters might help to identify the interaction of a heuristic with its environment; moreover, they might help to identify the use of different heuristics by different individuals within the same environment, or of different heuristics by the same individual across different environments.

The demonstrated relationship between CPT, the information processing architecture of a heuristic, and the structure of the environment could explain apparent inconsistencies in empirical investigations (see also Hertwig \& Gigerenzer, 2011)-for instance, why the same person's sensitivity to probability information appears low at some times and high at others. Such observations of variability need not mean that CPT's parameters cannot be measured reliably, or that different heuristics are used. They could arise from the interaction of a heuristic's lexicographic architecture with various choice environments. If decision problems are constructed such that a user of the priority heuristic is always able to terminate search after examining the options' minimum outcomes, the person's probability sensitivity will appear low. If they are constructed such that the same person must always move beyond the minimum outcomes and examine their probabilities, the person will seem to be highly sensitive to probabilities.

Relatedly, the elaborated relationship between CPT and heuristic processing not only allows the interactions of a heuristic to be tracked across different environments, but it may also allow differences in strategy selection between individuals within the same environment to be identified. It therefore suggests an alternative interpretation of the observed link between CPT's
parameters and variables that influence risky choice, such as gender. Fehr-Duda, De Gennaro, and Schubert (2006), for instance, concluded that women tend to be less sensitive to probability changes than men (see also Booij \& van de Kuilen, 2009). To the extent that CPT reflects differences in terms of probability sensitivity also between strategies, this finding might indicate that men and women rely on different strategies that differ with regard to their probability sensitivity.

Moreover, CPT's parameters might not only reveal differences between individuals, but also within an individual. For instance, a decision maker might use different strategies for different contexts. In a study on the difference between affect-rich and affect-poor risky choice, Suter, Pachur, and Hertwig (2013b) found that people's choices in affect-rich tasks were consistent with a more strongly inverse $S$-shaped weighting function relative to choices in affect-poor tasks. However, in a model comparison, they found that in affect-rich choices the majority of the participants were better described by the minimax heuristic, a choice strategy that neglects probabilities and only decides based on the minimum outcomes, than by CPT; in affect-poor tasks, in contrast, participants were better described by a strategy that is sensitive to probabilities. Thus, the differences apparent on the weighting function could indicate the selection of a different strategy. Similarly, Abdellaoui, Diecidue, and Öncüler (2011) reported that, relative to lotteries with immediate outcomes, people's responses to lotteries with delayed outcomes are consistent with a less inverse Sshaped curvature (indicating higher probability sensitivity). The authors hypothesized that this difference might be due to a decreased anticipated emotional reaction the more delayed lotteries are (cf. Rottenstreich \& Hsee, 2001). Again, the impact observed on the weighting function might thus reflect the use of different strategies.

Thus, rather than merely describing contextual or individual differences in prospect theory's concepts, such as differences in probability sensitivity, one could go one step further and use differences on CPT's parameters to hypothesize about individual differences in terms of information processing and strategy use. By better understanding how information processing as embodied in heuristics manifests in CPT's parameters, we can gain a more cognitive perspective on CPT and its parametric framework (for an ecological account of the shape of CPT's functions, see Stewart, Chater, \& Brown, 2006).

# Scope of Real Beliefs in Belief Revision 

Alexander B. Swan (swan@psych.ucsb.edu) Alexandra Y. Chambers (chambers@psych.ucsb.edu)<br>Russell Revlin (revlin@psych.ucsb.edu)<br>Department of Psychological and Brain Sciences, University of California, Santa Barbara<br>Santa Barbara, CA 93106-9660 USA

#### Abstract

The present study examines the decisions made by reasoners when they are asked to revise their beliefs in the face of new, counterfactual information. Participants indicated the Scope (the degree of set inclusion) of semantic generalizations about real categories in a Pretest. In subsequent experiments, these Scope values were used to predict the willingness of participants to retain statements in their existing knowledge sets. When those sets were logically compatible with a Modus Tollens (MT) structure, participants were more likely to retain the general statements, but not when the sets were logically compatible with a Modus Ponens (MP) structure. However, the MP retention rates increased when locatives were added to the generalizations. These findings are inconsistent with several prevailing proposals of belief revision but do support the concept of belief revision as following Possible Worlds logic.

Keywords: belief revision; counterfactual reasoning; scope.

## Introduction

The process of belief revision is known by many terms (e.g., belief updating, belief change or belief dynamics). Simply put, belief revision involves the possibility of changing a previously held belief in light of new and assumed true information. At its very basic level, this involves updating knowledge and resolving inconsistencies within a pre-existing knowledge structure.

True belief revision must involve commitment to true beliefs. The earliest belief revision studies employed dictionary definitions without proper verification that those definitions had merit or that the students were committed to those definitions (Revlis \& Hayes, 1972). Later studies examined belief revision with artificial categories or groups, of which a participant might have had no previous knowledge (e.g., Byrne \& Walsh, 2002; Elio \& Pelletier, 1997; Politzer \& Carles, 2001; Revlin, Cate, \& Rouss, 2001). Revlin, Calvillo, and Ballard (2005) specifically created a fantasy world with Lego figures and various arbitrary rules about knights and kings (see also Van Hoeck, Revlin, Dieussaert, \& Schaeken, 2012). In each of these cases, real beliefs were not tested. It is difficult to assess the process of belief updating when the epistemic system is limited to arbitrary or unverified knowledge. The findings from such studies have supported conflicting theoretical treatments (e.g., Byrne \& Walsh, 2002; Wolf, Rieger, \& Knauff, 2012; Revlin et al., 2001; Revlis \& Hayes, 1972). The focus of the present study is to identify the basic
cognitive processes in true belief revision while still employing an established paradigm.

A basic paradigm for studying natural belief revision has been borrowed from the philosophical treatment of beliefcontravening problems (Rescher, 1964): It consists of a set of beliefs that are relevant to a counterfactual assumption, whose introduction requires a revision of the belief set. For example,
(1a) All whales are mammals
(1b) This creature is not a mammal
(1c) This creature is not a whale
(1d) Assume that this creature is a whale
A typical adult reasoner with the current knowledge of statements (1a-1c) would appreciate the inherent consistency of these statements. This collection of statements follows the logical form of Modus Tollens (MT; $p \rightarrow q, \sim q, \therefore \sim p)$. However, if someone is faced with statement (1d), an inconsistency is introduced to the knowledge structure and the revision process requires the reestablishment of a consistent epistemic set that entails the retention of (1d). To accomplish this, the reasoner notices that statement (1d) is in direct contradiction to statement (1c), which can be easily eliminated. However, there is a larger issue. The remaining statements ( $1 \mathrm{a} \& 1 \mathrm{~b}$ ) jointly create a contradiction with (1d). To resolve this inconsistency, a choice must now be made: Does the individual accept statement (1a), retaining the previously held belief that all whales are mammals, and that it cannot be true that there is an creature that is classified as a whale that is not a mammal? Or does the individual accept statement (1b), and claim that it could be true that there are creatures classified as whales that are not mammals? The revision process requires the elimination of one of the two statements. Either path is equally logical, although standard logic fails to encourage a preference, only indicating to the reasoner that there is an inconsistency (Chisholm, 1946). While an individual can reject both statements, the goal is generally to retain the maximum number of statements that already exist within the epistemic set. A second logical form typically used in belief-contravening problems is that of Modus Ponens (MP; $p \rightarrow q, p, \therefore q$ ), illustrated in (2) below:
(2a) All whales are mammals
(2b) This creature is a whale
(2c) This creature is a mammal
(2d) Assume that this creature is not a mammal

The assumption (2d) introduces the same direct and indirect contradictions as (1) above, and the reasoners must revise the belief-set to resolve the inconsistencies that are created. Notice that the MP assumption (2d) undermines the credibility of the generality (2a) by changing the properties of the specific instance (2b) that is already within a category-thereby making the category incoherent. In contrast, the MT assumption (1d) adds a new member to a category (1b) with seemingly different group membership or properties, while not changing the credibility of the generality as in the case of the MP assumption.

Despite the fact that standard logic is unable to guide the selection made by reasoners, they have shown distinct patterns of resolution for each of the logical forms, which vary with the content of the studies. In some studies, reasoners show a distinct preference to retain the generalities in problems like (1) above (e.g., Revlin et al., 2005; Revlin, Calvillo, \& Mautone, 2003). In other studies, preference has been shown for creating disabling conditions (or exceptions to the generality or rule), which allows them to be supported with caveats (Khemlani \& Johnson-Laird, 2011). In some studies, no preference among reasoners has been shown, especially for problems like (2) above (Byrne \& Walsh, 2002). We propose here that these differential findings may be a consequence of the degree of reality of the beliefs to be revised.

In addition to examining the role of real beliefs, the present study will focus on the importance of Scope in belief revision. The Scope of a quantified statement specifies the instances of the generality (or rule) that are subsumed within it across time and space. To demonstrate, consider the statements: all the coins in my pocket on VE Day are silver (Goodman, 1954) and all whales are mammals (Ryle, 1949). While these statements are both universally quantified generalities, the first is considered an accidental generality (it just so happens that all the coins in the pocket are silver), and the second is a scientific law (which spans space and time). A reasoner would prefer to retain the second statement because of its law-like quality; such statements are intended to act as inference tickets in new situations (Ryle, 1949). A reasoner should regard the Scope of the first statement about the silver coins to be quite small. In contrast, a reasoner should recognize that the second generality regarding mammalian whales has a large Scope (imagine all the whales that have existed in the past, present, and future and classify them into the superordinate category of mammals). The Scope of these relationships is generally an important proxy for knowledge preservation and credibility. It is possible that belief revision with artificial categories employed generalities with restricted Scope, which impacted revisions.

In the experiments in this study, Scope is either presented implicitly (with statements from the Pretest) or explicitly (the inclusion of numbers in the generality expression), and the goal is to determine whether Scope affects belief revision. To gain a sense of a statement's Scope at a granular level, we asked participants to indicate the number
of instances of a large category that possess a critical property-e.g., the number of whales that are mammals.

A pretest was used to assess participants' commitment to Scope values of general statements that were derived from theories of semantic knowledge (e.g., Collins \& Quillian, 1969; Quillian, 1968; Rips, 1989). In Experiment 1, these generalities were included in a basic belief revision paradigm where problems took the logical forms seen in example problems (1) and (2). In Experiment 2, locatives were added to the statements to constrain the law-like quality of the statements and to de-couple real world categories from the reasoning context. In Experiment 3, the Scope of the statements was explicitly manipulated into small and large proportions of a given set (Scope) to determine the effects of explicitly stated Scope on the reasoning process.

## Pretest

In order to create test materials for the belief revision task (Experiments 1-3), a pretest was developed to measure the implicit Scope values of various general statements.

Ninety-one undergraduates volunteered to participate in this pretest condition for course credit. They viewed 24 universally quantified statements. There were four conditions of statements created by crossing two levels of Ontology (Definitionally true or Empirically true statements) by two levels of Relation (Class-Inclusion or Property-Assignment).

Students identified the Scope of each statement on an 8point scale, where each point corresponded to a power of 10 . The scale was anchored by " 0 " and " 7 ". For example, a Scope of " 4 " encompassed a Scope size from 1,000 to 10,000 . The order of the statements was randomized in the booklet.

As anticipated, Scope values were greater for Definitional statements ( $M=6.26, S D=.90$, e.g., All trees are plants) than Empirical statements ( $M=5.65, S D=.82$, e.g., All professors are teachers). Class Inclusion statements ( $M=$ $6.09, S D=.88$, e.g., All oranges are fruit) received greater Scope values than Property-Assignment statements ( $M=$ 5.82, $S D=.83$, e.g., All mammals have hair). These findings are in keeping with the importance of these variables for semantic verification (e.g., Collins \& Quillian, 1969; Quillian, 1968; Rips, 1989)

## Experiment 1

The goal for Experiment 1 was to examine belief revision in the context of statements that have verified believability and Scope. Using the Scope values recorded from the Pretest, we aimed to compare those values with retention rates to determine the role of Scope in a statement's retention. We predicted that for both MT and MP problems, retention rates would increase as the Scope of the generality increased because Scope reflects the law-like aspect of the statements.

## Method

Seventy-seven undergraduate students participated in this experiment for course credit. Two booklets of belief revision problems were created from the Pretest materials. One booklet contained MT belief revision problems and the second contained MP belief revision problems. Within each booklet, there were four types of problems (Problem Type) that result from the crossing of Ontology (Definitional or Empirical relations and Relation (Class-Inclusion or Property-Assignment). There were three exemplars for each type of problem, chosen randomly from the Pretest, creating booklets of 12 problems each.

The problems were randomly ordered in each booklet and the booklets were randomly assigned to participants. For each problem, participants were asked to accept the assumption as true, and discard (by crossing-out) the statements that contradicted the assumption.

## Results and Discussion

Participants' preference to retain the generality was scored for each problem and compared with chance (50\%).

Table 1: Mean (SD) Retention Rates for MT and MP Revisions in Experiment 1

|  |  | MT |  |
| :--- | :--- | :---: | :---: |
| Problem Type |  | MP |  |
| Definitional | Class | $91 \%(.21)^{* * *}$ | $56 \%(.40)$ |
|  | Property | $93 \%(.18)^{* * *}$ | $67 \%(.41)^{*}$ |
| Empirical | Class | $80 \%(.25)^{* * *}$ | $46 \%(.39)$ |
|  | Property | $71 \%(.36)^{*}$ | $48 \%(.38)$ |
|  | Binomial analysis: ${ }^{*} \mathrm{p}<.05,{ }^{* *} \mathrm{p}<.01,{ }^{* * *} \mathrm{p}<.001$ |  |  |  |

Table 1 displays the rate of retention of generalities and shows that participants prefer to retain the generalities in all MT problems significantly more often than chance, but preference for generalities in MP problems was not reliably different from chance (MT: $M=.84, S D=.25$ and MP: $M=$ $.54, S D=.40 ; F(1,66)=18.44, p<.001)$. Analysis also revealed a significant difference in retention rates for Problem Type, $F(3,198)=13.98, p<.001$. There was no significant interaction between Problem Type and Logical Structure, with both MT and MP following similar trends, $F(3,198)=1.28, p=.28$.

Simple regression analyses were conducted to determine if retention rates changed in relation to the Scope of the generality (derived from the Pretest). Overall, Scope ( $\beta=$ $.81, p=.001$ ) significantly predicted overall retention rates $\left(F(1,10)=19.37, p=.001, R^{2}=.66\right)$. Specifically, for MT contradictions, retention of the generalities increased with Scope $\left(\beta=.89, p<.001 ; F(1,10)=37.39, p<.001, R^{2}=\right.$ .80). However, for MP contradictions, Scope ( $\beta=-.55, p=$ .06) was a negative predictor of commitment to generalities, $F(1,10)=4.40, p=.06, R^{2}=.31$.

When reasoners seek to revise true beliefs in order to return consistency to a set of statements, they show a stronger commitment to the generalities when the logical
structure was expressed as an MT argument than as an MP argument even though the generalities are identical in the two conditions.

The Scope of the generality correlates positively and strongly with the tendency of reasoners to retain them in a MT argument structure, but Scope was negatively related to retention of generalities in MP arguments.

## Experiment 2

In this experiment, we once again assess the importance of Scope for belief revision. Here we try to constrain the Scope of the generalities by including a location in each epistemic set that implicitly constrains the generalities' Scope in space and time. When a locative is introduced, does it undermine the impression that the generalities are true across space and time? For example, consider "All snakes slither." This statement entails a large Scope (shown in Experiment 1). However, if a special desert is referred to (e.g., Rich lives in a desert where all the snakes slither), it invites the question whether there could be something peculiar about the location or why would it be introduced? Here we assess whether a specific location limits the Scope of the generalization and therefore the pattern of belief revision. Alternatively, perhaps the cognitive processes employed to uncouple the generalization from the location would result in enhancing the reasoner's commitment to the generality.

## Method

Seventy-eight undergraduate students participated in this experiment for course credit. Participants solved the same belief revision problems used in Experiment 1, but those in Experiment 2 introduced novel locatives for each problem. Participants were either given MT contradictions or MP contradictions of the same problem set to solve (betweensubjects). Participants solved 12 problems in total.

## Results and Discussion

Table 2 shows the retention of generalities for Logic Structure and Problem Type. It reveals that participants preferred to revise beliefs by retaining the general statements significantly more often than would be expected by chance $(50 \%)$ for each condition. As the table reveals, reasoners show a preference in all conditions to revise beliefs by retaining generalities. Logical Structure was important to revisions: participants who solved MT contradictions ( $M=.88, S D=.33$ ) were more likely to retain the generality of the problem than those who solved MP contradictions $(M=.71, S D=.34 ; F(1,63)=7.69, p=$ .007). The Ontology of the statements' relations was also critical, with participants retaining the Definitional generalities $(M=.82, S D=.25)$ more often than Empirical ones $(M=.77, S D=.27 ; F(1,63)=3.62, p=.06)$. There was no effect of Relation (Class vs. Property) and no interaction among the variables in this study.

Scope was not found to be a significant predictor of retention rates for either MT contradictions $(\beta=.27, p=$
.39) or MP contradictions ( $\beta=.21, p=.51$ ). In fact, the trend line seen in Experiment 1 for MP problems reverses direction (from negative to positive). This shows that providing a locative altered the importance of Scope.

Table 2: Mean (SD) Retention Rates for MT and MP Revisions in Experiment 2

|  | MT |  |
| :--- | :---: | :---: |
| Problem Type | $M(S D)$ | $M(S D)$ |
| Definitional | $90 \%(.35)^{* * *}$ | $74 \%(.36)^{* *}$ |
| Empirical | $85 \%(.36)^{* * *}$ | $69 \%(.38)^{*}$ |
| Binomial analysis: ${ }^{*} \mathrm{p}<.05,{ }^{* *} \mathrm{p}<.01,{ }^{* * *} \mathrm{p}<.001$. |  |  |

Overall, the presence of a locative still allows an effect of Logic: participants tended to retain the generality for MT problems more often than those participants evaluating MP problems. However, comparing across experiments, the retention of MP generalities increased at a much higher rate $(t(64)=-2.19, p=.03)$ than those observed in Experiment 1, while no change was observed in the retention rate of generalities in the MT structures.

## Experiment 3

The aim of Experiment 3 was to examine belief revisioning in artificial environments (e.g., the locatives of Experiment 2), but with real categories, whose Scope has been modified. Scope was expressed as either a small proportion or a large proportion of the total members of the reasoning categories (e.g., Kelly has a hive where 5 bees out of 104 insects have wings vs. Logan has a honeycomb where 91 bees out of 104 insects have wings.). In Experiments 1 and 2, Scope was implied. Here, it is explicitly stated. We anticipated that explicitly stating the Scope of the generalities would-along with the locatives-decouple the categorical expressions from their normative senses and therefore make the belief revision context more artificial.

## Method

Fifty-four undergraduate students participated in this experiment for course credit. In addition to the variables present in the task for Experiment 2 (Logic, Ontology, and Relation), a new between-subjects variable was added to the problem set: Scope proportion (Small or Large). There were four total conditions: MT Large, MT Small, MP Large, and MP Small. Participants solved 12 belief revision problems where Scope information was given either in a Small (5\%) or Large ( $87 \%$ ) Proportion. The instructions and procedure for this task were the same as Experiments 1 and 2.

## Results and Discussion

Table 3 shows that participants prefer to revise their beliefs by retaining the generality (Binomials, $p<.05$ ). Overall, reasoners who solved MT contradictions ( $M=.89, S D=$ .29) were slightly more likely to accept the generality of the problem than those who solved MP contradictions ( $M=.77$,
$S D=.29 ; F(1,50)=3.99, p=.05)$. Compared with previous experiments, the retention rates of generalities in MT contradictions were at ceiling and those of MP contradictions were higher than previous. Such increased retention rates overshadowed any effect of Scope, which was not a significant predictor for MT or MP problems in either Small or Large Proportion conditions.

Table 3: Mean (SD) Retention Rates for MT and MP Revisions in Experiment 3 for Small and Large Scope Conditions

|  |  | MT | MP |
| :--- | :--- | :---: | :---: |
| Problem Type | $M(S D)$ | $M(S D)$ |  |
| Small | Definitional | $89 \%(.42)^{* * *}$ | $77 \%(.40)^{* *}$ |
|  | Empirical | $85 \%(.49)^{* *}$ | $70 \%(.48)$ |
| Large | Definitional | $95 \%(.42)^{* * *}$ | $87 \%(.40)^{* * *}$ |
|  | Empirical | $86 \%(.49)^{* *}$ | $74 \%(.48)^{*}$ |
|  | Binomial analysis: ${ }^{*} \mathrm{p}<.05,{ }^{* *} \mathrm{p}<.01,{ }^{* * * \mathrm{p}<.001 .}$ |  |  |  |

The locatives appear to influence the decision-making by de-coupling the artificial context from the implicit Scope of the categories, thus allowing increased retention of generalities.

## General Discussion

Revising our beliefs when we are confronted with conflicting information is ubiquitous. Yet, the cognitive processes underlying this kind of reasoning are poorly understood because the prevailing research has not studied belief revision with consistent content. Some tasks have used artificial content, with no relational structure among the beliefs. In others, the artificial beliefs have been part of simple assertions or immersed in stories. In cases where presumed beliefs have been used, they are often not verified. The present study created belief revision conditions where the meaning of the statements and the degree to which they could be interpreted as scientific laws-their Scope-have been independently verified along with reasoners’ commitment to them.

By controlling the Scope of statements, we were able to identify the importance of the logical structure in which the belief revisions are contained. In an MT structure, reasoners prefer to revise their beliefs by retaining the most law-like generalities and by eliminating the particular statements that are inconsistent with the generalities. For the MT structure, the Scope of the generalization predicts the tendency to retain these true statements: the greater the Scope, the more likely will the generalization be retained. In contrast, when the epistemic structure is cast as an MP argument, reasoners do not show a preference for generalities or facts nor does Scope play an appreciable role.

Belief on its own is not critical to the belief revision process. We know this because the MT problems employed the same generalities as the MP problems, yet the former were retained significantly more often than the latter. These
findings show that critical to belief revision are the dual factors of (a) a statement's Scope and (b) the argument's structure in which the statement is immersed. Neither factor alone is sufficient to account for how people revise a set of beliefs. This leaves the question of why these two factors should dictate the belief revision process.

Pursuant to David Lewis' theory of Possible Worlds (Lewis, 1973, 1986), we propose that when revising their epistemic system, reasoners imagine an organized possible world, closest to the current one. To accomplish this, they rank-order the beliefs in terms of degrees of necessity, with the law-like propositions given the highest ranking. In MT, the general statement tends to be the one with the greatest Scope and is the starting point in the revision process with the deletion of any statement inconsistent with it. In contrast, in MP, the assumption statement challenges the modal status of the generality, diminishes its ranking, and rending all statements equivalent (Rescher, 1963, 2007). As a result, no preference for retaining any statement is revealed. In this case, the generalizations in MP problems do not possess the same commitment post-assumption as they do pre-assumption. Hence, Scope is less predictive of the decisions to retain statements in these problems. However, when the context is rendered artificial (as with a locative) it enhances sensitivity to the implicit modal status of the generalization even in the MP logical structures.

The relation between believability of statements and the logic of the belief revision context can be explained by the Conditional Probability Hypothesis (e.g., Evans, Handley, \& Over, 2003; Wolf et al., 2012). It states that for MP problems, the probability of the truth of the generality is zero in the face of the counterfactual assumption. To understand this, recall MP example (2) above:
(2a) All whales are mammals
(2b) This creature is a whale
(2c) This creature is a mammal
(2d) Assume that this creature is not a mammal
The conditional probability of the generality is stated as $P(\mathrm{q} \mid \mathrm{p})=$ probability of "mammal" given the rule stated conditionally as "if whale, then mammal". The assumption statement (2d) states that the probability of being a mammal is zero. Therefore, $P(\mathrm{q} \mid \mathrm{p})=0$; therefore the probability that the rule is true is also zero. This leads to the expectation that there will be no discernible preference for retaining either the generality or the particular statement in MP. In contrast, consider the case of the MT argument repeated below:
(1a) All whales are mammals
(1b) This creature is not a mammal
(1c) This creature is not a whale
(1d) Assume that this creature is a whale
In the case where the a priori belief in the generality is greater than zero, the assumption does not alter that. Therefore, the preference for the generalities in this MT structure will typically be greater than what is found for MP. This will be true even though the general statements are syntactically identical in the two logical structures. In brief, the conditional probability hypothesis is able to account for
the typical finding that belief revision varies with logical structure, all things being equal.

However, the contrasting preferences shown in Experiments 1 and 2 are not readily explained by the conditional probability hypothesis. The retention of the generalities in Experiment 2 is reliably greater than those in Experiment 1 and this is especially the case for MP. The problems differ in the presence of a locative in Experiment 2, which is intended to reduce the law-like properties of the generality by reminding the reasoner that the truth of these statements may be limited in space and time. These locatives should also reduce the a posteriori probability of the inclusive category (e.g., "mammal") and reduce the retention of generalities especially in MP. The procedure produced the opposite result. So, while the conditional probability hypothesis has much to recommend it as an account for belief revision, more work needs to be done to understand the cognitive processes contributing to the retention of beliefs.

A second account of belief revision has focused on Disabling Conditions. The claim has been made that in the face of the counterfactual assumption, reasoners construct explanations for the inconsistencies (Khemlani \& JohnsonLaird, 2011). These explanations focus on the generalizations because they contain many component elements and reasoners imagine that one of these elements has been disabled, thereby allowing for an inconsistency. The degree to which such disabling conditions are contrived is indirectly related to the strength of belief in the generality. This approach makes the following predictions: (a) generalities will be rejected in order to retain consistency in the epistemic set; (b) since rejection of the generalities are based on believability, the disabling conditions (and therefore rejection of the generality) will be equivalent across logical structure.

These predictions are not consistent with the present findings. Overall, generalities are retained more often than would be expected by chance. Generalities whose Scope is artificially low (Experiment 3) should show the effect of disabling conditions more so than when the Scope is artificially high, yet no difference in retention is shown for these types of statements. While the presence of potential disabling conditions may play a role in some aspects of belief-revision, it is clearly not the underlying mechanism employed for confronting the counterfactual assumptions.

## Conclusion

We are obliged to revise our system of beliefs when we accept a new piece of information that introduces an inconsistency into our knowledge structure. Here we are faced with the task of retaining some old information and rejecting others. The present study examined how people perform this task when dealing with real beliefs and facts.

Scope and Logical Structure were jointly important predictors of whether students would retain a statement when required to revise their epistemic sets. When the statements fit within an MT structure, reasoners organized
their revisions around the law-like generalizations. In contrast, when the statements fit within an MP structure, the participants did not show a preference in how they organized their beliefs. This suggests that the importance of belief strength is influenced by the structure in which they are immersed.

These findings lend empirical support to the philosopher David Lewis' view that belief revision is characterized by Possible Worlds logic in which reasoners structure their revisions by organizing their epistemic systems so as to give priority to the most law-like statements.

## Acknowledgments

The authors would like to thank Desiree I. Garcia for all her hard work during data collection.

#### Abstract

By 8 months of age, infants use statistical regularities and perceptual cues to orient attention (e.g. Kirkham et al., 2007; Wu \& Kirkham, 2010). However, it is unclear whether infants are sensitive to the reliability of individual attentional cues. In this eye-tracking study, 8 -month-olds were familiarized with a reliable face, which always looked to a box where an animation appeared, and an unreliable face, which looked only $25 \%$ of the time to the box containing the animation. At test, when the animations did not appear, infants searched longer in the corner cued by the reliable face, but did not search longer in the corner cued by the unreliable face. These results suggest that even young infants can track the the reliability of potential informants and use this information to distribute attention in support of early learning.

Keywords: Psychology; attention; spatial cognition; infancy; eye-tracking

## Introduction

For young infants, the natural world is a constant stream of dynamic, multi-modal sensory experiences. In a short time, they are able to parse this sensory overload into discrete and recognizable objects, faces, and events. Selective attention plays a critical role in this early learning, as infants must focus on items that contain useful information while ignoring random variation and meaningless noise. A number of studies have demonstrated that infants can allocate attention selectively in support of task-relevant learning (Mareschal \& Johnson, 2003; Richardson \& Kirkham, 2004; Tummeltshammer \& Kirkham, in press; Wu \& Kirkham, 2010). However, the selection process by which they are able to filter relevant information from noise is less well understood.

Given that the natural world contains a high degree of statistical redundancy, showing considerable consistency across space and time (Field, 1994), and there is evidence that the developing response properties of some visual neurons exploit the statistical nature of the input (Olshausen \& Field, 1996), it would be advantageous for the system to selectively attend to statistically reliable and coherent events. Research with young infants robustly shows that they are sophisticated statistical learners, tracking
probabilistic events across multiple instances and updating their representations of the world based on incoming data (Fiser \& Aslin, 2002; Kirkham et al., 2002; Kirkham et al., 2007; Saffran, Aslin \& Newport, 1996; Smith \& Yu, 2008; Wu, Gopnik, Richardson, \& Kirkham, 2011).

Recent studies have demonstrated that infants distribute attention selectively based on statistical information (Kidd, Piantadosi, \& Aslin, 2012; Tummeltshammer \& Kirkham, in press), which may guide early learning of events and features that are reliably linked. For example, new evidence from Kirkham and colleagues (2012) shows that young infants prefer to look at objects with correlated rather than uncorrelated parts and are surprised when statistically coherent parts split apart (Wu, et al., 2011). Infants also deploy attention with the influence of external cues, including bottom-up perceptual salience and even abstract cue-target associations (Cohen, 1972; Colombo, 2001; Johnson, Posner, \& Rothbart, 1991; 1994; McMurray \& Aslin, 2004). If these cues contain reliable information, then they may guide the infant toward learnable content; however, a mismatch between external cues and statistical coherence may drive infants to distraction and prevent them from encoding the critical stimulus events. A few studies have shown that young infants will use central cues to orient attention to peripheral locations when individual cues and targets are perfectly correlated (Johnson, Posner \& Rothbart, 1991; McMurray \& Aslin, 2004). At present, however, there is little evidence to address whether infants use statistical information to evaluate the reliability of salient attentional cues.

Faces offer a good opportunity to test whether attention to salient cues is mediated by statistical reliability. From birth, infants are drawn to faces, particularly those expressing eye contact (Senju \& Johnson, 2009), and very young infants will orient faster to visible targets in the direction of an adult's gaze (Farroni, Massaccesi, Pividori, \& Johnson, 2004; Hood, Willen, \& Driver, 1998). Infants follow faces from 4 months of age, and are sensitive to the relationship between an adult's gaze and the locations of objects (D’Entremont, 2003; Senju, Csibra, \& Johnson, 2008). Indeed, there is recent evidence that infants learn better
from faces than other attention-directing cues (e.g., flashing lights; Wu \& Kirkham, 2010). It is unclear whether infants follow faces as a category of salient attentional cues or perhaps have a general expectation that faces will provide information. It remains an empirical question whether infants track the statistical coherence of associations between cues and their targets, and further, whether they can update their expectations of individual face cues to guide attention optimally.

Research on 'selective trust'/‘source monitoring' with young children has demonstrated that they take an informant's knowledge into account when soliciting or accepting new information. Preschoolers prefer to engage with informants who are knowledgeable rather than ignorant (Koenig \& Harris, 2005), and will extend labels to novel objects when they were provided by a reliable rather than an unreliable adult (Clement, Koenig, \& Harris, 2004; Koenig, Clement, \& Harris, 2004). This work has recently been extended down to older infants: In a recent study, Begus and Southgate (2012) found that 16 -month-olds point more to solicit information from adults who had previously labeled objects correctly than from those who had mislabeled objects. In addition, across two studies, Poulin-Dubois and colleagues found that 14 -month-olds were sensitive to an adult's reliability in a search task, and were more likely to follow a reliable adult's gaze behind an occluder (Chow, Poulin-Dubois, \& Lewis, 2008) and to imitate a reliable adult's actions (Poulin-Dubois, Brooker, \& Polonia, 2011). These studies suggest that infants as young as 14 months can make an association between an informant's actions and the true state of the world and use it to guide their own responses.

There are, however, some reasons to suspect that young infants may have difficulty tracking the reliability of face cues and allocating attention accordingly. First, while young children may be sensitive to the reliability of an informant, young infants may not attend to the relationship between a salient cue and its target outcome. This could be due to a general bias to follow faces, or the inability to simultaneously attend to the face cue and keep track of its reliability over trials. Second, young infants may have difficulty making within-category distinctions; even if they could successfully track the reliability of a category of attentional cues (e.g. 'Faces offer reliable information'), infants may fail to make separate inferences for individual instances of the same category (e.g. 'Face A is reliable, but Face B is not'). Third, young infants may form initial associations between cues and targets that are difficult to update in light of noisy data. In all of the studies described with young children, the unreliable or ignorant adults always provided false or incongruent information, so children may have simply represented those adults as 'wrong' or 'unsuccessful' without having to update their inferences.

The present eye-tracking study aimed to investigate whether 8 -month-old infants are sensitive to the statistical
reliability of attentional cues. Infants were familiarized with four audio-visual animations of animals that appeared within four boxes in each corner of the screen. On separate trials, the locations of the animals were cued by either a reliable or an unreliable face. The reliable face always looked in the box where an animal would then appear, while the unreliable face looked in the box containing an animal only $25 \%$ of the time (and rather, looked in an empty box $75 \%$ of the time). Following familiarization, infants viewed test trials in which the faces looked in the previously-cued boxes and the animal sounds played, but the animations did not appear. If infants had learned to expect an animation in the cued box, then we hypothesized that they should search longer in the cued box than in the uncued boxes. In addition, infants viewed generalization trials in which the faces looked to boxes that were never cued before and novel animal sounds played, but again no animations appeared. If 8 -month-old infants were able to track the reliability of the individual faces across trials, then we hypothesized that they should follow the reliable face to a new box, but abstain from following the unreliable face.

## Methods

## Participants

Twenty-four 8 -month-old infants (11 females, $M=8$ months 13.4 days, range: $7 \mathrm{~m} 12 \mathrm{~d}-9 \mathrm{~m} 7 \mathrm{~d}$ ) participated in the experiment, with an additional four infants tested but not included due to fussiness, inattention and/or failure to calibrate. Infants were recruited on a voluntary basis via local advertisements. Informed consent was received from all caregivers, and babies received a small gift.

## Apparatus and Stimuli

Infants were eye-tracked using a Tobii TX300 eye-tracker (www.tobii.com) with a 23 " built-in monitor. Stimuli were presented using Tobii Studio presentation software, and sounds were played through stereo external speakers. Throughout testing, infants were monitored via a built-in video camera and their eye movements through the Tobii Studio Live Viewer display. Two female actors were filmed in controlled settings and their footage was edited into face cue stimuli in Final Cut Express HD3 (Apple Inc., CA). The animated clips were created using Macromedia Director MX 2004 and combined with the face cues in Final Cut Express.

Infants saw a full-screen display (1920 X1080 pixels) comprised of four white boxes in the four corners of a black screen. Within each box, an animated animal appeared: a barking dog in Box 1, a croaking frog in Box 2, a gurgling fish in Box 3, and a chirping bird in Box 4. The animations were preceded by centrally presented face cues. On each trial, one of two female faces appeared in the center, smiled at the infant and said "Wow, look!". She then turned to one of the boxes and froze. An animal sound played and after a 500 ms delay, the corresponding animal appeared in its box. The animated animal moved within the box for 3.5 seconds, while the face remained frozen, as shown in Figure 1.

Figure 1. Examples of four familiarization trials with a reliable face cue (left) and four familiarization trials with an unreliable face cue (right). While the reliable face always looked to the correct box, where an animal would appear, the unreliable face only looked to the correct box on one out of four trials.

## Design and Procedure

All infants were tested individually in a quiet room, seated on their caregiver's lap approximately 60 cm away from the monitor. A 5-point calibration sequence (the four corners and center of the screen; for details, please refer to von Hofsten, Dahlström, \& Fredricksson, 2005) was used to obtain a reliable signal. Infant needed to fixate each point before the experimenter manually advanced the calibration sequence; if fewer than four points were accurately calibrated, the sequence was repeated.

Following successful calibration, infants were familiarized with a reliable face and an unreliable face on separate blocks (order counter-balanced across infants). The reliable face always looked at the box in which an animal animation would appear, reliably cueing two different boxes on separate trials. The unreliable face also cued two different boxes on separate trials, but only looked $25 \%$ of the time at the box containing an animation; that is, for the unreliable face, the animals often appeared in boxes that did not correspond to where the face had looked. For example, if the reliable face looked in Boxes 1 and 2 on four separate trials, either the $\operatorname{dog}$ (Box 1) or the frog (Box 2) would appear to match where the face had cued (see Figure 1A). However, if unreliable face looked in Boxes 1 and 3 on four separate trials, either the frog (Box 2) or the fish (Box 3) would appear, so that the cue and animation only matched on one of the four trials (see Figure 1B). Critically, one box was only cued by the reliable face, a second box was cued by both faces on separate trials, a third box was only cued by the unreliable face, and the last box was never cued.

Following familiarization, infants viewed test trials and generalization trials. On a test trial, the face looked to the box it had previously cued (whether reliably or unreliably) and the animal sound played; however, the animation did not appear. Instead, all four white boxes flashed briefly (200 ms ) to encourage infants to make a saccade. On a
generalization trial, the face looked to the box it had never looked at before and a new animal sound played. Again, no animation appeared, but all four white boxes flashed briefly to encourage saccades.

Infants viewed four blocks of four familiarization trials, with the reliable and unreliable faces on alternating blocks, followed by the two test blocks. This sequence was then repeated, for a total of 40 familiarization ( 20 reliable, 20 unreliable), 4 test, and 4 generalization trials ${ }^{1}$.

## Data Analysis

Eye movements were recorded and filtered into discrete fixations using a spatial filter of 30 pixels and a temporal filter of 100 ms . On test and generalization trials, when all four boxes flashed but no animations appeared, accumulated looking times (i.e. the summed durations of all fixations) to each of the four boxes were measured as a proportion of total looking time.

## Results

## Familiarization Trials

There were no differences in infants' attention to the faces (i.e. proportion of total accumulated looking time spent on the face) across familiarization trials, suggesting that infants looked equally to the reliable face $(M=0.609, S E=0.017)$ and the unreliable face $(M=0.621, S E=0.016)$, paired $t(23)=1.02$, $p=n s$.

[^223]
## Test Trials

Proportions of looking time to the four boxes during test trials, displayed in Figure 2, were analyzed with a 2 (Reliability) x 4 (Box) repeated measures ANOVA ${ }^{2}$. Results show a significant main effect of Box, $F(3,66)=3.64$, $p=0.017, \eta_{p}{ }^{2}=0.142$, as well as a significant Reliability x Box interaction, $F(3,66)=3.55, p=0.019, \eta_{p}{ }^{2}=0.139$. This interaction was unpacked using separate univariate ANOVAs for test trials with reliable and unreliable face cues. On reliably cued trials, a significant main effect of Box was apparent, $F(3,66)=8.32, p<0.001, \eta_{p}{ }^{2}=0.274$, and post-hoc comparisons indicated that infants looked longer at the cued box than at any other box, $p<0.040$ (Bonferronicorrected). However, on unreliably cued trials, no effect of Box emerged, $F(3,66)=0.21, p=0.888$, indicating that infants did not look longer at the cued box, nor at any other single box. Finally, a planned comparison across reliably and unreliably cued test trials confirmed that infants looked more to the cued box when it was cued by a reliable face than by an unreliable face, $t(22)=2.66, p=0.014$.

Figure 2. Mean proportions of looking time to the four boxes on test trials with the reliable and unreliable face cues.

## Generalization Trials

Similarly, proportions of looking time to the four boxes during generalization trials, shown in Figure 3, were analyzed with a 2(Reliability) x 4(Box) repeated measures ANOVA ${ }^{3}$. Results show a slight main effect of Box, $F(3,63)=2.70, p=0.053, \eta_{p}{ }^{2}=0.114$, as well as a significant Reliability x Box interaction, $F(3,63)=9.83, p<0.001$, $\eta_{p}{ }^{2}=0.319$. This interaction was explored using separate univariate ANOVAs for generalization trials with reliable and unreliable face cues. On reliably cued trials, a significant main effect of Box emerged, $F(3,63)=12.39$, $p<0.001, \eta_{p}{ }^{2}=0.379$, and post-hoc comparisons indicated that infants followed the cue to the new box, looking longer

[^224]at the new box than at any other box, $p<0.024$ (Bonferronicorrected). However, on unreliably cued trials, no effect of Box was apparent, $F(3,63)=0.40, p=0.754$, indicating that infants did not follow the cue to the new box, nor did they look longer at any other single box. Finally, a planned comparison across reliably and unreliably cued generalization trials confirmed that infants followed the cue to the new box more when it was a reliable face cue than an unreliable face cue, $t(21)=4.20, p<0.001$.

Figure 3. Mean proportions of looking time to the four boxes on generalization trials with the reliable and unreliable face cues.

## Discussion

Previous research has demonstrated that young infants are sensitive to statistical and perceptual cues and can use them to allocate attention in their busy, multisensory world. The present study suggests that infants can also integrate these sources of information to infer the reliability of individual cues and modify their responses. In the current study, infants searched consistently in the box cued by the reliable face, and even followed it to search in a box where no animation had appeared before. At the same time, infants did not follow the unreliable face, and rather searched at chance among all four boxes. These differences in looking behavior could not be accounted for by mere differences in global attention, as infants looked equally long at both reliable and unreliable face cues during familiarization trials.

Cue reliability also appeared to have important consequences for infants' audio-visual learning. Infants correctly predicted where a reliably cued animal would appear, but did not learn to localize the animal that had been unreliably cued. This study adds to a growing body of research suggesting that appropriate cues can enhance infants' processing and learning of cued events (Reid, Striano, Kaufman, \& Johnson, 2004; Senju, Csibra, \& Johnson, 2008; Yoon, Johnson, \& Csibra, 2008; Wu \& Kirkham, 2010). For example, Wu and Kirkham (2010) found that 8 -month-olds were better able to remember the spatial locations of audio-visual targets preceded by social cues compared to uncued targets. It is possible that infants' sensitivity to reliable cues may act as a driving force for
early learning, with cued attention helping the learner gather information and integrate it over time (Smith, Colunga, \& Yoshida, 2010). Indeed, enhanced detection and processing of cued stimulus events are well-documented in studies of selective attention with adults and children (Goldberg, Mauer, \& Lewis, 2001; Mackintosh, 1975; Posner, 1980).

While the present results suggest that infants are sensitive to the reliability of attentional cues, it remains unknown whether this sensitivity is face-specific or would extend to other types of cues. A few studies have shown that infants struggle to direct attention with a non-social central cue (Varga et al, 2009), though they seem to succeed in learning the cue-target relationship when the cue is perceived as social (Corkum \& Moore, 1998; Deligianni, Senju, Gergely, \& Csibra 2011; Johnson, Slaughter, \& Carey, 1998; Wu \& Kirkham, 2010). However, in these studies, cues have been used to direct infants' attention to one of multiple objects, with the result that infants look equally to both cued and uncued objects. Perhaps, then, infants need to learn the function of an abstract, non-social cue with a singular target (as in McMurray \& Aslin, 2004) before it can be used to disambiguate multiple targets. Future experiments will aim to evaluate whether infants consider the statistical reliability of attentional cues more broadly.

The mechanisms driving statistically cued attention are also unclear and worth investigating in future research. A modelling approach, using infants' own trial-by-trial data as input (cf. Piantadosi, Kidd, \& Aslin, in press; Yurovsky, Hidaka, \& Wu, 2012), may help to characterize the multiple processes involved in statistical learning of cued events, such as selective attending to cues and targets, tracking the correspondence between them, and deciding which cues to follow. Further, it would be interesting to distinguish whether infants' selective attention to cued events is motivated by the prospect of an exciting reward, or if there may be something intrinsically motivating about the predictive information itself. Bromberg-Martin and Hikosaka (2009) found that macaque monkeys prefer to have predictive cues rather than unpredictive cues, even when the ensuing rewards were identical. In the present study, infants received audio-visual animations on both reliably cued and unreliably cued trials, but did not develop a preference for the reliable (or unreliable) face. This may be due, in part, to the salience of the faces, or perhaps because infants were not trained to make a choice between cues as the monkeys were in Bromberg-Martin and Hikosaka (2009). Nevertheless, future research will aim to explore interactions in cued attention between the reliability of the cue and the salience of the reward.

## Conclusions

The present study demonstrates that 8 -month-olds can distinguish reliable and unreliable faces and use this inference to modify attention to cued targets. These results extend the existing literature on 'selective trust'/ssource monitoring' to young infants, suggesting that a sensitivity to the reliability of potential informants may be present early
in development. Selective trust, like selective attention, is influenced by statistical regularity, external cues, and the extent to which these factors are weighted in a particular context. This study has provided evidence that 8 -month-old infants can track the reliability of individual cues to deploy attention optimally in support of early learning.

## Acknowledgments

We thank Irati Rodriguez Saez de Urabain, Leslie Tucker, \& Marian Greensmith for their help with testing and recruitment. This work was funded in part by a grant from the Nuffield Foundation to NZK, and by Grant G0701484, awarded to Mark Johnson by the UK Medical Research Council.

#### Abstract

We study structural properties of a turn-based game called the Marble Drop Game, which is an experimental paradigm designed to investigate higher-order social reasoning. We show that the cognitive complexity of game trials, measured with respect to reaction time, can be predicted by looking at the structural properties of the game instances. In order to do this, we define complexity measures of finite dynamic two-player games based on the number of alternations between the game players and on the pay-off structure. Our predictions of reaction times and reasoning strategies, based on the theoretical analysis of complexity of Marble Drop game instances, are compared to subjects' actual reaction times. This research illustrates how formal methods of logic and computer science can be used to identify the inherent complexity of cognitive tasks. Such analyses can be located between Marr's computational and algorithmic levels.

Keywords: cognitive difficulty; strategic games; higher-order social reasoning; theory of mind

## Introduction

In recent years, questions have been raised about the applicability of logic and computer science to model cognitive phenomena (see, e.g., Frixione, 2001; Stenning and Van Lambalgen, 2008; Van Rooij, 2008). One of the trends has been to apply formal methods to study the complexity of cognitive tasks in various domains, for instance: syllogistic reasoning (Geurts, 2003), problem solving (Gierasimczuk et al., 2012), and natural language semantics (Szymanik and Zajenkowski, 2010). It has been argued that with respect to its explanatory power, such analysis can be located between Marr's (1983) computational and algorithmic levels.

More recently, there has also been a trend to focus on similar questions regarding social cognition, more specifically, theory of mind. Especially, higher-order reasoning of the form 'I believe that Ann knows that Peter thinks ...' became an attractive topic for logical analysis (Verbrugge, 2009). Here, the logical investigations often go hand in hand with game theory (see, e.g., Osborne and Rubinstein, 1994). In this context, one of the common topics among researchers in logic and game theory has been backward induction (BI), the process of reasoning backwards, from the end of the game, to determine a sequence of optimal actions (Van Benthem, 2002). Backward induction can be understood as an inductive algorithm defined on a game tree. The BI algorithm tells us which sequence of actions will be chosen by agents that want to maximize their own payoffs, assuming common knowl-
edge of rationality. In game-theoretical terms, backward induction is a common method for determining sub-game perfect equilibria in the case of finite extensive-form games. ${ }^{1}$

Games have been extensively used to design experimental paradigms aiming at studying social cognition (Camerer, 2003), recently with a particular focus on higher-order social cognition: the matrix game (Hedden and Zhang, 2002), the race game (Gneezy et al., 2010; Hawes et al., 2012), the road game (Flobbe et al., 2008; Raijmakers et al., 2013), and the Marble Drop Game (henceforth, MDG) (Meijering et al., 2010, 2011, 2012). All the mentioned paradigms are actually game-theoretically equivalent. They are all finite extensiveform games that can be solved by applying BI. As an example in this paper we will consider MDG (see Fig. 1).

Many studies have indicated that application of higherorder social reasoning among adults is far from optimal (see, e.g., Hedden and Zhang, 2002; Verbrugge and Mol, 2008). However, Meijering et al. $(2010,2011)$ report on a near ceiling performance of subjects when their reasoning processes are facilitated by, for example, a step-wise training. Still, an eye-tracking study of the subjects solving the game suggests that backward induction is not necessarily the only strategy used (Meijering et al., 2012).

We still do not know exactly what reasoning strategies ${ }^{2}$ the subjects are applying when playing this kind of dynamic extensive form games. One way to use formal methods to study this question has been proposed by (Ghosh et al., 2010; Ghosh and Meijering, 2011): to formulate all reasoning strategies in a logical language, and compare ACT-R models based on each reasoning strategy with a subject's actual performance in a sequence of games, based on reaction times, accuracy and eye-tracking data. This corresponds to a study between the computational and algorithmic levels of Marr's (1983) hierarchy.

[^225]

Figure 1: Examples of a zero-, first-, and second-order Marble Drop game. The blue marbles, on the left-hand side in the bins, are the participant's payoffs and the orange marbles, on the right-hand side, are the computer's payoffs. The marbles can be ranked from the lightest to the darkest. For each player, the goal is to get the white marble to drop into the bin with the darkest possible marble of their color. The participant controls the blue trapdoors (i.e., blue diagonal lines) and the computer controls the orange ones (the second set of trapdoors from the left). The participants are told that the computer aims at maximizing its pay-off. The dashed lines represent the trapdoors that both players should remove to attain the darkest possible marble of their color. See http://www. ai.rug.nl/~meijering/marble_drop.html for an interactive demo. Backward induction reasoning proceeds from the last decision, which in 1c is Player 1's decision between the blue marbles in payoff-pairs C and D. Player 1 would decide to remove the left trapdoor because $C$ contains the darker blue marble. Backward induction would then proceed with the second-to-last decision, which is Player 2's decision between the orange marbles in payoff-pairs B and C. Player 2 would decide to remove the left orange trapdoor, because B contains the darker orange marble. Backward induction reasoning stops at the third-to-last decision, which is Player 1's decision between the blue marbles in payoff-pairs A and B. Player 1 would remove the right blue trapdoor, because B contains the darker blue marble.

Here, we aim to tackle the problem from a somewhat more generic, complexity-theoretic viewpoint: we propose to study the problem on the computational level. Specifically, we will identify inherent, structural properties of the game that make certain MDG trials harder than others.

## Alternation type

Every instance of a finite extensive form game can be presented as a decision tree. The second-order trials of MDG have the abstract tree form presented in Fig. 2.

How to approximate the complexity of a single instance of MDG? In the worst-case scenario, the backward induction algorithm, based on breadth-first search from the leaves of the tree upwards, will have to travel through all the nodes of the decision tree. Thus, it will find the rational solution (Nash Equilibrium) in time and space proportional to the number of nodes plus the number of edges in the tree, $O(|V|+|E|)$. However, the size of the tree does not seem to be a psychologically plausible complexity measure. To see this, consider two trees of equal size, but in the first one all the nodes are

Figure 2: Nodes $s$ and $u$ are controlled by Player 1. $t$ is controlled by Player 2. If a player controls a node then in that node he can choose whether to go left, $l$, or right, $r$. Every leaf is labeled with the pay-offs for Players 1 and 2.
controlled by Player 1 while in the second tree, the players alternate. Obviously, the problem posed by the second tree is much more complex. This suggests that one of the key aspects of the problem is the structure of the move alternation in the game tree. Let us then categorize game trees with respect to such alternations. In the following, we restrict the analysis to two-player games, although it would be possible to extend the ideas to finite dynamic games for more than two players.

Definition 1 Let us assume that the players $\{1,2\}$ strictly alternate in the game; Let player $i \in\{1,2\}$. Then:

- In a $\Lambda_{1}^{i}$ tree, all the nodes are controlled by Player $i$.
- $A \Lambda_{k+1}^{i}$ tree, a tree of $k$-alternations for some $k \geq 0$, starts with a Player i node. ${ }^{3}$

For instance, the tree in Fig. 2 is $\Lambda_{3}^{1}$, a 1-game tree of 2 alternations, because Player 1 has the first move at the root, followed by an alternation of Player 1 to Player 2 and another alternation of Player 2 to Player 1.

## Pay-off structure and cognitive difficulty

From the psychological perspective, it seems really crucial to take pay-offs into account when comparing the difficulty of particular MDG tasks. For instance, the two trees from Fig. 3 are $\Lambda_{3}^{1}$, because they both start with Player 1 and both have two alternations, from Player 1 to Player 2 and back again. However, clearly, the first game, represented by $T_{1}$, is much easier for Player 1 than the second game, represented by $T_{2}$. In the first game it is enough for Player 1 to realize that 999 is the highest possible pay-off, and then he can instantly move left and finish the game.

To explain the eye-tracking data of the subjects solving the Marble Drop game, Meijering et al. (2012) suggest that subjects may be using forward reasoning with backtracking (henceforth FRB), based on statistical analysis of eye gaze sequences. For instance, in the game from Fig. 1c, Player 1 will find out that B contains the darkest blue marble. He has to ask himself whether that marble is attainable. In other words, he

[^226]

Figure 3: Two $\Lambda_{3}^{1}$ trees.
has to reason about whether Player 2 would remove the left orange trapdoor. Therefore, Player 1 has to look at the orange marbles in bins $\mathrm{B}, \mathrm{C}$ and D to find out that bin D contains Player 2's darkest orange marble. The reasoning continues with Player 1 asking himself whether Player 2 thinks that her orange marble in bin D is attainable. In other words, Player 1 has to reason about whether she thinks that he would remove the right blue trapdoor of the rightmost set of trapdoors. Player 1 knows that he would not remove that trapdoor, but that he would remove the left one instead. He also knows that she is aware of this, as both players are aware of each other's goals. Therefore, Player 1 knows that Player 2 knows that her darkest orange marble in D is unattainable. Therefore, Player 1 has to go back to the second decision point (i.e., the orange trapdoors). There, Player 2 would compare the orange marbles in B and C and decide to remove the left orange trapdoor, because the orange marble in $B$ is the darkest orange marble that she can still attain. To conclude, Player 1 knows that his darkest blue marble in $B$ is attainable, and will thus remove the right blue trapdoor of the leftmost set of trapdoors.

As it is relatively hard to conclude from the eye-tracking data whether subjects apply exactly the above described forward reasoning with backtracking, we propose an orthogonal idea. We aim to identify the properties of the games that make certain trials harder than others and see whether such an explanation is congruent with forward reasoning plus backtracking. In order to do that, we put forward the following definitions. The idea here is that subjects may be looking for the highest possible pay-off and then try to reach it.

Definition 2 A game $T$ is generic, if for each player, distinct end nodes have different pay-offs.

Note, for instance, that the game in Figure 1c is generic: the four bins contain marbles of four different hues of blue
and four different hues of orange.
Definition 3 Suppose $i \in\{1,2\}$. If $T$ is a generic game tree with the root node controlled by Player $i$ and $n$ is the highest possible pay-off for Player $i$, then $T^{-}$is the minimal subtree of $T$ containing the root node and the node with pay-off $n$ for Player i.

To illustrate this definition, Figure 4 shows the restricted $T^{-}$trees for the two trees shown in Figure 3.
Hypothesis 1 Let us take two MDG trials $T_{1}$ and $T_{2} . T_{1}$ is easier for participants than $T_{2}$ if and only if $T_{1}^{-}$is lower in the tree alternation hierarchy than $T_{2}^{-}$.

Hypothesis 1 takes into account pay-off structures. According to it, the first tree from Fig. 3, $T_{1}$, should be easier for participants than the right tree, $T_{2}$, as $T_{1}^{-}$is a $\Lambda_{1}^{1}$ tree while $T_{2}^{-}$is still $\Lambda_{3}^{1}$, see Fig. 4. Moreover, it is possible that some subjects may try to apply the procedure iteratively: check if the maximum pay-off is reachable, if not then check for the second-best pay-off, and so on.

Figure 4: The maximum pay-off restricted trees corresponding to the trees in Fig. 3.

As an additional question, we ask whether the following predictions agree with the proposal of Meijering and colleagues (Meijering et al., 2012) that the subjects in the game are applying forward reasoning, with backtracking when necessary (FRB). First of all, why would subjects ever apply FRB?

Hypothesis 2 For an average random game with 3 decision points structured as the $\Lambda_{3}^{1}$ game of Figure 2, the forward reasoning plus backtracking algorithm needs fewer computation steps to yield a correct solution than backward induction.

Furthermore, if subjects used forward reasoning, then we could observe the following by running FRB algorithm on the game trees:
Hypothesis 3 Let us take two MDG trials $T_{1}$ and $T_{2}$. The forward induction with backtracking algorithm yields a correct solution for $T_{1}$ faster than for $T_{2}$ if and only if $T_{1}^{-}$is lower in the tree alternation hierarchy than $T_{2}^{-}$.

## Experimental results

To experimentally corroborate our hypotheses, we analyzed performance and reaction time data from (Meijering et al.,
2012). Twenty-three first-year psychology students (14 female) with a mean age of 20.8 years (ranging from 18 to 24 years) participated in the experiment and were asked to solve Marble Drop trials, in the sense that they had to make a decision 'left' or 'right' at the first decision point. All experimental game trials had payoff structures that required Player 1 to reason about the decision at each of the three decision points, structured as the $\Lambda_{3}^{1}$ game of Figure 2. Therefore, the experiment was constructed in a way to be diagnostic for second-order theory of mind (see Meijering et al., 2012, for more information on the experimental design).

We divided experimental trials into two sets: Accessible ones, in which the highest possible pay-off for Player 1 is obtainable for him and Inaccessible ones, where his highest possible pay-off is not obtainable. For example, the game of Figure 1c is accessible, because Player 1 can reach the marble of the darkest hue of blue, which is located in bin B, by opening the right trapdoor; after all, Player 2 will also choose to stay there. Note that in general, if $T_{1}$ represents an accessible game and $T_{2}$ an inaccessible one, then $T_{1}^{-}$is lower in the alternation hierarchy than $T_{2}^{-}$.

Therefore, according to Hypothesis 1, our prediction was that the shortest reasoning times will be recorded in the condition "Accessible", where the highest pay-off was obtainable for Player 1.

Furthermore, by simulating forward reasoning with backtracking on experimental trials and computing the number of reasoning steps, we investigated hypotheses 2 and 3. Again, our prediction was that the number of steps should be smaller in "accessible" cases, where the highest-possible pay-off for Player 1 was obtainable.

## Hypothesis 1: pay-offs and alternation type

To investigate the first hypothesis, we compared reaction times (RTs) in games in which the highest payoff was accessible against RTs in games in which the highest payoff was not accessible. The RTs were log-transformed to approximate the normal distribution.

A paired-samples t-test indicated a significant (withinsubjects) difference, $\mathrm{t}(12)=4.07, \mathrm{p} ; .01$. The RTs decrease if the maximum payoff is accessible, which can be seen in Figure 5.

## Hypothesis 2: simulating the algorithms

When looking at all possible payoff-structures in Marble Drop games with two alternations (or three decision points), we implemented the forward reasoning plus backtracking algorithm as a set of heuristics based on several cases that can occur in the Marble Drop game; we used the same algorithm that we derived in (Meijering et al., 2012) from the participants' eye-tracking data. ${ }^{4}$

When using the algorithm on all 576 possible pay-off structures, we see that forward reasoning with backtracking in

[^227]

Figure 5: Players' reaction times with respect to accessibility, namely the attainability of the highest payoff for Player 1.
general requires fewer steps than backward induction, e.g., in 288 cases only 1 step is enough. More specifically, forward reasoning with backtracking requires on average 3 steps, whereas backward induction would always require 6 steps, irrespective of payoff structure. Table 1 provides a cross-table of payoff structures and number of steps. This simulation supports our Hypothesis 2.

Table 1: Cross-table of payoff structures and the necessary number of steps when using forward reasoning with backtracking.

| \# of steps | 1 | 2 | 4 | 5 | 6 | 8 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| \# of payoff structures | 288 | 72 | 48 | 56 | 16 | 96 |

These simulation results imply that, on average, it pays off to use a forward reasoning strategy. In fact, Meijering et al. (2012) found a strong prevalence of forward reasoning with backtracking, even though participants were presented with a subset of hard-to-solve games in which backward induction would actually be more efficient on average. However, participants did not know that they were presented with this particular subset of very difficult games.

## Hypothesis 3: FRB and structural complexity

The implementation of the forward reasoning plus backtracking (FRB) algorithm was applied to the subset of actually presented experimental games to determine the number of reasoning steps required for each game. In the following analyses, number of steps was included as a predictor of the reaction times. We label the factor simply as 'forward reasoning with backtracking'.

The log-RTs were analysed by means of linear mixedeffects (LME) models (Baayen et al., 2008) to account for random effects of participants and unequal numbers of observations across all experimental conditions. Traditional (repeated measures) ANOVAs could not be performed as they
require equal numbers of observations.
Fitting LMEs on the log-transformed reaction times, we see that forward reasoning plus backtracking (FRB) is a good predictor. The model with FRB cannot be rejected in favor of a simpler model without FRB as a predictor, $\chi^{2}(1)=8.4, p=$ 0.004 . We discuss the best model below.

Again, the reaction times significantly decrease if the maximum Player 1 payoff is accessible (Table 2a). In case of games in which the maximum payoff is not accessible, the reaction times do not significantly increase with each additional reasoning step (Table 2 b ). Those games require in between 6 and 8 reasoning steps, which is too small a difference to find a significant effect on the RTs. In contrast, the RTs do significantly increase with each additional reasoning step in games in which the maximum payoff is accessible (Table 2c).

Table 2: Output of full-factorial linear mixed-effects model with factors Accessibility (A), Steps of forward reasoning with backtracking (FRB).

| Parameter | Estimate | St. Error | t-value | p-value |
| :--- | :--- | :--- | :--- | :--- |
| a) Accessible | -0.689147 | 0.271256 | -2.54 | .000 |
| b) FRB | 0.008767 | 0.034930 | 0.25 | .418 |
| c) A:FRB | 0.084336 | 0.037277 | 2.26 | .000 |

## Discussion

We have investigated the structural properties of the Marble Drop Game, an experimental paradigm designed to study higher-order social reasoning. Using theoretical approaches from logic and complexity theory, we identified inherent properties of the game trials responsible for the cognitive difficulty of the task. Meijering and colleagues’ (2012) reaction time data can be explained by looking at the alternation type and pay-off distribution of the particular game items. It turned out that the game items are harder if the maximum possible pay-off for Player 1 is not accessible for him. This observation is consistent with the assumption that participants were mostly applying forward reasoning with backtracking to solve the games. By simulating forward reasoning with backtracking on the experimental items, we have shown that the reaction times and the number of necessary comparisons significantly decrease if the maximum Player 1 payoff is accessible. As MDG is game-theoretically equivalent to many other experimental paradigms making use of turn-based games (see, e.g., Hedden and Zhang, 2002; Gneezy et al., 2010; Hawes et al., 2012; Flobbe et al., 2008; Raijmakers et al., 2013), we would expect that our results generalize to those cases.

One could wonder why the subjects did not use backward induction in the first place, as it is the method that always delivers the optimal pay-off (Osborne and Rubinstein, 1994). One possible answer is that they avoided backward induction in order to simplify the underlying reasoning. Recall, that
while backward induction reasoning always takes 6 steps in the Marble Drop game with 3 decision points, forward reasoning and backtracking takes on average only 3 steps, corresponding with the phenomenon that $T^{-}$is usually lower in the tree alternation hierarchy than $T$ itself. Moreover, iterating the forward reasoning strategy by backtracking in case the highest pay-off is not obtainable will finally lead to the optimal solution. Therefore, some subjects may choose to use that strategy to avoid higher-order reasoning, even though keeping the intermediate results in mind during backtracking is expected to tax working memory more than applying backward induction.

Subjects may as well use other heuristics that do not guarantee reaching the prescribed backward induction result, namely a Nash equilibrium of the game. For instance, as suggested by Hedden and Zhang (2002), subjects may assume that their opponents are playing according to some fixed patterns. Instead of assuming that the opponent is rational and correctly predicts Player 1's choice at the last decision point, Player 1 may take his opponent to be risk-averse or risk-taking. Such heuristics, essentially based on considering sub-trees of the initial game-tree, will also lead to simplified reasoning.

Of course, assuming that the opponent is of some specific type changes the game drastically and can lead to a very bad outcome, in case of wrong judgement of the other player's type. Still, people notoriously apply similar heuristics in strategic situations, for example, when joining a poker table, many players try to evaluate whether the opponents play 'loose' or 'tight'. ${ }^{5}$ An important question is what are the good alternative strategies. They should be not only easy to compute for people but also relatively safe to apply. It seems that the forward reasoning plus backtracking strategy in MDG might be a cognitively attractive strategy for people asked to solve turn-based games. First of all, it does not ask for the second-order social reasoning that is known to be very hard even for many adults (Verbrugge, 2009), and moreover, on average it demands fewer comparisons. One may even think that competent players know a collection of various strategies and their strategic abilities could be partially equated with the skill of choosing the right one, i.e., a strategy that may be safely applied in a given context to simplify the underlying reasoning.

## Outlook

Inspired by the logical study of backward induction and the cognitive science experiments with the Marble Drop Game, we investigated structural properties of turn-taking dynamic games and we provided a more refined analysis of the complexity of particular game trials, which takes into account alternation type of the game and pay-off distribution. We com-

[^228]pared our predictions to actual reaction time data from (Meijering et al., 2012).

Of course, there are many further topics to be resolved. For instance, it would be interesting to extend our analysis to account for imperfect information games. Also it would be fruitful to explore connections with various related logical formalisms and to investigate further epistemic phenomena. In parallel, we would like to confront Hypotheses 1 and 3 with the available eye-tracking data from (Meijering et al., 2012), as well as with eye-tracking data to be gathered from a wider class of turn-based two-player games. Moreover, we plan to investigate other reasonable reasoning strategies that subjects may successfully adapt in game-plays.

# A neural network model of working memory for episodes 

Martin Takac (takac@ii.fmph.uniba.sk)<br>Centre for Cognitive Science, Comenius University, Slovakia

Alistair Knott (alik@cs.otago.ac.nz)<br>Department of Computer Science, University of Otago, New Zealand

#### Abstract

We present a neural network model of the storage of episode representations in working memory (WM). Our key idea is that episodes are encoded in WM as prepared sensorimotor routines: i.e. as prepared sequences of attentional and motor operations. Our network reproduces several experimental findings about the representation of prepared sequences in prefrontal cortex. Interpreted as a model of WM episode representations, it has useful applications in an account of long-term memory for episodes and in accounts of sentence processing.

Keywords: working memory, episodic buffer, neural network models of language

## Introduction: working memory for episodes

The classical model of working memory (WM; Baddeley and Hitch, 1974) posits two representational media: one for visual material (the visuospatial sketchpad) and one for phonological material (the phonological buffer). Baddeley (2000) revised the model to include a third medium, holding semantic material-specifically, semantic representations of episodes-called the 'episodic buffer'. This medium stores semantic representations of actions, or events, or stative propositions. Our paper is about the episodic buffer.

Baddeley argues for the episodic buffer on several grounds. Some relate to models of language processing. When a sentence is being generated, the message which it is to express is standardly assumed to be maintained in the speaker's WM (see e.g. Levelt, 1989). When a sentence is being interpreted, several theorists envisage a set of competing episode representations being activated in the hearer's WM, with one of these eventually being chosen as the winner (see e.g. Mayberry and Miikkulainen, 2008). In each case we must assume a WM medium which stores semantic episode representations. Baddeley (2000) postulates bidirectional links between the episodic buffer and the phonological buffer, to support sentence-processing tasks. But in fact his primary argument for the episodic buffer has nothing to do with language processing. This argument concerns the neural mechanisms through which episodes are stored in long-term memory. The long-term neural storage of an episode is widely agreed to involve the hippocampus: specifically, the creation of links between hippocampal assemblies representing the various semantic components of the episode. But associations between hippocampal assemblies can only be learned if they are active almost simultaneously, within around 100 ms of one another (Abraham et al., 2002). Experiencing an episode often takes much longer than this. So we must envisage that episode representations are initially buffered in WM, and only relayed to the hippocampus when they are complete. This buffering
mechanism is likely to predate language, since apes are able to store episodes in long-term memory (see e.g. Schwartz and Evans, 2001). One interesting possibility is that evolution found a new use for the buffering mechanism in linguistic communication (see Knott, 2012; Takac et al., 2012). In this paper we present a connectionist model of WM storage which supports not only language processing, but also the prelinguistic role of the episodic buffer mediating transmission of episode representations to the hippocampus.

## WM episode representations as prepared sensorimotor routines

Our model is founded on the assumption that WM episodes provide an interface between the sensorimotor (SM) mechanisms through which episodes are apprehended and the hippocampal structures in which they are stored. On this assumption, we expect the structure of WM episode representations to reflect both the structure of SM processes and the structure of hippocampal representations. A strong commonality in the structures of these two domains is sequential organisation.

SM processing is strongly sequential at certain timescales, because it involves sequential deployments of the agent's sensory and motor apparatus. (For instance, saccades deploy the agent's fovea sequentially to targets in the world.) Ballard et al. (1997) propose that SM processing is organised into sequentially structured routines, whose atomic elements are discrete sensory or motor actions. These actions are termed deictic operations, and a sequence of such actions is termed a deictic routine. Through a case study of episodes involving reach-to-grasp actions, Knott (2012) argues that the SM processes through which concrete episodes are apprehended take the form of sequentially structured deictic routines.

The hippocampus stores associations between stimuli of many different kinds. But an emerging idea is that it is specially good at storing associations between sequentially structured items (Wallenstein et al., 1998). One recent finding which strongly supports this idea is that the hippocampus actively replays sequences of representations evoked during SM experience (see e.g. Lee and Wilson, 2002). The key result is that sequences of hippocampal place cells activated when a rat navigates a maze are replayed later when the rat is asleep. (Sequences are replayed at much higher speeds, perhaps consistent with the hippocampus' natural dynamics.) Since episodes are apprehended through well-defined sequences of SM operations, and sequences appear to be a natural unit of storage in the hippocampus, an interesting pos-
sibility is that WM episodes are also stored as sequences. Our model of WM episodes basically implements this idea.

We make two main proposals. First, we propose that a concrete episode is stored in WM as the sequence of SM operations through which it was experienced. We suggest that the order of SM operations in a deictic routine implicitly identifies the roles played by participants in the observed episode. Specifically, the object attended to first plays the role of the 'proto-agent': the entity which is most agentlike, animate or active (Dowty, 1991), and the object attended to next is the 'proto-patient'. This idea is motivated in detail in Knott (2012). Second, we propose that the sequence of SM operations is stored as a prepared deictic routine: i.e. as a prepared sequence of attentional and motor operations. Humans (indeed all primates) can prepare complex sequences of sensory and/or motor operations. If episodes are stored as prepared SM sequences, then there is a natural model of how they are transmitted to the hippocampus: they are simply replayed, at a speed commensurate with the associative learning mechanism in the hippocampus. Naturally, in replay mode the prepared attentional and motor operations are simulated rather than actually executed. (In fact, this proposal about the format of WM episode representations can be seen as a way of implementing 'simulationist' accounts of semantic representations; see e.g. Barsalou, 2008.) In summary: in our proposal episodes are experienced as sequences, stored in WM as prepared sequences, and then replayed to the hippocampus where they are stored more permanently as sequences.

## Representation of prepared sequences in prefrontal cortex

A bonus of the above model of WM episodes is that the neural mechanisms supporting preparation of SM sequences have been extensively studied, in single-cell recording experiments in monkeys. The principal mechanisms supporting sequence preparation are in dorsolateral prefrontal cortex (dlPFC; see e.g. Barone and Joseph, 1989; Averbeck et al., 2002). Several schemes for encoding prepared sequences have been found. In one scheme, individual neurons encode specific movements in particular contexts. For instance, Barone and Joseph (1989) found neurons which were active when a monkey prepared movement $A$, but only when it was followed by another movement $B$. In another scheme, neurons encode individual movements, and their position in the prepared sequence is given by their activation levels. For instance, in a monkey preparing a sequence of three movements $A B$ and $C$, Averbeck et al. (2002) found neurons representing each prepared action which were active in parallel, with the neuron encoding $A$ most active and that encoding $C$ least active. Interestingly, when the prepared sequence is executed, neurons encoding specific actions are inhibited just after their associated action is produced. Averbeck et al.'s (2002) findings strongly support a 'competitive queueing' model of sequence preparation, in which PFC assemblies encoding different actions compete against one another, with the winner triggering the associated
action, but also an operation to inhibit itself, so the next-most active assembly wins the competition at the next time point (see Rhodes et al., 2004). In competitive queueing, the representation of a prepared sequence is destructively updated in the medium in which competition occurs. We will call the sequence representations in this medium 'dynamic'. However, there is also evidence that prepared sequences are represented in a WM medium which is not destructively updated when a sequence is replayed. Perhaps most obviously, a given prepared sequence can be executed several times: each time, the sequence representation in the dynamic medium must somehow be restored from some more enduring medium. We will call representations in the enduring medium 'static'.

There is also evidence that a monkey can represent multiple alternative prepared sequences in dlPFC, in a medium which allows competition between candidate sequences and the selection of a winner. This evidence comes from a study by Averbeck et al. (2006), in which monkeys were trained to perform two sequences in response to two cues. Each day different cues were chosen to represent the two sequences. Halfway through the day, the mapping from cues to sequences was reversed, so the monkeys had to gradually learn the new mapping. During this period, dlPFC assemblies could be identified representing each prepared sequence, and the relative activation of the two assemblies after presentation of a cue could be used to predict the sequence which the monkey actually performed.

In summary, the prefrontal mechanism implementing sequence preparation appears to involve four distinct media. There is a medium holding representations of individual operations in a sequence, which encodes the context in which they appear. There is a medium holding distributed representations of whole sequences, in assemblies whose components encode individual actions, whose order is determined by their level of activation. Sequence representations in this medium are destructively updated when a prepared sequence is executed. But there is also a medium holding sequence representations which are not destroyed. Finally there is a medium in which alternative candidate sequence representations are active in parallel and compete with one another. If episodes are stored in WM as prepared SM sequences, then this mechanism would allow for WM episodes to be stored and replayed, and also for alternative WM episodes to compete amongst one another, with the winner being selected.

## A network for storing and selecting WM episodes

In this section we introduce a neural network which implements the sequence-preparation mechanism described above. One part of the network allows the storage and replay of experienced sequences in WM. However, another part of the network learns about commonly-occurring sequences, so it can make predictions about how a sequence being experienced will be completed, and or about which sequences are associated with reward for the agent. (We envisage the network
being used to control the process of 'experiencing an episode' both when the experiencer is acting and when he is watching an external episode.)

Our key aim for the network is that it learns the kind of representations of prepared sequences which are found in monkey PFC, as discussed above. However, there are also two other design criteria. Firstly, there should be a medium in which candidate SM operations compete with one another at every stage in the execution of a sequence. At any point, the operation which an agent executes is dictated partly by what is planned or expected, but also partly by bottom-up stimuli. We want a medium which allows competition between alternative operations from both these sources. Secondly, in the medium holding alternative possible SM sequences, there must be no scope for binding errors, whereby an item belonging to one sequence is falsely identified as part of a different sequence. Given that this medium must represent multiple sequences simultaneously, this is a difficult requirement. To address both these criteria, a key design decision is to use self-organising maps (SOMs; Kohonen, 1982). A SOM is a two-dimensional map of units fully connected to a layer of input units. When presented with training inputs, it learns to represent input vectors as localist units in the map, but also learns to represent similar inputs in similar regions of the map. It thus encodes similarities between its training input vectors even though it represents these in a localist scheme.

The architecture of our network is shown in Figure 1. The

Figure 1: Architecture of the network
network takes as input a sequence of SM signals at successive time points, evoked in the input SM signal area. Input SM signals can be thought of as representing either the agent's own actions (attentional or motor) or external stimuli in the world (objects or observed actions).

SM input signals are fed through an aggregate SM signal
area (see below) to a signal-encoding SOM. This SOM has recurrent connections, as described in Strickert and Hammer (2005): it takes as an additional input a context vector combining the weight and the context vector of the winner at the previous time point. When trained on a sequence of inputs, a recurrent SOM organises itself so that individual units encode signals occurring in particular sequential contexts, very much like the PFC units identified by Barone and Joseph (1989).

Units in the signal-encoding SOM represent signals in a localist way, so that alternative signals compete with one another. The winning signal at each time step is copied to an area which is isomorphic with the recurrent SOM called the dynamic episodic buffer. This area accumulates representations of each signal in an input sequence, with the first signal represented most strongly and subsequent signals being stored with decreasing activation, as in the prefrontal area studied by Averbeck et al (2002). When an input sequence is encoded in the dynamic episodic buffer, it can be replayed immediately by iteratively sending the dynamic episodic buffer's most active unit to the signal-encoding SOM (via the 'WTA' link) and then inhibiting this winning unit. To support repeated execution of a sequence, it can be stored in a static episodic buffer, which has the same structure as the dynamic one, and later reloaded.

At the highest level in the network there is another SOM called the candidate episodes buffer. This area encodes the distributed representations in the dynamic episodic buffer as localist units. During training it learns to represent episodes with similar encodings in the dynamic episodic buffer in neighbouring positions in the SOM. At every time point during presentation of a sequence this area represents a probability distribution over complete episodes. (If the network is being used to control the agent's own actions, this distribution represents action sequences which lead to reward; if it is being used to support observation of external episodes, it represents likely action sequences.) The distribution changes as new items arrive in the sequence and become encoded in the dynamic episodic buffer.

The winning unit in the candidate episodes buffer provides top-down activation to the static episodic buffer, through weights which are copies of those delivering input to the candidate episodes buffer. Since the winning unit always encodes a complete episode, the static episodic buffer likewise always encodes a complete episode, but in the same distributed format used by the dynamic episodic buffer. During presentation of a sequence, activity in the static episodic buffer is fed back to the signal-encoding SOM. This top-down input, when combined with the current context representation, produces a pattern of activity biased towards a representation of the next SM signal. The pattern is passed back to the aggregate SM signal area at the next time point. Thus the aggregate area receives both bottom-up inputs from the input SM signal and top-down ones from the static episodic buffer.

We conclude by reporting some details of the network architecture. Different SM operations are encoded in the 'input

SM signal' layer with 1-hot localist coding, i.e. one unit for each possible SM operation. The 'aggregate SM signal layer' is isomorphic with the input layer. The signal-encoding SOM is a 2-dimensional Merge SOM (Strickert and Hammer, 2005) with 400 units $(\alpha=0.4, \beta=0.5$, constant learning rate 0.1 and Gaussian neighbourhood decreasing from 10 to 0.5 ).

The static and dynamic episodic buffers are both isomorphic with the signal-encoding SOM, i.e. have 400 units each. Experiencing a sequence of SM operations creates a temporal pattern of active units in the signal-encoding SOM. This pattern is recorded in the dynamic episodic buffer as a 'trace' of the isomorphic units with exponentially decaying activity (the $n$th unit in the sequence has activity $\delta^{n-1}$ where $\delta=0.8$ and all unused units have zero activity). To prevent confusion of elements in the trace, we force the signal-encoding SOM to select a new winner in each step of the sequence (i.e. winners from previous steps of this sequence are excluded from competition). After completing the whole sequence, the 400dimensional vector representing its trace serves as a training input to the candidate episodes buffer, which is a standard SOM with 900 units, constant learning rate 0.9 and Gaussian neighbourhood decreasing from 10 to 0.5 .

Once a winner is selected in the candidate episodes buffer, activity is propagated back through the network, a process we call 'top-down reconstruction'. This process uses the property of SOMs that the memory of each unit is in its weights. During reconstruction, the weights of the winning unit in the candidate episodes buffer are copied back to the static and then dynamic episodic buffer. Destructive iterative updating of the dynamic episodic buffer causes a temporal sequence of activations of units in the signal-encoding SOM, which in turn project their weight vectors back to the aggregate SM signal layer where they represent top-down expectations.

## Experiments and results

Training We trained the model on sequences of SM operations, representing the SM routines through which different episodes are experienced. The SM sequences were built from 35 SM operations, e.g. MAN SNEEZE (intransitive episode), MAN CUP GRAB (transitive), MAN WALK HOUSE INTO (intransitive with PP complement), MAN CUP CAUSE BREAK (simple causative) and DOG BONE CAUSE ROLL TABLE UNDER (causative with PP). (For detailed justification of the orderings in these sequences, see Knott, 2012.) We repeated each simulation 10 times with different random initializations of connection weights in the model and different training sets (stochastically generated by the same set of transcription rules). Each training set consisted of 500 sequences, out of which on average 13.1 were of length $2,86.4$ of length $3,126.1$ of length 4 and 274.4 of length 6 . Sequences could contain duplicates: in all, $19.1 \%$ of sequences contained two copies of a single signal and $0.9 \%$ contained 3 . The training took 200 epochs; in each epoch the training sequences were presented in random order and the Merge SOM context was reset after each sequence. After training we tested the net-

work in three ways (all tests were repeated for the 10 different simulation runs and averaged).

Immediate serial recall The basic requirement for our network is that it can store and replay individual behavioural sequences. This capability relies on interactions between the signal-encoding SOM and the dynamic episodic buffer. We presented the trained network with 200 sequences of input signals: 100 taken from the training data and 100 new ones not seen before. Each sequence was coded in the dynamic episodic buffer; then the signal-encoding SOM's context was reset and the winning unit in the dynamic buffer was iteratively sent to the SOM and then inhibited. $99.4 \%$ ( $\mathrm{SD}=0.49 \%$ ) of training sequences were correctly replayed, and $98.6 \% ~(\mathrm{SD}=0.92 \%)$ of unseen sequences.

Predicted completions of sequences The network is also designed to generate top-down predictions about sequences, through activity in the candidate episodes buffer. The prediction is actually a retrieval of the most similar past episode as remembered in the weights of this buffer. The weights of the winning candidate are copied to the static episodic buffer and replayed in the signal-encoding SOM where they generate top-down biases for SM elements. To test this ability, we exposed the trained network to the 500 sequences encountered during training element by element, and examined the prediction about the possible completion of the sequence. At the beginning of an exposure, after seeing a short fragment of an episode, its completion is inherently ambiguous, as there may be many possible continuations (see Table 1). Later the number of candidates narrows down and the prediction can be more accurate. ${ }^{1}$ We can evaluate the retrieval from fragments of an episode of various lengths, up to complete episodes. The results are summarized in Table 2.

Note also that the network is not confused by sequences containing duplicate items. A regular competitive queueing network has problems representing duplicate items, because after the first instance of the item is presented it is inhibited in the competitive medium. But since the dynamic episodic

buffer receives inputs from the signal-encoding SOM where we forced a unique winner selection, different instances of a given input are represented differently, and it does not suffer from this problem. To verify this, we tested the prediction on a set consisting of 95 sequences with 2 repeating elements and 5 sequences with 3 repeating elements and the results were similar to those presented above (the average success in prediction from fragments of more than $75 \%$ of the sequence length was $91.8 \% ~(\mathrm{SD}=3.5 \%)$.

Relation to neural activation data As discussed above, PFC stores prepared sequences in several different ways. We examined the properties of representations in the trained network to see how they corresponded to representations identified in monkey PFC.

Some PFC units encode individual operations in a prepared sequence in a way which takes into account their sequential context (see e.g. Barone and Joseph, 1989). Inspecting units in the signal-encoding SOM shows that they have this property. We presented the trained signal-encoding SOM with five input sequences featuring six instances of the signal MAN in different serial positions. The SOM unit which represents mAN is different in each case, as shown in Figure 2.

Some PFC units encode individual operations in a prepared sequence in a format where relative activation levels indicates the serial order in which operations will be executed (see Averbeck et al., 2002). Of these units, some have activity which changes dynamically during execution of a prepared sequence, being maximal before execution of the action they encode and being inhibited thereafter. Others are invariant during execution of a planned sequence. Units in the dynamic episodic buffer have the former property, and units in the static episodic buffer have the latter property.

Finally, some areas of PFC provide a medium in which alternative prepared sequences can compete against one another (Averbeck et al., 2006). The candidate episodes buffer acts as such a medium. Table 1 shows the five most active candidates in the candidate episodes buffer as a response to the presentation of DOG BALL and DOG BALL CAUSE fragments. ${ }^{2}$

[^230]
## Summary and discussion

This paper contains two main proposals. Most concretely, we propose a network model of WM for behavioural sequences. We also propose a more far-reaching idea: that episodes are represented in semantic WM as prepared behavioural sequences. Specifically, we propose our model of prepared sequences as a model of the episodic buffer argued for cogently by Baddeley (2000). We now assess these proposals.

WM for sequences There are numerous network models of WM for sequences. However, most of these are explicitly models of phonological WM. We follow Baddeley (2000) in distinguishing between phonological WM and WM for episodes. This means our model does not directly compete with the best-known models of WM for sequences, for instance Burgess and Hitch (1999). It does not have to reproduce the classic effects found in immediate recall of phonological sequences, such as primacy and recency effects. Empirically, our focus is on modelling the neural sequencepreparation mechanisms found in monkeys, which it does quite successfully. There are some computational models which propose the same mechanism both for phonological WM and prepared action sequences-in particular Rhodes et al. (2004). We certainly envisage similarities between the mechanisms subserving these tasks. (In particular they both appear to involve competitive queueing.) But our suggestion is that they are separate, although, as Baddeley suggests, there are links between them, which support sentence processing. We will discuss some ideas about these links below.

Episode representation As a model of representation of episodes in WM, our network is just a first step. An obvious issue for discussion is our localist representation of episodes in the candidate episodes buffer. Since episode representations can have other episode representations nested within them, it is clearly infeasible to have a single assembly in this medium for each possible episode. However, we should distinguish episode representations from sentence representations. Our conception of epsiodes as stored SM sequences means that there are several kinds of nestedness in sentences which we do not have to model declaratively. For instance, to model The dog [which chased Mary] barked we can initially rehearse just the matrix episode The dog barked: when $d o g$ is activated we can temporarily evoke the subordinate episode The dog chased Mary in the candidate episodes buffer, so it can be rehearsed, and then inhibit it, so the matrix episode once again becomes dominant. This device of interrupting processing is not available to schemes which represent episodes declaratively in a static pattern of neural activity: we see this as a strong advantage of representing episodes as sequences. Sequentially structured episode representations also permit an interesting representation of nested sentential complements; see Caza and Knott (2012).

[^231]Sentence processing As regards sentence processing, the network can be extended in several interesting directions. These all enlarge on Baddeley's (2000) proposal that sentence processing involves interactions between two separate WM buffers, one for phonological material and one for episodes.

There is a natural way of extending the network to support sentence generation. A detailed model of sentence generation incorporating the current model of WM episodes is given in Takac et al. (2012). In this model, generating a sentence involves replaying a WM episode stored as a prepared sequence, in a special mode where SM signals can trigger learned articulatory motor plans. During this replay process, an interesting mixture of sustained and transient signals is evoked: in particular, there are tonically active representations of each action in the planned sequence in the static episodic buffer throughout the replay process. These tonic representations permit a neat account of the extended syntactic domain of verbs. Verbs can appear at various different positions in the structure of a clause, and they can carry inflections signalling agreement with arguments at distant positions in the clause (for instance subjects). The neural basis for this non-locality is currently a complete mystery. But if sentences are produced by replaying a prepared SM routine, and if verbs and their inflections are produced from planned motor and attentional action representations which are tonically active during replay, we have a promising explanation of this non-locality: the semantic representations from which inflected verbs are generated are active throughout the generation process, and can be produced at any time.

The WM episode network also has interesting uses in models of sentence interpretation. Neural models of sentence interpretation take sequences of words as input, and use various types of recurrent network to produce output semantic representations. Such a network could deliver episode representations directly to the candidate episodes buffer. After training, this buffer would activate a distribution of possible sentence meanings and a winner could be picked. In our network, this winner could then be simulated as a SM sequence, in line with embodied theories of meaning.

#### Abstract

There have been few studies on a cognitive model for algorithm understanding in a human-computer cooperative situation. In the present study, we conducted an experiment with participants to investigate the cognitive process of higher level abstraction (algorithm understanding) performed in a humancomputer collaboration task. The most recently used (MRU) algorithm, known to be one of the simplest adaptive algorithms, and probabilistic MRU algorithm were used to test the human capability to understand an algorithm. The experimental results showed that inductive reasoning in which participants observed the history of computer action, and they updated a statistical model while restricting their focus on a certain history with deteministic bias and Markov bias played key role to correctly understand the MRU algorithm. The results also showed that deductive reasoning was used to understand algorithms when participants rely on prior knowledge, and that there was a case in which the algorithm, even known to be the simplest one, was never understood.

Keywords: algorithm understanding; inductive reasoning; deductive reasoning; adaptive user interface;

## Introduction

The number of situations in which humans collaborate with computers has been increasing with the advance of information technology. Although user-adaptive systems that adapt to a user, including adaptive user interfaces, have been a main topic in the human-computer interaction community and artificial intelligence machine learning community (Findlater \& McGrenere, 2004; Oviatt, Swindells, \& Arthur, 2008; Bigdelou, Schwarz, \& Navab, 2012), an adequate design policy for implementing useful user-adaptive systems still remains unclear (Shneiderman \& Maes, 1997; Lavie \& Meyer, 2010; Gajos, Everitt, Tan, Czerwinski, \& Weld, 2008). Furthermore, there have been few studies on a cognitive model for algorithm understanding in the context of human-computer collaboration tasks.

In a human-human collaboration task, mutual intention understanding plays the key role in accomplishing successful work (Byrne \& Whiten, 1988; Call \& Tomasello, 2008). However, in a collaboration task with a computer, the abstraction level of behavior necessary to understand a collaborator's behavior is lower than that used in a human-human collaboration task (Dennett, 1987). Behavior abstraction in terms of
goal (intention) is not required in human-computer collaboration because a goal is given and explicitly shared with both a human and a computer. Instead, algorithm level abstraction is needed. In a human-computer collaboration task, understanding a computer's algorithms in order to accomplish the given goal is quite important because a human relies on the computer's underlying mechanisms in order to predict its behaviors and to adapt to it.

One way to predict the future behavior of a target is to use input-output association acquired on the basis of sequence learning (Clegg, DiGirolamo, \& Keele, 1998; Sun \& Giles, 2001a; Winkler, Denham, \& Nelken, 2009). In a typical sequence learning problem (Nissen \& Bullemer, 1987), humans learn a recurring loop of action sequences from given examples, and as a result, their reaction time for the given examples decreases. This learning is done both explicitly and implicitly (sensory-motor learning), and currently, implicit sequence learning is actively studied (Sun \& Giles, 2001b). The situation in which humans observe only the action sequences given to them is the same in both sequence learning and algorithm understanding. However, the learning target of algorithm understanding is procedures with variables that describe the internal states of computers, and this target is quite different from that of sequence learning (i.e., sequence patterns of values). Obviously, the number of hypotheses in algorithm understanding is far more than that in sequence learning, and this makes algorithm understanding very hard. Hence, algorithm understanding requires quite strong biases to find adequate algorithms. Another difference between understanding cooperative algorithms and sequence learning is the type of interactivity in the tasks. In algorithm understanding in a cooperative situation, a computer's behaviors change depending on the behaviors of humans because it adapts to them. In sequence learning, sequences are given to humans as physical stimuli.

The research objective of this study is to build a cognitive model to describe the human capability to understand computer algorithms in the context of a human-computer collaboration task. We introduce one of the simplest humancomputer collaboration tasks, in which a computer adapts to humans who are asked to try and understand the computer
algorithms. Concretely, we investigated how humans understand the most recently used (MRU) algorithm (Lee et al., 1999; Findlater \& McGrenere, 2004; Gajos et al., 2008). The MRU algorithm is well known to be one of the simplest adaptive algorithms in which a computer's current statement simply corresponds to the user's last one. Examples of the implementation of the MRU algorithm are the most recently used files (Amer \& Oommen, 2006), which lists the user's most recently accessed files in an application, and the most recently used menu (called adaptive menи (Arcuri, Coon, Johnson, Manning, \& Tilburg, 2000)), which lists the user's most recently used menu.

The MRU algorithm has succeeded in contributing to making useful interactive software that includes adaptive user interfaces (Findlater \& McGrenere, 2004). One reason is that it can be easily understood by users. If users can not find any meaning (regularity or rules for computer's behaviors) from a list in which the order of the items is frequently changed, the list causes the user stress. The reason the MRU algorithm is easily understood is that there are explicit descriptions of the algorithm, i.e., there may be a description such as "most recently used file." In this work, we investigate the human ability to understand an algorithm in a situation without such explicit knowledge.

One preferable explanation of algorithm understanding is induction because rule finding is considered to be an inductive process (Haverty, Koedinger, Klahr, \& Alibali, 2000; Simon \& Kotovsky, 1963; Verguts, Maris, \& Boeck, 2002; Schmid \& Kitzelmann, 2011). In general, induction needs to be done only with a small number of examples. It is hard to induce adequate rules with finite examples that can cover infinite facts because there is a huge number of hypotheses of rules that can be induced from the examples. Thus, we need heuristics (called inductive biases) to sufficiently restrict the hypothesis of rules for practical induction. In algorithm understanding, since humans have to induce computer algorithms only with tens of examples, we consider they have a strong bias for algorithm understanding. In this paper, to investigate human algorithm understanding, we hypothesize biases on algorithm understanding and verify them in experiments with participants.

## Cognitive Model of Adaptive Algorithm Understanding

Adaptive algorithm understanding is a subclass of algorithm understanding. An adaptation in human-computer interaction refers to a feature of algorithms in which strategies of a computer dynamically change according to user's input in order to pursue given goals. The goals refer not only corporation but also competition (Hampton, Bossaerts, \& O'Doherty, 2008). In the present study, we focus on a cooperative situation. We introduce a cooperative mark-matching game as a simplified and generalized task of human-computer adaptation in which a user adapts to a user-adaptive system.

## Cooperative Mark-Matching Game

The cooperative mark-matching game is a repeated game with two players. Each player has the same marks (e.g., $\boldsymbol{巾}$, $\diamond, \oslash$ ) and must secretly choose one of the marks. The players then reveal their own choices simultaneously. If the marks match each other, both players obtain a certain score, and if not, nobody obtains a score. In our experiments, the two players were a human and a user-adaptive system.
In a situation of the human-computer adaptation, a system predicts the user's next action (e.g., a menu item that will be chosen next by a user in an adaptive menu (Findlater \& McGrenere, 2004)) and adapts to him/her by modifying the user interface (e.g., changing the menu item positions (Findlater \& McGrenere, 2004)). If the prediction is correct (i.e., the two marks of the human and user-adaptive system matched in the game), the user and system obtain efficiency together. The number of the mark corresponds to the number of menu items in the adaptive menu. The key difference between a cooperative mark-matching game and human-computer adaptation with AUIs is that a user can freely choose his/her next action by him/herself in the game in contrast to the user's action sequence being determined to achieve a task with AUIs.

While the simplest strategy for a cooperative game is for participants in each trial to simply choose the action that in the recent past gave the most rewards (known as reinforcement learning), a more sophisticated strategy is to try to predict the system's next actions by taking into account a statistical model constructed on the basis of the history of prior actions. Studies on game theory (Fudenberg \& Levine, 1998)(Berger, 2005) and sequence learning (Sun \& Giles, 2001a) with an opponent player (a user-adaptive system) in a game situation suggest that opponent strategy is identified on the basis of a mixed strategy, which is defined as a probability distribution over the alternative actions available to each player.

## Statistical model

We hypothesize that, as mentioned earlier, a higher level abstraction, i.e., algorithm identification, for a computer's strategy is carried out on the basis of biases. We set the starting point of our discussion to statistics in which a human updates the conditional probability distribution of the system's next choice over time.

$$
\begin{equation*}
p\left(a_{t}^{s} \mid a_{t-1}^{s}, \cdots, a_{j}^{s}, a_{t-1}^{h}, \cdots, a_{k}^{h}\right) \tag{1}
\end{equation*}
$$

, where $a^{h}, a^{s} \in A$, and $A$ are available choices for both the system and human and $a_{t-1}^{s}, \cdots, a_{k}^{s}$ and $a_{t-1}^{h}, \cdots, a_{j}^{h}$ are the past choices of the system and human, respectively. Indices $j$ and $k$ denote the length of the history, which the human takes into account, and vary depending on focus. However, detecting the computer's algorithm on the basis of only observed behaviors is an ill-posed inverse problem because humans do not know how to restrict their focus to a certain history, and in addition, different strategies sometimes produce the same

Table 1: Conditional probability distributions correspond to most recently used and probabilistic most recently used algorithm

history. Thus, we consider that a human does sufficiently restricted exploration with inductive biases.

The MRU algorithm is formalized as the following distribution.

$$
\begin{equation*}
p\left(a_{t}^{s} \mid a_{t-1}^{h}\right) \tag{2}
\end{equation*}
$$

The actual distribution produced by the MRU algorithm in the cooperative mark-matching game is shown in Table 1(a). The system's choice $\left(a_{t}^{s}\right)$ depends only on the human's most recent choice ( $a_{t-1}^{h}$ ) and is independent from any other history of choices. If the human's most recent choice is heart, for example, the system's next choice will be heart, represented as $p\left(a_{t}^{s}=ऽ \mid a_{t-1}^{h}=\varnothing\right)=1$. Infinite numbers of trials are, theoretically, required to convince a human that the probability is 1 . Hence, one reasonable strategy for this problem is to use inductive biases to adequately control the inference process. As such inductive biases, we consider deterministic bias and Markov bias. If a human has a deterministic bias that assumes computer's behaviors are deterministic, not probabilistic, only one piece of evidence is necessary to estimate the probability distribution. Markov bias, in which the conditional probability distribution of the next choice depends only upon the present choice, not on the sequence of events, is also necessary to ignore any unnecessary history of choice.

## Experiments

We conducted an experiment with participants to investigate the cognitive process of higher level abstraction (algorithm identification) performed in the context of a human-computer cooperation task. The MRU algorithm and probabilistic MRU algorithm was used to test the human capability of algorithm understanding. Participants were asked to play a cooperative game with a computer, and after that they were asked to answer the computer's algorithm.

A 50-round repeated cooperative mark-matching game with different statistical profiles of the MRU algorithm was used. We used the following two conditions.
Deterministic (D) condition Computer's choice is completely the same as the human's most recent choice (deterministic MRU algorithm, see Table 1(a)).
Probabilistic (P) condition Although $90 \%$ of the computer's choices are the same as the human's most recent choices, $10 \%$ differs (probabilistic MRU algorithm). The

Figure 1: Interface of on-line experimental system: 1) history of both players' choices, 2) choice marks (marks are clickable), 3) round number and remaining time, 4) place for unveiling players' choice and scores for both players
actual distribution produced by the probabilistic MRU algorithm is shown in Table 1(b).

The P condition was prepared to contrast the effect of noise on the inductive reasoning performed to understand the MRU algorithm. In particular, we expected that the deterministic bias was strongly affected by the noise and performance deteriorated in the P condition. It was also expected that the score of those who participated in the P condition was at most $10 \%$ worse than that of the D condition if the participants merely estimated the probability distribution and did not use any biases to identify an algorithm.

## Experimental setup and measurement

The game was implemented with JavaScript and HTML and played in a Web browser (Firefox). Figure 1 shows the game interface. The computer's choices were automatically controlled by a JavaScript program. Participants were instructed to click the mark corresponding to his/her choice within 10 seconds for every round. Scores for both players were shown in the interface. The choices of the past five rounds for both players remained displayed so that the participant was able to recognize the computer's strategy.

A single-factor two-level between-subject experimental design was used. Fifty people ( 9 female) aged 19 to 47 (mean $=28$ ) recruited via direct e-mail participated in the experiment. All participants had moderate to high experience using computers. Participants were randomly assigned to either a deterministic or probabilistic condition. Participants were informed of an ostensible goal of the experiment - that the point of the experiment was to assess the usability of an on-line game system. They were also informed that "the computer was cooperative." Participants were told that they would win a PC gadget as a prize according to the score (under 20 points: around $\$ 5,21$ to 44 points: around $\$ 15,45$ to 50 : around \$30).

In the P condition, a 50 -round sequence with $10 \%$ random noise, which corresponds to 5 rounds in which MRU rules

Figure 2: Percentage of participants who won each round (solid line) and percentage of participants who started to take a "fixed choice strategy" (correct solution to the game) throughout the remaining rounds (dotted line)

Figure 3: Computer's algorithm identified by participants
are violated, is generated, and sequences that do not fit the following criteria are omitted: 1) errors do not appear in the first and last 5 rounds and 2) five errors appear within the remaining 40 rounds. The computer's choice for the first round was selected not to match the participant's choice in both conditions.
The outcomes of all 50 rounds were recorded. The round in which participants became aware of the correct solution to the game was identified by detecting the round in which participants started to continue to select the same mark throughout the remaining rounds. After the game, participants were asked to answer 7-point Likert scale questions, such as $Q$. Did the computer make its choices strategically?, and one openended question if participants gave a rating of 5 to 7 (positive) to this question - Describe the computer's strategy.

## Results

The average scores were $43.7(\mathrm{SD}=7.0)$ in the D condition and 31.4 ( $\mathrm{SD}=7.5$ ) in the P condition. ANOVA revealed that there was statistically significant difference $(F(1,48)=$ $33.99, p<0.01$ ) between the two conditions. The difference of the average scores between the two conditions was 12.3. A difference of more than $5(10 \%)$ indicates that participants used deterministic bias to accomplish the game. This gap is explained by the difference in the increasing rate of the winning percentage. While the winning percentage of the D condition rapidly reached a high value (e.g., $80 \%$ at the sixth round), that of the P condition slowly increased (e.g., $80 \%$ at the 35 th round). The slower increase of the winning
percentage in the P condition indicates that the $10 \%$ noise in the MRU algorithm caused the computer's algorithm to be difficult to identify and made the participants require longer rounds to identify it.

Figure 2 shows the percentages of the participants who won the round plotted against the round numbers (solid line). The dotted line in Figure 2 represents the percentage of participants who took a "fixed choice strategy," indicating the percentage of participants who became aware of the correct solution to the game. Note that the correct solution is found not only by identifying the MRU algorithm, but also by merely choosing the same mark without thought.

Figure 3 illustrates the computer's algorithm identified by participants. While $72 \%$ of participants in the D condition correctly identified the MRU algorithm after 50 rounds, only $52 \%$ in the P condition succeeded in identifying it. However, a chi-square test revealed that there was no statistically significant difference in the distribution of the identified algorithm between the two conditions $\left(\chi^{2}(4)=3.41, p=0.49\right)$.

## Discussions

In the present study, we investigated the human capability to understand the MRU algorithm. In particular, we expected that inductive biases such as deterministic and Markov bias are used to understand the algorithm. In the succeeding subsections, we will discuss whether these biases were applied to accomplish the game.

## Inductive algorithm understanding

The red dotted line in Figure 2 reveals that $60 \%$ of participants ( 15 participants) in the D condition found the correct solution to the game. The result of the questionnaire revealed that while 13 of the 15 participants inferred the computer's algorithm as the MRU, one inferred no strategy, and one inferred a fixed choice. A typical behavioral pattern for these kinds of participants is shown in Figure 4(a). They observed the history of the choices and might have inferred the MRU algorithm on the basis of the obtained statistical model. However, while detecting a statistical model of the computer's strategy essentially requires an infinite number of trials, they rapidly identified certain algorithms. One explanation for this rapid identification is the deterministic bias and Markov bias. If the algorithm was assumed to be deterministic, the participants did not need to take into account the six cases filled out as zero in Table 1(a) and required at least three trials to determine the computer's strategy. Without Markov bias, participants could not focus only on the one round past choice and required longer rounds.
The deterministic bias also accounts for the worse performance of those who participated in the P condition. If the participants merely estimated the probability distribution, as expected, an optimal strategy against a mixed strategy would have been taken, and performance would have been at most $10 \%$ worse than in the D condition.
The lowest score for all 50 participants was 19 , which was higher than the theoretically calculated score (16.67) when

#   

(a) Understanding algorithm on the basis of inductive reasoning (correct identification). After eight trials of active learning phase, the participant realized the algorithm was the MRU one.
(b) Understanding algorithm on the basis of inductive reasoning (wrong identification). The detected algorithm was "the computer increased the number of times by repeating the same choice."

(c) Understanding algorithm on the basis of deductive reasoning. The participants used a heuristic from the beginning: "Adaptive system $\Rightarrow$ MRU algorithm."

(d) The participant did not detect any algorithm.

Figure 4: Examples of typical behavioral pattern in the D condition. C : computer, H : human.
participants did not take any strategy, i.e., a random strategy. This implies that almost all of the participants arbitrarily attributed some kind of strategy to the computer's choice. In fact, the rules of the game allowed the participants to attribute strategies other than the MRU algorithm, such as "the computer simply selected the same mark" (fixed choice strategy) and "the computer changed its choice alternatively" or "the computer increased the number of times by repeating the same choice such as $\diamond \boldsymbol{\wedge} \cap \triangle \varnothing^{\prime \prime}$ (increasing number strategy), see Figure 4(b)). Three participants in the D condition answered that the computer's algorithm was "increasing number strategy." Interestingly, they did not aware that the timing to change the mark was determined by themselves. They completely unaware of the rule in which the computer changed its output according to their input.

## Deductive algorithm understanding

The results also indicated that some participants understood the algorithm on the basis of deductive reasoning. Sixteen percent of participants (four participants) in the D condition and four percent (one participant) in the $P$ condition fixed their choice in the first round and never changed during the game (see Figure 4(c)). Surprisingly, all of them described their identified computer algorithm as the MRU. The prior knowledge given to the participants in the instruction phase lead them to deduct the following logic:

$$
\begin{equation*}
\text { Adaptive system } \Rightarrow M R U \text { algorithm } \tag{3}
\end{equation*}
$$

In the instruction phase, participants were explicitly informed that the goal of the task was to get as much points as possible in cooperation with the partner computer. This top down adaptive bias might have enabled them to identify the algorithm immediately without exploring the computer's strategies. They might have logically inferred that the cooperative system acted adaptively to humans and that the most
efficient algorithm for human-computer cooperation was the MRU algorithm. In fact, their MRU algorithm hypothesis was confirmed by the computer's succeeding choice. The confirmation bias (Klayman \& Ha, 1987) was used to convince them that the computer used the MRU algorithm. They marked the highest score 49 (all participants were sure to lose the first round because of the game setting). There was no incentive to explore another strategy and gather evidence to test another hypothesis unless their hypothesis was violated because their goal was to get as many points as possible and not to detect the algorithm exactly. Indeed, while three participants in the P condition started to fix their choice in the first round, two of the three changed their choice after the noise pattern in the computer's choice appeared, indicating that their confirmation bias was destroyed by the noise (falsification).

## Algorithm detection fail

Surprisingly, even though the MRU has been supposed to be one of the most predictable adaptation algorithms, the result showed that two participants in the D condition and three in the P condition failed to identify any strategy in the 50 rounds (see Figure 4(d)). The visual cue shown in the history area in the game's interface might have been a strong cue indicating that the computer's choice was the same as participant's choice one round before. However, they could not detect the algorithm. Further investigation will be required to account for this failure.

## Summary

To the best of our knowledge, this is the first study to investigate the human capability to understand adaptive algorithm in a human-computer collaboration task. In the theoretical model of a human cognitive process for algorithm understanding, a user identifies a computer's algorithm by estimating the conditional probability distribution associated with a
particular strategy and restricting his/her focus on certain history data by using inductive biases. The most recently used (MRU) algorithm, known to be one of the simplest adaptive algorithms, was used to test the human capability to understand an algorithm. The probabilistic MRU algorithm was also used to contrast the effect of noise on the inductive reasoning performed to understand the MRU algorithm. The experimental results indicated that most participants correctly identified the MRU algorithm and used deteministic bias and Markov bias in their inductive reasoning for algorithm identification. The results also indicated that some participants understood the algorithm on the basis of deductive reasoning. Surprisingly, few participants failed to identify any algorithm within 50 rounds.

The present findings implies that designed behavior of computers is not necessarily understood correctly, suggesting that both an understandable algorithm and transparency of the internal state of a computer might be important for designing effective adaptive systems.

#### Abstract

This study investigated the degrees of consistencies in driving behavior when operating a real system (real car), a virtual system (high fidelity driving simulator), and a laboratory system (computer driving game). The same tendency of behavioral consistencies was confirmed among the three systems: i.e., the steering operation demonstrated the highest behavioral consistencies, followed by the acceleration and braking operations, respectively. The individuality of driving behavior emerged more in the braking and acceleration operations than in the steering operation. The same tendency for behavioral consistencies of braking, acceleration, and steering operations was confirmed in each of the three systems.

Keywords: behavioral consistency; driving behavior; individual differences; virtual environments

## Introduction

In studies of human factors, analyses of human behavior are usually conducted in actual environments using observational methods. However, advances in computer technology are now facilitating experiments on human factors by using various simulators because they provide a convenient and safe method for assessing human behavior. Thus many studies about human behavior in serious situations that may lead to accidents have been performed, such as people driving cars, operating airplanes, controlling industrial plants (e.g., dos Santos et al., 2008; Kemeny, 2003; J. D. Lee et al., 2002; Metzger \& Parasuraman, 2001; Parasuraman et al., 1996; Wickens \& Alexander, 2009). Driving simulators in particular have played an important role in automobile human factors research for more than three decades. Various studies using driving simulators have examined not only basic characteristics of driving behavior but also applied investigations of those effects of drinking and aging that relate to social problems because using automobiles is a major part of our daily lives (e.g., H. C. Lee et al., 2003; Mets et al., 2011; Pradhan et al., 2005; Rizzo et al., 1997).

However, virtual systems cannot simulate real systems completely. Therefore, many researchers agree that an examination of their validity is a crucial component in any study. The validity of driving simulators has previously been evaluated through a comparison of behavior when driving real cars and simulators (e.g., Törnros, 1998; Godley et al., 2002; Underwood et al., 2011; Shechtman et al., 2009; Mayhew et al., 2011). Previous studies have discussed both commonalities and specificities in the distributions of specific errors or characteristics of specific behaviors when operating real and virtual systems. Such discussions have an essential assumption of the consistency of behavioral characteristics when driving vehicles. However, we do not know to what human driving behavior is consistent. In the present study, we examined behavioral consistency (BC) when driving vehicles on road and using simulators.

The purpose of this study is to reveal the degree of BC by analyzing three basic operations of driving behavior: braking, acceleration, and steering operations. First, we investigate the BCs for the three operations when driving a real car. Then, we study the BCs in two other types of systems: a virtual system as a high fidelity driving simulator and a laboratory system as a low fidelity driving simulator (similar to a computer driving game). The following outlines our basic strategies for the investigation.

Imagine a situation in which drivers repeatedly drive on a specific course. The BC within each participant shows the degree of consistency in individual behavior when repeatedly driving on the same course. We also calculate the BCs across participants, demonstrating the degree of consistency in the general characteristics of human behavior independent of each participant's individuality. We refer to the former as the intrapersonal BC and the later as the interpersonal BC.

In our analyses, the interpersonal BC is treated as the baseline because it reflects the generality of BCs across partici-
pants. The intrapersonal BC is predicted to exceed the interpersonal BC. In this study, by comparing the inter- and intrapersonal BCs, we attempt to answer the following two research questions.

RQ1 To what degree is driving behavior, characterized by the three basic operations of braking, acceleration, and steering, consistent across individuals in the real system? Is the tendency observed in the real system confirmed in the two types of simulation systems?

RQ2 To what degree is individual behavior more consistent than behavior across individuals in the real system? Is the greater consistency of individual behavior in the real system confirmed in the two simulator systems? In other words, to what degree are the intrapersonal BCs greater than the interpersonal BCs in each system?

## Multi-layered experimental platform

In this study, to determine BCs within various systems, we constructed an innovative experimental platform consisting of three different types of systems: the real system using an electric vehicle, the virtual system using a high fidelity driving simulator, and the laboratory system implemented as a driving game(Figure 1).

## The systems

Real system We used an instrumented vehicle called COMS from Toyota Auto Body as the real system (Figure 1(a)). We equipped COMS with various sensors to record participant behavior, car dynamics, and environmental data. For participant behavioral data, manipulations of the steering wheel and brake/acceleration pedals were recorded. The car dynamics data were obtained from speed, acceleration, and angular velocity triaxial sensors. These data were collected at 2000 Hz . Three video cameras were mounted on the COMS in three different positions: front, downward, and face views. The front view camera captured the road conditions. The downward view camera was directed at the road surface and recorded road tags that identified where and when COMS passed specific course points. The face view camera captured the participants' facial expressions and steering control. Time codes were synchronized with the logged sensor and video data.

Virtual system A vehicle motion simulator called carSim from Mechanical Simulation Corporation was used as the virtual system (Figure 1(b)). The virtual system shared many characteristics with the real system, such as the front field of view that was $180^{\circ}$ on three screens and the driver's cockpit with the same interior as a real car. The manipulations of the steering wheel and brake/acceleration pedals were recorded as participant behavioral data. These data were collected at 100 Hz .

Laboratory system In the laboratory system, stimuli were presented to the participants on a 21 -inch computer screen
similar to a typical laboratory setting (Figure 1(c)). The laboratory system was different from the other two systems in many ways. For example, the road configuration was shown from a top-down view and the vehicle controlled by the participants was depicted as a black dot. The car dynamics provide simple reactions for participant inputs. The participants controlled the black dot using a gaming pad controller. When the participants input right or left on the steering control, the dot moved in the corresponding direction by pixels on the basis of the input time. Furthermore, the accelerator/braking operations increased/decreased the dot velocity. The participant operation data were collected at 25 Hz .

Figure 1: Multi-layered experimental platform

## Driving course

The participants controlled their vehicles on an experimental driving course. The course consisted of three physical configurations: sharp curves, gentle curves, and straight lines (Fig-

Figure 2: Overview of the driving course
ure 2). The driving courses used for each vehicle were similar and based on the vehicle's size.

## Method

## Participants

Study participants included twenty-one adults (11 males and 10 females) whose ages ranged from 31 to 55 (mean $=49$, SD $=3.0$ ). For the study to capture stable vehicle control, they were required to have over ten years of driving experience and currently drive a car more than ten days a month.

## Task

The experimental task assigned to the participants was to drive the vehicles toward the finish line using each system. They were instructed to drive as rapidly as possible and improve their lap times across the trials while maintaining driving safety.

## Procedure

The participants engaged in the task using each system as a within-participants design. The order of the experiments was counterbalanced between participants whenever possible.

For each system, the participants were involved in a practice and an experimental session. The practice session comprised of eight trials and the experimental sessions had six trials.

## Data treatment

In this study, we analyzed the BCs quantitatively. We defined the BCs of the braking, acceleration, and steering operations as similarities between feature vectors of each operation. In the real system, behavioral data of two participants were treated as missing values because of equipment trouble. In the virtual system, three participants could not participate for personal reasons. Furthermore, in the experimental session using the virtual system, all trials of two participants and four trials of four participants were treated as missing values due to 3D sickness.
Feature vectors Here, we summarize the definitions of feature vectors. For example, the feature vector of a braking operation is calculated as follows.
(1) The time-series data of a braking operation in a trial were divided into 26 sections. Each section corresponded to the region between two pairs of adjoining red pylons (see Figure 2 ).

Figure 3: Examples of feature vectors in the real system
(2) The average amount of a braking operation in each section was calculated.
(3) The series of 26 data points corresponded to a feature vector of a braking operation in each trial (see examples in Figure 3 (a)).

We calculated 6 vectorial data for each operation from all participants.
Behavioral Consistency as Similarity between Feature Vectors The BCs in each operation were calculated as an average of the similarity between two feature vectors using Pearson's product-moment correlation coefficient (Expression 1). The vector components of x and y in Expression 1 correspond to 26 data points each, as shown in Figure 3. Combinations of the feature vectors x and y are as follows from the viewpoint of the participant factor.

$$
S_{p}(\mathbf{x}, \mathbf{y})=\frac{\sum_{i=1}^{26}\left(\begin{array}{ll}
x_{i} & \bar{x}
\end{array}\right)\left(\begin{array}{ll}
y_{i} & \bar{y}
\end{array}\right)}{\sqrt{\sum_{i=1}^{26}\left(\begin{array}{ll}
x_{i} & \bar{x}
\end{array}\right)^{2}} \sqrt{\sum_{i=1}^{26}\left(\begin{array}{ll}
y_{i} & \bar{y} \tag{1}
\end{array}\right)^{2}}}
$$

Interpersonal BCs To discuss RQ1, the interpersonal BCs within each system were calculated to determine to what degree driving behaviors are consistent across individuals in the real system and whether such tendency observed in this system is confirmed in the other two systems. Specifically, first, one participant (Participant 1) was selected, and the correlation coefficients were calculated between the feature vectors of Participant 1 and those of another participant (Participant 2). Each had six feature vectors in each of the three operations of braking, acceleration, and steering; therefore, 18 (= ( $6 \times 6$ )/2) combinations were considered for the calculation. The average of the correlation coefficients among the 18 combinations was calculated. Second, in a similar manner, by repeating the calculation of the average of correlation coefficients between Participant 1 and the others, the average amount, defined as the correlation coefficient of Participant 1, was calculated. Finally, the interpersonal BCs within each system were calculated, defined as the average of the correlation coefficients of all participants (Participants 1-21).

Intrapersonal BCs To discuss RQ2, we calculated the intrapersonal BCs within each system to determine the degree to which individual behavior is more consistent than behavior across individuals in the real system and whether the greater consistency of individual behavior in this system is confirmed in the other two systems. Specifically, the correlation coefficients of one participant were calculated using 15 (= (6 x $5) / 2$ ) combinations and the average of the correlation coefficients among the 15 combinations was calculated. The intrapersonal BCs within each system were calculated, defined as the average of the correlation coefficients of all participants (Participants 1-21).

## Results

## Behavioral consistencies within the real system

Figure 4 shows the results of the inter- and intrapersonal BCs when using the real system. A two-way within-participants ANOVA for the operations (braking, acceleration, steering) and participants (interpersonal, intrapersonal) factors showed significant main effects of the operation and participant factors $(F(2,36)=76.35, p<.01 ; F(1,18)=14.47, p<.01$; respectively). Moreover, a significant interaction was noted between these factors $(F(2,36)=9.90, p<.01)$. The detailed results of the simple main effects tests are presented in Figure 4.

These results are summarized as follows: (1) In the interpersonal BCs, significant differences were found among the three operations, with the interpersonal BC of the steering operation as the highest, followed by those for acceleration and braking operations, respectively. (2) In the intrapersonal

BCs , this tendency was confirmed, and the intrapersonal BCs of the braking and acceleration operations were higher than their interpersonal BCs.

Figure 4: Behavioral consistencies within the real system

Figure 5: Behavioral consistencies within the virtual system

Figure 6: Behavioral consistencies within the laboratory system

## Behavioral consistencies within the virtual and laboratory systems

Figures 5 and 6 illustrate the results of the inter- and intrapersonal BCs when using the virtual and laboratory systems, respectively. The two-way ANOVAs showed significant main effects for the operations and participants factors in each system (virtual: $F(2,30)=103.71, p<$ $.01 ; F(1,15)=32.31, p<.01$, respectively, and laboratory: $F(2,40)=61.56, p<.01 ; F(1,20)=24.37, p<.01$, respectively). Moreover, significant interactions were observed between these factors (virtual: $F(2,36)=9.90, p<.01$, laboratory: $F(2,40)=7.97, p<.01)$. The results of the simple main effect tests are shown in Figures 5 and 6.

These results for the virtual and laboratory systems were similar to those for the real system. In the interpersonal BCs, significant differences were noted among the three operations, with the interpersonal BC of the steering operation being the highest, followed by those of the acceleration and braking operations, respectively. This tendency was confirmed in the intrapersonal BCs, with the braking and acceleration operations higher than their interpersonal BCs. Only in the laboratory system was a significant difference found between the inter- and intrapersonal BCs of the steering operation. However, the effect size (Cohen's $d$ ) in the steering operation was relatively smaller than in the brake and acceleration operation (braking: 0.89 , acceleration: 0.78 , steering: $0.57)$.

## Discussion

In this study, we constructed a multi-layered experimental platform to determine the BCs of driving behavior on the bases of two factors: the operations (braking, acceleration, steering) and participants (interpersonal, intrapersonal).

In this section, we summarize the results of the experiments from the viewpoint of each research question and then discuss them.

## Summary of Experimental Results

RQ1 asks to what degree driving behaviors are consistent across individuals in the real system and whether such a tendency is confirmed in the two different simulation systems. The results indicate that in the real system, the interpersonal BC of the steering operation was the highest, followed by those of the acceleration and braking operations, respectively This tendency was confirmed in the virtual and laboratory systems.

RQ2 is as follows: To what degree is individual behavior more consistent than behavior across individuals in the real system, and is the greater consistency of individual behavior in the real system confirmed in the other two systems? The analyses demonstrate that the intrapersonal BCs of both the braking and acceleration operations were lesser than that of the steering operation but they were higher than the interpersonal BCs for each system.

## Environmental Constraints

Experiment results reveal that the interpersonal BCs were different among the three operations in all systems: the interpersonal BC of the steering operation was the highest, followed by those of the acceleration and braking operations, respectively. This result suggests that each operation is regulated by different environmental constraints.
The higher environmental constraint on the steering operation than on the braking and acceleration operations might be caused by the arrangement of the driving course. Constraints based on driving course are recognized not only in the experimental setting but also in our daily driving situations. Our steering operations are strictly regulated by road configurations, whereas both acceleration and braking operations have high flexibility. That is, we usually do not out of traffic lanes, whereas the gas pedal or brakes can be used comparatively freely.

Additionally, there might be an interactive relation between the braking and acceleration operations. In some literature regarding the computational model of driver behavior based on cognitive architecture, the manipulation of vehicle controls has been defined as consisting of both lateral and longitudinal controls (e.g., Salvucci, 2006). The longitudinal control, or speed control, is achieved through coordination between the braking and acceleration operations, whereas lateral control is achieved by the steering operation. The mutually dependent relation between the braking and acceleration operations leads to an increase in their degrees of freedom. As a result, the BCs of the braking and acceleration operations might decrease more than that of the steering operation. Moreover, the velocity of the vehicle was mainly controlled by the gas pedal and not by the braking operation, causing different BCs for the braking and acceleration operations. In fact, as seen in the examples of feature vectors presented in Figure 3 (a) and (b), the frequency of the braking operation was substantially lower than that of the acceleration operation. Even though the participants typically controlled the vehicle velocity by using the gas pedal, in some accidental situations, they also had to press the brake to reduce the speed. As a result, the BC of the braking operation was lower than that of the acceleration operation.

## Individuality and Behavioral Consistencies

In studies of driving behavior, an important research topic has been to identify the uniqueness of individual driving behavior in order to develop intelligent driver assistance systems customized for individual drivers. More specifically, identifying an individual's deviation from ideal behavior leads to predicting accidents and possibly preventing them (e.g., Igarashi et al., 2004; Wakita et al., 2005; Okuda et al., 2009).
The results of our experiments imply that the braking and acceleration operations are useful measures for identifying individual driver behavior because substantial differences were noted between the inter- and intrapersonal BCs. On the other hand, only a small difference was found in the steering op-
eration because this operation was strongly regulated by the environmental constraints. Our experiments suggest that considering the generality and individuality of the environmental constraints in each operation is important when using behavioral data as personally identifying information.

## Conclusion

In this research, we discussed the behavioral consistencies (BCs) within multiple systems-real, virtual, and laboratory systems-on a multi-layered experimental platform. The results showed that the BCs of the steering operation were the highest, followed by those of the acceleration and braking operations, respectively. The intrapersonal BCs (BCs within individuals) of the braking and acceleration operations were higher than the interpersonal BCs (BCs across individuals) in all systems. Further, this tendency was consistent in all three systems. In this paper, we discussed the behavioral consistencies within each system and the similarity of their tendencies among the three different types of systems. These findings lead to another research question: To what degree is human behavior similar across the different types of systems when comparing behavioral characteristics directly? This question can be investigated in future studies.

## Acknowledgments

This research was conducted as a part of "Modeling and Detecting Overtrust from Behavior Signals," a study led by Kazuya Takeda. This took place within the "Creation of Human-Harmonized Information Technology for Convivial Society" project under the direction of Yoh'ichi Tohkura, Research Supervisor in the Core Research of Evolutional Science and Technology (CREST) program at the Japan Science and Technology Agency (JST).

# Is Lexical Access Driven by Temporal Order or Perceptual Salience? Evidence from British Sign Language

Vinson (d.vinson@ucl.ac.uk)<br>Neil Fox (neil.fox@ucl.ac.uk)<br>Gabriella Vigliocco (g.vigliocco@ucl.ac.uk)<br>Deafness, Cognition and Language Research Centre, Department of Cognitive, Perceptual and Brain Sciences<br>University College London, 26 Bedford Way, London, WC1H 0AP, UK

#### Abstract

While processing spoken language, people look towards relevant objects, and the time course of their gaze(s) can inform us about online language processing (Tanenhaus et al, 1995). Here, we investigate lexical recognition in British Sign Language (BSL) using a visual world paradigm, the first such study using a signed language. Comprehension of spoken words and signs could be driven by temporal constraints regardless of modality ("first in, first processed"), or by perceptual salience which differs for speech (auditorialy perceived) and sign (visually perceived). Deaf BSL signers looked more often to semantically related distracter pictures than to unrelated pictures, replicating studies using acoustically-presented speech. For phonologically related pictures, gaze increased only for those sharing visually salient phonological features (i.e., location and movement features). Results are discussed in the context of language processing in different modalities. Overall, we conclude that lexical processing for both speech and sign is likely driven by perceptual salience and that potential differences in processing emerge from differences between visual and auditory systems.

Keywords: lexical access; sign language; semantics, phonology, visual world; modality

## Introduction

General theories of language processing have developed on the basis of extensive data from spoken, but not signed languages, making it impossible to tease apart those aspects of language processing that are truly general from those dependent on the oral-aural language modality. While spoken language processing happens through aural perception of sounds, sign language processing occurs through visual perception which allows for more simultaneous input of information; spoken languages make use of mouth and vocal tract, while signed languages use slower manual articulators (hands, as well as eyes, mouth and body). An understanding of the processing differences that arise from these differing language modalities is critical for understanding the interaction of language processing with other cognitive systems such as perception and action. Here we take advantage of these physical differences in language processing for signed languages compared to spoken languages to investigate the nature of lexical processing and lexical access.

For spoken languages, it is generally uncontroversial that information is processed almost immediately as it comes in (e.g., Rayner \& Clifton, 2009). Such incremental moment-by-moment language processing is likely necessary to keep up with the incredibly fast rate of speech input (estimated to be between 150-190 words per minute, Marslen-Wilson, 1973). However, during incremental processing listeners, processing even a single word, are faced with many possible alternatives that match the current acoustic-phonetic input. Empirical evidence suggests that instead of waiting until temporary ambiguities are resolved, partial activation of possible words (i.e., lexical competitors) that match current phonological information proceeds, with potential words being eliminated across time as more information becomes available (e.g., McClelland and Elman, 1986; Gaskell \& Marslen-Wilson, 1997).

Evidence for incremental activation of lexical competitors during spoken language processing comes from the "visual world" paradigm (language presented simultaneously with related pictures; Allopena, Magnuson, \& Tanenhaus, 1998; Altman \& Kamide, 2004; Huettig \& Altmann, 2005; Yee \& Sedivy, 2006). For example, in Allopena et al. (1998), subjects heard an utterance like "Pick up the beaker" while viewing a display with four pictures including: 1) an object matching the noun (the target; e.g. "beaker"), 2) an object with a name beginning with the same phoneme (e.g. "beetle"), 3) an object with a name sharing the same rhyme (e.g., "speaker") and, 4) an unrelated object (e.g., carriage). The probability of fixating the target and onset competitor were identical immediately after word onset (when the two could not be distinguished from each other), and fixations to these picture types were higher than fixations to the rhyme or unrelated competitors. Immediately after reaching a phoneme differentiating the target and onset competitor, the probability of fixating the target rose sharply while the probability of fixating the related competitor fell. A weaker, but significant effect was also observed for rhyme competitors compared to unrelated competitors, indicating that activation is not restricted to words sharing onsets but is continuous (see for example McClelland and Elman, 1986).

A question of interest, then, is why words that share onsets make the strongest lexical competitors. One possibility is that strong activation of onset competitors compared to word rhymes is due to temporal considerations: i.e., word onsets occur earlier in time. This view about the
activation of onset competitors can be called a 'first in, first processed' account. However, onsets also tend to be salient, particularly in languages such as English (used in the majority of visual world studies) in which stress has the effect of lengthening the first syllable as well as adding both intensity and pitch change: all of which serve to make the first part of a word more salient. Evidence that stress is important to lexical access comes from Reinisch, Jesse, and McQueen (2010). In a visual world study they found that participants use lexical stress information to direct eye gaze such that upon hearing a word with initial stress (e.g., octopus) fixations on printed target words with first-syllable stress (e.g., octopus) were more frequent than fixations on differently stressed competitors (e.g., October, with stress on the second syllable). Thus, an alternate account of the strong activation of onset competitors observed in visual world studies is that word onsets are the most auditorily salient part of a word and that auditory salience drives lexical access for processing efficiency. However, because spoken word onsets tend to be both temporally early and auditorily salient, it is difficult to tease apart these alternate accounts based on previous studies.

Interestingly, unlike spoken words, for visually processed signs there is evidence that the phonological features that form the onset of a sign (i.e., the first features to be formed as a sign moves through time) may not coincide with the most visually salient features (i.e., the features that can be seen most easily, for example, under visually noisy conditions). Just as in spoken languages, signed languages have sub-lexical units (phonological features) that combine in rule-governed ways to form words/signs. Signs are made up of phonological features from three major parameters (handshape, movement, and location [place of articulation]; see Sandler \& Lillo-Martin, 2006 for discussion, and Figure 1 for examples of signs sharing these features). In terms of sign onsets, results from early gating studies (single frame presentation of a sign, with subsequent presentations increasing in length; Grosjean, 1981, Emmorey \& Corina, 1990) suggest that handshape and location features are recognized first across time. In Emmorey \& Corina (1990) subjects' initial responses tended to share the handshape and location of the target sign but differed in movement features. Once the movement of the sign was identified, the target sign also tended to be identified. The authors suggest that lexical recognition in a signed language is a two-stage process such that handshape and location are identified almost from the start of the sign (i.e., form the onset of the sign) followed by movement which coincides with sign recognition.

In terms of sign salience, Corina \& Hildebrandt (2002) used a sign similarity judgement task and found that subjects preferred to pair non-signs with other non-signs sharing location and movement features more frequently than pairing non-signs with matching handshape and location features, or handshape and movement features, suggesting that they are paying attention to these feature pairings. Further support for the salience of movement and location features is found in Corina \& Knapp (2006) who
used a picture sign interference task (subjects named a picture in ASL while trying to ignore a superimposed image of a related distracter) and found that distracter signs sharing both movement and location with the target sign resulted in significant facilitation effects at all stimulus onset asynchronies ( $-130,0,130 \mathrm{~ms}$ ), while signs sharing handshape and location, or handshape and movement features did not affect picture naming.

Figure 1: Examples of phonological minimal pairs in BSL. Top: car and robot share location and movement (up and down) parameters, but differ in handshape. Middle: saxophone and computer share handshape and movement (finger wiggle) features, but differ in location. Bottom: mouse and nose share handshape and location features, but differ in movement (mouse, with a twisting movement and nose with a tapping movement).

While location features are available early in sign perception, movement features only emerge later and are therefore crucial in teasing apart whether lexical access (at least for signs) is driven by temporal constraints or by perceptual salience. If temporal constraints drive lexical access in sign, signers should pay attention to handshape and location features which are available at the start of a sign and ignore movement features which emerge later. Movement features have been argued to be the most sonorous or salient part of a sign (Perlmutter, 1992). Thus,
if perceptual salience is instead key to lexical access, then signers may pay attention to movement features.

Here we investigate lexical recognition in BSL using a visual world paradigm and asking whether or not the nature of access in a dynamic visual language is also incremental and graded with alternate possible words considered simultaneously over the time-course of processingFurther, we consider the nature of activation of lexical competitors (if any) and whether sign access supports a first in, first processed pattern, or a pattern driven by visual salience.

We include two critical conditions. First, a semantic condition will determine if a visual world paradigm can be a successful methodology using sign language which must be presented visually. Previously subjects have been found to look towards semantically related competitor pictures during spoken language visual world studies (Huettig, \& Altmann, 2005). Here we explore whether eye movements are drawn to a semantically related object in a signed visual world in the absence of a phonological or visual relationship. The Visual World paradigm has never been used with sign language stimuli and a semantic condition (see methods) serves as our test case, under the assumption that semantic relationships should hold regardless of language. If the visual world methodology is successful with BSL, we should expect subjects to look more frequently to distracter pictures that are semantically related to a given target sign. Secondly, we examine the nature of sign recognition in real time using pictures that have phonologically related signs. If temporal information is most important, and signers process information primarily through sequential, incremental, first-in first-processed order, then signs sharing handshape and location features should be particularly salient for them. Alternatively, if perceptual salience is more relevant then signers may instead look more frequently to distracters that share movement and location features.

## Method

## Subjects

24 Deaf signers ( 13 women, 11 men, mean age 34.8 ) were recruited from deaf communities in England and took part in the experiment. Of these, eleven were native signers (born to deaf signing parents), four began signing by the age of five (early signers) and 9 learned BSL after age five. All subjects use BSL as their preferred and primary language.

## Materials

For each trial, four pictures of objects were presented simultaneously with a centrally located video clip (see Figure 2). In each video clip, a native BSL signer produced the carrier phrase, "I see...", followed by the target sign. Subjects were asked to indicate (with button press, "yes" or "no") as quickly and accurately as possible whether the target BSL sign matched one of the pictures. "Target Present" trials ( $\mathrm{n}=79$ ) in which a picture of the target sign was present constituted our fillers. On critical "Target

Absent" trials ( $\mathrm{n}=28$ ), three unrelated distractor pictures with no semantic, phonological or visual relationship to the target sign were presented along with a related distracter picture. Related distracter pictures had signs that were either semantically (e.g., target: banana, distracter: strawberry, target: zipper, distracter: button) or phonologically related to the target. Phonologically related pictures were minimal pairs that shared two out of three parameters (see Figure 1 for examples). Semantically related distracter pictures were not phonologically related to the target, and phonologically related pictures were not semantically related.

Figure 2: Example of a single trial. Areas of interest for gaze analyses were set directly around the ( $250 \times 250$ pixels) pictures and the ( $320 \times 240$ pixels) video.

## Procedure

After giving consent to participate, subjects were presented with video-recorded instructions in BSL (signed by N.F., a native BSL signer) and invited to ask clarification questions. Subjects were then fitted with a head-mounted eye-tracker (SR Research, EyeLink II) and initial calibration was performed (9 fixation points). Subjects were seated 50 cm from the monitor with the tracker positioned in front of the right eye. There were four practice trials before the experiment began. Another calibration check was performed after these practice items and then again after every 36 trials (the final set had only 35 trials), at which time subjects took a self-paced break (total 107 trials, 3 sets). Additionally, drift correction on a single centrally located fixation point was performed at the start of each trial. Responses were recorded using a hand-held joypad with buttons that can be located tactilely without the need to look at keys. The entire experiment (with instructions and calibration) took approximately 20 minutes to complete. In order to ensure that all pictures were familiar to the subjects as well as to obtain naming data, subjects named all of the pictures used in the visual world experiment before we began.
The location of the pictures was balanced so that each picture type (related distracter, unrelated distracter [filler]) occurred a roughly equal number of times in each location within a given condition. Additionally, we created two sets of stimuli such that half the subjects saw any one picture in one location and half of the subjects saw it in a different location. The order of trial presentation was randomized
throughout. Pictures were presented simultaneously with the sign video.

## Results

First we analyzed signs produced during picture naming to ensure that signs for target and related pictures in the phonological conditions were indeed phonologically related in subjects' lexicons. Individual trials were excluded when subjects produced a sign (for either target or related pictures) that did not have the intended phonological relationship (6\%). Error trials, in which participants mistakenly indicated that the target sign matched a picture on the screen $(12.4 \%)$ were also excluded from analyses of response latencies and eye gaze. The number of trials by condition along with average correct response latencies and percent of correct answers across different conditions are reported in Table 1. A one-way repeated measures ANOVA by subjects revealed no significant differences for accuracy between conditions: $\mathrm{F}(3,69)=1.686, \mathrm{p}=.178$. However, a significant difference was found between conditions for response latencies $\left(F(3,66)^{1}=3.202, p=.029\right)$. Post-hoc tests revealed that responses were slower for handshapemovement trials than other conditions.

Table 1. Average correct response time (standard deviation by subjects in brackets) and percent correct as a function of relatedness type. Sem: related picture sharing a semantic relationship to the target; HS-MV: related picture sharing the handshape and movement of the target sign; LOC-MV: sharing the location and movement of the target sign; HSLOC: sharing both the handshape and location of the target sign.

|  | Items | $\boldsymbol{R T}$ (SD) | \%Correct |
| :--- | :--- | :---: | :---: |
| SEM | $\mathrm{n}=11$ | $2792(462)$ | 88.3 |
| LOC-MV | $\mathrm{n}=5$ | $2730(421)$ | 91.1 |
| HS-MV | $\mathrm{n}=6$ | $2887(421)$ | 87.9 |
| HS-LOC | $\mathrm{n}=6$ | $2662(446)$ | 83.2 |

Five areas of interest within each time period were identified: the location of the signer in the middle of the screen (displayed as video), and one corresponding to each of the pictures displayed (coded as target, related, unrelated and matching in size to the actual pictures). The dependent measure of interest was dwell time (summed gaze duration in a given area, measured in milliseconds). Not surprisingly, across all trial types, gaze was primarily directed to the signer in the video ( $\mathrm{M}=86.9 \%$ ). This led to fewer looks towards pictures than would be expected in a study with auditory stimuli, so we started with a broad analysis. Specifically, for each trial, we identified two time windows. The early period, began at the start of the trial and ended when the carrier phrase "I see..." finished. Because the

[^232]target sign was not yet produced during the early period, gaze could not yet be informed by the target. The late period was defined as the period from the start of the target sign until the button was pressed. Gaze during the late period should provide information about processing of the target sign.
In the first set of gaze analyses across the different pictures, we tested whether subjects looked longer at related pictures than unrelated pictures in the late time period, once the meaning of the target sign could be processed. We conducted hierarchical linear regressions, treating subjects and target signs as random effects, including picture relatedness (considering only related vs. unrelated pictures) and time period (early vs. late) as predictors, and dwell time (in milliseconds) as the dependent measure. Separate models were fit for each relatedness condition (semantic, location-movement, handshape-movement, handshapelocation) ${ }^{2}$. Across all conditions there was a main effect of time period indicating longer gaze overall in the late period: semantic (95\% CI [183.7, 221.1], $p_{M C M C}<.001$ ); locationmovement ( $95 \%$ CI [134.0, 199.3], $p_{\text {МСМС }}<.001$ ); handshape-movement ( $95 \%$ CI [135.8, 190.0], $p_{\text {MCMC }}$ $<.001$ ); and handshape-location (95\% CI [121.3, 172.4], $p_{M C M C}<.001$ ). The main effect of picture relatedness was not significant in any of the four conditions (all $p_{M C M C}>.67$ ).
The crucial effect is the interaction between picture relatedness (related vs. unrelated) and time period (early vs. late) on dwell times, as increased looks to related pictures should only start to occur once the target sign is being produced. For semantic trials, the picture by time period interaction was significant ( $95 \%$ CI of relative increase for related pictures in the late period [63.5, 107.9], $p_{M C M C}$ $<.001$ ) reflecting longer gaze to related compared to unrelated pictures in the later time period (that is, after the carrier phrase was complete and the target sign was being produced). A significant interaction of picture by time period was also observed in location-movement trials ( $95 \%$ CI of relative increase for related pictures in the late period [20.9, 96.6], $p_{M C M C}=.001$ ), again reflecting longer gaze to related than unrelated pictures in the later time period when information about the target sign becomes available. However, for the other two phonological conditions (handshape-movement and handshape-location) the interaction of picture and time period did not reach significance (both $p_{M C M C}>.3$ ).
We next conducted a Wilcoxon signed-rank test comparing looks to related and unrelated distracter pictures to explore possible differences in gaze across time, beginning at target sign onset. Cumulative fixations, analyzed as arcsine transformations, were grouped into

[^233]100ms bins starting from 400 ms after the target onset and continuing until 1000 ms (see Figure 3 for time course plots). 100 ms bins were used to ensure the presence of sufficient fixations to each area of interest during each time period for statistical analyses. Additionally, analyses began at 400 ms after the start of the target period because during the first 300 milliseconds of the target period across all trials, subjects fixated the sign video almost exclusively. For semantic trials, cumulative gaze toward related pictures differed significantly from the unrelated pictures across all bins from $400-1000 \mathrm{~ms}$ (range of Z from -2.20 to -3.59 , all $\mathrm{p}<.03$ ). This same pattern of results was observed for location-movement trials (range of Z from -2.31 to -3.63 , all $\mathrm{p}<.02$ ). There was no difference between related and unrelated picture gaze for handshape-location trials across all bins (all $p_{>} .24$ ). However, there were significantly more looks to related pictures compared to unrelated pictures for the handshape-movement condition, but this difference was found only from $800 \mathrm{~ms}-1000 \mathrm{~ms}$ ( $\mathrm{p}<.05$, between $800-$ 100 ms ; all $\mathrm{p}>.2$ up to 800 ms ).

Figure 3: Time course of eye gaze from onset of the target sign for 1000 ms for target-absent trials across the four conditions (from left to right: semantic, location-movement, handshape-location, handshape-movement).

## Discussion

Overall, we found both semantic and phonological effects during online processing of BSL using a visual world paradigm. Once information about the target sign became available, subjects looked at related pictures longer than unrelated pictures during the semantic condition. During the production of the target sign, related pictures also attracted more looks than unrelated pictures for one phonological condition (location-movement) but not for the others (handshape-location and handshape-movement). Importantly, in the early period of each trial (i.e. before the target sign was produced), there was no difference in gaze patterns to the different picture types (related and unrelated) confirming that the results are not driven by visual characteristics of the related pictures.

In the semantic condition, subjects looked at semantically related distracter pictures more frequently than unrelated pictures, the first time such findings have been demonstrated for a signed language. This result is predicted under the view that activation of semantically related lexical competitors should not be affected by the modality in which a language occurs. The results from the semantic condition reveal that despite the need for split visual attention to both visual linguistic stimuli and pictures related to that stimuli, it is possible to investigate sign language processing using visual world and related paradigms.
The results from the three phonological conditions pairing different phonological parameters produced differing results. Phonological competitors that shared information occurring at the onset of the sign (handshape and location features) did not draw more looks either at the onset of the period in which the target sign was produced (as evidenced by our analysis of the time period from $400-1000 \mathrm{~ms}$ after the target sign onset) or during the entire time period from the target sign onset until a button press decision was made (the late time period). This finding suggests that onsets may not be as relevant to sign language processing as has been suggested for spoken language processing (e.g., Gaskell \& Marslen-Wilson, 1997).
Crucially, in the location-movement condition, subjects looked significantly more toward the phonologically related picture than unrelated pictures in the late time period. This finding parallels the Corina and Knapp (2006) study that found effects only for signs sharing location and movement features. Further, for location-movement trials, looks to the related and unrelated pictures differed significantly from 400 ms after the onset of the target sign, a time comparable with that found in spoken language studies (e.g., Allopena et al, 1998). Finally, competitor pictures that shared handshape and movement features with the target did not draw more looks than unrelated pictures during the late time period. However, there was a significant, but short-lived difference such that looks to related and unrelated pictures differed between $800-1000 \mathrm{~ms}$ after the start of a target sign. Because a difference between related and unrelated pictures was not observed in the overall late period analyses we conclude that, while subjects may be aware of the phonological similarity of signs sharing handshape and movement features, they are likely not making use of these feature pairs during online processing. Instead, looks to related pictures occurring between 800 and 1000 ms (relatively late after the onset of the target sign) appears to be a post-lexical effect in which subjects consider alternate competitor pictures before determining that the target picture is not shown. Crucially, the pattern of gaze in the handshapemovement condition differs from the location-movement condition for which gaze to the related competitor picture is early and consistent. Thus, we suggest that gaze toward related competitors in location-movement trials is indicative of active online lexical processing as has been found in spoken language studies.
In the introduction, we offered two explainations for why onsets play a special role in auditory lexical access (i.e.,
either temporal constraints or salience). In terms of sign language processing, if temporal constraints are driving lexical access, then signers in our study should have paid attention to handshape and location features because these features are available at the start of a sign. Instead, the sign language results suggest that sign onsets are not similarly privileged to spoken word onsets, which in turn suggests that lexical processing is not temporally driven.
Alternatively, the data support a view under which perceptual salience drives sign access. Specifically, our data show that signers pay attention to movement features which are visually salient, but which occur relatively late in sign production: only trials with related distracters that share movement features show differences between looks to unrelated filler pictures and related competitor pictures. Further, the pairing of location-movement features appears to be of greatest importance during online processing.
The nature of acoustically perceived speech in languages such as English makes it impossible to determine why word onsets seem to have privileged status in lexical access: either due to temporal characteristics (perceived first) or perceptual salience. Investigating signed languages such as BSL allows us to clearly tease these apart, because the most salient perceptual properties (e.g. movement) are not available at the onset but only become available later. Thus, increased looks towards related distracter pictures in the location-movement condition may provide insight, not only into the nature of online sign processing but online speech processing as well. It is important to note that there is no a priory reason to assume that (visual) signs and (auditory) words will be processed similarly and therefore different strategies might be used.

Overall, the results here reveal important characteristics of lexical access concerning the role of lexical variables (semantic condition) and relative time course of access to different phonological parameters (phonological condition) for sign language processing. More broadly, our current understanding of language processing is intimately tied to oral-aural modality of spoken languages. The current work clearly shows that language processing interacts with modality, and that the key to lexical access for both signed and spoken languages may be perceptual saliency, instead of temporal recency.

# A Natural Cure for the Pet Fish Problem: Feature Emergence as Classificatory Composition 

Chris Thornton Informatics<br>University of Sussex<br>Brighton<br>BN1 9QH<br>UK<br>c.thornton@sussex.ac.uk

#### Abstract

Where do emergent features come from? This has long been an intriging puzzle. The concept of pet fish illustrates the difficulty. Most people expect pet fish to live in bowls, even though this is not something either pets or fish normally do. The inference that pet fish have the feature of living in bowls cannot be explained purely in terms of the constituents themselves. The feature seems to emerge. The present paper aims to explain this effect using notions of classificatory composition. Adjoined concept references are taken to construct classifications rather than combinations; a pet fish is taken to be a fish classified as a pet rather than a combination of a pet a fish. It is also shown that, where concepts have a compositional representation, feature emergence can be accounted for in terms of compositional accommodation.

## Introduction

The concept of pet fish is one of the best known examples of a conceptual combination that produces difficult to explain 'emergent features.' People expect pet fish to live in bowls, even though this is not expected of either pets or fish (Murphy, 1988). The feature lives-in-bowls somehow leaps into existence when the concepts pet and fish are combined. But how and why? The effect seems to be something to do with the way the combination is explained. But giving a precise and general account is not straightforward (Rosch, 2011). This is the so-called Pet Fish problem, also known as the Guppy problem (Osherson and Smith, 1981)

Simple cases of concept combination are dealt with relatively easily. Let's say we combine the concept brown with the concept cow to form the concept, brown cow. Linguistically, the effect is to apply an adjective to a noun. In conceptual terms, the process is said to involve attachment of a modifier concept (brown) to a head concept (cow). Various explanations can then be set out. Assuming a schematic, slot/filler type of representation, the effect can be seen as one in which the modifier concept brown becomes the new filler for the color slot in the cow representation (cf. Hampton, 2011).

Simple explanations of this sort run into problems quite quickly, however. One relates to typicality effects. Consider the concept of a road bridge. For residents of the UK, a highly typical case of a road bridge is the Forth Road Bridge in Scotland. Unfortunately, this entity is unlikely to be considered typical of either roads or
bridges, on which basis there is a mystery about how the combination acquires typicality attributions not given to either constituent. This is known as the conjunction effect (Smith and Osherson, 1984).

Schematic theories of representation (Rumelhart and Ortony, 1977; Rumelhart, 1980) seem to offer a way of dealing with such problems. Let's say an apple concept is represented by a schema with slots for color and size. The fact that apples are typically green may be captured by placing a high typicality value on green as a color value (Murphy, 2002, p. 447). If constructing the concept of a red apple has the effect of placing red into the color slot of the apple schema, while also giving it a high typicality value, the expected typicality effect is reproduced. A red apple is then modeled as more typical of the concept red apple than it is of the concept red, or the concept apple. This approach to typicality values is at the heart of the selective modification proposal of Smith and Osherson (1984; Smith et al., 1988). ${ }^{1}$

The immediate difficulty with this idea is that it depends on there being a suitably modifiable slot in the head schema (Machery, 2009). In many cases, this seems to be ruled out. Consider Murphy's example of a 'party dog'. A plausible idea is that a party dog is a dog that does tricks. It is much less plausible that a dog schema will have a does-tricks slot, however. Combinations in which the head concept seems to lack any usefully modifiable slot abound. As Murphy notes, it is simply 'not the case that an adjective can automatically pick out a single dimension to modify' (Murphy, 2002, p. 450).

The general difficulty is the way in which concept combination goes beyond what can plausibly be conjured from constituent representations. The concept of pet fish is the classic illustration but 'Harvard-educated carpenter' is also revealing. People described as instances of this concept are likely to be seen as non-materialistic (Kunda et al., 1990). This seems to involve reasoning with relations that have nothing to do with the constituent concepts. Kunda et al., describe the process as the development of a 'causal narrative.' A simpler ex-

[^234]ample is 'big dog'. This entity seems to have features that cannot be explained in terms of representations for the concept big and the concept dog. A big dog is presumably small in relation to a house, for example. Any theory that models the combinational process purely in terms of constituent representations cannot explain such effects.

Explaining how concept-combination goes beyond processing of constituent representations is thus a key part of most proposals. In the concept specialization model of (Cohen and Murphy, 1984; Murphy, 1988) the process is understood to involve placing a representation of the modifier concept into a slot selected on the basis of background knowledge. This is then interpreted and elaborated taking 'outside knowledge' into account (Murphy, 1988, p. 533). ${ }^{2}$ The model allows scope for emergence of features through explanation. It has also been extended by Wisniewski to incorporate mechanisms of property-mapping, concept hybridization and relationlinking (Wisniewski, 1997; Wisniewski and Love, 1998).

Other proposals envisage ways in which processes of reasoning might directly mediate the combinational process. In Thagard's Amalgam theory (Thagard, 1984) application of procedural rules regulates slot/value selection in ways that promote an interpretation that reconciles 'the conflicting expectations contained in the candidate concepts' (Thagard, 1984, p. 4). Hampton's composite prototype model (Hampton, 1987, 1988, 1991) also deems combination to involve processes of reasoning, although here the process is based on theory-driven relations connecting slots of the original representations. Another proposal is the CARIN model of Gagne and Shoben (1997; Gagne, 2000; Gagne and Shoben, 2002). Here, the key idea is that combinational processes access a small library of fundamental thematic relations, including Cause, Has, About, Make, For, Use and Located-at. The model envisages combination to involve constructing an integrated slot/filler representation based around one or more of these foundational relations.

A variety of combinatorial mechanisms are proposed in the literature, then. Each has its pros and cons from the explanatory point of view (Ran and Duimerang, 2009; Murphy, 2002). The present paper aims to add a new explanatory proposal but does not hypothesise any new form of combinatorial mechanism. Rather it aims to explain featural effects in terms of the compositional properties that concepts inherently possess. It aims to show the sense in which feature emergence is a natural outcome of conceptual compositionality.

The hypothesis, more specifically, is that feature emergence can be explained in terms of natural concept com-

[^235]position. Conceptual structure assembled by this process has the distinguishing feature of being held together purely by the classificatory properties of concepts in the structure. There is no superimposed, compositional framework. The features which emerge from combining two concepts, it is argued, can be explained as the constructs that grow out of extending a natural compositional structure to accommodate constituent representations. However, it is to emphasized that the examples set out are intended to illustrate possible mechanisms. They are not intended to be realistic models of cognitive structure. The proposal is set out in two main sections. The section immediately to follow introduces the idea of natural concept composition. The second section shows how this type of conceptual structure can be a way of explaining cases of feature emergence.

## Natural concept composition

Although the classificatory functions of concepts are normally viewed as applying to non-conceptual entities, they can also be seen as applying to concepts themselves. A fork concept is the means of classifying something as a fork. A plastic concept is the means of classifying something as plastic. But some forks are plastic, on which basis the plastic concept can also be a way of classifying the fork concept. What is picked out is the extensional intersection - the set of all plastic forks. This is just the extension of the concept of plastic forks. Where extensions intersect in this way, the effect of using one concept to cross-classify another can thus be a new concept: it is the concept whose extension is the intersection arising. Cross-classification of one concept by another has the potential to yield an implied concept, with an extension that is derived by intersection.

The more complex case of this is where we have a concept that classifies an $n$-tuple of entities (i.e., a relation). For example, let's say we have a male-celebrity concept, a female-celebrity concept and a married-couple concept. There is the potential for a male and female celebrity to be classified as a married couple. The married-couple concept is a potential classification of an $n$-tuple comprising the male-celebrity and female-celebrity concepts, then. The result is a celebrity-couple concept, whose extension is the set of couples made up of a male and a female celebrity.

Classifications of this type exist whenever the extension of the classifying concept contains at least one of the possible permutations of instances. To formalize this, we have to work in terms of cartesian products. A crossclassification exists if the extension of the classifying concept intersects the cartesian product of the extensions of constituents in the classified $n$-tuple. ${ }^{3}$ Provided we allow singleton $n$-tuples, this deals with all cases, since the

[^236]cartesian product of a single set is just the set itself． A general rule can be stated accordingly．
－Cross－classification rule：concept $x$ classifies some $n$－tuple of concepts（not including $x$ ）if the cartesian product formed from their extensions intersects the extension of $x$ ．

It is then possible to define the situation where a set of concepts gives rise to an implied concept by means of classificatory composition．
－Composition rule：if within some set of concepts there is a valid cross－classification that gives rise to an extension that is new for the set，this composition is an implied concept．

The idea of＇compositional completion＇can then be set out．A set of concepts may be said to be compositionally complete just in case it has no implied concepts．This either means all of them have already been added，or there were none to begin with．The compositional com－ pletion of a set of concepts is the set of implied concepts given rise to，then．The composition rule specifically re－ quires that an extension be new for the original set of concepts．This accommodates the possibility of having two or more implied concepts with the same extension．

Notice the rules allow for cumulative effects：the iden－ tification of one implied concept can give rise to another． The result in such cases is a compositional structure of two levels－one classification inside another．There is no limit on the number of times this can happen，and thus no limit on the structural complexity that may emerge．The compositional completion of a set of con－ cepts may comprise conceptual structures of arbitrary compositional complexity．These structures have the distinguishing feature of being held together purely by the classificatory properties of the concepts they contain． There is no superimposed，compositional formalism．For this reason，the process is called natural concept compo－ sition．

## Couples example

The dynamics of natural concept composition can be illustrated by extending the celebrity－couples example． Let＇s say we start with a set of five concepts defined as follows．

```
male-celebrity = {Brad, David, George}
female-celebrity ={Ange, Posh, Rita}
pets ={Fido, Twinkle, Rover}
couples = {\langle\mathrm{ Brad Ange }\rangle,\langle\mathrm{ David Posh }\rangle,\langle\mathrm{ Fido Qi}\rangle}
pet-owners = {\langleBrad Ange Fido\rangle, \langleJo Sam Rover }\rangle
```

These definitions should be self－explanatory．The exten－ sion of the male－celebrity concept is defined to be $\{\mathrm{Brad}$ ，

David，George\}. The extension of the couples concept is $\{\langle\operatorname{Brad}$ Ange $\rangle,\langle$ David Posh $\rangle,\langle$ Fido Qi $\rangle\}$ ，and so on． All elements of extensions are understood to be $n$－tuples， but where $n=1$ ，the angle brackets are omitted．

Examination of the definitions reveals that initially there is just one compositional implication．The exten－ sional cartesian product of male－celebrity and female－ celebrity intersects the extension of the couples con－ cept，with the intersection being $\{\langle$ Brad Ange $\rangle,\langle$ David Posh〉\}. The classification of 〈male-celebrity femalecelebrity $\rangle$ by the couples concept is an implication of the set，then．For purpose of notating this，the conven－ tion used here is to enclose the classifying concept and its constituents in square brackets，with the classifying concept placed first．The implied construction is thus written

## ［couples male－celebrity female－celebrity］

The concept is that of a celebrity couple：it is referred to as the celebrity－couple concept below．The extensional definition is $\{\langle$ Brad Ange $\rangle,\langle$ David Posh $\rangle\}$ ．
Once this implied concept has been identified，there is a knock－on effect resulting from the ability of the pet－ owners concept to classify a composite of celebrity－couple and pets．The cartesian product derived from this in－ cludes $\langle$ Brad Ange Fido〉，which is within the extension of pet－owners．A second implied concept then exists，in which the initial construction plays the role of a con－ stituent．This is a structure of two levels：

```
[pet-owners
    [couples male-celebrity female-celebrity]
    pets ]
```

The implied concept is that of a celebrity－couple classi－ fied as pet owners．In other words，it is the concept of a pet－owning celebrity－couple．This is the final implica－ tion in the present case．The compositional completion of this set comprises just two concepts，then．

## Feature emergence

The second part of the proposal can now be set out．The hypothesis is that feature emergence results from natu－ ral concept composition．Viewing concept combination as classificatory composition has the effect of making fea－ ture emergence an expected outcome．Where a feature is seen to emerge as a result of combining two concepts， the process can be modeled in terms of compositional conceptions brought into existence by activating compo－ sitional representations．

In the simplest cases，concept combination can be ex－ plained purely in terms of schematic representation，and the ways in which activating one schema modifies an－ other．Such accounts are straightforwardly translated into the present framework．From the compositional point of view，a slot／filler schema is a construction in
which the classifying concept is that of combination, and each constituent is a one-level construction in which a filler value classifies a slot value. An apple schema has something like the following form, then.
[combination [green color] [round shape]]

Any account in which concepts are deemed to be combined by means of schema modification can then be expressed in terms of conceptual integration. Taking the concept of red to have the form [red color], an integration of the apple and red concepts would produce this conception of a red apple, for example.
[combination [red color] [round shape]]

This is the sense in which compositional processes can model schema-updates. ${ }^{4}$ But notice the classificatory viewpoint that is imposed. On the assumption of the combination being represented compositionally, a red apple is an apple that is classified as red. It is not a red thing that is also an apple.

Combinations of more relevance to the Pet Fish problem are ones which yield emergent features via inferential explanation. The account in the case of 'pet fish' has already been noted: people expect pet fish to live in bowls (even though this is not the usual behavior of either pets or fish) because this is a way of explaining how fish can be both kept, and kept alive (cf. Murphy, 1988). The process is seen to involve the construction of an inferential explanation in which living in bowls is inferred to be the only way of meeting the requirement for fish to be kept in water.

The procedure for translating an explanatory process into a compositional one involves treating each inferential step as a conception. Inferences involving a schematic idea are seen as combinatorial conceptions (i.e., classifications based on the concept of combination). Inferences involving a categorical idea are seen as unifying conceptions (i.e., classifications based on the concept of unity). The process of connecting one inference to another is conceptual construction. Such connections are established by making one conception a constituent of another.

The explanatory process prompted by 'pet fish' integrates the schematic inference that fish need to live in water with the schematic inference that pets are kept in enclosures. Assume the construction of the pet conception is
[combination [habitat enclosure] [role amusement]],

[^237]The corresponding conception of fish is
[combination [habitat water] [activity swimming]].

The two schematic inferences are then straightforwardly accomplished-they result directly from activating the constituent representations. Their integration, on the other hand, requires a combining conception. Given the understanding that a pet fish is a fish classified as a pet, this must impose the habitat classification from the pet conception on the habitat classification in the fish conception. The construct obtained is then

```
[combination
    [habitat [enclosure water]]
    [role amusement]
    [activity swimming]].
```

On the assumption that [habitat [enclosure water]] constructs a conception of a habitat containing water, something akin to the lives-in-bowls feature is reproduced.

Figure 1: 'Pet fish'.

This compositional story is set out schematically in Figure 1. In this diagram, triangles represent conceptions: the name of the conception appears at the apex, with the classifying concept placed above the lower edge, and the classified constituents below it. Where we have a classification with a single constituent, a stack arrangement is used. The classifying conception is placed immediately above the classified constituent, with a line between them.

More complex cases of feature emergence give rise to more complex interpretations. But the principles of translation remain the same. Consider the case of 'Harvard-educated carpenter'. The emergent feature in this case relates to an attitude: Harvard-educated carpenters are inferred to be 'non-materialistic' (Kunda et al., 1990). The combination of high earning power and modest remuneration in a single individual is taken to imply that the individual must have a care-less attitude to money. The feature that emerges is a known classification of a combination of features. But these features are inferred rather than given.

Figure 2: 'Harvard-educated carpenter'.

Modeled as natural concept composition, the explanatory process has the form depicted in Figure 2. The inference that a Harvard education produces high earning power comes from activating the relevant compositional representation (which incorporates the conception [elevation earning-power]). The inference that a carpenter is likely to have limited remuneration is produced in a similar same way, by activating the relevant compositional conception. An attitude of non-materialism is then inferred by means of an existing combinatorial conception for non-materialism based on these particular constituents. Again, the interpretation enforces a classificatory understanding. A Harvard-educated carpenter is not taken to be a combination of a carpenter and a Harvard education. It is seen to be the classification of a carpenter as Harvard-educated.

More complex still is the idea of an apartment dog. This phrase is found to suggest the idea of a dog that is small, even though this is not normally a property of either apartments or dogs (Murphy, 1988). The complication is the involvement of an intermediate idea. An apartment dog is not seen to be a dog classified as an apartment, let alone a dog that is also an apartment. It is expected to be a dog that lives in an apartment. Part of the explanatory process entails the idea of a particular type of agent residing in a particular type of dwelling.

The inferential steps in the explanation are seen to be essentially as follows (cf. Murphy, 2002). There is the categorical inference that apartments are types of dwelling, and the categorical inference that dogs and occupants are both types of agent. There are also three schematic inferences: the inference that apartments offer limited scope for exercise, the inference that dwellings have residents that are suitable, and the inference that suitability of an occupant for a dwelling requires correspondence between the occupant's size and exercise requirement. The structure labeled A in Figure 3 shows these five steps as compositional conceptions. The concepts utilized for classification include that of combination, of unity, and of correspondence.

Given this model, the conclusion that apartment dogs are small can be seen to result from an interaction be-

Figure 3: 'Apartment dog'.
tween two conceptual processes. Reference to an apartment activates a dwelling conception in which exercisescope is classified as restricted. A conception of residence is then realized, incorporating a suitability conception that classifies the size of the occupant as corresponding to the (restricted) exercise-scope of the dwelling. The only way of integrating the conception activated by the dog reference is then by inferring the dog to be the occupant in the residence conception. There is then an implicit classification (via the suitability conception) of the size of the dog as corresponding to the exercise-scope of the dwelling. A restriction is inferred to apply to the size of the dog. Emergence of the infered feature of smallness is obtained by means of a sequence of interacting, compositional constructions.

Modeling concept combination in this way has the advantage of parsimony. Notions of schematic representation and explanatory inference are collapsed to the idea of compositional conceptualization. The approach can deal with simple cases involving direct transfer of features as well as more complex cases involving explanation. But it cannot be emphasized too strongly that the examples set out are not intended to be realistic models of human cognition. It is not claimed that these particular conceptions are the ones people use. Given a free choice of what concepts are given, and no restriction on the number of constructive levels that can be brought into play, there are infinitely many ways in which any conception can be constructed. The examples set out are purely illustrative of the way in which feature emergence might result from classificatory composition.

## Conclusion

Adjoined concept references are normally viewed as constructing combinations. The phrase 'toy vehicle' is considered to combine the concepts toy and vehicle, the phrase 'pet fish' is considered to combine pet and fish, and the phrase 'apartment dog' is considered to combine apartment and dog. Hence the name of the area
of study. But as the present paper shows, these phrases can also be seen as classifications. A 'toy vehicle' can be a vehicle classified as a toy, a pet fish can be a fish classified as a pet, and an apartment dog can be a dog classified as living in an apartment. This leads to a new way of explaining feature emergence. On the assumption that concepts are represented as classificatory compositions (rather than as one-leveled schemata), explanatory feature emergence can be seen to grow out of compositional conceptualization. This avoids the need to think in terms of dedicated mechanisms of combination and explanation. The phenomenon is seen to result from activation of naturally constructed, compositional representations.

#### Abstract

Before children acquire the precise definitions of time words, like minute and hour, how do they interpret them? And how are such proto-meanings acquired in development? Here we present three experiments, and assess children's early understanding of seven time words: second, minute, hour, day, week, month, and year. Our findings indicate that children first learn time words as a lexical class, then learn their ordinal relations, but initially have little to no knowledge of their relative durations. This understanding emerges late in development - many years after children first start using time words in speech - and in many children does not emerge until they have acquired formal definitions for the words.

Keywords: abstract word learning; time perception; language acquisition; number-line estimation

## Introduction

Understanding the nature of time is a hard problem, not only for physicists and philosophers who debate its status in the universe, but especially for young children who are exposed to artifacts and linguistic representations of time from early in life. We rely on clocks, calendars, and words like second, minute, and hour to measure and keep track of time, and to coordinate our activities with others. Interestingly, although children begin using time words relatively early in life - by as young as 2 - and 3 -years of age, most do not receive formal instruction regarding the meanings of these words until much later, when they enter school. This raises the question of how children interpret these words prior to formal instruction, and how these words are initially related to their subjective experience of time, and the relative durations of events. In the present study, we explored this question, and asked what types of information children use to make sense of early time words, and thus how they begin to acquire their meanings in early development.

Duration words like time, day, and year, are among the most frequent nouns in English (Kucera and Francis, 1967). In addition to duration words, which we focus on in the present study, time is also conveyed through verb tense, through temporal adverbs such as yesterday and tomorrow, through spatiotemporal metaphor (e.g., "a long meeting"), and through the sequential structure of narrative itself. The rich and varied ways in which language encodes the dimension of time make it possible to reason and communicate about events that are not currently happening.

Despite this abundance of temporal language, acquiring the meanings of time words presents a considerable challenge to the early language learner. Time can neither be
seen nor heard. Unlike concrete nouns referring to whole objects that can be easily pointed out, and even more challenging abstract terms like color words (referring to properties of objects) and number words (referring to sets of objects), there is no static perceptual stimulus to which a duration word like minute refers. Word-learning principles such as "fast mapping" and mutual exclusivity, which describe useful strategies for learning the names of new objects or object properties in the context of familiar ones, do not easily apply. Rarely in everyday life (in the absence of clocks and timers) are there explicit perceptual markers denoting when events or specified temporal periods start and end, further complicating the task of figuring out the proper referents for time words.

Children are not typically taught the formal definitions of duration words (e.g., one minute equals sixty seconds) until they reach school age, but they begin hearing and even producing these words much earlier, albeit with very low accuracy. In child-directed speech, mothers of preschoolers use time words less often, but in a wider variety of contexts, than color and number words (Tare et al., 2008). While over $80 \%$ of children produce duration terms, including minute(s) and $\operatorname{hour}(s)$, by age 5 , only $22 \%$ of 5 -year-olds reportedly use hour(s) appropriately (Grant and Suddendorf, 2011). Here we are interested in whether, during these years of inaccurate production, before learning the adult definitions (e.g., that an hour is 60 minutes), children acquire naive meanings based on other information, and, if so, what information they use to do so.

There are two broad sources of information children could use in forming intuitive definitions of duration words. One source is their capacity to perceive and represent the durations of experienced events, and the other is their linguistic input. Children's ability to use and combine information from these two sources leads to three possible hypotheses characterizing the extent of their early learning, each increasingly sophisticated.

By the first account, which we call the Nominal hypothesis, children rely upon linguistic input to construct a lexical category for time words, thus understanding only that hour and minute belong within a common class of words. Consistent with this, Shatz and colleagues (2010) observed that, when asked "how long" or "how much time" an event takes, a much higher proportion of preschool-aged children are able to respond appropriately (using a quantity word and a duration word) than are able to respond accurately (Shatz et al., 2010). Children apparently understand what kinds of words can answer a question
about time before they can map those words onto specific durations.

Second, children might learn the ordinal relations among time words. This requires an additional inference: duration words vary along a common scale. Linguistic input could also be used to support this level of understanding. For instance, if a child hears an adult utterance such as, "We're leaving for the zoo in an hour, so you only have ten minutes to finish eating lunch," without knowing the precise definitions of either duration word, he could still use the linguistic context to conclude that an hour must be longer than a minute, if he understands that both those words denote amounts of time. By the Ordinal hypothesis, beyond simply learning that time words share a nominal class, children also learn the ordinal relationships among their list of known time words, e.g., year $>$ month $>$ week $>$ day $>$ hour $>$ minute $>$ second.

Third, children might learn the approximate ratios between the durations encoded by time words. How could this most knowledge be acquired before explicit instruction on time words? The Ratio hypothesis relies on duration perception, as understanding of relative temporal magnitudes requires that duration words be associated with nonverbal representations of duration. By the Ordinal account, above, a child will know only that a minute is 'bigger' than a second, but by the Ratio account, he would also know approximately how much bigger than a second a minute is (a ratio of 60:1).

We experience duration, thus children might be able to map this dimension onto language. Experimental work has shown that even nonverbal animals use temporal information to guide behaviors such as seeking food or avoiding shocks that come at predictable intervals. The human mind must have means of representing elapsed time, and many cognitive models have been proposed describing the operation of mental clocks and pacemakers. By four months, babies habituate to the temporal pattern of a flashing visual stimulus, and react when a flash is omitted at a prescribed time, revealing a very early sensitivity to elapsed duration (Columbo \& Richman, 2002). Basic psychophysical tasks have also measured the precision with which adults and children can estimate and compare the durations of auditory and visual stimuli, usually on the order of milliseconds or seconds. Although temporal sensitivity does not reach adult levels until around age 8, even the youngest children tested are able to discriminate stimuli on the basis of duration (Droit-Volet et al., 2004).

If the duration representations are available to children, how would the mapping between duration and language be formed? Perhaps a child hearing adult speech about time may associate unfamiliar duration words with the familiar events they describe or in whose context they are uttered, resulting in associative mappings between duration words and perceived temporal magnitudes. Evidence that children have knowledge of the durations of familiar events that they are not currently experiencing (and which extend beyond a few seconds in temporal extent) comes from a study by

William Friedman (1990). Friedman first taught children that a spatial array of nine boxes, much like a number-line, represented duration, from a very short time (the leftmost box) to a very long time (the rightmost box). He then had children indicate how long familiar events, such as drinking a glass of milk or watching a cartoon show, took, by placing a cube in the appropriate box. Four-year-old children correctly ranked-ordered the activities by duration, and by 5 years their mean placements on the 9-point scale were wellcorrelated with adult-estimated durations of the activities. Friedman's tasks did not utilize any conventional duration terms such as minute or hour. Our Experiment 3 asks whether children are able to use a number-line paradigm to estimate the durations represented by conventional time terms as well as by familiar events.

Few prior studies of language acquisition have assessed children's early comprehension of time words. Such studies probe what children know about time words before they can produce them accurately, for instance by requiring a forced choice. In Shatz et al. (2010)'s Study 2, children were introduced to a puppet "from far away" who "didn't know very much," and were asked show him which of two pictures represented an activity taking a specific amount of time, such as 10 minutes. Five-year-olds performed above chance overall, and 6 -year-olds were near $70 \%$ correct. This study suggests that 5 -year-olds have a rudimentary understanding of the meanings of duration words and how they relate to familiar activities. However, the results are difficult to interpret because each prompt combined duration words, number words, and events. Children could succeed (or fail) at the task based on their level of understanding in any of these three areas. Though Shatz et al. interpreted their results as favoring a lexical domain hypothesis, they do not rule out the possibility that children may rely on quantitative representations of duration as well.

Here we present three experiments designed to assess whether children understand time words at the Nominal, Ordinal, or Ratio level. Experiment 1 uses a forced-choice procedure to ask whether children can make time quantity comparisons on the basis of duration words alone (Nominal hypothesis predicts failure, Ordinal and Ratio hypotheses predict success). Experiment 2 introduces number words into the forced-choice, asking whether children can combine their knowledge of time words with their understanding of number (only Ratio hypothesis predicts success on critical trials). Experiment 3 uses number-line estimation to assess children's ability to map time words and events onto a spatial scale representing duration, providing data that can be analyzed both by ordinality (testing the Ordinal hypothesis) and by relative distance (testing the Ratio hypothesis). Finally, we assess children's explicit knowledge of the formal definitions of duration words, and use this as a predictor of their number-line estimation performance.

## Materials and Methods

## Participants

For Experiment 1, we recruited 89 children from the San Diego area, including 253 -year-olds, 264 -year-olds, 205 -
year-olds, and 18 6-year olds. For Experiment 2, 85 children participated, including 254 -year-olds, 225 -year-olds, 226 -year-olds, and 16 7-year-olds. Fifty-two children participated in Experiment 3, including 225 -year-olds, 17 6 -year-olds, and 137 -year-olds. 36 young adults (Mean age $=20.6$ years) also participated in Experiment 3. An additional 16 children also participated but were excluded from analysis due to failure to complete the task (8), failure to comprehend the task (4), being outside the age range of interest (3), and experimenter error (1).

## Procedure, Experiments 1 and 2: Forced-choice

Two action figures, Farmer Brown and Captain Blue, were placed on a table in front of the child. On each trial, the experimenter read a short scenario such as, "Farmer Brown [jumped] for [a minute]. Captain Blue [jumped] for [an hour]." This was followed by a two-alternative forced choice, "Who [jumped] more, [Farmer Brown or Captain Blue]?" If the child was reluctant to give a verbal response, she was encouraged to point to the character that did the action more. Procedures for Experiment 2 were identical to those of Experiment 1, but the time words were modified by number words. For example, "Farmer Brown [jumped] for [two] [minutes]. Captain Blue [jumped] for [three] [hours]." Each child completed a total of 26 trials in the Experiment 1, or 30 trials in Experiment 2.
Trials and coding, Experiment 1. Children completed two blocks of thirteen duration comparisons involving seven time words: second, minute, hour, day, week, month, and year. The comparisons tested were: week vs. month, day vs. week, month vs. year, hour vs. day, day vs. month, week vs. year, minute vs. hour, second vs. minute, hour vs. week, day vs. year, minute vs. day, second vs. hour, and second vs. day. Six action verbs, all of which were high-frequency words denoting activities that could be done for variable lengths of time, were used: jumped, slept, cried, played, danced, and talked. Within each block, trials were conducted in quasi-random order. Verbs were randomly assigned to duration comparisons, with the stipulation that the same verb was never used in two consecutive trials. Trials were counterbalanced with respect to whether the larger duration word came first, which character represented the correct answer, and which character was prompted first. Half the participants received one item-order, and the other half received the reverse order. For analysis, the child's response on each trial was coded as correct (1) or incorrect(0). These numbers were then converted into proportions correct.
Trials and coding, Experiment 2. Trials in Experiment 2 included the same six verbs from Experiment 1. However, only five time-word comparisons were used in Experiment 2: minute vs. hour, week vs. year, day vs. year, day vs. week, and second vs. hour. For each of those five time-word pairs, 7 different types of number-word comparisons were made (Table 1). One trial included no numbers (identical to Experiment 1,), 3 included "small" numbers (2 and/or 3), and 3 three included "big" numbers (6 and/or 9). Each comparison was designated Same, Congruent ,or

Incongruent, depending on whether the larger number word was paired with the larger time word (see Table 1).All 30 trials were conducted in quasi-random order. Half the participants received one item-order while the other half received the reverse order.

Table 1: Experiment 2 trial types

| Number <br> comparison | Number size | Example |
| :--- | :--- | :--- |
| No numbers | None | a minute vs an hour |
| Same | Small | 2 minutes vs 2 hours |
|  | Big | 6 minutes vs 6 hours |
| Congruent | Small | 2 minutes vs 3 hours |
|  | Big | 6 minutes vs 9 hours |
| Incongruent | Small | 3 minutes vs 2 hours |
|  | Big | 9 minutes vs 6 hours |

## Procedures, Experiment 3: Number-line estimation

Participants were given a sheet of 8.5 'x11' paper with four horizontal, $17-\mathrm{cm}$ lines printed in a vertical column down the center of the page. Each line had circles on both endpoints and no other markings. Children were told that the top line was a number-line going from 0 to 100 . "Each number has its own place on the line," said the experimenter. "You're going to show me where certain numbers go on the number-line. Look, 0 goes here [experimenter draws vertical mark at left endpoint] and 100 goes here [experimenter marks right endpoint]." For each of four number stimuli (see Table 2), the experimenter instructed the child, "The [first] number is [4]. Can you show me where [4] goes? Can you draw a line with the [blue] pencil?" The first line was intended to give a baseline measure of children's ability to perform an estimation task using a number-line. For each of the next three tasks, the line represented duration rather than numerical quantity. This was explained to the participants as follows: "Now, this line is different. It shows how much time things take to do. It goes from a very short amount of time to a very long amount of time. Each amount of time has its own place on the line, and the further you go over here [gesturing along the line], the more time something takes. You're going to show me how long certain things take to do on the line. Something very short, like blinking your eyes, goes here [experimenter marks left endpoint]. Something very long, like the time from waking up in the morning to going to bed at night, goes here [experimenter marks right endpoint]. For each stimulus (see Table 2), the child was instructedto think about how long the activity takes to do and to mark theline accordingly. Participants were reminded that each subsequent line represented duration and what the endpoints represented (blinking eyes, morning to night) in between the remaining tasks and if confused.

## Trials and coding, Experiment 3.

Stimuli for Experiment 3 are shown in Table 2. Each participant estimated number on the first line, familiar event durations on the second, conventional time word durations
on the third, and combinations of time words and number on the fourth. Within each line, half the participants received the four stimuli in the order shown in Table 2, while the other half received the reverse order. As in Experiments 1 and 2, participants were presented with time word stimuli (lines 3 and 4) in the context of events that could take variable amounts of time, e.g. "[jumping] for a minute."

Table 2: Experiment 3 Number-line stimuli

| Number | Event | Time word | Num + time |
| :---: | :---: | :---: | :---: |
| 4 | Watching movie | Hour | 2 hours |
| 45 | Washing hands | Second | 6 hours |
| 18 | Trip to zoo | Minute | 9 min |
| 61 | Eating lunch | Day | 3 min |

Explicit knowledge. Following completion of the four number-line tasks, the participant was asked 3 follow-up questions: how minutes are in an hour, how many hours are in a day, and how many seconds are in a minute. Responses were coded as either correct (1) or incorrect (0), and were converted to proportions correct.
Estimation. To analyze the number-line data, we measured the distance (in cm , to the nearest tenth) from the left endpoint of the line to the intersection of the number-line with each of the participant's pencil marks. Marks falling exactly on the left endpoint were recorded as 0.1 cm (to avoid divide-by-zero errors) and those falling exactly on the right were recorded as 17.0 cm . To assess knowledge of relative durations, we computed ratios between each pair stimuli (e.g., $\mathrm{min} / \mathrm{sec}$, hour/sec, hour/min, day/sec, day/min, day/hour). Children's estimation performance was assessed by comparing their distances and ratios with corresponding means from the adult participant group. We focus on the results from the time word numberline task, which most directly bear on the Ordinal and Ratio hypotheses.
Ordinality. Responses to each trial were also coded for ordinality. To do this, each of the four stimuli for each line was rank-ordered by increasing magnitude or duration. In the case of line 2, the correct (adult-estimated) rank order was: 1 . washing your hands, 2 . eating lunch, 3 . watching a movie, 4. going on a trip to the zoo. The participant's marks were also ranked by increasing distance from zero. For each estimated item which fell in the correct rank, the participant was awarded a 1 , for each incorrectly ranked item, the participant was given a 0 , which were converted into proportions correct for each child and each age group.

## Results and Discussion

We began with three alternative hypotheses for how to characterize children's early knowledge of duration words prior to learning their definitions. The Nominal hypothesis is that children simply understand that durations words belong to a common lexical category, the Ordinal hypothesis is that children have knowledge of the ordinal relations among the words within this category, and the Ratio hypothesis is that children have knowledge both of the
ordinal relations and of the relative lengths of the durations to which the words refer. Of these three possibilities, only the Ratio hypothesis requires that children form associations between duration words and nonverbal representations of duration.

## Experiment 1

The primary goal of Experiment 1 was to distinguish between Nominal and Ordinal/Ratio understanding of time words, by asking whether children are able to compare two lengths of time strictly on the basis of the conventional duration terms used to describe them. In order to succeed at this two-alternative forced choice task, children must possess some understanding of the ordinal relations among the various time words. Unlike in prior forced-choice studies of time word comprehension (Shatz et al., 2010), here participants could not rely on their knowledge of number or of familiar events in order to succeed. Measuring overall accuracy in Experiment 1, we found that while our youngest group of participants, the 3 -year-olds, did not perform better than $50 \%$ accuracy, as predicted by chance ( $M \pm$ SEM $=0.48 \pm 0.02 p=0.2$,n.s.), the 4 -, 5 -, and 6 -year-old groups all performed significantly better than chance ( $M \pm$ SEM, respectively, $=0.57 \pm 0.02 ; 0.67 \pm 0.04 ; 0.81 \pm 0.03$, all $p \prime \mathrm{~s}<0.005$ ). Furthermore, each age group performed significantly better than each younger group (all $p$ ' $s<0.05$ ). While the question of whether 3-year-olds have nominal understanding of some or all of the terms is left open, these data reject the possibility that children 4 years and older know only that time words belong to a common category. It is also noteworthy that our oldest age group, the 6-year-olds, while performing quite well, were not at ceiling, despite the simplicity of the task and the likelihood that this sample had already received some formal instruction on duration words.

We were also interested in possible comparison effects or time-word effects in the data, as these may provide important clues into the order in which duration words are acquired. We hypothesized that, if these words are truly associated with durations, we might observe patterns such as greater accuracy on comparisons between more distant terms (sec. vs. day $>$ sec. vs. min.), or greater success on comparisons involving shorter, and thus easier-to-represent durations, such as second and minute, than comparisons involving longer terms, such as month and year, which may be harder to represent nonverbally. Though a mixed logistic regression predicting the probability of making the correct choice as a function of the participant's age and the timeword comparison type did find significant effects of each (Age: $\quad \mathrm{c}^{2}(3)=142.7, \quad p<0.001$, TrialType: $\quad \mathrm{c}^{2}(13)=59.0$, $p<0.001$ ), as well as an interaction between them ( $\mathrm{c}^{2}(36)=71.2, p<0.001$ ), there was no evidence indicating that the relative durations encoded by the two words being compared were driving the effect. Furthermore, collapsing the data across all comparisons involving each time word so as to compare overall accuracy for each word revealed no differences in performance $(F(6,595)=1.2, p=0.3$, n.s.). As accuracy improved from age group to age group, it improved across the board, with equal improvement on each
tested word, as would be expected if these words are being learned as a set, with performance on each word being limited by overall understanding of the ordinal relations among the words in the list, without direct associations between each individual term and duration per se (consistent with the Ordinal, rather than the Ratio hypothesis).

## Experiment 2

Experiment 2 assessed children's ability to integrate their knowledge of number with their understanding of time words, pitting the Ordinal and Ratio hypotheses against one another by probing the specificity of children's knowledge of the relative lengths of time referred to by conventional duration terms. In Congruent trials (e.g., 3 hours vs. 2 minutes), the numbers provide an additional cue to the correct answer. Even a child with no idea how long either an hour or a minute is might still choose correctly, based solely on his understanding of 3 vs. 2, thus improving overall performance on Congruent relative to Same/No Number trials. We expect the children with the least precise understanding of time words to show the greatest increase in performance in Congruent relative to Same trials. However, in Incongruent trials (e.g., 2 hours vs. 3 minutes), basing the choice on number alone would lead the child to make the wrong choice. While a qualitative understanding that an hour is more time than a minute is sufficient to succeed in the Same or Congruent trials, only a quantitative understanding will suffice on Incongruent trials. Making the correct choice requires sufficient understanding of the relative durations encoded by time words to realize that their ratio far exceeds that of the number words, 3:2. Knowing the order of the time words alone is insufficient, so the Ordinal hypothesis predicts lower performance on Incongruent trials. Only the Ratio hypothesis, in which time words are mapped onto representations of duration, predicts equal success on Incongruent and Same trials.

Overall accuracy in Experiment 2 was similar to that found in Experiment 1 for those age groups represented in both. All groups performed significantly above chance. Proportions correct ( $M \pm$ SEM) for the 4-, 5-, 6-, and 7-yearolds groups, respectively, were $0.55 \pm 0.02,0.71 \pm-0.03$, $0.81 \pm 0.04,0.97 \pm 0.02$. The critical comparison between Same, Congruent, and Incongruent trials is shown in Figure 2. Data were collapsed across time-word comparison types and number sizes, as neither was a significant predictor of children's performance in Experiment 2. Performance in the Same number case was not significantly different from that in the No Number case.

While the 4 -year-old group was both helped by number word congruency and hindered by incongruency, as predicted by the Ordinal hypothesis, the 7-year-olds were near ceiling on the task in all conditions, with no cost to incongruency or benefit to congruency, as predicted by the Ratio hypothesis. The intermediate age groups show different patterns, with the 5 -year-olds showing a cost of incongruency and no benefit to congruency, and the 6-year-
olds showing no cost to incongruency and a benefit to congruency. Strikingly, these results suggest that there are children who know both that 3 is greater than 2 and that an hour greater than a minute, but fail to accurately compare 3 minutes with 2 hours.

Figure 1: Effect of congruency of time word comparisons and number word comparisons in Experiment 2.

Taken together, the results of Experiments 1 and 2 suggest that children learn duration words as a lexical class, and they begin to learn the ordinal structure of that class by age 4, prior to mapping them onto nonverbal representations of duration. Further, children do not have a full understanding of how these words encode relative duration, consistent with the Ratio hypothesis, until at least the age of 7, after they've encountered time words in school. One possibility is that children do not map these words onto specific durations until they learn their definitions. Another possibility is that younger children do associate these words with durations, perhaps relying on their experience hearing them used in relation to familiar events to make these associations, but these representations are imprecise, not easily combined with number knowledge.

A limitation of the forced-choice methodology employed in the first two experiments is that each trial probed knowledge of two different duration words, conflating the participant's knowledge of them which may have precluded finding differences in the acquisition of individual words. To further probe children's ability to estimate the durations encoded by individual time words, and to obtain a more precise measure of participants' ability to rank-order a set of time words, we used the number-line method in Experiment 3. This also allowed us to compare children's ability to estimate the durations of familiar events and conventional time words, and to ask whether overt knowledge of the definitions of the duration words predicted better duration estimation performance.

Figure 2: Proportion of ordinal estimates in Experiment 3 and proportion of correct definitions of duration words

## Experiment 3

Estimation data were analyzed in terms of their distance from 0 along the line representing elapsed duration. Overall time word estimation performance for the three age groups was assessed by plotting each child participant's estimated duration ratios (see Methods) as a function of adults' mean ratios and fitting the data for each age group with a linear model. The closer the slope of that line approximates 1 , the more adult-like the estimation. Slopes for the 5, 6, and 7-year-old groups, respectively, were $0.14,0.57$, and 0.86 . These data confirm that children have essentially no quantitative understanding of the relative durations encoded by these words at the age of 5 (despite their above-chance performance in Experiments 1 and 2), but obtain this understanding in the early school years.

Results from the ordinality measure (see Methods) are shown in Figure 2, alongside results from the follow-up questions testing overt knowledge of the duration words definitions. Comparing time word and event estimation, the five-year-olds perform better with familiar events, lending moderate support to the idea that young children extract duration information from familiar activities and use that knowledge to aid them in learning duration words, via associative mappings. By six, however, children are estimating better overall with conventional time words than without. The probability of successfully rank-ordering the 4 time words is correlated with having explicit knowledge of their definitions. Almost no 5-year-olds but most 7 -yearolds know these definitions. Sorting the 6 -year-old data according to whether each child knows the formal definitions of the words reveals that those who know them perform like 7 -year-olds while those who do not perform like 5-year-olds, highlighting the importance of this factor.

An intriguing possibility is that learning duration words not only improves our ability to estimate the lengths of events described in those terms, but also provides a useful cognitive framework for encoding and estimating the durations of perceived events in general. However, by this account we expect explicit knowledge of time words to
improve performance on duration estimation in both the Event and Time word tasks. However, while we find that accuracy on the follow-up questions (e.g., How many seconds are in a minute?"), when added to a model including age group, was a significant predictor of children's proportions of ordinal responses in the time word task, it did not account for additional variance in event estimation performance.

In conclusion, the three experiments presented here suggest that, prior to acquiring their adult definitions, children learn the nominal category of time words as well as the ordinal structure of that category. However, we find no evidence that children map these terms onto precise representations of duration until after they learn their formal definitions.

#### Abstract

Research under the paradigm of the label feedback hypothesis has proposed a causal role for verbal labels in the online learning and processing of categories. Labeled categories are learned faster, and are subsequently more robust. The present study extends this research paradigm by considering the relationship between verbal labels and flexible categorization. Flexibility is a key trait of human cognition, and flexible categorization is important in a number of tasks. Participants learned to categorize 'friendly' and 'unfriendly' aliens either with or without names, followed by a transfer task. While selective attention to a particular dimension slowed relearning, no effect of label was found for either category learning or relearning with one exception; labels facilitated flexibility when selective attention was not involved in the transfer. The inability to replicate effects of verbal labels in category learning using similar methodologies raises interesting theoretical issues, questioning the extent to which this relationship applies.

Keywords: Categorization; Label Feedback Hypothesis; Flexible Cognition; Selective Attention

## Introduction

Language, along with use in communication, provides a symbolic system of representation through which a speaker contemplates the world around them. The emergence of the capacity for symbolic representation transformed human cognition (Deacon, 1997; DeLoache, 2004), permitting abstract thought and making possible cultural transmission of knowledge. Yet the relationship between language and other cognitive processes is still controversial. For many who view language as a distinct mental module (Gleitman \& Papafragou, 2005; Pinker, 1995), language is merely a formal medium that is used to describe mental representations, while remaining independent of the concepts they express (Li \& Gleitman, 2002). Recent work in understanding the relationship between language and thought has provided evidence against this disassociation. Instead, it has been suggested that language is best understood as built upon domain general cognitive processes, and thus potentially in a mutually transformative relationship with these processes (Bowerman \& Choi, 2001; Gumperz \& Levinson, 1996).

With habitual use of the specific set of conceptual symbolic representations afforded by a language, an individual may be biased towards these representations in problem-solving and other cognitive tasks. How a language may accomplish this is not well understood. One possibility
is that language reduces the ability to flexibly adjust categories outside the structure provided for by the words of a particular language. As such, it is important to consider the influence of language on the ability to dynamically activate and modify the cognitive process of categorization in response to changing task demands. The ability to think and act adaptively, while not a uniquely human trait, is a mental capacity uniquely well developed in human cognition and intelligent behavior (Deák, 2003). For the purposes of the current study, flexible cognition will be defined as a property of the cognitive system, rather than a specific mechanism or process (Deák, 2003; Ionescu, 2012). This definition allows for the consideration of flexible cognition in the interaction of interest; that between categorization and language, specifically verbal labels.

Recent work lead by Gary Lupyan and colleagues on the role of labels in categorization has demonstrated a special status afforded to verbal labels (see e.g. Lupyan, Rakison, \& McClelland, 2007; Lupyan \& Thompson-Schill, 2011). Verbal labels participate in the learning of categories, facilitating learning, creating mental categories that are more robust than when the categories are learned without words (Lupyan, Rakison, \& McClelland, 2007), and encouraging selective attention (Brojde, Porter, \& Colunga, 2011). However, no study has looked directly at the influence of verbal labels on the perceptual and attentional processes that underlie flexibility after learning. Similarly, while a number of studies have looked at how language aides in an individual's ability to flexibly adjust the level of categorization, or switch from taxonomic to thematic (Blaye, Bernard-Peyron, Paour, \& Bonthoux, 2006), no previous research has investigated how individuals flexibly adjust their categorization strategies in regards to the same domain, on the same level. The present investigation seeks to illuminate further the relationship between verbal labels and the cognitive processes underlying categorization. In developing an understanding of the role that verbal labels play in the construction and maintenance of categories, we further our understanding of the relationship between language and the domain general cognitive processes, such as categorization, upon which language is built.

## Background

## Flexibility in Categorization

Categorization, the process by which discriminably different things are classified into groups and therefore responded to in kind, is a ubiquitous cognitive operation relevant to all aspects of human life. How categories are learned is a key issue in understanding the relationship between verbal category labels and flexibility in cognition. A number of studies have demonstrated that the relationship between perceptual descriptions, how the category or concept is defined, and conceptual representations, such as verbal labels, are mutually influential (Goldstone, 2000; Lin \& Murphys, 1997). It is widely accepted that adults tailor the categories they form to the current demands of the task or situation (Barsalou, 1983), and can spontaneously group objects in several ways (Ross \& Murphy, 1999). Categorical flexibility is thus a within-subject variable corresponding to the ability to switch, (or relearn), between different representations of a given object or set of objects.

Related work has focused on the way that categorization influences perceived similarities (e.g. Goldstone, Lippa, \& Shiffrin, 2001). According to these studies, conceptual and categorical flexibility must be accompanied by flexibility in perceptual and attentional processes (Goldstone 1998). Two mechanisms are considered key to perceptual category learning and flexibility: selective attention and differentiation of dimensions (Goldstone \& Steyvers, 2001). Selective attention refers to the process by which, in categorization learning, individuals learn to attend to some features of the objects and ignore irrelevant features. Selective attention is key to models of categorization such as Nosofksy's (1986) exemplar model, in which an object is measured in similarity compared to a stored category member in a multidimensional space. The distances between points along dimensions within this space compress and expand depending on the attention given to particular dimensions. Dimensional differentiation refers to the psychological process by which previously unified dimensions become perceptually and cognitively distinct. For example, in developing categories for circles and squares one must first learn to separate the dimension of shape from task-irrelevant dimensions such as color or size. In order to study these mechanisms, Goldstone \& Steyvers (2001) applied a learning/transfer task, wherein subjects first learned to distinguish between two categories, and then at transfer had to relearn the categories based on altered relevance of dimensions. By making dimensions that were previously diagnostic for categorization unimportant, or the reverse, allows for a measure of the role of selective attention in categorical flexibility. Similarly, new dimensions may exist in the transfer stimuli set that did not exist in the training set, allowing a separate measure of dimensional differentiation.

## Categorization and Verbal Labels

The processes of selective attention and dimensional differentiation in categorization lead stimuli to be considered more similar when in the same category, and more easily distinguishable when in different categories (Harnad, 1987). Recent studies have demonstrated that verbal labels influence categorization, speeding up the attentional processes that focus in on diagnostic properties of categorized objects. It has been suggested that simply sharing a label, defined as a name for a category, causes two objects to be perceived as more similar than those that do not (Lupyan et al., 2007).

There are a number of explanations for this relationship. Researchers have provided evidence that labels offer more maximally informative feedback during categorization learning, making rule-based categories, those categories that are learned explicitly with diagnostic rules that are easily verbalized (Ashby \& Maddox, 2005), easier to learn (Maddox et. al, 2008). Others consider labels as physical, external symbols upon which our categories are hung (Clark, 2006; Lupyan et al., 2007). In this sense, language is viewed as a self-constructed cognitive niche, with words providing the material scaffolding required to promote abstract thought and reason, by providing a target for more basic capacities such as statistical and associative learning (Clark, 2006). These latter theories have been generalized by Lupyan within the Label Feedback Hypothesis framework (Lupyan, 2007).

Labels have been implicated in the learning of categories, but what of their maintenance and adjustment? Lupyan, Rakison, and McClelland (2007) provided evidence that categories associated with verbal labels are not only learned faster, but are maintained more robustly after initially training. If one of the main uses of language is the creation of associations between concepts and words in such a way that the labeled concepts are learned fast and remain more robust, it is possible that a verbal label will also reduce the categorical flexibility by strengthening selective attention to a diagnostic dimension. In contrast, if labels, as suggested by Maddox et al. (2008), simply aid in categorization of rule-based categories by providing a more maximally informative feedback mechanism, it is possible that labels may also positively affect categorical flexibility.

## The Current Investigation

The present study seeks to add to the literature on labels and categorization by investigating the rigidity of categorization both with verbal labels and in their absence. When an individual needs to restructure the categorical divisions of a particular domain, especially when this restructuring requires a shift in attention to a previously non-diagnostic dimension, having verbal labels for categories already established could slow down the relearning curve. The influence of verbal labels on learned sensitivity to dimensions was tested using a category-learning paradigm in which participants received an initial category learning followed by a relearning transfer task, in which either the
diagnostic dimension changed, requiring a shift in selective attention, or the behavioral response but not the diagnostic changed (see Transfer Procedure below).

## Methodology

Subjects 192 participants were drawn from the undergraduate psychology subject pool at CU, Boulder, in exchange for course credit. Subjects were randomly assigned to either label or no label training conditions and one of three transfer conditions, giving six total conditions.

Materials Categories were organized based on the kind of eyes "aliens" exhibited. To this end, 36 gabor patches were created, varying along the dimensions of frequency and orientation (figure 1); these patches were embedded in the stimuli as the aliens' eyes.

Figure 1: Example stimuli demonstrating the range of frequencies across and orientation downward.

Training Procedure Following the procedure from Lupyan, Rakison, \& McClelland (2007), participants were told that they were to take part in a NASA training program before traveling to a newly found planet. In training, it was explained that previous explorers to the planet had discovered two aquatic alien species, one of which was friendly and could be approached, and one that was dangerous and should be avoided. In the label conditions, the participants were told that the explorers had decided to name the aliens, and that the friendly aliens were named 'Gowachi', while the dangerous aliens were named 'Caleba'. Thus, participants were asked to learn to distinguish between two categories within a set of novel stimuli. This distinction was based on either the orientation or the frequency of the alien's giant eye. Individual trials began with a fixation marker in the middle of the screen, presented for 500 milliseconds. For each trial, an alien was presented briefly, ( 500 ms ), before a scuba diver appeared in one of four locations; above, below, or on either side of the alien. The participant then decided whether to approach or escape the alien using the directional keys on a standard keyboard. For example, if a scuba diver appeared on the left
of a friendly alien, the participant should press the "right" key to move the scuba diver closer. After a response was made, feedback was provided in either minimal (a chime for correct, a buzz for incorrect) or maximal (minimal feedback + correct category label) conditions. If the participant waited for longer than 3 seconds, feedback was given without response. After the feedback, the alien and scuba diver remained on the screen for additional 800 ms before the start of the next trial and the representation of the fixation marker. Each unique alien + diver trial was presented once in random order, for a total of 144 trials of training ( 36 alien exemplars x 4 diver locations). All subjects received the same number of categorization learning trials and had equal exposure to the stimuli across conditions.

Transfer Procedure After training was complete the participants were told that they were now ready to travel to the Planet Teeb. In all but the control, or 0 degree, transfer conditions, upon arrival on the planet the participants were alerted that something has gone wrong, and that the aliens are not behaving as expected. Participants in these conditions faced two distinct relearning tasks. In the 90 degree transfer condition, the diagnostic dimension changed, requiring a modulation in selective attention. Participants who learned during training that the friendly aliens had thick bands in their eyes, and the unfriendly aliens thin ones, here had to learn to categorize the friendly and unfriendly aliens based on the steepness of the orientation of the bands, ignoring thickness. This meant that half of each category learned during the first phase subsequently became part of the new category structure learned during transfer testing, or that half of the Gowachi must now be considered Caleba and the reverse. For the 180 degree transfer condition, the diagnostic dimension remained the same, but the escape/approach responses were switched. Here, participants who first learned that aliens with steeply oriented bands in their eyes were friendly now had to learn to treat them as unfriendly, or that the Gowachi and Caleba were opposite what had been learned. These two transfer conditions were compared to the 0 degree transfer condition, in which no change between the training and testing occurred.

Having all conditions transfer to the same categorization allowed for a clear relationship between initial categorization and participants' ability to relearn categorization strategies flexibly (see e.g. Goldstone \& Steyvers 2001). The post-transfer phase consisted of a second set of 144 randomized trials. During the transfer phase trials only minimal feedback (chime or buzz) were given in all conditions, whether label or no label.

## Results

Trials were grouped into blocks of 36 , giving four blocks each for training and transfer phases. Each correct trial was scored as 1 , each incorrect trial as 0 , and each trial in which the participant did not answer was dropped. Accuracy across
block was then calculated. The data from those participants who did not reach at least $50 \%$ accuracy by the end of training were not included (13 participants in total). Data was then entered into a mixed factor ANOVA.

First, we tested for an effect of label on training, collapsing across transfer type, to see if previous findings on the advantage of having a label would replicate, (Lupyan, Rakison \& McClelland, 2007). However, while participants did learn to categorize correctly $F(3,438)=103.42(p<$ .001 ), there was no main effect of label type on this learning trajectory $(p=.312)$. A similar pattern was seen in the testing phase, with a significant effect of block $(F(3,438)=$ $13.140 p<.001$ ), without an effect of label, or a label by block interaction $(F(3,438)=1.263, p=.287)$, (See Figure 2). There was one significant four-way interaction involving label that will be discussed below.

Figure 2: Average accuracy by block for label and no label conditions collapsing across transfer type.

Turning from label to transfer type, while there was no main effect of transfer type $(F(2,146)=.104, p=.901)$, there as a significant interaction between phase (whether training or transfer) and transfer type $(F(2,146)=80.553, p$ $<.001$ ), with accuracy worse when transfer required a switch in selective attention, (see figure 3).

Figure 3: Learning (blocks $1-4$ ) and transfer (blocks $5-8$ ) trajectories for the 0 degree, 90 degree, and 180 degree transfer conditions.

Of final interest was a significant four-way interaction between phase, block, label type, and transfer type ( $F(6$, $438)=2.18, p<.05$ ). As this was the only significant interaction involving label, this interaction was pursued further, with the analysis first involving separating out each transfer type. For the 0 and 90 degree transfer conditions, there were the expected effects of block and phase (all $p \mathrm{~s}<$ .01 ), but no main effects or interactions involving label (all $p \mathrm{~s}>.05$ ). In the 180 degree transfer condition, however, a significant interaction of phase*block*label type was found, $(F(3,132)=4.527, p<.05$. Using a general linear model to explore this interaction further, we found that for the first two blocks of transfer in the 180 degree transfer condition, there was an interaction between block and label type ( $F(1$, $44)=11.595, p<.001$ ), (see figure 4). Thus, there was evidence for an effect of label on transfer learning in the condition that required not a shift in attention, but a shift in the behavioral response from what had been learned in training.

Figure 4: Average accuracy by block for participants in the label and non-labeled conditions of the 180 degree transfer.

## Discussion

The results of the present experiment did not find support for a general advantage for learning categories with labels over categories without labels as seen in previous similar experiments (Lupyan et al., 2007). One important difference between the stimuli used here and that used by Lupyan and colleagues is that their aliens were categorized by shape features, whether the ones in the present study were categorized by what could be seen as textural features. The lack of a label advantage in learning is in line with previous work showing that the effect of labels depends on the sort of categorization being learned (Brojde et al., 2011).

More interesting to the question of this paper, however, is the way labels influenced performance at transfer. In the 180 degree condition, when participants had to relearn that those aliens who had been approachable were now not approachable and vice versa, there was a significantly faster recovery after transfer for those participants who were provided with labels during training. Our results suggest that labels play a positive role in the relearning of
categorization when the boundaries of the categories do not change, and the relevant dimension does not change, but the categorical behavioral responses do, (i.e. whether the astronaut should approach or retreat from the alien). Having verbal labels for the categories allowed the participants to more flexibly adapt to the changing task demands. It is possible that since verbal labels become attached to the categories which they are used to express (Lupyan \& Thompson-Schill, 2011), that when the categories themselves do not change, but only the responses change, these labels continue to act as more easily computed symbolic abstractions of the categories for which they stand. It then becomes possible for the participants in the 180 degree transfer condition to switch from 'Gowachi' and 'Caleba' to 'not Gowachi' and 'not Caleba'.

The visibility of this effect of label on transfer flexibility seems to be made possible by the low cost of transfer when the transfer does not involve modulation of selective attention. The cost of transfer, however, was much larger for those who had to relearn their categorization strategies based on a previously unimportant dimension. Those participants who learned during training to categorize based on frequency of the lines of the eyes and discovered on the planet that the aliens were either friendly or unfriendly based on the orientation demonstrated reduced ability to flexibly adjust to this new categorization strategy. While selective attention is an important process in the development of accurate categorization (Goldstone, 1998), it also reduces the degree of flexibility present in categorization cognitive processes.

At transfer, these participants must not only learn to pay more attention to the previously ignored dimension, they must also inhibit attention to the previously diagnostic features (Goldstone \& Steyvers, 2001). This is demonstrated by the comparison of the four blocks of training for the identification condition with the four blocks of transfer for those participants whose transfer included a change in the diagnostic dimension, despite having had 144 trials more experience than those approaching the task for the first time. This is a clear indication of the cost that comes with increased attention to one historically predictive dimension combined with decreased attention to all other dimensions. This is in contrast with Goldstone and Steyvers (2001), who found that when the categorization rules are orthogonal, participants do no differently than those learning a completely new set. Their analysis of this finding was to posit an equalizing effect of negative transfer from selective attention with positive transfer from dimensional differentiation, meaning that regardless of the type of transfer, it helps to have practice in separating the two perceptual dimensions of the stimuli. By matching the same categorization strategy across training, taken as a control, and transfer, rather than having participants relearn a completely new category during transfer, we demonstrate that the positive effect of dimensional differentiation is not large enough to make the performance of those participants
who transferred across dimensions on par with those coming to the same task without any previous experience.

This role of selective attention in reducing flexibility was not, however, modulated by the presence of verbal labels corresponding to the categories being learned. While participants did learn the correct categories over the course of training, across all conditions this learning trajectory was not modulated by the presence or lack of label as feedback on individual trials. Similarly, transfer-learning trajectories were not significantly affected for those participants whose initial training included verbal labels, for better or for worse. The inability of the current data to replicate previous findings on the influence of verbal labels in category learning draws into question the extent to which the Label Feedback Hypothesis can be extended into categorization.

Previous studies that have demonstrated a positive influence of verbal labels have focused mostly on shapebased categories, including the study upon which the present study is based (e.g. Lupyan et al., 2007; Lupyan \& Thompson-Schill, 2011). Very early in language learning, English-speaking children develop a bias towards categorizing labeled object categories based on shape (Yoshida \& Smith, 2005; Colunga \& Smith, 2005). It's possible that, as shape-based categories are based on dimensions that are historically predictive for English language speakers, the effect of labels during this type of categorization would be stronger than for other types of learning. This is supported by findings from Brojde, Proter, and Colunga (2011), who demonstrated that verbal labels hinder category learning defined by texture or brightness. They argue that the advantage of label comes about only when the relevant dimension aligns with the relevant dimensions in previous similar tasks, which in the case of our English-speaking participants would be shape over features such as orientation and frequency of line.

## Conclusion

The purpose of the current investigation was to assess the effect of verbal labels on the ability to flexibly adjust categorization strategies when faced with changes in the environment. Previous literature (Lupyan et al., 2007; Lupyan \& Thompson-Schill, 2011) has demonstrated that verbal labels influence category learning, improving both speed of learning and strength of representation. Some have argued that this effect of verbal labels is a demonstration of the top-down modulation of labels during learning and therefore shows that verbal labels are directly involved in the learning of concepts and categories (Lupyan, 2009). In this theory, labels work as material symbols upon which categories are attached (Clark, 1996), and so take part in the category learning process, possibly by modulating selective attention (Goldstone, 1998; Goldstone \& Steyvers, 2001). Others, however, have argued that verbal labels are simply a more maximal form of feedback, and are therefore simple a form a facilitation, separate from the categories themselves (Maddox et al., 2008). In order to tease these two views apart, the present study considered the role of verbal labels
in flexible cognition, more specifically the ability of individuals to flexibly adjust their categorization strategies.

Despite a replication of the effect of selective attention across stimuli dimensions, the previous finding of the positive effect of labels as feedback for category learning was not replicated. The failure to replicate a positive effect of label on category learning raises questions as to the generalizability of the label feedback hypothesis. Given the issues raised in the current study above, it appears that not all types of category learning benefit from the presence of verbal labels (see also Brojde et al., 2011). Similarly, there is no evidence that labels modulate selective attention in a way that would either help or hinder flexibly adjusting one's categorization strategies. There was however, an effect in a single transfer condition that demonstrates that labels may aid in recovery from transfer when the type of transfer does not involve a change in selective attention. In the 180 degree transfer condition, while labels did not have a positive effect on learning during training, labels did interact with accuracy immediately after transfer, allowing those who learned with labels to recover faster. Future endeavors could continue to develop an understanding of the relationship between concepts, categories, and the words we use to invoke them.

## Acknowledgments

We would like to thank Bhuvana Narasimhan, Claire Sims for their comments on an earlier draft, and the members of the CU language project for assistance in collecting data.

# Diverse Evidence for Dissociable Processes in Inductive Reasoning 

Eoin Travers (etravers01@qub.ac.uk)<br>School of Psychology, Queen's University Belfast<br>University Road, Belfast BT7 1NN

Aidan Feeney (a.feeney@qub.ac.uk)<br>School of Psychology, Queen's University Belfast<br>University Road, Belfast BT7 1NN

#### Abstract

Previous work suggests that inductive and deductive reasoning may be accomplished by different processes. Here, we examine whether different phenomena of inductive reasoning, previously explained in the same way, may rely on different types of processes. In Experiment 1 we show that trials which examine sensitivity to sample size in inductive reasoning have greater effects on secondary task performance than do trials examining sensitivity to the diversity of the sample. In Experiment 2 we show that in a surprise recognition memory test, participants have significantly better memory for the content of diversity trials than for sample size trials. Both findings are consistent with the suggestion that some phenomena of inductive reasoning may be rule-based, whereas others may depend on feature-level processing.

Keywords: Reasoning; induction; diversity effect; law of large numbers.

## Introduction

Not all thinking is the same. Because the same experimental manipulations affect them differently, it has been claimed that inductive and deductive thinking are dissociated (see Rips, 2001; Heit \& Rotello, 2010). Heit and Rotello argue that deductive reasoning calls more on processes that are sensitive to logical validity, whereas inductive reasoning relies more on associative processes. However, a background assumption appears to be that inductive reasoning, for example, consistently draws on the same processes, and most theories of inductive reasoning attempt to capture different experimental phenomena in the same way (see Osherson et al, 1990; Sloman, 1993; Rogers \& McClelland, 2004). Here, we will consider whether different processes underlie different phenomena that have been observed in people's inductive reasoning. Specifically, we will examine whether sensitivity to the size of the sample upon which an inductive inference is based may be due to rule-based processes, whereas sensitivity to the diversity of the evidence may call on more feature-based processing.

## Sensitivity to the size and diversity of samples

Despite claims made by Kahneman and Tversky (1972), there is much evidence that adults, and sometimes children, are sensitive to sample size (see Piaget \& Inhelder, 1975; Nisbett, Krantz, Jepson \& Kunda, 1983). In experiments on category-based induction, where participants are typically taught that members of certain categories possess a novel property and are asked whether members of some other
category also possess that property, the tendency to prefer arguments based on a larger sample of categories is known as the monotonicity effect (see Osherson et al., 1990). However, not everyone displays the monotonicity effect in such experiments (see Feeney, 2007).

Whereas sensitivity to sample size has been intensively studied in the literature on judgment and decision making, sensitivity to sample diversity has most often been studied in the literature on category-based inductive reasoning (for a review, see Heit, Hahn \& Feeney, 2005). Although preference for more diverse evidential samples has been informally advocated by a variety of philosophers of science (e.g. Bacon, 1878; Carnap, 1950; Popper, 1963), attempts to formally justify a diversity principle are rarer and there are arguments against the existence of a general principle (see Lo, Sides, Rozelle \& Osherson, 2002; Medin et al., 2003). Nonetheless, there are numerous demonstrations in experiments on category-based induction in which a majority of people consider arguments with more diverse premises to be stronger. People are sensitive to the diversity of the evidence, at least some of the time.

## Accounts of sensitivity to sample size and diversity

Accounts of sensitivity to sample size are to be found in a variety of literatures whereas sensitivity to sample diversity is accounted for only by theories of category-based induction. Fong, Krantz \& Nisbett (1986) claimed that sensitivity to sample size occurs because people possess intuitive but abstract rules that correspond to the law of large numbers, and showed that sensitivity to the law of large numbers can be enhanced by training. This account is similar in some respects to Piaget's (Inhelder \& Piaget, 1975). In particular, both accounts stress the centrality of sensitivity to sample size to reasoning about probability more generally. Stanovich and West (1999) offer a dual process account of sensitivity to sample size, where such sensitivity when it is observed, is the result of effortful processes that draw on working memory in order to apply normatively justified rules or principles for reasoning.

Sensitivity to sample size, or adherence to the monotonicity principle, is explained very differently in models of category-based induction. For example, the similarity-coverage model (Osherson et al., 1990) holds that arguments are strong to the extent that the conclusion category is "covered" by the categories in the premises.

That is, to the extent that instances sampled at random from the conclusion category are similar to the categories in the sample. As a larger sample is more likely to better cover the conclusion category than a smaller sample, people judge arguments based on larger samples to be strong. Sloman (1993) predicts that arguments will be judged strong to the extent that there is overlap in the features of the conclusion category and the features of the categories in the sample. This account predicts sensitivity to sample size on the grounds that larger samples, on average, lead to greater featural overlap. Notably, all accounts of category-based induction, including Bayesian models (Tenenbaum, Kemp \& Shafto, 2007) explain sensitivity to sample size and diversity in the same way.
In summary, different explanations of sensitivity to sample size posit different types of process. Early developmental and decision making accounts posit the existence of abstract and intuitive rule-like representations which, according to some accounts (see Stanovich \& West, 1999) are effortfully applied. On the other hand, accounts of sensitivity to sample size in the literature on category-based induction appeal to processes operating over the relations between specific members of the sample. Some accounts (e.g. Sloman, 1993; Rogers \& McClelland, 2004) hold that the application of these processes is relatively effortless. Accounts of sensitivity to sample diversity appear only to be found in the literature on category-based induction, and are similar to the accounts of sensitivity to sample size that are to be found in the same literature.

## Dissociating the effects: Two different paradigms

The goal of the experiments to be described below was to examine whether similar or different processes underlie the sample diversity and sample size effects in induction. To achieve this goal we derived hypotheses about possible differences between the two phenomena in terms of the effort required by each and about the side effects of the underlying reasoning processes.

Effort and secondary tasks To the extent that models of category-based inductive reasoning are correct in assuming that sensitivity to sample size and diversity require the operation of the same processes, we should expect to find no differences between the effort required in order to demonstrate each effect. However, if sensitivity to sample size requires the operation of a rule-based process (Fong et al, 1986) that draws on working memory (Stanovich \& West, 1999) then we might expect to be able to show that sample size trials require more cognitive effort than do diversity trials. To test this hypothesis we presented reasoning trials (the primary task) concurrently with a memory task (the secondary task). Such designs have previously been employed to test hypotheses about the effort required by particular types of thinking (see De Neys, 2007). If sample size materials require more effort than diversity materials, we should expect to observe (a) a greater effect of the secondary task on sensitivity to sample
size than on sensitivity to diversity; or (b) greater effects of the sample size task than the diversity task on the secondary task; or (c) both effects. The first experiment to be described below tested these hypotheses.

Induction then recognition $A$ contentious claim in the literature is that the processes applied during reasoning may have consequences for the type of representation which reasoners construct of the problem material, and hence for their ability to accurately recognize the materials they reasoned about (see Sloutsky \& Fisher, 2004). There is evidence that following a simple inductive reasoning task, children have better recognition memory for the problem materials than to adults, although they perform equally well on the reasoning task. Sloutsky and Fisher (2004) claimed that this recognition memory effect was a consequence of children and adults using different processes to reason. They claim that adults reason on the basis of category membership and therefore construct category-level or gist (Brainerd, Reyna \& Forrest, 2002) representations of the reasoning stimuli. Children, on the other hand, reason on the basis of correspondences or similarities between the entities in the reasoning problem. This leads them to construct a verbatim (Brainerd et al., 2002) representation of the materials. When all participants are subsequently presented with old pictures and new critical lures, it is children with their more detailed representation of the original materials who are better able to discriminate between old and new items.
Although there has been disagreement about whether the original induction-then-recognition experiments necessitate conclusions about developmental changes in reasoning processes (Wilburn \& Feeney, 2008; Hayes, McKinnon \& Sweller, 2008), the paradigm may be a very useful tool for determining whether different reasoning phenomena are caused by different reasoning processes. For example, if sensitivity to sample size in category-based induction is due to the application of an intuitive rule, then we would not expect participants to encode verbatim representations of the reasoning stimuli. On the other hand, if sensitivity to diversity requires representation of the relations between the entities in the reasoning problems, then participants should be more likely to construct verbatim representations of the entities in those reasoning materials. This difference in the type of representation that is constructed might have consequences for participants' ability to subsequently recognize the entities that they have previously reasoned about. Specifically, participants may have better recognition memory for diversity materials than for sample size materials. On the other hand, if the same processes are involved in sensitivity to both phenomena, we would expect no differences due to reasoning phenomena in recognition accuracy. Experiment 2 below will test these hypotheses.

## Experiment 1

The aim of this experiment was to test for differential effects of a secondary task on sensitivity to sample size and
diversity in inductive reasoning, and to test for differential effects of these reasoning phenomena on performance of a secondary task.

To facilitate the use of the Induction then Recognition paradigm in Experiment 2, across both experiments we adopted a paradigm recently used to test for diversity effects in children (Rhodes, Brickman \& Gelman, 2008) in which participants are asked to select between a diverse and nondiverse sample of category members in order to help them decide whether all members of the category possess a novel property.

## Method

Participants Sixty students (29 males) were recruited in a quiet area of the library at QUB, and paid $£ 2$ each to take part in the study. The mean age was 28.63 years.

Materials In each reasoning task, participants were told about a novel property that might be possessed by all members of a category, alongside two samples of members of that category, and were asked which sample they would like to test in order to decide whether all members of the category possess the property. On the five trials assessing sensitivity to diversity, the diverse sample consisted of pictures of two category members of different coloration, species, or breeds (in the case of dogs), while the nondiverse sample consisted of one of the diverse sample members, and another similar category member. On the five trials assessing sensitivity to sample size, the small sample consisted of two category members, and the large sample consisted of the same two category members plus one additional member. Unique categories, images, and properties were used on each trial.

Because of the possibility that participants might complete the sample size trials without processing the content of the images, we included five control trials at the end of the experiment which asked participants to choose between a small diverse sample and a larger non-diverse sample. If some participants complete the sample size trials without processing the content of the images in the samples, we should find that participants choose the large sample in the control trials as often as in the sample size trials. In addition, there should be a strong correlation between the tendencies to choose the large sample in both types of trial.

The secondary task (see De Neys, 2006) required participants to memorize an array of dots on a $3 x 3$ matrix before each reasoning task, and recreate it immediately afterwards.

Procedure All participants completed the experiment on a laptop computer running E-Prime software. They were told before beginning that the experiment would investigate how people make judgments about category members and their properties. On each trial, participants were presented with a statement at the top of the screen, with the two possible samples below it on either side. They were instructed to press the ' 1 ' button to choose the left sample, and the ' 2 '
button to choose the right sample. There were two practice reasoning trials before the experimental trials began. The first ten trials tested for sensitivity to sample size and diversity and their order was randomized separately for each participant. The final five trials pitted a two-member diverse sample against a three-member homogenous sample.

Before the beginning of each trial, participants were presented with a $3 x 3$ grid for 1000 ms , containing either four dots in random positions (complex condition), or three dots in a straight or diagonal line across the grid (simple condition). After given a response in each reasoning trial, they saw a blank grid, and were required to recreate the pattern seen previously. Participants were instructed to remember the dot pattern as well as they could, while still paying attention to the reasoning task.

Figure 1: Timeline for trials in Experiment 1. At (a) participants were presented with a simple or complex spatial array to memorize; after 1000 ms they were presented with a reasoning problem (b) requiring them to choose one of two samples; and (c) once they chose a sample they recreated the spatial array.

## Results

Primary task performance Across secondary task conditions, participants showed sensitivity to diversity on only $52.3 \%$ of trials ( $\mathrm{SD}=24 \%$ ), and sensitivity to sample size on $72 \%$ of trials ( $\mathrm{SD}=28 \%$ ). A 2 (secondary task: complex vs simple) x 2 (trial type: montonicity, diversity, \& control) mixed ANOVA revealed a main effect of trial type only, $\mathrm{F}(1,58) 21.44, \mathrm{p}<.001$. Neither the effect of load nor the interaction between trial type and load achieved statistical significance.

Secondary task performance Participants' ability to correctly recall the dot arrays broken down by complexity condition and trial type is to be seen in Figure 2. A 2x2 mixed ANOVA revealed a significant main effect of complexity condition, $\mathrm{F}(1,58)=50.90, \mathrm{p}<.001$, and a significant interaction between complexity condition and
trial type, $\mathrm{F}(1,58)=12.88, \mathrm{p}=.002$. Post hoc tests on the means involved in this interaction revealed that reasoning about diversity trials had a significantly greater effect on simple secondary task performance than did reasoning about sample size trials, $\mathrm{t}(29)=2.92, \mathrm{p}<.01$. However, performance on the complex secondary task was affected to a greater degree by sample size trials than by diversity trials, $\mathrm{t}(29)=2.48, \mathrm{p}<.02$.

Figure 2: Interactive effect of trial type and secondary task on secondary task performance in Experiment 1.

Control performance One potential issue with interpreting the results of this experiment and the next is that participants may complete the sample size trials by simply counting the number of images in each sample without processing the content of the samples. One finding that suggests this did not happen is that the mean inspection time for sample size trials was almost identical ( 6377 ms ) to the mean inspection time for the diversity trials ( 6380 ms ). In addition, analysis of the control trials revealed that participants selected the large sample in the control trials $60 \%$ ( $\mathrm{SD}=30 \%$ ) of the time which is significantly less often, $\mathrm{t}(59)=2.36, \mathrm{p}<.03$, than in the sample size trials. If participants had not been processing the content of the samples but only their size, we would have expected the rate at which the large sample was chosen to be virtually identical in these two conditions. In addition, there was almost no association between the tendency to select the large sample in the sample size and control trials, $r(60)=$ . 02.

## Discussion

Participants in Experiment 1 demonstrated less sensitivity to sample size than to sample diversity, and they performed better on the simple than on the complex secondary task. Furthermore, performance on the complex secondary task was significantly worse when the primary task required sensitivity to sample size than when it required sensitivity to sample diversity. On the other hand, performance on the simple secondary task was worse when the primary task required sensitivity to diversity. These results are consistent
with the claim that different processes underlie the sample size and diversity effects. The findings for the complex secondary task, in particular, suggest that participants who are sensitive to sample size may possess a simple rule. Because the operation of such a rule requires general cognitive processes related to working memory (see Stanovich \& West, 1999), performance of a complex secondary task which also requires working memory, is particularly impaired. Fong et al. (1986) suggested that the sample size rule is abstract but intuitive. Its intuitiveness may explain why sensitivity to sample size was observed on a relatively high proportion of trials, and why performance on the simple secondary task was barely impaired when the primary task required sensitivity to sample size.

Notably, performance on the primary task was not affected by the nature of the secondary task and it is not clear why this was the case. One possibility is that participants prioritized the reasoning task.

## Experiment 2

The aim of Experiment 2 was to provide further evidence for dissociation between sensitivity to the size and diversity of the sample in inductive reasoning. To do this we asked participants to complete a surprise recognition memory test once they had completed the reasoning items. If sensitivity to sample size involves the application of an intuitive rule, then we might expect participants to build a gist rather than a verbatim representation of the content of the samples. This representation should lead to relatively poor recognition memory for the entities in the samples. Memory for the entities presented in the diversity trials should be more accurate, if sensitivity to diversity depends on more featurebased processing of the images in the samples. Such processing should be more likely to result in verbatim representations of the pictures in the samples which will better support accurate recognition of those entities.

## Method

Participants 59 QUB students ( 25 males) were tested in a quiet area of the university library, and paid $£ 2$ each to take part in the study. The mean age was 26.5 years.

Materials Materials were the same as used in Experiment 1, except that there were seven diversity and seven sample size trials. We did not include control trials in this experiment. The recognition memory task consisted of 63 images: 28 pictures previously seen in the reasoning tasks (2 from each trial, one of which was featured twice in the trial), 28 previously unseen pictures of members of the previously featured categories, and 7 pictures of categories not featured at any stage in the experiment.

Procedure The procedure for the reasoning part of the experiment was broadly similar to the procedure followed in Experiment 1. However, the secondary task was omitted, trial type was blocked and block order was counterbalanced.

The order in which trials were presented within blocks was randomized.

Once they had completed the reasoning trials, participants were told that the second part of the experiment would consist of a surprise recognition test, and instructed to try to identify which images had been seen previously in the reasoning tasks. Images were presented one at a time and participants pressed the ' 1 ' button for pictures seen before, and the ' 2 ' button for new pictures.

Materials check Our hypothesis is that recognition memory for the contents of diversity trials will be better than for the contents of sample size trials. We carried out a check to ensure that the materials used in the diversity trials were no more memorable than those used in the sample size trials. We presented the materials used in the reasoning part of the experiment to 34 participants. The information about properties was not included and instead of asking participants to make a choice between the samples, we instructed them to memorize the images for a subsequent memory test.

## Results

Reasoning task Participants selected the diverse sample on $73.6 \%$ of trials (SD = 25\%), and the larger sample 81.8\% of the time ( $\mathrm{SD}=26 \%$ ). Participants were significantly more sensitive to sample size than they were to sample diversity, $\mathrm{t}(58)=2.105, \mathrm{p}=.04$.

Recognition memory Performance on the recognition memory test was analyzed with the A' statistic (Snodgrass \& Corwin, 1986), a non-parametric analogue of the d' signal detection measure. An A' of .5 corresponds to chance

Figure 3: A' scores from Experiment 2 broken down by trial type and whether participants reasoned about the materials or studied them for memory.
discrimination between old and new stimuli, while a score approaching 1 indicates perfect discrimination. In Figure 3, A' scores for the main experiment are presented alongside scores from the materials check. While A' scores for diversity and sample size materials were almost identical for
participants in the baseline memory condition ( $\mathrm{A}^{\prime}=.82$, and .81 respectively, SDs $=.09$ and .07$), \mathrm{t}(33)=.177$, amongst participants in the main reasoning condition, recognition was much better for the diversity materials $\left(\mathrm{A}^{\prime}=.78, \mathrm{SD}=\right.$ .13) than the sample size materials ( $\mathrm{A}^{\prime}=.66, \mathrm{SD}=.13$ ), $\mathrm{t}(58)=6.343, \mathrm{p}<.001$.

Inspection times We measured the time between presentation of each reasoning item and participants' responses. The average of this inspection time was 5579 ms (SD $=2055 \mathrm{~ms}$ ) for diversity trials, and 5256 ms ( $\mathrm{SD}=$ 2273 ms ) for sample size trials. This difference was nonsignificant, $\mathrm{t}(58)=1.003$. Thus, the difference due to reasoning phenomenon in the recognition memory data cannot be attributed to differences in how long participants looked at the materials for each trial type.

## Discussion

As we predicted, participants had better recognition memory for the entities they reasoned about in the diversity trials than they did for the entities in the sample size trials. Additionally, the results of our materials check confirmed that the diversity entities were not more memorable than the sample size entities. These results suggest that different processes underlie sensitivity to diversity and sensitivity to sample size. Whereas the former requires feature-based processing of the entities, resulting in a verbatim-type representation which supports accurate recognition memory, the latter is driven by the application of a rule, which leads to a gist representation of the samples and significantly less accurate recognition memory.

## General Discussion

Both experiments reported here show evidence of a disassociation between the processes underlying sensitivity to the sample diversity and size. In Experiment 1, sensitivity to sample size and to diversity differentially impacted upon the secondary task, indicating a dissociation of the underlying mental processes. Similarly, in Experiment 2 materials used in diversity trials were remembered significantly better, suggesting a greater degree of feature-based processing. Taken together, these findings are problematic for single-process accounts of inductive reasoning (e.g. Osherson et al, 1990; Sloman, 1993; Rogers \& McClelland, 2004).

Recent findings have challenged the classical view that inductive inference is the product of similarity-based or associative processes, while deduction relies on the application of abstract logical rules (Evans, 2012). On one hand, similarity-driven processes have been shown to underlie some deductive phenomena (Sloman, 1998). On the other, Heit and Rotello (2010; see also Rips, 2001) have shown that both similarity and logical validity determine inductive and deductive argument strength, but with induction drawing more heavily on similarity-based or associative information. With the blurring of the boundaries
between the processes underlying the two forms of reasoning, it has become somewhat unclear what is distinctive about induction. Heit (2007) offers two views on defining induction: the process view, which relates to the processes by which we make an inference, and the problem view, relating to the structure of the inference to be made. While from the problem view deduction and induction remain discrete, our findings suggest that, from the process view, reasoning cannot be so easily partitioned. Our results, from two diverse paradigms, suggest that there is a disassociation between the processes underlying sensitivity to sample size and to sample diversity in category-based induction, and by extension, that inductive reasoning cannot be captured by single process accounts.

#### Abstract

The present study investigates two key aspects of analogical retrieval: (1) whether other activities different from problem solving automatically elicit a search for analogical sources, and (2) whether strategic search can overcome the superficial bias observed in classical experiments. In Experiment 1, participants had to generate persuasive arguments for a target situation under three experimental conditions: without indication to use analogies, with instruction to use analogies, and with indication to search for sources within four predefined domains: health, human relations, housekeeping, and breeding of animals and plants. Responses from the first condition showed that argumentation rarely triggers spontaneous analogical retrievals, a result that is at odds with most studies on problem solving. Results from the remaining conditions demonstrated that the superficial bias can be strategically reversed when participants are suggested to focus on specific domains. Experiment 2 replicated this last result with the simple instruction to search within domains different from that of the target (i.e., without being provided with a list of specific domains). The theoretical and educational implications of these findings are discussed.

Keywords: Analogy, retrieval, similarity, transfer.

## Introduction

Analogical reasoning consists in acknowledging that the objects of two situations are organized by an identical system of relations (Gentner, 1983). Across activities as diverse as problem solving, instruction or argumentation, finding the right analogical correspondences allows transferring knowledge from a known situation (the base analog: BA) to novel situation (the target analog: TA) in order to improve the representation of the latter. A traditional taxonomy distinguishes between intradomain analogies (i.e., when BA and TA pertain to the same thematic domain) and interdomain analogies (i.e., when BA and TA belong to thematically separate domains). In intradomain analogies, the compared analogs maintain superficial similarity, as corresponding objects and relations tend to be semantically similar.

A number of empirical studies have demonstrated that people can easily understand analogies even in the absence of superficial similarity (e.g., Gentner, Rattermann, \& Forbus, 1993, see Holyoak, Novick \& Melz, 1994, for a review). In contrast with the relative easiness of finding the right mapping between a BA and a TA that are simultaneously active in working memory (WM), the process of retrieving interdomain BAs from Long Term Memory (LTM) turns out to be rather taxing. As in most studies in the memory literature, the standard paradigm for investigating the conditions that foster analogical retrieval comprises two different phases. During the learning phase, participants receive the BAs embedded in tasks aimed at enforcing a proper encoding of the BAs in LTM. During the retrieval phase, sometimes temporally and/or contextually separated from the first, participants receive the TAs embedded in target tasks for which retrieving the BAs becomes crucial, and experimenters assess whether the processing of the TA triggers the retrieval of the critical BA. Studies using this paradigm showed that intradomain BAs are retrieved between two and four times more frequently than interdomain BAs (Holyoak \& Koh, 1987; Keane, 1987). These findings led researchers to conclude that superficial similarity represents a crucial precondition for analogical retrieval. On the other hand, computational modelers of analogical retrieval agree that the computational cost implicated in carrying out a structural mapping between a TA and every potential BA in LTM would be psychologically implausible (Forbus, Gentner \& Law, 1994; Thagard, Holyoak, Nelson \& Gochfeld, 1990).

Under these considerations, proponents of the structure mapping theory (Gentner, 1983) developed MAC/FAC (Forbus, Gentner \& Law, 1994), an algorithm designed to mimic human patterns of analogical retrieval through psychologically realistic computations. MAC/FAC, for Many Are Called, Few Are Chosen, divides retrieval into two phases: MAC, a fast superficial filter, and FAC, a structural matcher.

The MAC phase begins by generating content vectors for the TA and every representation in LTM, with each content vector being generated by assigning a position in an ordered series to all concepts in LTM, and counting how many times each concept appears in each BA. Upon taking the vector products between the content vector of the TA and the vector of all situations in LTM, the MAC stage submits the winning BAs (most of them superficially similar to the TA) to the FAC stage. For each BA, FAC starts by creating all possible local mappings between elements of the same formal type, with the added restriction that mapped relations must have identical meaning. The program then incrementally coalesces local matches into global mappings that satisfy the constraints of parallel connectivity (if two predicates are mapped, their arguments must also be mapped) and one-toone mapping (elements in one analog must map to only one element in the other analog). Finally, FAC scores the quality of global mappings as a function of their size, their depth, and the semantic similarity of their corresponding objects. This last criterion amplifies MACs' bias towards BAs bearing superficial similarity with the TA.

LISA (Learning and Inference with Schemas and Analogies; Hummel \& Holyoak, 1997) is the latest matcher developed by proponents of the multiconstraint theory of analogy (Holyoak \& Thagard, 1989, 1995). Its architecture aims at encompassing retrieval, mapping, inference and schema abstraction by a unified set of core processes that are more neurally plausible than in earlier attempts (e.g. ARCS; Thagard, Holyoak, Nelson \& Gochfeld, 1990). LISA's architecture is a system for representing dynamic role-filler bindings in WM and encoding them in LTM for later retrieval. When a proposition unit (P) like John loves Mary gets activated, it propagates top-down activation to subproposition units (SPs) that represent bindings between each of the case roles of the proposition and its corresponding filler. During the lapse while each SP unit remains active, it transfers top-down activation to two independent structure units representing a case role and its filler (e.g., John and lover) which fire in synchrony with each other and out of synchrony with the units of the complementary SP (i.e. Mary and beloved). Case roles and their fillers-which represent the lower level in the structural hierarchy-in turn activate a collection of semantic units representing their meaning. Therefore, when a proposition such as John loves Mary is selected, the semantic primitives of lover (e.g., emotion1, positivel, and strongl) fire in synchrony with the semantic primitives of John (e.g., human, male and adult), while units representing the beloved role (e.g., emotion2, positive 2 and strong2) fire in synchrony with units representing Mary (e.g., human, female and adult). When the semantic primitives of a given role-filler binding in the TA fire in WM, predicate, object and SP units from one or various BAs compete in responding to this array as a function of the extent to which their semantic units overlap. As in MAC/FAC, LISA's reliance on semantic similarities between BAs and TAs leads to a majority of superficial remindings.

In contrast with the emphasis placed in justifying the appropriateness of the representational and computational assumptions incorporated in each of the above models (e.g MAC/FAC uses serial operations on symbolic representations while LISA uses connectionist computation on distributed representations), the proponents of these models are ambiguous as to whether the models account for spontaneous remindings, voluntary remindings, or both. Given the importance of this distinction within current memory research (see Mace, 2010, for a review), the first objective of the present study is thus to investigate to what extent the search for BAs in LTM is automatically triggered by the processing of the TAs. A second objective of the present study concerns whether voluntary retrieval of BAs is invariably biased towards superficial matches, as in current implementations of the above models, or if search for BAs can be strategically circumscribed to areas of knowledge different from that of the target-a central preoccupation of psychologists and educators (see, e.g., Loewenstein, 2010). Before presenting our study, the available evidence bearing on these two questions is briefly reviewed.

## Automatic vs. Voluntary Search for Base Analogs

It is a common experience to be spontaneously reminded of analogous cases while carrying out thoughtful activities like science teaching, explanation, and persuasive argumentation. However, a sensible question to be asked concerns to what extent being engaged in the above activities automatically initiates a search for BAs in LTM. Even though no single study has yet manipulated whether or not participants are explicitly invited to "think of analogous problems", acrossstudies comparisons within the problem-solving literature suggest that participants' attempts to find a solution automatically elicit a search for BAs. For instance, using roughly comparable stimuli, Keane (1987) and Holyoak and Koh (1987) assessed the retrieval of a BA during a temporally and contextually separated problem solving activity. Even though the former study (but not the latter) explicitly asked participants to look for analogous problems prior to attempting a solution, both obtained comparable rates of retrieval, which suggests that the mere disposition to find solutions suffices to trigger a search for BAs. Other studies of spontaneous analogical retrieval during problem solving (e.g., Chen, Mo \& Honomichl, 2004) point in the same direction. With these antecedents in mind, the specific question that concerns us here is whether other thoughtful activities such as those listed above also trigger a search for analogous cases in a reliable manner.

A likely candidate task for automatic analogical retrieval is persuasive argumentation. A series of naturalistic studies (e.g., Blanchette \& Dunbar, 2000; Trench, Oberholzer \& Minervino, 2009; Trench, Olguín \& Minervino, 2011) have shown that when being asked to generate analogies to convince somebody of performing an action, people easily retrieve BAs from their autobiographical memory. As in these studies, the procedure followed by one of the groups of the first experiment reported in the present study consisted
in presenting participants with a target situation admitting two alternative lines of action, and asking them to provide as many analogies as they could in favor of one of such actions. In order to shed light on whether the activity of finding persuasive arguments automatically triggers a search for relevant BAs, we had another group receive the same TA and the same instructions to argue in favor of the intended action, but without any hint to base their arguments on analogous situations.

## Voluntary Analogical Search: Fixed or Strategic?

As stated above, a wealth of laboratory studies demonstrate that search for BAs yields mostly superficial matches to the TA. Even though most retrieval algorithms were specially engineered to mimic such pattern of results, some of them left open the question of whether such superficial bias could be "tuned" by the analogizer, be it by means of adjusting the weight given to object attributes by the structural component of the system (FAC), or by having the whole retrieval algorithm run on a subset of MLP selected via other general mechanisms of memory such as spreading activation or indexing (Gentner \& Forbus, 1991, p. 4).

Consistent with this last possibility, Ripoll (1998) postulated the psychological reality of a synthetic level of representation that specifies the thematic domain to which a given problem/story belongs, and demonstrated how these "domain tags" operate during the time-course of analogical retrieval. The procedure consisted in coupling superficially similar and superficially dissimilar target problems with a heading intended to activate a domain tag (e.g., "a learning problem"), which could match (or not match, depending on the condition) the domain tag of the base problem. Using concurrent measures of retrieval, Ripoll (1998) found that the presence of shared surface features facilitated retrieval, but only when the domain tags of the problems matched.

In the first experiment of the present study, the second and third groups received a TA and an instruction to search for potential analogous situations that could be used to convince the main character of the TA to pursue a given action. However, while participants of the second group were not given any indication to focus search in any particular direction, participants of the third group were provided with domain tags representing domains thematically distant from the TA, and were asked to search for potential situations within such domains. The comparison between the types of analogies provided by these two groups seeks to extend Ripoll's (1998) findings in two ways. On the one hand, they test the psychological reality of domain tags outside the realm of analogical problem-solving. Most importantly, though, they explore whether these tags can be strategically exploited by the analogizer during voluntary analogical reminding.

## Experiment 1

## Method

Participants and Design One hundred and twenty undergraduate students at Universidad Nacional del Comahue
volunteered to participate in the experiment (Mean age $=$ $21.49, S D=3.42$ ). An even number of participants was randomly assigned to the argumentation condition $\left(\mathrm{G}_{\mathrm{AR}}\right)$, the analogical argumentation condition $\left(\mathrm{G}_{\mathrm{AN}}\right)$, and the analogical argumentation with predefined domains condition $\left(\mathrm{G}_{\mathrm{AN}+\mathrm{D}}\right)$. The variables indication to use analogies (two levels: with and without explicit indication to use analogies) and provision of search domains (two levels: with and without indication to search within particular domains) received between subjects manipulation. The dependent variables were the number and type (intra/interdomain) of the proposed BAs.

Materials and Procedure Before advancing to the target task, participants of all groups received an instructional material on argumentation. The material handed to the $\mathrm{G}_{\mathrm{AR}}$ covered general features of arguments, but did not describe specific types of arguments (e.g., analogies). The material handed to the $G_{\text {AN }}$ and the $G_{\mathrm{AN}+\mathrm{D}}$ described the use of analogies in persuasion, illustrating with two examples the distinctions between intra and inter-domain analogies, as well as between analogies based on situations retrieved from memory and analogies based on invented situations. Once the 10 min allotted to reading the instructional material had elapsed, participants of all groups were given TA describing the situation of a family that was accumulating an important debt in the balance of their credit card. All groups had to generate as many arguments as they could to persuade them to cut expenses immediately in order to cancel the debt, on the grounds that otherwise it would grow so big that future cuts would need to be even more dramatic. Whereas instructions given to the $\mathrm{G}_{\mathrm{AR}}$ did not mention the convenience of including analogies to prior cases among the persuasive arguments, participants of the $G_{A N}$ and $G_{A N+D}$ were asked to base their arguments on analogies to known situations. The difference between $G_{\text {AN }}$ and $G_{\text {AN }+\mathrm{D}}$ was that while participants of $\mathrm{G}_{\mathrm{AN}}$ received no instructions concerning the domains of the BAs, participants of the $\mathrm{G}_{\mathrm{AN}+\mathrm{D}}$ were asked to sequentially focus their search within four domains different from economy: health, human relations, housekeeping, and breeding of animals and plants. In order to prevent participants of the $G_{\text {AN+D }}$ and $G_{A N+D}$ from reporting BAs not originated in retrieval processes they were encouraged to base their analogies on past episodes which had happened to them or to others, or that were learned from verifiable sources such as newspapers, books, movies, etc. Participants of $G_{A R}$ and $G_{A N}$ were given 20 min to complete the argumentation task. In the case of $\mathrm{G}_{\mathrm{AN}+\mathrm{D}}$, participants were allotted 5 min for each of the suggested domains. Once this time had elapsed, participants of all groups were allotted 5 more minutes to report all other arguments (or analogies, depending on the group) that had come to mind during the previous phase but were not reported for whatever reasons. This question was intended to neutralize an eventual conscious editing of retrieved BAs, (cf. Trench, Olguín \& Minervino, 2011), like when a BA is rejected for not being persuasive, or for not pertaining to the specific domain that was requested (e.g., in $\mathrm{G}_{\mathrm{AN}+\mathrm{D}}$ ).

Data analysis Two judges received instruction on the concept of analogy, as well as on the general distinction between intra and interdomain analogies. For the particular TA at stake, they were instructed to regard as "analogical responses" all proposals including the following elements: (1) a problem of increasing magnitude, (2) a delay in the attempts to solve it, and (3) a consequent increase in the cost of solving it. Regarding the intra/interdomain distinction, judges were instructed to score as intradomain all situations where the problem of increasing magnitude was economic (e.g., a public debt) and to score as interdomain all instances in which the problem of increasing magnitude was not of economic nature (e.g., an illness or addiction). Given that we sought to detect all the BAs that were retrieved from LTM in response to the target task, judges were handed all responses produced by the participants, regardless of whether they were reported during the argumentation phase, or during later requirement to list all other situations that had come to mind during the first task, but were not included among the final proposals. Judges agreed in $82 \%$ of the cases regarding the analogical status of proposals, and in $94 \%$ of the cases regarding their intra/interdomain nature. Cases of disagreement were resolved by open discussion.

## Results and Discussion

Across conditions, participants proposed a mean of 2.10 responses ( $S D=.94$ ), out of which $44 \%$ were rendered "analogical" by the judges. Further comparisons and statistical analyses were restricted to analogical proposals. Our first empirical question concerned whether the task of generating persuasive arguments would reliably elicit a search for BAs in LTM, as observed within the literature on analogical problem solving. Taking together intra and interdomain proposals, participants of $\mathrm{G}_{\mathrm{AR}}$ retrieved a total of 7 BAs in response to the TA $(M=.18, S D=.45)$. This level of analogical retrieval is markedly lower than that of $\mathrm{G}_{\mathrm{AN}}$ ( $M=.73, S D=.60$ ), where participants were explicitly asked to base their arguments on analogies to known situations, $t(72.14)=4.658, p<.01$. Given the performance exhibited by the $G_{A N}$, the disappointing number of BAs retrieved by participants of $G_{\text {AR }}$ cannot be attributed to a lack of BAs available in LTM for retrieval. Rather, it indicates that that the pragmatic of generating persuasive arguments for a realworld target situation does not reliably elicit a spontaneous search for relevant analogs in LTM. A likely explanation for the difference between our results and those obtained with problem solving tasks might lie in the fact that the types of problems typically used (e.g. the tumor problem) do not admit direct methods of solution (e.g., means-ends analysis). Perhaps with other types of problems, the spontaneous use of analogies would be less frequent, as it happened in the present study.

Our second empirical question dealt with whether the search mechanisms underlying voluntary analogical retrieval are invariably set to favor superficially similar BAs. Judges' analysis of analogical proposals reported by the $\mathrm{G}_{\mathrm{AN}}$ showed that $62 \%$ of the retrieved BAs were semantically similar to
the TA, and $38 \%$ of retrieved TAs were semantically dissimilar from the TA, a result that reproduces the pattern typically obtained in the literature. In contrast with this standard pattern of retrievals, judges' analyses of analogies generated by the $G_{\text {AN }+\mathrm{D}}$ showed that whereas $35 \%$ of the retrieved BAs came from the same domain of the TA, $65 \%$ of the retrieved BAs were interdomain, a result that goes against the superficial bias typically obtained in the literature on analogical retrieval. A comparison between the $\mathrm{G}_{\mathrm{AN}}$ and the $\mathrm{G}_{\mathrm{AN}+\mathrm{D}}$ in terms of their relative proportions of superficially similar vs. superficially dissimilar retrievals thus demonstrates that the participants can strategically favor the retrieval of one or the other type of BAs, $Z=-2.54, p<.05$.

Figure 1. Mean number or retrievals, Experiment 1
An intriguing question raised by the possibility of shifting search away from the target domain concerns whether the increased number of distant matches comes at the expense of missing a number of intradomain BAs that would be retrieved under a non strategically-oriented search, as a "shift of focus" metaphor might suggest. A comparison between the $G_{\mathrm{AN}}$ and the $\mathrm{G}_{\mathrm{AN}+\mathrm{D}}$ in terms of the mean number of superficially similar and superficially dissimilar BAs showed that whereas the mean number of distant BAs generated by the $\mathrm{G}_{\mathrm{AN}+\mathrm{D}}(M=1.23, S D=1.17)$ clearly surpassed the mean number of distant BAs retrieved by the $\mathrm{G}_{\mathrm{AN}}(M=.28, S D=.45), t(50.48)=4.806, p<.001$, participants of $\mathrm{G}_{\mathrm{AN}+\mathrm{D}}$ did not retrieve a lesser amount of superficially similar BAs than participants of $\mathrm{G}_{\mathrm{AN}}(M=.65$, $S D=.83$, vs. $M=.45, S D=.50$, respectively), $t(64.14)=$ $1.299, p>.05$. Rather than simply shifting the focus towards interdomain retrieval, it seems that participants of $\mathrm{G}_{\mathrm{AN}+\mathrm{D}}$ are broadening the scope of their search, an operation that boosts access to distant analogs while still retaining baseline levels of intradomain analogizing.

Even though the educational implications of the observed increment in interdomain analogizing are easy to foresee, an interesting question to be asked concerns whether a reasonable increase in the absolute and relative amounts of interdomain retrievals can still be obtained without providing participants with a set of promising domains within which to search for useful BAs. In Experiment 2, we tested this possibility by comparing the analogical argumentation condition (i.e., the former $\mathrm{G}_{\mathrm{AN}}$ ) against a pro-interdomain argumentation condition without the provision of predefined search areas ( $\mathrm{G}_{\text {ANint }}$ ).

## Experiment 2

## Method

Participants and Design Fourty students at Universidad Nacional del Comahue (Mean age $=20.71, S D=2.05$ ) were randomly assigned to two experimental conditions. The variable type of argumentation (two levels: with indication to use analogies vs. with indication to use interdomain analogies) received between subjects manipulation. The dependent variables were the number and type of the proposed BAs.

Materials and Procedure The materials and procedure applied to the $\mathrm{G}_{\mathrm{AN}}$ were a replication of those followed with the $\mathrm{G}_{\mathrm{AN}}$ of Experiment 1. The materials and procedure employed with the $G_{\text {ANint }}$ were identical to those of the $G_{\text {AN }}$ with the sole difference that participants were asked to base their persuasive analogies on episodes pertaining to domains different from that of the TA (i.e., economy). Data analysis was identical as in Experiment 1, with judges' agreement reaching $85 \%$ with regards to the analogical status of proposals, and $96 \%$ regarding their intra/interdomain nature.

## Results and Discussion

Experiment 2 was carried out to assess whether an increase in the absolute and relative amounts of interdomain retrieval could still be obtained without providing participants with a set of interdomain search areas to look for analogous situations. A comparison between the $G_{A N}$ and the $G_{\text {ANint }}$ showed that the relative proportion of interdomain analogies proposed by the $\mathrm{G}_{\text {ANint }}$ was higher than in the $\mathrm{G}_{\mathrm{AN}}, Z=-$ 1.97, $p<.05$. Whereas the analogies proposed by the $\mathrm{G}_{\mathrm{AN}}$ were $63 \%$ intradomain and $37 \%$ interdomain, the analogies proposed by the $G_{\text {ANint }}$ were $40 \%$ intradomain and $60 \%$ interdomain. Though not as strong as in Experiment 1, this reversal demonstrates that participants can voluntarily alter the superficial bias classically obtained in experiments of analogical retrieval with the mere intention to search for thematically distant sources in LTM.

Figure 2. Mean number or retrievals, Experiment 2
As in Experiment 1, the augmented proportion of interdomain retrievals in the pro-interdomain condition was not obtained at the expense of missing a number of intradomain retrievals. A comparison between $G_{A N}$ and $G_{\text {ANint }}$ in terms of the mean number of intra and interdomain retrievals showed that whereas $\mathrm{G}_{\text {ANint }}(M=.65, S D=.98)$ clearly surpassed the $\mathrm{G}_{\mathrm{AN}}(M=.30, S D=.46, t(55.80)=2.05, p<.05)$ in the
number of interdomain retrievals, both groups retrieved similar amounts of intradomain BAs $(M=.43, S D=.59$ vs. $M=.50, S D=.60$, respectively, $t(78)=0.562, p>.05$ ). Once again, it seems that a strategic search for interdomain BAs can powerfully boost access to distant analogs, while still retaining baseline levels of intradomain retrieval.

## General Discussion

In order to reproduce human patterns of analogical retrieval, extant computational models have specified in great detail a number of assumptions about the types of representations and computations implied in retrieving BAs from LTM. In contrast to this long-lasting preoccupation, their presentations are ambiguous as to whether the postulated mechanisms account for the processes of spontaneous reminding, strategic retrieval, or both. Albeit unsystematic, the evidence related to this matter comes mainly from studies of analogical problemsolving, and suggests that both types of search yield similar results, since the mere disposition to find a solution to a problem reliably elicits a search for analogous BAs in LTM.

The first experiment of the present study tackled two interrelated issues. The first one was concerned with spontaneous analogical retrieval, and had to do with whether other thoughtful activities different from problem solving (in this case, persuasive argumentation) can also elicit spontaneous remindings reliably. Results of Experiment 1 showed that when participants are not explicitly asked to base their arguments on analogies to prior cases, this activity seldom occurs spontaneously. In light of the performance of a second group that was explicitly asked to use analogies, the low level of spontaneous retrieval obtained by the first group cannot be attributed to a lack of available BAs in LTM. Rather, it shows that the pragmatics of generating persuasive arguments does not reliably elicit a search for BAs in LTM. These results have implications for models of analogical retrieval, since they can help specify the conditions under which the proposed mechanisms operate.

Our second concern was related to strategic analogical retrieval, and dealt with whether this second type of process can potentially reverse the superficial bias observed in behavioral studies of analogical retrieval, and simulated by computational models. Results showed that when participants are asked to base their arguments on analogies to known situations, they retrieve more superficial than distant matches. However, when provided with a series of distant domains to focus their search, this proportion reverses-a pattern of results that claims for an extension of Ripoll's (1998) domain tags to the arena of voluntary analogical retrieval. It should be noted, however, that our conclusions were based on the use of a single TA. In future studies, it would be desirable to replicate these results with a wider set of materials.

Albeit never implemented, the developers of MAC/FAC left open the possibility of relaxing its superficial bias by either suspending FAC's computation of object attributes, or by having the system run on a subset of LTM selected via mechanisms of spreading-activation or indexing. Given the strong superficial constraints imposed by the MAC stage, it
seems that only by running on a subset of LTM (e.g., on a subset defined by thematic search areas, or domains) the program might have a chance of coping with the pattern of interdomain analogizing elicited during strategic analogical retrieval. In relation to this possibility, the fact that in Experiments 1 and 2 participants of the pro-interdomain conditions still retrieved a significant amount of intradomain matches suggests that, at least with our materials, strategic search can be somewhat demanding, leading to recurrent cycles of non strategic retrieval attempts.

The present results on strategic analogical retrieval also suggest interesting instructional applications, since educators and researchers have long strived to find ways of facilitating cross-domain transfer. In recent times, attention has shifted from promoting an abstract encoding of BAs (e.g., Catrambone \& Holyoak, 1989) to improving the encoding of TAs at retrieval time, such as providing participants with two structurally identical TAs, and asking them to compare such TAs prior to attempting a solution (Gentner, Loewenstein, Thompson \& Forbus, 2009; Kurtz \& Loewenstein, 2007). As Loewenstein (2010) points out, the appeal of this approach lies in its potential to foster retrieval of BAs which might have been encoded in suboptimal ways. However, a practical limitation of the target-comparison method used in the above studies lies in the fact that participants need to be provided with a second TA for every new TA. Even though participants of our $\mathrm{G}_{\mathrm{AN}+\mathrm{D}}$ were also provided with targetspecific information at retrieval time (a set of promising domains to search for BAs), the $G_{\text {ANint }}$ of our second experiment retrieved mostly interdomain BAs with the sole instruction to search within domains different from the TA, that is, without receiving target-specific information. We believe that the austerity of this last intervention opens up encouraging perspectives for the flexible use of analogy in educational environments.

# A Dynamic Dual-Process Model of Decision-making Under Uncertainty 

Jennifer S. Trueblood (jstruebl@uci.edu)<br>Department of Cognitive Sciences, University of California, Irvine<br>Irvine, CA 92697 USA

#### Abstract

Current dynamic models of decision-making assume that a unitary system is responsible for forming preferences. However, extensive research has shown that decision-making and behavior result from the interaction of two separate systems of reasoning - one that is fast, automatic, and experiential and one that is slow, deliberative and rational. This paper develops the first dynamic dual-process model of decision-making that can account for choice, response times, and prices. The model is applied to several phenomena from the risky decisionmaking literature including enhancements in preference by small losses, preference reversals due to response mode, and the influence of price and affect on preference.

Keywords: Decision-making, dual-process theory, preference reversal, dynamic models

## Introduction

Existing dynamic models of decision-making such as Decision Field Theory (Busemeyer \& Townsend, 1993) assume there is a single system of thought that produces preferences. However, there is substantial research supporting the idea that preferences are formed from a dual process of reasoning. This paper introduces a dynamic dual-process model of risky decision-making. The model generalizes a previous static two systems model developed by Mukherjee (2010) to account for choice, response times, and prices.

Dual-process theory postulates that there are two fundamentally different systems that can process information. One system is described as automatic, intuitive, fast, and experiential. The other is labeled as deliberative, analytical, slow, and rational. The former system is typically referred to as System 1 and the latter System 2 (Stanovich \& West, 2000). (In this paper, System 1 is labeled the affective system and System 2 the deliberative system following the terminology of Mukherjee (2010).) Research has shown that dual-process accounts are often more successful at explaining behavioral phenomena than unitary approaches (Hogarth, 2001; Kahneman, 2003; Sanfey, Loewenstein, McClure, Cohen, et al., 2006). There is also evidence from the neuroscience community for two separable systems in the brain that contribute to decision-making (Damasio, 1994; Sanfey et al., 2006).

The paper begins by describing the Dynamic Dual-Process (DDP) model for choice and response times which is later extended to also account for pricing elicitation methods. The model is used to make new predictions about the relationship between response time and the involvement of the affective system. It is shown that in some situations greater involvement of the affective system leads to faster decisions as expected. However, the model also predicts that in other situations the two systems can compete with one another resulting in longer response times. DDP is also applied to three
phenomena from the risky decision-making literature: the enhancement effect which occurs when a small loss is added to a positive gamble, preference reversals due to response mode, and the influence of price and affect on preference.

## A Static Two Systems Model

The DDP model generalizes the Dual System Model (DSM) by Mukherjee (2010). DSM is a utility model of risky decision-making where the overall utility for a gamble is composed of two components: the utility of the gamble with respect to the deliberative system and the utility of the gamble with respect to the affective system. Mathematically, the overall utility can be written as $V(G)=V_{A}(G) \oplus V_{D}(G)$ where $V_{A}(G)$ is the evaluation due to the affective system and $V_{D}(G)$ is the evaluation due to the deliberative system.

Based on experimental results by Hsee and Rottenstreich (2004), Mukherjee made two assumptions about the evaluation of outcomes. The first assumption was that the deliberative system evaluates outcomes linearly so that $V_{D}(x)=k x$ where $x$ is an outcome and $k$ is a free parameter. The second assumption was that the affective system evaluates outcomes with respect to a concave value function in the gain domain and a convex value function in the loss domain similar to the value function in prospect theory (Kahneman \& Tversky, 1979). Mukherjee postulates that for positive outcomes this value function can be approximated by $V_{A}(x)=x^{m}$ for $m<1$.

Mukherjee made two additional assumptions about the perception of probabilities based on experimental work by Rottenstreich and Hsee (2001). He assumed that the deliberative system perceives probabilities directly without distortion so that the probability weighting function is $w(p)=p$ as in Expected Utility theory. He also assumed that the affective system is insensitive to probabilities and only recognizes whether or not an outcome is possible. Thus, each possible outcome receives equal weight so that for $n$ outcomes the probability of any single outcome is $1 / n$.

Let $\left(p_{1}, x_{1} ; \ldots ; p_{n}, x_{n}\right)$ be the gamble $G$ with $n$ positive outcomes $x_{i}$. Using the four assumptions above, Mukherjee defined the utility for the deliberative system as $V_{D}(G)=$ $\sum_{i}^{n} p_{i}\left(k x_{i}\right)$ and the utility for the affective system as $V_{A}(G)=$ $1 / n \sum_{i}^{n} x_{i}^{m}$. The overall utility $V(G)$ is simply the convex combination of the two utilities for the two different systems:

$$
\begin{align*}
V(G) & =\gamma V_{A}(G)+(1-\gamma) V_{D}(G) \\
& =\gamma \frac{1}{n} \sum_{i}^{n} x_{i}^{m}+(1-\gamma) k \sum_{i}^{n} p_{i}\left(x_{i}\right) \tag{1}
\end{align*}
$$

where $\gamma$ is the weight given to the affective system. DSM can account for a wide range of choice phenomena including
violations of nontransparent stochastic dominance, ambiguity aversion, common consequence effect, and the common ratio effect (to name a few).

## The Dynamic Dual-Process Model

While DSM has been very successful in accounting for a variety of phenomena, it does not describe the dynamic process underlying decisions. Like most models of judgment and decision-making, DSM is a descriptive model concerned with theorizing at the highest level. Because DSM is a static utility model, it cannot make predictions about response times. On the other hand, DDP is a processing model aimed at explaining the mechanisms that produce behavior. In this way, it is similar to other dynamic models of decision-making such as Decision Field Theory (Busemeyer \& Townsend, 1993). DDP is the first two systems model that can account for both choice and response times.

Another drawback to DSM is that it has not been applied to experiments using pricing elicitation methods such as asking how much money one is willing to pay (WTP) for an option or how much money one is willing to accept (WTA) to sell an option. Many of the experiments in affective decisionmaking use these pricing procedures including the majority of the experiments by Rottenstreich and Hsee (2001) and Hsee and Rottenstreich (2004) that served as motivation for DSM. The DDP model can easily be extended to account for pricing elicitation methods as described in a later section.

The DDP model is formulated with respect to the typical risky decision task of choosing between two gambles. Let $G_{1}=\left(p_{1}, x_{1} ; \ldots ; p_{n}, x_{n}\right)$ and $G_{2}=\left(q_{1}, y_{1} ; \ldots ; q_{m}, y_{m}\right)$ be gambles with outcomes $x_{i}$ and $y_{i}$ and probabilities $p_{i}$ and $q_{i}$ respectively. As a decision-maker considers the two gambles, his or her preference evolves across time. Let $P(t)$ be the individual's preference at time $t$ where positive preference states represent momentary preference for gamble $G_{1}$ and negative preference states represent momentary preference for gamble $G_{2}$. A new preference state $P(t+1)$ is formed at each moment in time from the previous preference state according the linear stochastic difference equation:

$$
\begin{equation*}
P(t+1)=P(t)+d+\varepsilon(t) \tag{2}
\end{equation*}
$$

where $\varepsilon(t)$ is the stochastic error term and $d$ is the difference in the evaluations of the gambles. The evaluation of each gamble is determined by evaluations from the affective and deliberative systems as in DSM. The difference $d$ is given by

$$
\begin{equation*}
d=V\left(G_{1}\right)-V\left(G_{2}\right) \tag{3}
\end{equation*}
$$

where $V\left(G_{1}\right)$ and $V\left(G_{2}\right)$ are calculated as in equation 1.
The preference state starts at an initial state $P(0)=z$ reflecting an initial bias for one gamble over the other. Specifically, if $z>0$, then there is an initial bias for $G_{1}$ and if $z<0$, then there is an initial bias for $G_{2}$. The preference state evolves until it reaches a threshold. There are two thresholds for the model, a positive threshold $\theta$ associated with $G_{1}$ and a negative threshold $-\theta$ associated with $G_{2}$. When the
preference state reaches the positive threshold, $G_{1}$ is selected. When it reaches the negative threshold, $G_{2}$ is selected.

In total, DDP has six parameters. Three parameters, $k, m$, and $\gamma$, are used in the evaluation of the gambles given in equation 1. Parameters $\theta$ and $z$ define the threshold and initial bias respectively. There is an additional variance parameter $s$ used to define the amount of noise in the accumulation process.

DDP is a Wiener diffusion process (the continuous-time, continuous-state version of the random walk). Link and Heath (1975) derived equations for choice probabilities and the conditional mean response time for the Wiener process. Thus, DDP is computationally tractable and easy to apply.

## Response Time and Affect

The affective system is typically characterized as automatic and fast as compared to the deliberative system which is analytic and slow. As such, when the affective system plays a larger role in the decision-making process, decisions should be quick. In terms of the DDP model, this implies that as $\gamma$ increases, response times should decrease.

To test the relationship between response time and the involvement of the affective system, two gambles of equal expected value were analyzed: $G_{1}=(4 / 10, \$ 9 ; 6 / 10, \$ 0)$ and $G_{2}=(9 / 10, \$ 4 ; 1 / 10, \$ 0)$. Choice and response times from DDP were examined for all possible values of $\gamma$. The $m$ parameter used to specify the curvature of the affective valuation function was also allowed to vary from $0.1 \leq m \leq 0.9$. The scaling parameter $k$ in the deliberative value function was fixed to $k=1$ so that $V_{D}(x)=x$ without distortion. The initial bias was fixed to $z=0$ reflecting no bias towards one gamble over the other. The threshold parameter was fixed to $\theta=10$, and the variance parameter was fixed to $s=1$ as is common in response time modeling.

The top left panel of Figure 1 shows the choice probability for gamble $G_{1}$ over $G_{2}$ for different values of $\gamma$ and $m$. As $\gamma$ increases, the probability of selecting $G_{1}$ increases. This reflects the assumption that the affective system ignores probabilities when evaluating gambles. As the affective system becomes more involved, the gamble with the highest payoff is viewed more favorably. As $m$ decreases and the value function for the affective system becomes more concave, the two gambles are viewed as indifferent. Thus, favorability for $G_{1}$ by the affective system is moderated by increasing risk aversion (i.e., decreasing $m$ ). The top right panel of Figure 1 shows the mean response time conditional on selecting $G_{1}$. As predicted, increases in $\gamma$ lead to faster response times. In general, for gambles of equal expected value, as the affective system becomes more involved, decisions become quick and high payoff options are preferred.

When gambles have unequal expected value, it is not necessarily the case that response times decrease with increased involvement of the affective system. The bottom panels of Figure 1 show choice probabilities and response times for the gamble $G_{1}^{*}=(3 / 10, \$ 9 ; 7 / 10, \$ 0)$ as compared to $G_{2}$. In this situation, $G_{2}$ has a greater expected value than $G_{1}^{*}$. When the

Figure 1: Top panel: choice probability (left) and conditional mean response time (right) for gambles with equal expected value for various values of $\gamma$ and $m$. Bottom panels: choice probability (left) and conditional mean response time (right) for gambles with unequal expected value. Red values indicate larger choice probabilities and longer response times.
deliberative system is more involved as indicated by small values of $\gamma, G_{2}$ is preferred. However, as $\gamma$ increases and the affective value function becomes less concave (corresponding to an increase in $m$ ), $G_{1}^{*}$ is preferred. Response times are fast for small values of $\gamma$ paired with small values $m$ and for large values of $\gamma$ paired with large values of $m$. In other words, quick decisions can be made for $G_{2}$ by the deliberative system and for $G_{1}^{*}$ by the affective system, but response times increase when there is conflict between the two systems. The influence of system conflict on response time is a new prediction by DDP which could be tested in future experiments.

## Enhancement by Small Loss

Slovic, Finucane, Peters, and MacGregor (2002) found that adding a small loss to a positive gamble can increase its attractiveness rating and choice probability. When asked to rate the attractiveness of gamble $G_{1}=(7 / 36, \$ 9 ; 29 / 36, \$ 0)$ and $G_{2}=(7 / 36, \$ 9 ; 29 / 36,-\$ 0.05)$, participants rated gamble $G_{1}$ with no loss lower (mean $=9.4$ on a $0-20$ scale) than gamble $G_{2}($ mean $=14.9)$. The gambles were then each paired
with a sure gain of $\$ 2$ (denoted by $S$ ). Half of the participants were asked to choose between $G_{1}$ and $S$ and the other half were asked to choose between $G_{2}$ and $S$. Only $33.3 \%$ chose $G_{1}$ over the gain whereas $60.8 \%$ chose $G_{2}$ over the gain. Slovic et al. (2002) explained these findings by the affect heuristic. The inclusion of a small loss enhances the perceived benefit of $\$ 9$ producing a positive affective feeling for $G_{1}$ leading to higher attractiveness ratings and choice probabilities.

The enhancement in choice probability by the inclusion of a small loss can also be explained by DDP. Based on the idea that $G_{2}$ produces a more affective response than $G_{1}$, it is assumed that the affective system is more activated by $G_{2}$ than $G_{1}$. Mathematically, this implies that $\gamma_{2}>\gamma_{1}$ where $\gamma_{1}$ is associated with the choice between $G_{1}$ and $S$ and $\gamma_{2}$ is associated with the choice between $G_{2}$ and $S$.

To test the enhancement effect, the difference in probabilities $\operatorname{Pr}\left(G_{2} \mid\left\{G_{2}, S\right\}\right)-\operatorname{Pr}\left(G_{1} \mid\left\{G_{1}, S\right\}\right)$ was examined for different values of $\gamma_{1}, \gamma_{2}$ and $m$. For this analysis, $\gamma_{1}$ was allowed to vary from 0.1 to 0.5 and $\gamma_{2}$ was defined in terms of $\gamma_{1}$ by
the equation $\gamma_{2}=\gamma_{1}+\alpha$ where $\alpha$ varied from 0.1 to 0.3 in increments of 0.05 . As in the previous demonstration, $k=1$, $\theta=10, z=0$, and $s=1$. Because the affective value function postulated by Mukherjee (2010) only applies to positive outcomes, the function was generalized to $V_{A}(x)=-|x|^{m}$ for negative outcomes. Figure 2 plots the difference in probabilities for different values of $\gamma_{1}$ given along the $x$-axis. The different curves in the figure are associated with different values of $\gamma_{2}$ The $m$ parameter was fixed to 0.3 in the top panel and 0.5 in the bottom panel.

Figure 2: Enhancement effect shown as the difference in choice probabilities for $G_{2}$ and $G_{1}$ for different values of $\gamma_{1}$. The top panel shows the effect when $m=0.3$ and the bottom panel shows the effect when $m=0.5$. An enhancement effect occurs when the difference is greater than zero.

In the figure, the enhancement effect occurs when the difference in probabilities is greater than zero. When $m=0.5$, this happens for all values of $\gamma_{2}$. When $m=0.3$ implying greater risk aversion, the enhancement effect only occurs for
large values of $\gamma_{2}$ (when $\alpha>0.25$ ) suggesting greater involvement in the affective system is needed in order to produce the effect. In sum, the figure shows that the DDP model can easily account for the enhancement in choice probability by small losses. Further, the model makes new predictions about the magnitude of enhancement with respect to risk aversion and affect.

## Extending DDP for Pricing Elicitation Methods

In many decision tasks, participants are asked to report a value such as a price that they are willing to assign to a particular option. For example, participants might be asked how much they are willing to pay (WTP) to play a certain gamble. DDP can be extended to account for such elicitation methods. The approach taken is similar to the one developed by Busemeyer and Goldstein (1992) and Johnson and Busemeyer (2005). The basic idea is that when an individual is determining price equivalence, they search through a range of possible prices. When a particular price is being considered, the individual can decide that it is too low, too high, or equivalent to the gamble. In the case when the price is too low, the individual increases the price. When the price is too high, the individual decreases the prices. If the price is equivalent, then it is reported.

Mathematically, this search process can be formulated as a discrete Markov chain as illustrated in Figure 3. The states in the chain correspond to possible prices increasing from left to right. The range of possible states is determined by the problem. For example, if an individual is asked how much they would pay to play the gamble $(7 / 36, \$ 9 ; 29 / 36, \$ 0)$, the the range of possible prices would be $\$ 0$ to $\$ 9$. The search process is assumed to begin near the middle of the candidate prices. A step to the right in the chain corresponds to increasing the price. The probability $p$ of stepping to the right is the choice probability from DDP of choosing the gamble over a sure gain of $\$ x$ where $\$ x$ is the candidate price. A step to the left in the chain corresponds to decreasing the price. The probability $q$ of stepping to the left is the choice probability from DDP of choosing a sure gain of $\$ x$ over the gamble. The probability of exiting the search process and reporting a price occurs with probability $r$ whenever DDP enters a neutral state. The neutral state is the point of indifference between the gamble and a sure gain and corresponds to $P(t)=0$ in DDP. Details about implementing Markov chain models can be found in a Diederich and Busemeyer (2003) and Johnson and Busemeyer (2005).

## Response Mode Preference Reversals

A puzzling phenomenon in decision-making is the occurrence of preference reversals with changes in response mode (Lichtenstein \& Slovic, 1971, 1973). For example, Slovic et al. (2002) asked subjects to rate the attractiveness of gambles $G_{1}=(29 / 36, \$ 2 ; 7 / 36, \$ 0)$ and $G_{2}=(7 / 36, \$ 9 ; 29 / 36, \$ 0)$ on a $0=20$ scale. On average, participants rated $G_{1}$ (mean 13.2 ) as more attractive than $G_{2}$ (mean 7.5). Yet, when asked how much they would be willing to pay to play the gambles,

Figure 3: Markov chain model for pricing elicitation methods. Transition probabilities $p$ and $q$ are determined by the DDP model.
participants were willing to pay more to play $G_{2}$ (mean \$2.11) than $G_{1}$ (mean \$1.25).

The DDP model explains this preference reversal by assuming that a high attractiveness rating is associated with a strong affective response. Because $G_{1}$ had a higher attractiveness rating than $G_{2}$, it is hypothesized that the affective system is more involved with decisions about $G_{1}$ than $G_{2}$. Mathematically, this implies that the $\gamma$ parameter for $G_{1}$ should be greater than the $\gamma$ parameter for $G_{2}$. To test this hypothesis, a grid search was performed over the $\gamma$ and $m$ parameters to find the ranges of these parameters that produce price equivalences similar to those in the experiment. Specifically, parameter pairs that produced prices within $\$ 0.20$ of the mean prices from the experiment were examined. For this analysis, $k=1, z=0$, and $s=1$ as before. Matrix methods (Diederich \& Busemeyer, 2003) were used to determine the transition probabilities from DDP rather than using analytical solutions. This was done to accommodate the inclusion of the exit probability $r$. Because the matrix methods only provide an approximation to the choice probabilities, the threshold was fixed to $\theta=50$ to improve the estimates. For gamble $G_{1}$, the states of the Markov chain ranged from $\$ 0$ to $\$ 2$ in increments of $\$ 0.10$. Similarly, for gamble $G_{2}$, the states of the Markov chain ranged from $\$ 0$ to $\$ 9$ in increments of $\$ 0.10$. The exit probability was set to $r=0.01$.

Figure 4 plots the $\gamma$ and $m$ parameter pairs that produce prices in the given ranges. The blue region shows the parameters that yield prices between $\$ 1.05$ and $\$ 1.45$ for $G_{1}$ and the red region shows the parameters that yield prices between $\$ 1.91$ and $\$ 2.31$ for $G_{2}$. From the figure, it is clear that the $\gamma$ parameter for $G_{1}$ must be greater than the $\gamma$ parameter for $G_{2}$ to produce prices in these ranges. Thus, the DDP model can explain preference reversals by greater involvement of the affective system for more attractive gambles.

## Influence of Probability and Affect on Price

Rottenstreich and Hsee (2001) found that the amount of money participants were willing to pay to play a gamble depends on both the probability of winning and whether the outcome is affect-rich or affect-poor. In their experiment, participants were asked how much they were willing to pay to play a gamble offering a $\$ 500$ coupon for a European vacation or a $\$ 500$ coupon for tuition at their university. The European vacation coupon was designed to be affect-rich whereas tu-

Figure 4: Results of a grid search over $\gamma$ and $m$ for WTP prices. The blue region shows the parameters that produce prices for $G_{1}$ within $\$ 0.20$ of the mean price of $\$ 1.25$. The red region shows the parameters that produce prices for $G_{2}$ within $\$ 0.20$ of the mean price of $\$ 2.11$. As predicted, $\gamma$ for $G_{1}$ is greater than $\gamma$ for $G_{2}$.
ition coupon was designed to affect-poor. Rottenstreich and Hsee (2001) also manipulated the probability of winning the coupons. Some participants were told they had a $1 \%$ chance of winning and others were told that they had a $99 \%$ chance of winning. They found that even though the coupons were worth the same redemption value, the median price for the European coupon was $\$ 20$ as compared to $\$ 5$ for the tuition coupon when there was only a $1 \%$ chance of winning. However, when there was a $99 \%$ chance or winning, participants were willing to pay more for the tuition coupon (median price $\$ 478$ ) than for the European coupon (median price $\$ 450$ ).

Rottenstreich and Hsee (2001) explained this preference reversal by greater involvement of the affective system in the European coupon gamble than the tuition coupon gamble. For the low probability gamble, the affective system overweights the probability of winning and thus the affect-rich European coupon is valued more than then affect-poor tuition coupon. However, for the high probability gamble, the affective system underweights the probability of winning and the European coupon is valued less than the tuition coupon.

Following the intuition of Rottenstreich and Hsee (2001), the DDP model explains this preference reversal by using a larger $\gamma$ parameter for the affect-rich European coupon as compared to the affect-poor tuition coupon. For this analysis, the $\gamma$ parameter for the European coupon gamble was set to $\gamma=1$ implying complete involvement of the affective system and no involvement of the deliberative system. For the tuition coupon gamble, $\gamma=0$ implying complete involvement of the deliberative system and no involvement of the affective system. These parameter settings reflect the extreme case when only one system is involved in the decision-making process. In reality, it is more likely that both systems are involved in
both gambles with $0<\gamma_{T}<\gamma_{E}<1$ where $\gamma_{T}$ is associated with the tuition coupon and $\gamma_{E}$ is associated with the European coupon. For ease of demonstration, the extreme $\gamma$ values were used, but the results also hold for more intermediate values of $\gamma$.

As before, $k=1, z=0, s=1, \theta=50$, and $r=0.01$. For the European coupon, the $m$ parameter was allowed to range from 0.1 to 0.9 . For the tuition coupon, $m$ has no impact because $\gamma=0$. Table 1 shows the WTP prices from DDP for the two different coupons and two different chances of winning. In the table, a range of prices is given for the European coupon showing the maximum and minimum prices as $m$ is varied. Because $m$ does not play a role in the tuition coupon, a single price is shown. From the table, the DDP model produces the same pattern of results as Rottenstreich and Hsee's experiment. Namely, the price for the European coupon is greater than the price for the tuition coupon when there is a low probability of winning and the price for the tuition coupon is greater than the price for the European coupon when there is a high probability of winning.

Table 1: WTP prices from the DDP model for the European and tuition coupons for two different probabilities of winning.

| Coupon | $1 \%$ chance | $99 \%$ chance |
| :--- | :--- | :--- |
| European $(\gamma=1)$ | $\$ 32.59-\$ 39.38$ | $\$ 303.48-\$ 491.94$ |
| Tuition $(\gamma=0)$ | $\$ 5.14$ | $\$ 492.97$ |

## Discussion

The DDP model synthesizes ideas from several lines of research in decision-making and cognitive modeling. DDP draws upon the static DSM model developed by Mukherjee (2010) to explain how dual systems of reasoning evaluate options. DDP formalizes the the formation of preferences as an accumulation of information over time similar to other dynamic models such as Decision Field Theory (Busemeyer \& Townsend, 1993). DDP also employs a Markov chain model to account for pricing elicitation methods as in Busemeyer and Goldstein (1992) and Johnson and Busemeyer (2005). In sum, DDP provides a unified theory of how dual systems interact to produce choices, response times, and prices that is grounded in decades of research.

Future work will develop new experiments to rigorously test DDP and to investigate novel predictions from the model. In particular, DDP makes new predictions about the interaction between systems and response times. The affective system is typically conceived as being fast and automatic. Thus, when it is engaged in a task, responses should be quick. DDP suggests that the relationship between response time and the affective system is not this simple. It predicts that response times are influenced by many factors including conflict between the two systems, risk attitudes, and the options themselves.

#### Abstract

Holistic processing and left-side bias are both behavioral markers of expert face recognition. In contrast, expertise in Chinese character recognition involves left-side bias but reduced holistic processing (Hsiao \& Cottrell, 2009). Here we examine whether the reduction in holistic processing associated with expert Chinese character recognition can be better explained by writing rather than reading experience. Compared with non-Chinese readers (novices), Chinese readers who had limited writing experience (Limited-writers) showed increased holistic processing, whereas Chinese readers who could also write characters fluently (Writers) showed reduced holistic processing. These results suggest that writing/sensorimotor experience can modulate holistic processing effects, and that the reduced holistic processing observed in expert Chinese readers may depend on writing rather than reading experience. By contrast, both Writers and Limited-writers showed a similar level of left-side bias in processing symmetric Chinese characters, left-side bias may therefore be a consistent expertise marker for object recognition uninfluenced by motor experience.

Keywords: Chinese character recognition, holistic processing, reading, writing, left-side bias

## Introduction

Holistic processing (HP) is the tendency to process separate features of an object as a single whole unit (Richler, Wong, \& Gauthier, 2011), and it is shown to be a behavioral marker of face recognition expertise. Some have speculated that HP applies to other types of expert-level object recognition because it facilitates within-category discrimination by incorporating featural and configural information beyond individual parts (e.g., Bukach et al., 2006; but for a contrasting view, see McKone et al., 2007). For example, training participants to recognize novel artificial objects, Gauthier and colleagues (1998) found a positive correlation between HP and expertise in within-category object recognition. Wong and colleagues (2009) also showed that participants had an increase in HP when trained to individualize an artificial object type.

Left-side bias (LSB) is also consistently reported in face perception; it refers to the effect that a chimeric face made from two left half-faces is usually judged more similar to the original face compared with one made from two right half-faces from the viewer's perspective (Brady, Campbell, \& Flaherty, 2005; Fig. 1), perhaps due to right hemisphere (RH) involvement in face recognition (Burt \& Perrett, 1997).

Fig. 1. Examples of chimeric face stimuli. Two left halves of an original face (middle) were combined to form the left chimeric face (left), and the two right halves formed the right chimeric face (right).

Chinese characters, sharing many visual properties with faces, may induce similar processing effects for expert readers in face recognition (McCleery et al., 2008). More specifically, the Chinese writing system is logographic; Chinese characters have a homogenous, square configuration, and each character is a grapheme that maps onto a morpheme (Shu, 2003). Strokes are the basic units of Chinese characters which combine to form more than 200 basic stroke patterns in the Chinese writing system (Hsiao \& Shillock, 2006); these stroke patterns in turn form the characters. A typical literate recognizes 3,000 to 4,000 characters. In addition, Chinese characters are generally recognized regardless of variations in font and handwriting style, similar to face recognition regardless of differences in facial expressions (Hsiao \& Cottrell, 2009), and experts recognize Chinese characters individually like faces (Wong \& Gauthier, 2006).

Indeed, similar to face recognition, Hsiao and Cottrell (2009) showed that expert Chinese readers demonstrated left side bias when viewing mirror-symmetric Chinese characters, whereas novices did not. Their finding suggests that LSB is an expertise marker for both face and Chinese character recognition and was consistent with research suggesting a RH involvement in Chinese orthographic processing (e.g. Yang \& Cheng, 1999). However, unlike face perception, the expertise marker for Chinese character recognition turned out to be reduced HP (Hsiao \& Cottrell, 2009). Experienced Chinese readers engage in less HP than novices in perceiving Chinese characters; perhaps they are more sensitive to the constituent components of Chinese characters and can more readily ignore some configural information unimportant for character recognition, such as exact distances between features (Ge et al., 2006). Such constituent components may not look easily separable to novices, probably because novices are less able to distinguish individual features and
components in Chinese characters (Ho, Ng, \& Ng, 2003). Hsiao and Cottrell (2009) have therefore suggested that HP is not a general expertise marker for object processing; it depends on the features of the stimuli and the tasks typically performed on the stimuli (see also Wong et al., 2009).

Note however that learning to read Chinese characters is different from learning to recognize faces-for instance, while a typical Chinese reader can read and write characters proficiently, one is not expected to draw out all the faces seen every day. Thus, the reduced HP effect in expert Chinese character processing, in contrast to expert face processing, may be related to expert readers' writing rather than reading experience. Unlike writing alphabetic words, which only requires recalling a few dozens of letters in an alphabet together with the specific combinations corresponding to their sounds, writing Chinese characters requires retrieving more than a thousand pieces of script information from long term memory. One may have to attend analytically to detailed stroke patterns of individual Chinese characters in order to memorize and write them. Perhaps expert Chinese readers in Hsiao and Cottrell's (2009) study had reduced HP because of their writing experience. Indeed, Zhou and colleagues (2012) found that artists with face drawing experiences had reduced holistic face processing compared with ordinary observers.

In Hong Kong, although the internal structures of Chinese characters are not explicitly emphasized in formal lessons, Chinese children acquire better orthographic awareness as they progress to higher grades (Ho et al., 2003). One explanation has to do with motor programming through extensive copying and reading at school (Tan et al., 2005). Copying performance (McBride-Chang et al., 2011; Tan, et al., 2005), and dictation performance (McBride-Chang et al., 2011) is correlated with reading performance. Writing performance may predict reading performance because children may consolidate knowledge of orthographic structures of characters with graphomotor memory of strokes as they copy the stroke sequences (Tan et al., 2005). Learning to write indeed seems to strengthen Chinese character recognition (Guan et al., 2011); writing experience also seems to shape the neural representation specialized for reading (e.g. James \& Atwood, 2009; Longcamp et al., 2003). Together, these results suggest a close relationship between increasing sensory-motor integration through writing practice and reading skills development.

However, Tso, Au and Hsiao (2011) identified some Chinese readers who have high reading proficiency but far poorer writing ability - whom we will call "Limited-writers (LW)". They are usually students or graduates of international schools who have learned to "write" in Chinese using computer software that converts input in a phonic alphabet (e.g., the Pinyin system) into Chinese characters, expatriates living in Chinese speaking countries, or overseas Chinese immigrants who learned to read in Chinese from environmental prints including Chinese mass media. Because writing in Chinese is more complex and resource-intensive than writing in an alphabetic language (Chan et al., 2006;

Chung \& Ho, 2010), marked discrepancy between reading and writing performance in Chinese is possible. With limited writing practice but plenty of reading experience, LW may recognize the holistic structures of characters similarly to face recognition, with limited analysis of the constituent structures. Thus, the cognitive processes involved in Chinese reading for LW may be different from readers who have received intensive character writing training (Writers). Without extensive writing experiences, these LW may still process Chinese characters holistically.

Here we aim to investigate whether perceptual expertise effects such as holistic processing (HP) and left-side bias (LSB) effects can be modulated by motor experience through examining how novices, Chinese Writers and limited-writers (LW) process Chinese characters. We first examine whether Writers perceive characters less holistically than LW, and whether the reduced HP effect is related to their reading and writing performance. Since writing practice may enhance orthographic awareness of characters and de-emphasize configural information in character recognition, Writers may perceive characters less holistically than LW, and this effect may be related to their difference in writing rather than reading performance - contrary to what the research literature suggests. The ability to perceive characters analytically (less holistically) may also be the underlying mechanism for how writing experience enhances Chinese character recognition. We also predict that compared to novices, increase in HP marks expert Chinese character recognition in LW whereas Writers show reduced HP.

We then examine whether LW and Writers have a similar LSB effect in Chinese character perception. Brady et al. (2005) showed that the LSB effect in face perception was stronger when viewing familiar faces compared with unfamiliar faces; this phenomenon suggests that the LSB effect may be related to familiarity with the stimuli. Since both Writers and LW are proficient readers and thus are familiar with Chinese characters, we predict that Writers and LW will have a similar degree of LSB in perceiving Chinese characters, while no LSB is shown in novices.

## Methods

## Participants

60 participants in Hong Kong participated in our study. 20 participants reported having no prior experiences in reading Chinese characters (i.e. novices); the remaining 40 were Cantonese native-speaking Chinese readers: 20 of them had always attended traditional local schools and reported to have fluent reading and writing proficiency (i.e., Writers), while 20 had either studied overseas or at international schools and had not received formal Chinese lessons that prepared students for the local public Chinese examinations (i.e., Limited-writers, LW). All LW reported being capable of reading Chinese but with limited writing ability. Writers' and LW's reading and writing abilities were tested by a word-naming and a dictation task respectively (see Procedures); their performance was used to corroborate their self-reports. That is, LW were expected to have similar
performance in the word-naming task as Writers, but have poorer performance in the dictation task (see Results). They were all right-handers, had normal or corrected-to-normal vision and similar college-level education background.

## Procedures

## Test for holistic processing

We adopted procedures from Hsiao and Cottrell (2009). 80 pairs of medium to high frequency Chinese characters in Ming font were chosen (character frequency information was obtained from Ho and Kwan, 2001). In each trial, participants were presented with two characters and instructed to attend to only half (either top or bottom) of each character and judge whether they were the same or different. Twenty pairs were presented in each of the four conditions (Fig. 2a): same in congruent trials, different in congruent trials, same in incongruent trials, and different in incongruent trials. The complete composite paradigm (Gauthier \& Bukach, 2007) was adopted so that in congruent trials, the attended and irrelevant halves corresponded to the same response (i.e., both were the same or different) while in incongruent trials, the attended and irrelevant halves corresponded to different responses. Holistic processing was operationalized as the performance difference between the congruent and incongruent trials; it reflected the amount of interference from the irrelevant parts in the matching of the attended parts. This paradigm was adopted to avoid response biases that may occur in the partial composite design in which the irrelevant halves are always different (see Richler, Cheung, \& Gauthier, 2011).

Fig. 2. (a) Illustration of stimulus pairs in the complete composite paradigm; the attended components are shaded in red. (b) Trial sequences.

After $1,000 \mathrm{~ms}$ of central fixation in each trial, participants were cued with a symbol that directed their attention to the particular halves of the stimuli. The pair of characters was then presented, with one above and one below the initial fixation point, followed by a mask. During the 500 ms presentation time, participants looked at each character once and responded as quickly and accurately as possible by pressing corresponding buttons to judge if the character parts were the same or different (Fig 2b). We measured participants' discrimination sensitivity $A^{\prime}$ as:

$$
A^{\prime}=0.5+\left[\operatorname{sign}(H-F) \frac{(H-F)^{2}+|H-F|}{4 \max (H, F)-4 H F}\right]
$$

H and F are the hit rate and false alarm rate, respectively. $A^{\prime}$ is a bias-free nonparametric measure of sensitivity; we did not use d' because response biases may affect its measurement when assumptions of normality and homogeneity of variance are not met(Stanislaw \& Todorov,
1999). The $A^{\prime}$ difference between incongruent and congruent trials (i.e., Holistic $A^{\prime}$ ) measures HP—a more positive value marks a stronger HP effect.

## Test for left-side bias

We adopted the procedure from Hsiao and Cottrell (2009). 80 Chinese mirror-symmetric characters of high frequency were selected (Ho \& Kwan, 2001). There were a total of 160 trials with each character presented twice: once in Ming font (a common font in print) and once in Feng font (an unfamiliar font that simulates handwriting; Fig. 3). For characters presented in each font, mirror images were used in half of the trials; if a character was presented in Ming font, then the mirror image of the character was presented in Feng font, and vice versa; this was to counterbalance any differences between the two sides of each character. For each character, we counterbalanced the fonts used for the original and mirror-image characters across participants.

Fig. 3.An example of a Ming font (a) and a Feng font (b) character.

Fig. 4. (a) Examples of the stimuli, and (b) the test sequence in the LSB experiment(note that the chimeric characters are still legal Chinese characters).

For each character image, the left chimeric character was created from two left halves and the right chimeric character was created from two right halves of the character (Fig. 4a), similar to chimeric faces. Each character spanned about 6.7 degree of visual angle with a viewing distance of 55 cm . In each trial, after $1,000 \mathrm{~ms}$ of a central fixation, the original character was presented randomly either on the left or right side of the screen, at about 7.2 degree of visual angle away from the center. The left and right chimeric characters were presented along with the original image, with one above and one below an arrow at the center; the arrow directed the location of the original character at which participants were told to look first. Each character was about 3 degree of visual angle away from the center. The stimuli stayed on the screen until participants' response. Participants judged which of the two chimeric characters looked more similar to the original one by pressing the corresponding buttons (Fig. 4b). We measured the LSB effect as the percentage of trials in which the left chimeric character was selected.

## Tests for reading and writing performance:

Naming and dictation tasks were administered to assess, respectively, reading and word recalling/writing abilities.

Naming task: Participants read aloud 40 two-character words arranged from high to low frequency (According to Taiwan Ministry of Education, 1997) as quickly and accurately as possible. Each trial started with a central fixation cross for 500 ms , followed by the character presentation. After the response, the screen turned blank and the experimenter pressed a button to record the accuracy and to start the next trial. The response time was measured as the time difference between the stimulus onset and the onset of the pronunciation, detected by a microphone.

Dictation task: Participants wrote down 40 two-character words (same words as in the naming task) as quickly and as accurately as possible when they heard each word said in a female voice presented by a computer. Two-character words were used instead of characters to reduce ambiguity due to the many homophonic characters in the Chinese lexicon. Each trial started with the words "Get ready" on the screen for 500 ms . After hearing the word, participants pressed buttons to indicate whether they could recall the word or not, before they started writing. After they finished writing, the experimenter pressed a button to indicate accuracy and to reveal the next word. Accuracy was recorded.

These experiments were all conducted using E-prime v2.0 (Psychology Software Tools, Pittsburgh, PA).

## Results

Chinese reading and writing proficiency (Writers vs. LW) ANOVA revealed that Writers and LW did not differ in word naming accuracy, $F(1,38)=.471$, n.s., suggesting that both groups had high reading proficiency for words. Nevertheless, Writers had significantly shorter response times (RT) in word naming than $\mathrm{LW}, \mathrm{F}(1,38)=12.365, \mathrm{p}<.01$. In the dictation task, Writers were significantly more accurate than LW, $F(1$, 38) $=140.53, p<.001$. Fig. 5a contrasts the discrepancy between dictation (word writing) and word naming accuracy in Writers and LW (i.e., they had similar word reading accuracy but differed in dictation/writing accuracy).

## Holistic Processing

Repeated-measures ANOVA was used to investigate HP effects (congruency: congruent vs. incongruent x group: novices vs. LW vs. Writers). On $A^{\prime}$, we found a main effect of congruency, $F(1,57)=21.83, p<.001$, and an interaction between congruency and group, $F(2,57)=5.421, \mathrm{p}<.01$, but no main effect of group, $F(2,57)=.433$, n.s. Both novices and LW had a significantly smaller $A^{\prime}$ in incongruent trials than in congruent trials $(t(19)=3.592, p<.01$, and $t(19)=$ 5.001, $p<.001$, respectively), while this difference was not significant for Writers, $t(19)=0.390$, n.s. In a post-hoc analysis, novices had a larger Holistic $A^{\prime}$ than Writers, $t(38)=$ 2.160, $p<.05$, but a marginally small Holistic A' than LW, $t(38)=1.58, p=0.089$. LW had a larger Holistic $A^{\prime}$ than Writers $t(38)=2.832, p<.01$ (Fig. 5b). For RT, we found a main effect of congruency, $F(1,57)=13.05, p<.01$, and an interaction between congruency and group, $F(2,57)=4.18, p$ $<.05$, but no main effect of group, $F(1,57)=2.26$, n.s. LW responded significantly more slowly in incongruent trials ( $M$ $=592 \mathrm{~ms}$ ) than in congruent trials $(M=499 \mathrm{~ms}), t(19)=5.489$,
$p<.001$, while both Writers and novices recorded similar response times in congruent ( $M=476 \mathrm{~ms}$ and $M=569 \mathrm{~ms}$ respectively) and incongruent trials ( $M=488 \mathrm{~ms}$ and $M=$ 611 ms respectively), $t \mathrm{~s}(19)=0.894$, n.s.

These results reveal an inverted U-shape pattern in which Writers perceived Chinese characters less holistically than LW, while novices perceived Chinese characters more holistically than Writers ${ }^{1}$ but less holistically than LW.

Fig.5. (a) Accuracy rate of Limited-writers and Writers for the dictation and word naming task (***p $<.001$ ). (b) $A^{\prime}$ of Limited-writers and Writers in congruent and incongruent trials of the holistic processing task ( ${ }^{* *} p<.01$ ).

## Left-side bias

We found that both Writers and LW had a stronger LSB effect in Ming font than in Feng font $(t(19)=2.111, p<.05$ : and $t(19)=2.778, p<.05$, respectively), while this font effect in novices was not significant $(t(19)=.693$, n.s.). There was a significant LSB effect in Ming font in both Writers, $\mathrm{t}(19)=$ 2.378, p < .05, and LW, $\mathrm{t}(19)=2.271, \mathrm{p}<.05$, whereas no significant LSB was found in Feng font in either Writers or LW. Novices neither showed LSB in Ming font nor Feng font (Fig 7).When we compared Writers with LW, there was no group or font effect, nor interaction between group and font; this showed that both Writers and LW had a similar degree of LSB in perceiving Chinese characters in either font. On the other hand, when we compared novices with either Writers or LW, novices had a smaller LSB in Ming font than Writers, $t(38)=2.394, p=.022$ and LW, $t(38)=2.396, p=.022$. These results suggested that expert readers exhibited LSB for Chinese characters only in a familiar font (Ming) but not in

[^238]an unfamiliar font (Feng), and LSB is a consistent expertise marker for Chinese character recognition unaffected by writing experience.

Fig. 6. Preference for left chimeric characters in Novices, Writers and Limited-writers in Ming and Feng fonts ( ${ }^{*} \mathrm{p}<.05$ ).

## Discussion

Here we investigated how different learning experience modulates perceptual expertise effects, including HP and left side bias, through examining whether the following groups differ in how they process Chinese characters: Chinese Writers, who read and write Chinese proficiently; LW, who had similar Chinese reading proficiency as Writers (as measured by word naming accuracy) but much poorer writing performance than Writers (as measured by word dictation accuracy); and novices of Chinese characters. Compared with novices, LW processed Chinese characters more holistically, whereas Writers processed Chinese character less holistically. This U-shape pattern suggests that the reduced HP observed in expert Chinese readers (i.e., Hsiao \& Cottrell, 2009) may be related to writing rather than reading performance, or more specifically, the ability to recall and write Chinese characters. These results are consistent with Zhou et al.'s (2012) findings that artists with face drawing experiences had reduced holistic face processing compared with ordinary observers. These effects suggest a close relationship between writing/motor experience and reduced HP in the recognition of Chinese characters/faces/visual stimuli. LW perceived Chinese characters more holistically than novices, consistent with the expertise hypothesis. It seems that HP is still an expertise marker for Chinese character recognition for experts with little or no writing experiences with Chinese characters. Consistent with previous evidence for sensorimotor learning influencing perception (James \& Atwood, 2009; Longcamp, et al., 2003), here we showed how writing experiences could be associated with reduced HP in Chinese character recognition. Note however that LW had slower naming time for Chinese words compared with Writers; thus, they were not as expert at reading Chinese as Writers, given that naming RT has been frequently used as a measure of perceptual expertise (e.g., Tanaka, Curran, \& Sheinberg, 2005). A larger HP observed in LW may indicate an intermediate perceptual change from novices to high-performing experts in Chinese character recognition. Future work will further examine the relationship between HP and writing/motor experience by training novices to
recognize Chinese characters/visual stimuli under different instruction conditions and observe their changes in HP.

Our study also showed that both Writers and LW had a significant left side bias effect in perceiving characters in Ming font (a familiar font) but not those in Feng font (an unfamiliar font); while novices showed no LSB effects. The LSB in Chinese character perception seems to depend on font familiarity. Since both Writers and LW exhibited a similar degree of LSB, writing/motor experience does not seem to modulate the LSB effect. The font familiarity effect is consistent with Brady et al.'s (2005) finding that people showed stronger perceptual asymmetries for familiar faces than for unfamiliar faces; however, their participants showed LSB even in the perception of unfamiliar faces, whereas in our study, the participants did not have significant LSB in an unfamiliar font. This may be due to processing differences between face and Chinese character recognition. In particular, configural information, i.e., distances between parts have been shown to be important in face recognition (Farah et al., 1998) but not in Chinese character recognition, since changes in distance among character components do not change the character identity (e.g., Ge et al., 2006). Recent literature has also suggested a link between configural processing and RH lateralization (see Hsiao \& Cheung, 2011). Thus, face recognition may involve more RH processing than Chinese character recognition, and this involvement of RH configural processing may be transferable to the processing of unfamiliar faces/novel exemplars of a category. In contrast, the LSB/RH lateralization of Chinese character processing may be specific to familiar stimuli; this effect is consistent with the literature showing that the left visual field/RH advantage in tachistoscopic Chinese character identification was only found in real characters, but not in non-existing characters such as pseudo- or non-characters (Cheng \& Yang, 1989). This difference between face and Chinese character recognition also suggests that the RH lateralization in face and Chinese character processing may involve different cognitive processes (Hsiao \& Cheung, 2011).

In conclusion, our study is the first to report on the community of proficient Chinese readers with limited writing ability and to suggest a close relationship between writing experience - rather than reading experience as suggested by prior research - and reduced HP in Chinese character recognition. We uncovered an inverted U-shape pattern: compared with novices, increased HP marked the expertise in LW, while reduced HP marked a higher level of expertise in Writers. In contrast, the LSB effect of Chinese characters depended on font familiarity and is uninfluenced by writing experiences. Our results offer a window on HP and LSB in relation to expertise of complex object recognition by showing that HP can be modulated by both visual and motor experiences, whereas the LSB seems to be a reliable expertise marker not affected by motor experience.

## Acknowledgments

#### Abstract

Early in acquisition children overgeneralize verbs to ungrammatical structures. The retreat from overgeneralization is linked to the acquisition of verb classes, the semantics of which constrain the structures in which a verb can appear (e.g., Pinker 1989; Ambridge, Pine \& Rowland, 2012). How children learn these classes remains unclear. Some argue that distributional regularities in linguistic input provide sufficient evidence for verb classes to emerge and become linked to particular structures. A corpus analysis of the English locative construction (e.g., the woman sprayed water onto the wall/the wall with water) demonstrated that children have similar verb classes to adults. A correspondence analysis revealed that distributional regularities in the input could support these verb classes. Finally, a connectionist simulation was able to model early overgeneralization and retreat through distributional learning of verb classes. These results support a distributional learning account of verb semantics.

Keywords: Child language acquisition; locative construction; distributional learning; naturalistic speech; Dual-Path model.

Children's acquisition of grammatical constructions remains one of language acquisition's most puzzling phenomena. Even young children are readily able to generalize known constructions to new verbs, and indeed, early in acquisition children overgeneralize these constructions to contexts in which they are ungrammatical (e.g., *she filled the juice into the glass). However, over time children learn to constrain their choice of structure, despite the lack of evidence for ungrammaticality in the adult speech they hear (Ambridge, Pine, Rowland, Jones \& Clark, 2009).

This remarkable ability has been linked to the semantics of the verbs that appear in these constructions. According to this semantic verb class hypothesis (Pinker, 1989), verbs fall into discriminable classes based on the semantics of the event they describe. These verb classes then constrain the structures in which verbs can appear. For example, pour and drip both describe the movement of an object/substance into/onto a location via gravity, and both appear in the theme-locative (TL) structure only (e.g., the woman poured water into the bucket vs. *the woman poured the bucket with water). In contrast, cover and coat both describe a location being completely covered with a layer of substance or object(s) (e.g., the woman covered the table with the blanket vs. *the woman covered the blanket onto the table). Finally, spray and squirt both describe ballistic motion of a
liquid along a trajectory, are in a class that does not emphasize theme or location, and therefore alternate between both LT and TL structures (e.g., the woman sprayed the wall with water vs. the woman sprayed water onto the wall). Although Pinker's verb classes motivated early work on such verb-structure mappings, recent work has questioned whether it is these particular classes which guide structure choice (Ambridge, Pine \& Rowland, 2012). Nonetheless, it is widely agreed speakers categorize verbs, and that these classes help to guide structural choices and explain overgeneralization.

One account of the acquisition of semantics is based on using situational information in the world (St. Augustine, 397/2001). For verbs, this might involve learning that verbs like coat refer to events where an object is completely covered with some substance. Since the object is more saliently changed by the action than the substance, the situational meaning would classify this verb as belonging to a verb class that prefers the LT structure, which emphasizes the LOCATION (e.g., the man coated the $[\text { table }]_{\text {LOCATION }}$ with paint). However, this situational account of verb meaning is limited: it may not be the case that every child hears every verb that they know in an unambiguous situational context that classifies it precisely (e.g., Harris, Jones \& Grant, 1983).

An alternative, distributional account states that verb semantics are learned from distributional regularities in the linguistic input (Fisher, Gleitman, \& Gleitman, 1991). For example, if spray is always followed by a noun phrase which specifies a liquid (e.g., spray the water), then children might categorize spray with other verbs that take similar arguments (e.g., splash the water). This verb class might then be associated with certain locative structures (e.g., he sprayed/splashed the water onto the wall). The advantage of this account over the situational account is that it allows verb classes to be acquired from heard input without any situational context.

To examine how these accounts relate to behavioral data, we performed a corpus analysis of the British English locative. Then, to explore whether distributional information is sufficient to support the emergence of verb classes, we performed a correspondence analysis on the corpus data. Finally we investigated whether distributional regularities can influence structural choice in a connectionist model of sentence production which learns both syntactic
structures and their verb class associations from the input alone.

## A corpus analysis of the English locative

We queried all UK corpora in CHILDES (MacWhinney, 2000) for the 142 locative verbs listed in Pinker (1989). A main sample of 38,231 utterances was retrieved. A subsample of 2,685 morphologically-tagged utterances was coded by hand for construction type (see Table 1). Importantly, we divided transitives into those where the post-verbal noun was a THEME (spray the water, T transitive) or a LOCATION (spray the wall, L transitive).

Table 1: Constructions and handcoded frequency

| Structure | Example | N |
| :--- | :--- | :---: |
| LT locative | brushing me with it? | 100 |
| TL locative | spread it on your biscuit | 232 |
| L transitive | for him filling the glasses | 271 |
| T transitive | you dump the lady's toys | 294 |
| Ambiguous transitive | brushed it | 608 |
| L intransitive | tape on | 24 |
| T intransitive | it attached on like that | 20 |
| Ambiguous | I brushing | 205 |
| intransitive |  |  |

The subsample was generated by selecting all utterances containing candidate locative verbs tagged as a verb or a participle. Utterances were separated by speaker (adult or child) and post-verbal preposition (with, indicating a candidate LT locative; into, onto or over, indicating a candidate TL locative; or no preposition, indicating some other construction). For the 13 categories containing more than 50 utterances, a random sample of 50 utterances was coded. Since there were very few tagged utterances for conversations involving children over 40 months, we extracted an extra $20 \%$ of child utterances and $5 \%$ of adult utterances from the untagged data for this age group. We excluded 221 non-verb utterances from the analyses. As can be seen in Table 1, only $6 \%$ of the coded locative verbs occurred in the LT locative structure, and $13 \%$ occurred in the TL locative structure.

The situational account predicts that verb classes in children and adults can differ, especially if children do not always understand events in adult-like ways. On the other hand, the distributional account predicts that children learn their verb classes from adult linguistic utterances, so there should be a close match between the two. To examine these predictions, we calculated the proportion of LT out of total locative constructions in the hand-coded data. This controls for raw frequency of each form and variation due to other structures, providing a measure of the bias for these two structures. Figure 1 depicts proportion LT for both children and adults for a range of verbs that occur more than 10 times in the hand-coded adult data. There seems to be a class of non-alternating LT verbs like fill, a class of nonalternating TL verbs like pour, and several alternating verbs
like $r u b$ and splash. Importantly, children have similar verb classes to adults, even though these data come from a range of different situations, which children may or may not understand in adult-like ways.

Figure 1: Proportion LT structures, adult and child speakers

To see whether these structural preferences change over development, we calculated proportion of adult and child transitive and locative utterances with location as object (L or LT) for each age of child included in the sample (Figure 2). A linear model was fit to the data with Structure (locative $=1$, transitive $=0$ ), Child Age (months) and Speaker Group (adult vs. child) crossed. There was no main effect of age, suggesting that $L$ transitive proportion did not vary over age. LT production was lower than L transitive production (beta $=-0.9, t(116)=3.1, p<.003)$. An interaction between Age and Structure (beta $=0.02, t(116)=$ $3.1, p<.003$ ) provided evidence for an increase in the production of LT structures over development. The lack of any interaction with Speaker Group suggests that adults adapted their structural choices to fit children's preferences. The TL bias in young children is also seen in experimental studies, where children reproduce TL structures at a higher rate than LT structures (Gropen et al., 1991a, 1991b), and in diary studies, where TL overgeneralizations are more frequent (Bowerman, 1982).

In our data set, transitives are more frequent than locatives - we found 565 transitive utterances, but only 332 locative utterances. Of the 50 verbs that appeared in a transitive, a locative or both structures, 35 appear in the locative while 44 appear in the transitive. Using transitive contexts to learn about locative verbs provides a better coverage of these verbs, suggesting that children may be able to learn about locative verbs from their appearance in $L$ and T transitive structures.

To examine this hypothesis, we used adult ratings of locative verbs' LT and TL preference from Ambridge et al. (2012) and Bidgood, Ambridge, Pine \& Rowland (under
review) to create a graded LT rating measure for each verb. This was correlated with the proportion LT and L structures in the adult input to children from the corpora. There was a significant correlation between the LT rating and LT corpus distribution $(r(30)=.53, p=.002)$, indicating that the LT/TL biases of verbs in locative structures in child-directed speech match adult ratings of those verbs' LT/TL preference. There was also a significant correlation between LT rating and L corpus distribution ( $r(38)=.32, p=.04$ ), which shows that the L/T biases of verbs in transitive structures in child-directed speech also reflect LT/TL preference ratings.

Figure 2: Proportion L/LT locatives by child age

## Correspondence analysis

The corpus analysis shows that children learn biased verb classes in their first five years. We used correspondence analysis (CA; Greenacre, 2007) to investigate whether distributional regularities can support the development of these classes. CA is a technique for clustering categorical data in a low-dimensional space based on the similarity in how elements co-occur.

We performed a CA on adult utterances including utterances that were not handcoded. Similarity was calculated based on the co-occurrence of each verb with the two post-verbal words, however if a preposition (on, to, with, in, into, onto, over) occurred post-verbally, the
preposition and all following words were excluded. Thus, verbs that occurred in the same context (e.g., the woman poured water and a boy dripped water) were classified as more similar than verbs that occurred in different contexts. In order to have a range of words to support categorization, we only included verbs which occurred more than 40 times. The CA generated six factor scores for each verb.

To determine which factors in the CA best predicted the LT/TL rating measure used earlier, we submitted factor scores for each verb to a regression with LT rating as the dependent variable, and Factor (1, 2, 3, 4, 5, 6) as independent variables. LT rating was significantly predicted by Factor 4 (beta $=0.03, t(27)=2.06, p=.05)$ and Factor 6 (beta $=0.06, t(27)=3.72, p<.001$ ), explaining $39 \%$ of the variance $(F(6,27)=2.85, p=.03)$.

Figure 3 illustrates the relationship between Factors 4 and 6 and LT rating. Verbs rated as more grammatical in LT structures (e.g., the woman poured water into the bucket) cluster in the top right hand corner of the figure, and verbs rated as more grammatical in TL structures (e.g., the woman filled the bucket with water) cluster in the bottom left hand corner. Furthermore, there is evidence of clusters reflecting Pinker's (1989) narrow semantic verb classes; for example, fill and cover are both members of Pinker's cover-type class and they are clustered together. In line with existing studies (e.g., Ambridge, Pine \& Rowland, 2012), however, not all classes generated by our data conform to these narrow verb classes. For example, fill and pack are similar on Factor 4, despite being members of different classes according to Pinker's classification.

Figure 3. CA results for Factors 4 and 6.

Overall, the distributional regularities with which verbs and post-verbal words co-occurred generated two factors in a CA which predicted adult ratings of verbs' grammaticality in LT structures. Substantial evidence exists that children can track such statistical co-occurrences in their environment (Fisher, Gertner, Scott \& Yuan, 2010). Thus, if children record the distributional regularities of locative verbs, they may also create verb classes, helping them to constrain their choice of structure and retreat from overgeneralization. The CA provides an explicit model of how a distributional learning mechanism can create these classes.

## A connectionist model of locative acquisition

The corpus analysis suggested that children may learn about the semantics of locative verbs from transitive structures. Further, the correspondence analysis showed that distributional regularities in the input could support the emergence of verb classes that constrain structural choice. However, a full account requires a mechanism that can learn not only verb classes but also syntactic structures, and link them appropriately. Critically, if this mechanism is similar to the language acquisition system in children, then it should create a TL bias early in development.

To explore the nature of such a mechanism, we adapted the Dual-Path model, a connectionist model of sentence production (Chang, 2009, Chang, Dell \& Bock, 2006). The model learns linguistic representations from messagesentence pairs and can acquire different languages (e.g., English, Japanese). We trained the model with two simple grammars that included both transitive and locative structures. Grammars contained five classes of verbs, one of which was L/LT -only and one of which was T/TL -only. Our principal manipulation was the frequency with which the remaining "alternating" verb classes were associated with the various structures.

## Model

The Dual-Path model's architecture includes separate sequencing and meaning systems. The sequencing system is a simple recurrent network that allows the model to learn syntactic representations (Elman, 1990). The model's internal representations are acquired through error-based learning, in which the model predicts the next word in a sentence, then uses the difference between the prediction and target (error) to modify its internal representations. Since categories are useful for prediction, the sequencing system acquires syntactic categories that support syntactic structures. Verb classes can be seen as a refinement of verb categories to incorporate their biases. The meaning system encodes the message as a set of weights between role and concept units (e.g., AGENT=WOMAN). The simple recurrent network selects appropriate concepts by activating their role at particular positions in sentences. Detailed motivation for the model's architecture is provided in Chang (2002; 2009).

Messages include roles for the various concepts in the sentence as well as a role that selects the verb. In the
current architecture, structural alternations were modeled by associating different structures with the same message. For example, the TL locative sentence the woman sprays water onto the wall and LT locative sentence the woman sprays the wall with water have approximately the same meaning and hence share the message ACTION=SPRAY AGENT=WOMAN THEME=WATER LOCATION=WALL. When given this message, the model must decide whether to activate to LOCATION role after the verb and produce the LT structure, or the THEME role and produce the TL structure. Critically, because they are located in the meaning system, the SPRAY semantics can only be used for selecting the word spray and do not directly influence structural choices in the sequencing system. Thus, the model must acquire a syntactic representation of the verb within the sequencing system using distributional learning.

## Testing different input distributions

Verb classes in the simple recurrent network were shaped by the distributional properties of the input. To see if these classes reflected the behavior of human children's verb classes, we compared two different input distributions: Full and Transitive (Table 2).

Table 2: L/LT ratios in input grammars (LT:TL)

| Structure | Full Distribution | Transitive Distribution |
| :--- | :---: | :---: |
| Locative A | $100: 0$ | $100: 0$ |
| Locative B | $90: 10$ | - |
| Locative C | $50: 50$ | - |
| Locative D | $10: 90$ | - |
| Locative E | $0: 100$ | $0: 100$ |
| Transitive A | $100: 0$ | $100: 0$ |
| Transitive B | $90: 10$ | $100: 0$ |
| Transitive C | $50: 50$ | $50: 50$ |
| Transitive D | $10: 90$ | $0: 100$ |
| Transitive E | $0: 100$ | $0: 100$ |

Our input distributions contained five classes of verbs (A, $\mathrm{B}, \mathrm{C}, \mathrm{D}, \mathrm{E}$ ), each paired with LT and/or TL locative structures (e.g., the woman sprayed the wall with water / water onto the wall) and L and/or T transitive structures (e.g., the woman sprayed the wall/water). Verbs in class A occurred only in L/LT structures, while verbs in class E occurred only in T/TL structures. In the "Full Distribution" simulation, verbs occurred more frequently in L/LT structures in Class B, equally often in either structure type in Class C, or more frequently in T/TL structures in Class D. The "Transitive Distribution" simulation tested the idea suggested by the corpus and correspondence analysis that transitive uses of verbs might be the basis for verb classes. Classes B, C, and D were therefore only biased in transitive structures (and more strongly than in the Full Distribution) and hence tested whether the transitive distribution could influence locative generalization. The raw frequency of TL structures was also higher than that of LT structures in the Transitive Distribution to simulate the data in Table 1.

Ten randomly generated training sets were used to create ten model subjects. Each model was trained for 40,000 epochs on 2,000 message-sentence pairs. Every 1,000 epochs the model was tested on a set of 1,000 grammatical and ungrammatical locative sentences ( 100 per verb class).

Results. Figure 4 depicts proportion location-based sentences for each of the five verb classes, for each of the simulations.

Figure 4: Proportion location-based sentences
Results from the Full Distribution (Figure 4 top panel) suggest that distributional regularities in the input do indeed support the emergence of verb classes. First, the Full Distribution simulation learned nonalternating classes A and E. To establish whether the model distinguished classes B, C and D according to the frequency of $\mathrm{L} / \mathrm{LT}$ and $\mathrm{T} / \mathrm{TL}$ structures for these classes in the input, a mixed effects model was fit to Proportion LT (empirical logit transformed) with Verb Class and Epoch crossed. Verb Class was coded numerically ( $\mathrm{B}=1, \mathrm{C}=0, \mathrm{D}=-1$ ). Model subject was included as a random variable and there were by-subject slopes for Verb Class crossed with Epoch (Barr, Levy, Scheepers \& Tily, 2013). There were no main effects of Verb class or Epoch on LT production, however an interaction (beta $=0.016, \chi^{2}(1)=14.49, p<.001$ ), confirmed that verb classes differentiated as epoch increased. The negative logit intercept coefficient captures the model's initial TL bias ( beta $=-0.16$ ).

The Transitive Distribution simulation (Figure 4 bottom panel) also distinguished classes $\mathrm{B}, \mathrm{C}$ and D in the locative, despite receiving no locative input for these classes. It did so based on the frequency with which these verb classes occurred in L and T structures. Class D, for example, was a class that preferred THEME-type objects rather than

LOCATION-type objects in the post-verbal position. To test this, we fitted a mixed effects model to the Transitive Distribution data. There were no main effects of Verb Class or Epoch on LT production, but again there was an interaction (beta $=0.01, \chi^{2}(1)=6.90, p=.009$ ), demonstrating that verb classes differentiate over development. Finally, this model also exhibited an early TL bias, as denoted by the negative logit intercept coefficient (beta $=-0.54$ ). The preferences in the transitive naturally generalize to locative structures because these structures have similar argument preferences (i.e., TL locatives prefer theme-type objects in the post-verbal position). Thus, the model is able to acquire locative verb classes from transitive distributions.

Our corpus analysis revealed that children have an early preference for the TL locative. This was captured by the model. Like the children, LT production increases over development, but remains outstripped by TL production (overall proportion LT for Transitive Distribution at epoch $10,000=0.36$, epoch $40,000=0.44$; Fig. 4). This simulation captures the early TL bias because the sequencing system does not have access to verb meaning and is biased to learn syntactic categories that fit the frequent TL structure. This structure becomes the default means to express three arguments (i.e., AGENT, THEME, LOCATION). Slowly the model develops verb classes that help predict the nouns that follow verbs. These classes later help support the differential use of LT and TL structures.

## General Discussion

The current study presents naturalistic data which show that children are biased to use TL structures early in acquisition. We hypothesized that the more frequent TL overgeneralization errors in diary studies are due to this general TL bias. The increase in use of LT between two and five years can therefore be interpreted as a metric of an underlying retreat from overgeneralization. If, over development, children acquire verb classes that predict which structure to use, then they will become more likely to produce these structures in verb-specific ways, and consequently less likely to make errors. To explain how children acquire verb classes when the target classes and structures are not explicitly provided, we suggest that they perform a distributional analysis on the words they hear, in a similar manner to our CA. Here, we have shown that an unsupervised clustering algorithm can create component factors that predict structural choices.

Bayesian and other statistical mechanisms have also been applied to verb-structure learning. These systems often assume that the initial state of the learner includes syntactic structures, semantic features (e.g., cause, change-of-state), or even abstract verb classes (Alishahi \& Stevenson, 2008; Niyogi, 2002; Perfors, Tenenbaum \& Wonnacott, 2010). A clear example of this approach can be seen in Niyogi (2002), who developed a Bayesian model of the locative alternation. The model uses manner and path features from scene and syntactic frame regularities to select among verb
class hypotheses. A key feature of this model is that it can assign verb classes quickly from a few exposures; it therefore does not explain the protracted development of the LT structure in children. Furthermore, the model cannot learn locative classes from transitive input, because locative verb classes are not an optimal fit for transitive structures (superordinate motion classes are a better fit). The limitations of these models highlight the fact that language development is not just the fast, optimal weighting of syntax and semantic cues.

In contrast with these models, the Dual-Path model does not start with syntactic structures or verb class hypotheses. It learns its structures with a slow learning algorithm designed to mimic the slow biological changes that support learning in the brain (cell growth). Due to its inability to predict when to use LT and TL structures, the frequent TL initially dominates. As in the CA, the model develops verb classes from the distribution of post-verbal words in frequent transitives. Later, these verb classes become the basis for distinguishing TL and LT structures and thus condition their use.

Taken together, the current studies are the first to characterize how children use a wide range of verbs in locative structures between two to five years of age. We showed that locative production is asymmetrical during this period, with the TL structure dominating. This dominance can causes children to place a newly-learned verb into the TL structure regardless of its own bias, producing an overgeneralization error. We also showed that distributional regularities in child-directed speech are useful for creating classes that predict adult ratings of locative structure preference for this diverse set of verbs. Finally, we showed how distributional learning in the Dual-Path model can be used to learn both the syntactic categories that support structures, as well as the verb classes that bias structural choice. By trying to simultaneously solve both of these difficult learning problems, the model can explain both the early TL bias and slow development of verb classes that support the retreat from that bias.

# Moves in the World Are Faster than Moves in the Head: Interactivity in the River Crossing Problem 

Frédéric Vallée-Tourangeau, Lisa G. Guthrie and Gaëlle Villejoubert<br>Department of Psychology, Kingston University<br>Kingston-upon-Thames UNITED KINGDOMKT1 2EE<br>f.vallee-tourangeau/l.guthrie/g.villejoubert@kingston.ac.uk

#### Abstract

In solving a variety of problems people interact with their external environment, often using artefacts close at hand to supplement and augment their problem solving skills. The role of interactivity in problem solving was investigated using a river-crossing problem. All participants performed the task twice, once in a high interactivity condition and once in a low interactivity condition. Moves to completion were higher in the high interactivity condition but latency per move was much shorter with high than with low interactivity. Moves in the world were easier to implement than to simulate mentally and acted as epistemic actions to facilitate thinking. In addition, when participants experienced the low interactivity version of the task second, their performance reflected little learning. However, when the high interactivity version was completed second, latency to solution and latency per move were substantially reduced. These results underscore the importance of investigating problem solving behaviour from a distributed cognition perspective.

Keywords: Problem solving, interactivity, epistemic actions, distributed cognition

## Introduction

Scientists and lay people alike naturally create and build artefacts or recruit existing ones to help them solve problems. To be sure, artefacts such as calculators, data management software, computers can facilitate complex computations. But others, of more modest complexity, such as pen and paper, can help articulate and structure thinking. Space itself is a tool that can facilitate thinking, that is it can be structured, designed (and redesigned) such as to make thinking easier (Kirsh, 1995, 1996, 2010). Thus solving jigsaw puzzles involves physically juxtaposing different pieces to gauge their fit; in Scrabble, letter tiles are physically rearranged to facilitate word production; in Tetris, tetrominoes are physically rotated to determine their optimal place along a line. And beyond puzzles and games, experts structure an external environment to support thinking. Scientists use physical objects and their arrangement in space to formulate and test hypotheses: Watson (1968, pp. 123-125) describes how he cleared his desk, cut out shapes corresponding to the four nucleobases, and manipulated them until he saw
which ones could be paired to hold the double helix together. Artefacts recruited in thinking are rich, varied and modifiable. Their recruitment is at times strategic, such that their users actively engage in their design and engineer their function, and at others, opportunistic, that is they are picked up from the environment in an ad hoc fashion to help solve a problem, capitalizing on a fortuitous interaction.

From a distributed cognition perspective, thinking is the product of a cognitive system wherein internal and external resources are coupled to create a dynamic, fluid, and distributed problem representation (Villejoubert \& Vallée-Tourangeau, 2011; Weller, Villejoubert, \& ValléeTourangeau, 2011). The nature of the external resources recruited in thinking and their functional role are guided by principles of cognitive economy, effort and efficiency (Clark, 1989; Kirsh, 2010). Actions complement and augment thinking by providing new information, unveiling new affordances, and can sometimes serve to create a more cognitively congenial problem presentation (Kirsh, 1996). Through the creation, recruitment and manipulations of artefacts, new perspectives are gained, encouraging the development or retrieval of problem solving strategies, and improving the prospect of solving the problem (Magnani, 2007). As the environment shoulders some of the representational and computational burden, valuable cognitive resources such as working memory capacity and executive functions may be freed to draw on stored knowledge or develop new solutions (Magnani, 2007). For example, recent work on mental arithmetic indicates that people are more accurate, more efficient, and create more congenial interim totals when they can manipulate number tokens that configure the problem presentation, than when they perform the mental arithmetic without (Vallée-Tourangeau, in press).

## River Crossing

Transformation problems have been the focus of research in cognitive psychology for the past 50 years. In these problems, a well-defined space connects an initial and a goal state. Legal moves are defined in terms of simple rules and enacted with simple operators. Participants must reach the goal state by transforming the initial state
through a series of intermediate states. A well-studied class of transformation problems are river-crossing problems. In these problems, objects (people, animals, or things) must be carried from one "riverbank" to another on a "boat" but with a set of constraints on moves that can be selected to reach the goal. A common version involves three missionaries and three cannibals (Reed, Enrst, \& Banerji, 1974; or three hobbits and three orcs, Thomas, 1974). In transporting all cannibals and missionaries from one bank to the other, cannibals must not outnumber missionaries or either bank. The boat can take at most two passengers, and at least one. The problem space is relatively narrow since illegal moves cannot produce blind alleys of any depth (Reed et al., 1974) and can be completed in 11 steps. In different versions, problem difficulty is a function of the rules that constrain the number of objects that can be moved at any one time, which combinations of objects are allowed on the boat, and which combinations can be left on either bank. The number of objects and the rules that govern their transport map out a problem space that links the initial state with all objects on one side of the river to a goal state with all objects on the other riverbank. Cognitive psychologists have used this task as a window onto problem solving, particularly planning (Greeno, 1978), search and move selection (Reed et al., 1974; Simon \& Reed, 1976). As such river crossing problems have been used as a testing platform for a number of process models of search and move selection, strongly influenced by developments in AI (Greeno, 1978; Simon \& Reed, 1976).

The river-crossing task involves moving people or things across a surface and as such foregrounds the importance of interacting with an external task representation. However, interactivity in river crossing problem solving has never been the explicit focus of investigation. The manner with which the river-crossing task has been implemented varies a great deal across studies. For example, Reed et al. (1974) used different types of coins to represent missionaries and cannibals. Jeffries et al. (1976) developed a basic computer interface where participants typed in the objects they wanted to put in the boat on a given crossing. The interface accepted only legal moves and updated the simple representations (often with letters and numbers, such as ' 3 M ' for three missionaries) on either side of the riverbank. Participants kept on typing in their moves until they managed to transport all objects from one bank to the other. Knowles and Delaney (2005) designed a more realistic interface with icons representing travellers against a backdrop of a river with two banks and a boat. Participants selected moves by clicking on the travellers, which then appeared next to the boat on the screen. In all these instances participants were never offered a three-dimensional work surface on which objects transparently corresponding to the scenario protagonists are manipulated and moved by hand. In contrast, developmental psychologists who
worked with the river crossing task, being less sanguine about 'formal operations' presumably, have taken care to design rich interactive thinking environments with physical materials representing the boat, the river, and figurines corresponding to the cover story characters (e.g., Gholson, Dattel, Morgan, \& Aymard, 1989).

A more explicit experimental focus on interactivity may unveil interesting aspects of problem solving performance. For example, there is evidence that in other transformation problems interactivity substantially transformed problem solving behaviour. ValléeTourangeau, Euden and Hearn (2011) reported that mental set is significantly reduced in Luchins's volume measurement problems when participants interact with an actual physical presentation of the problem. The manipulation of water jars created a dynamic problem representation revealing solutions that were not simulated mentally. The selection of moves was guided and governed by three-dimensional perceptual feedback and participants were less likely to persevere using a more complicated solution for the test problems. In a rivercrossing task, interactivity may help participants work out the quality of different moves not by simulating their consequences mentally, but rather by simply completing the move and observing the results. Such moves then are 'epistemic actions' (Kirsh \& Maglio, 1994)—moves that may not, in themselves, necessarily help narrow the gap with the goal state, but rather provide information as to what to do next. As such, move selection can be opportunistic, although not necessarily mindless; rather the strategic consequences of a certain move can simply be observed. Kirsh and Maglio (1994) demonstrated that it is faster and easier to physically rotate the tetrominoes in Tetris than to simulate their rotation mentally, leading to better and more efficient problem solving behaviour. In a similar vein, moves in the world, rather than moves in the head, may help participants solve river-crossing problems more efficiently as the reduced cognitive costs of physical moves will enable them to select more moves more quickly, than they would if they were completing the task with a non-interactive problem presentation.

## The Present Experiment

The present experiment examined performance in the river crossing problem when presented with or without artefacts as an aid to solution. This was measured in terms of number of moves, latency to completion and latency per move. In a high interactivity condition, the problem was presented with a board, a raft and six figurines: Participants had to move the raft and the figurines across the board to register a move until they had moved all six figurines from one bank to the other. In a low interactivity version, the problem was described on a piece of paper and participants were asked to verbalise the moves they would make to reach the goal. They performed the problem twice, once with the high interactivity version
and once with the low interactivity version; the order was counterbalanced across participants. This experiment employed a mixed design with interactivity level as the repeated measures factor and order-low interactivity first, high interactivity first-as the between subjects factor. As moves can act as epistemic actions, we predicted that participants would produce more moves, would solve the problem more quickly and that hence latency per move would be shorter in the high compared to the low interactivity condition. We also predicted that participants would complete the second presentation of the task more quickly than the first since they would be familiar with the procedure and may well exploit an episodic record of their trajectory to help them select better moves, and select them more quickly. A high interactivity problem solving environment may more clearly showcase evidence of learning because of the ease and speed with which moves can be made in the world.

## Method

## Participants

Sixty-four university undergraduates participated in the experiment in return for course credits. Due to testing errors the data from three participants were incomplete, therefore unsuitable for analysis. Of the remaining sixtyone participants, nine did not complete the river crossing problem and were excluded from further analyses. The final sample was composed of 52 participants ( 45 females, 7 males, $M_{\text {age }}=21.4, S D=5.1$ )

## Procedure

Chickens and wolves were the protagonists in the rivercrossing scenario used for this experiment. The objective was for the six animals to be transported from the left riverbank to the right one. The selection of a move had to comply with the constraints and rules of the problem. The same instruction sheet explaining the objective of the task and the rules of the problem was used for both conditions and could be read by the participants throughout the duration of the task. The sheet read:

Three wolves and three chickens on the left bank of a river seek to cross the river to the right bank. They have a boat which can carry only two animals at a time, but there must always be an animal on the boat for it to move.
However if at any time the wolves outnumber the chickens on either bank the wolves will eat the chickens. Thus you cannot move the animal(s) in a manner that will result in the wolves outnumbering the chickens on either bank.
The goal of the task is to move all the animals from the left bank to the right bank.

In the low interactivity version of the task, the researcher transcribed each move as verbalised by the participant onto a record sheet. The record sheet was a simple representation of the raft between the left and right banks of the river, with slots to record the nature and number of the animals on either side (which was denoted with a 'C' for chickens and 'W' for wolves; see Fig. 1); each page represented only one move. At any one time, participants could only inspect their previous move as they dictated their next move to the experimenter. As soon as the next move was dictated, the sheet with the previous move was turned over. Thus participants could not inspect a historical record of previous moves. Illegal moves proposed were noted, but the experimenter did not transcribe the move on the recording sheet. Rather, participants were invited to re-read the task instructions to discover why such a move was not allowed.

Figure 1: Record sheet for the river crossing moves in the low interactivity condition.

The high interactivity version of the task involved the use of six plastic figurines, three wolves $(9 \mathrm{~cm} \times 7 \mathrm{~cm} \times$ 2 cm ) and three chickens ( $4 \mathrm{~cm} \times 5 \mathrm{~cm} \times 1.5 \mathrm{~cm}$ ), one popstick raft ( $9 \mathrm{~cm} \times 6 \mathrm{~cm}$ ) and a painted board ( $60 \mathrm{~cm} \times 45 \mathrm{~cm}$ ) representing the river and banks (see Fig. 2). As the participants interacted with the artefacts, the experimenter recorded the moves, but this record was never shown to the participants. An illegal move prompted the experimenter to instruct participants to move the raft and the animals back to the previous state and, as in the static condition, they were invited to re-read the instruction sheet to determine which moves were possible.

Figure 2: Board, raft and figurines in the high interactivity condition.

Figure 3: Mean latency to completion (left panel), mean number of legal and illegal moves (middle panel), mean latency per move (right panel) as a function of order (completed first or second) in the low interactivity (light grey) and high interactivity condition (dark grey). Error bars are standard errors of the mean.

The river crossing task was embedded in a testing session during which participants completed a number of other problem solving tasks unrelated to the present experiment. In the low interactivity version, the boxes on the first record sheet were completed with three C's and three W's on the left bank. Prior to the selection of a move, the researcher would draw an arrow above the raft to represent the direction in which it was travelling. The participants were discouraged from touching or pointing to the record sheet; they could not sketch out a move using pen and paper beforehand.

In the high interactivity condition, the board was placed on a table in front of the participant with the researcher placing all animals on the bank closest to the participant and positioning the raft on the river. This ensured all participants commenced the task with the same presentation. A move was defined as completed when whichever wolf (wolves) or chicken(s) being transported for that particular move were removed from the raft onto the other bank. Illegal moves were identified before they were completed, with animals and raft returned to the previous position on the board. In both conditions participants were given 15 minutes to complete the river crossing problem.

A 20 -minute interval was designed between the two presentations of the river crossing problem during which participants completed a number of non-verbal puzzles, including finding similarities and differences between series of pictures, and identifying the odd picture in a series of thematically related pictures. Finally, the river crossing task was presented again in the alternate condition (either low or high interactivity) to that which was presented first; the order was counterbalanced across participants. Thus, the independent variables manipulated were condition (static, interactive) and order (static first, interactive first) in a $2 \times 2$ mixed design. Performance in
both conditions was measured in terms of latency to solution, number of legal and illegal moves, and latency per move.

## Results

## Latency

Latencies to solution, displayed in the left panel of Figure 3, suggest that order had little effect on participants in the low interactivity condition but the problem was completed much quicker in the high interactivity condition when it was experienced second. A $2 \times 2$ mixed analysis of variance (ANOVA) revealed that the main effect of interactivity condition was not significant, $F(1,49)=2.14, p=.150$, while the main effect of order was significant $F(1,49)=$ 4.20, $p=.046$, as well as the condition by order interaction $F(1,49)=5.32, p=.025$. Post hoc tests indicated that latencies in the low interactivity condition did not decrease significantly from the first to the second presentation, $t(49)$ $=0.090, p=.929$. In turn, participants were quicker in the second than in the first presentation of the problem in the high interactivity condition, $t(49)=3.744, p<.001$.

## Moves

The mean number of legal and illegal moves are plotted in the middle panel of Figure 3. The high interactivity condition elicited a higher number of legal moves to solve the river crossing problem compared to the low interactivity condition and this was observed for both orders. In a $2 \times 2$ ANOVA the main effect of condition was significant $F(1,49)=11.63, p=.001$, while the main effect of order was not significant, $F<1$, nor was the condition by order interaction, $F(1,49)=1.26, p=.267$.

In turn, the mean number of illegal moves was greater in the high interactivity condition when it was experienced
first, but the frequency of illegal moves was relatively stable in the low interactivity condition across both presentations. In a 2X2 ANOVA the main effect of condition was significant, $F(1,49)=7.16, p=.010$, while the main effect of order was not significant, $F(1,49)=$ 3.34, $p=.074$ nor was the condition by order interaction, $F(1,49)=2.69, p=.108$.

## Latency per Move

The latency per move data are shown in the right panel of Figure 3. Latency per move in the low interactivity condition was unaffected by order, however participants appeared faster at enacting moves in the high interactivity condition, especially the second time the participants engaged with the task. In a $2 \times 2$ mixed ANOVA the main effect of condition was significant, $F(1,49)=20.0, p<$ .001 , but the main effect of order was not, $F(1,49)=2.33$, $p=.133$; the condition by order interaction was significant $F(1,49)=11.4, p<.001$. Post hoc tests revealed that the mean latency per move in the low interactivity condition did not decrease significantly from the first to the second presentation, $t(49)=0.858, p=.395$; in turn moves were selected faster in the high interactivity condition when that condition was experienced second, $t(49)=4.60, p<.001$.

## Discussion

This experiment investigated the impact of interactivity on problem solving performance for a river crossing problem. All participants were required to solve the problem twice, once in a low interactivity context in which move selection could only be simulated mentally and once in a high interactivity context where moves could be implemented in the world with a three-dimensional manipulable presentation of the problem. The repeated measures design eliminated random variance arising from between-subjects differences: Any performance improvement emerging in the high interactivity condition could not be attributed to a different group of participants with a differing pool of internal resources.

A high level of interactivity encouraged participants to make more moves in reaching a solution than when they completed the problem in the low interactivity condition; however, the order in which participants completed the task had no effect on the number of moves. In turn, the order in which the conditions was experienced had an effect on latency to solution. More important still, the main effect of order was qualified by a significant interaction: solution latencies in the low interactivity condition were similar whether this was completed first or second, while latencies dropped substantially when the high interactivity condition was experienced second. The latency per move data indicated that participants were always quicker to select a move in the high interactivity condition, and were generally quicker to select a move during the second presentation of the problem. However, the more important
pattern in these data was the condition by order interaction: Latency per move dropped precipitously when the second presentation of the problem occurred in the interactive condition.

As Kirsh (2010, p. 442) puts it: "Cognitive processes flow to wherever it is cheaper to perform them". Moves were cheap in the high interactivity condition - it is easier to move the pieces in the world than to simulate their movement in the head. More moves were made when the participants were given the freedom to transport the artefacts around the board to reach the solution than when moves were simulated mentally.

## Learning Manifest Through Interactivity

The second presentation of the problem offered the opportunity to gauge the degree of learning and transfer. There was much evidence of learning, when the second opportunity to solve the problem took place in a context that favoured a high level of interactivity: Participants completed the problem in less time and selected moves at a faster rate than when the second presentation of the problem was in the low interactivity condition. In fact, when the low interactivity condition was experienced second, performance reflected little learning and transfer. This pattern of results suggests two competing explanations: (i) the process and quality of knowledge acquisition is different as a function of the level of interactivity or (ii) interactivity is a performance facilitator and a high level of interactivity more clearly showcases learning. Let's take each in turn.

First exposure to the problem without much interactivity might have fostered the acquisition of a sounder and more actionable representation of the task and appreciation of an efficient sequence of moves to solution. In contrast, experiencing the problem in a context that fosters a high level of interactivity might not be accompanied by the same investment in cognitive effort, proceeding primarily on the basis of procedural learning, which in turn might interfere with the development of an accessible and transferable conceptual representation of the problem. As a result, when the problem is encountered for the second time in a condition without much interactivity, the procedural knowledge does not facilitate performance; however, when the second presentation occurs in the high interactivity condition, performance substantially benefits from the knowledge acquired on the basis of the experience in the low interactivity condition.

Alternatively, the substantial improvement in the high interactivity condition when participants are presented the problem a second time might not reflect differences in the type and quality of experience but rather release from a performance bottleneck. In other words, interactivity is a performance facilitator. Cognitive efforts and task demands are more exacting with low interactivity-as evidenced by the significantly longer latency per move. When participants encounter the problem a second time
but this time can indulge in cheaper move selection by moving artefacts on the board, they experience a release from the cognitive demands of the low interactivity condition and are quicker at producing moves.

The moves data offer some support for the performance facilitating interpretation. The number of legal moves to completion increased from an average of 15.8 when the high interactivity condition was experienced first to 17.2 when it was experienced second. And while this was not a significant increase, the pattern suggests that participants did not acquire an appreciation of a more efficient path to solution-which would lead to the selection of fewer moves - on the basis of their experience with the low interactivity condition. The release from the cognitively demanding experience with the low interactivity condition coupled with familiarity with the problem lead participants to select more moves, and interactivity enabled them to do so quickly. Moves provide information, and as participants produced more moves, they were able to reach the goal state faster.

A higher level of interactivity led to improved performance in the river-crossing problem, when preceded with the experience of solving the problem in a context that did not afford the physical manipulation of the problem presentation. Learning from previous experience with the problem, coupled with the reduction in the mental cost of making moves through interactivity provided the solver with the freedom to experiment with more moves. Through the interaction with artefacts, individuals were provided with the opportunity to extend the process of thinking beyond the mind and into the physical world. These data underscore the importance of pursuing a program of research that explicitly contrasts performance when participants can manipulate a physical problem presentation and when they cannot. In addition, we would argue that such research efforts offer a more representative window onto problem solving behavior observed outside the psychologist's laboratory.

## Acknowledgments

We would like to thank Natalie Dorman and K'Dee Bernard for their assistance with the recruitment and running of the participants, and Chris Askew for helpful suggestions.

#### Abstract

Individuals make decisions under uncertainty every day based on incomplete information concerning the potential outcome of the choice or chance levels. The choices individuals make often deviate from the rational or mathematically objective solution. Accordingly, the dynamics of human decisionmaking are difficult to capture using conventional, linear mathematical models. Here, we present data from a twochoice task with variable risk between sure loss and risky loss to illustrate how a simple nonlinear dynamical system can be employed to capture the dynamics of human decision-making under uncertainty (i.e., multi-stability, bifurcations). We test the feasibility of this model quantitatively and demonstrate how the model can account for up to $86 \%$ of the observed choice behavior. The implications of using dynamical models for explaining the nonlinear complexities of human decisionmaking are discussed, as well as the degree to which nonlinear dynamical systems theory might offer an alternative framework for understanding human decision-making processes.

Keywords: Decision-making; Complex Systems; Dynamical Systems Modeling; Risky Choice; Multi-stability; Phase Transitions.

## Introduction

Decision-making is part of almost everything humans do. Decisions can be commonplace or trivial but can also have lifelong consequences. Therefore, it is important to understand how individuals make decisions and how various factors play a role in decision-making processes. One such factor is uncertainty, which occurs in situations where there is limited information, ambiguous information, or unreliable information. Another factor is risk, which is different from uncertainty and can be defined as 'probabilized' uncertainty (Etner, Jeleva, \& Tallon, 2010).

Johnson and Busemeyer (2010) distinguish three major streams of development in decision theory: normative research, descriptive research, and the computational approach. While the normative approach defines what would be the optimal decision in a given situation, descriptive research describes how humans actually decide. For example, this approach has lead to the insight that individuals are sensitive to framing. When a decision is framed in terms of potential loss, the majority of participants avoid taking risk, but when the same decision is framed in terms of potential gain, the majority of
participants do take risk (Tversky \& Kahneman, 1974). In another study, Kahneman and Tversky (1979; 1983) showed that risks with low probabilities are either grossly overweighed, or completely neglected, and that there is large heterogeneity among individuals. Specifically, individuals show more variability in deciding about potential loss than potential gain (Tversky \& Kahneman, 1981). These examples suggest that human decision-making behavior under uncertainty can well be described using a nonlinear, dynamic narrative; individual decision behavior is highly context-specific, unstable, and heterogeneous.

The aim of this article is therefore to investigate the feasibility of extending current efforts in decision science towards a nonlinear, dynamical approach.

## Decision-Making and Multi-Stability

Heterogeneity, multi-stability, and context-sensitivity in general, are all strong indications that decision-making under uncertainty is characterized by nonlinear dynamics. A multi-stable system can, for the same input, settle in more than one possible internal stable state. A possible consequence of multi-stability is hysteresis, which is the phenomenon whereby a system's immediate history influences the current state of the system. Sir James Alfred Ewing first coined the term hysteresis while observing the phenomenon in magnetic materials (Ewing, 1881).

Figure 1A displays hysteresis in the magnetization and demagnetization of a magnet as a result of varying strength of the magnetic force. Depending on the direction of change of the magnetic field, the change from magnetization in one direction to the opposite direction occurs at a different moment. The system has a primitive form of memory, and remains in an existing stable state longer than expected. The opposite of hysteresis, reversed hysteresis, can also occur in multi-stable systems. Rather than remaining in the existing stable state longer (as with hysteresis), the system changes to another stable state sooner.

Hysteresis and reversed hysteresis are important indications of nonlinearity (Kelso, 1995). Hysteresis in behavioral dynamics has been found in body-scaled transitions like grasping of objects (Richardson, Marsh, \& Baron, 2007; Lopresti-Goodman, Turvey, \& Frank, 2011), speech categorization (Tuller, Case, Ding, \& Kelso, 1994), perception of whether a slanted surface supports upright
standing (Fitzpatrick, Carello, Schmidt, \& Corey, 1994), and problem-solving (Stephen, Boncoddo, Magnuson, \& Dixon, 2009).

Figure 1: Hysteresis in magnets (A) and risky choice (B). A) A magnet is magnetized by a magnetizing force $H$, into direction $B$ (state I ). If the strength of $H$ is then slowly decreased, the saturation of the magnet will change until it becomes fully magnetized into the opposite direction $-B$
(state II). If $H$ is increased again, the change towards saturation in the positive direction $B$ happens at a different value for the strength of the magnetic force $H$. B) See text.

In order to test for hysteresis and reversed hysteresis in decision-making, we will adopt a standard model of risky decision behavior with the implicit assumption that realworld decisions under uncertainty have the same properties as a monetary gamble (Hertwig \& Erev, 2009). Figure 2 displays a typical example of the type of monetary gamble researchers use to study risky decision behavior; the choice between a sure option A, and a risky option B (Kahneman et al., 1981). Choice A and B have the same expected values, thus from a rational choice perspective, they are equivalent.

## Choose between:

A. a sure loss of $\$ 750$
B. $75 \%$ chance to lose $\$ 1000$, and $25 \%$ change to lose nothing

Figure 2: Example of a risky choice.

This kind of gamble, hereafter called risky choice, can be formulated in terms of potential loss (as in the example above) or in terms of potential gain. For the remainder of this article, we will focus on loss, as potential loss is expected to maximize the variability among participants. The parameters in a risky choice are the probability to lose $P$, and the values of $R$ and $S$. The outcome is either a riskseeking choice for $R$ or a risk-avoiding choice for $S$.

Finding hysteresis or reversed hysteresis in risky choice behavior will provide evidence that decision-making under uncertainty is indeed characterized by nonlinear dynamics.

## Sequential Risky Choice

Two key components to finding hysteresis or reversed hysteresis in risky choice are to (1) change the context in two opposite directions, and (2) do this in a systematic way. It is necessary to find an input parameter for which, at different values, the system's output can have opposite, or at least, qualitatively different values. In risky choice, the key parameter that drives the choice between risk-seeking and risk-avoiding behavior is the amount of risk that is present in $R$. There are several ways to vary the amount of risk in $R$; we have opted to manipulate the value of the risky loss (in $\$$, a high value of $R$ corresponds with a high risk). Only when the value of $R$ is first increased and then decreased or vice versa, there will be an opportunity to observe hysteresis and/or reversed hysteresis. A sequential risky choice task is therefore a sequence of consecutive risky choices between $S$ and $R^{1}$, in which the value of $R$ is either increased or decreased in a step-wise fashion.

In a sequential choice task, hysteresis looks like this: A decision-maker is presented with a risky choice where the risk in $R$ is minimal (relative to $S$ ), and chooses $R$. Next, the decision-maker is presented with a second risky choice, in which the risk in $R$ is slightly higher. Next, another risky choice occurs that is even riskier, and so on. All the while the decision-maker continues choosing $R$. Then, at some switch-point (see definition below), when the risk in $R$ has become too high, the decision-maker will switch to choosing $S$ and continue to do so until the risk in $R$ is maximal (relative to $S$ ). Then, the whole process is reversed by decreasing the risk in $R$ again, causing the decisionmaker to switch back from choosing $S$ to choosing $R$ at another switch-point. If the second switch occurs for a lower risk in $R$ than the first, we have found an indication of hysteresis. If the second switch occurs for a higher risk in $R$ than the first, we have found an indication of reversed hysteresis (see also figure 1B).

## Method

Participants and Design Thirty-six undergraduate students from the University of Cincinnati were presented with three

[^239]sets of sequential risky choices between a risky loss $R$ and a sure loss $S$. In the first and third set, the amount of risk in $R$ was systematically varied, either in increasing, and then decreasing order (ID), or vice versa ( $D I$ ). The second set contained the same choices in randomized order to mediate carry-over effects between the first and third sets. Half of the students were presented first with the $I D$ set, followed by the random set and the $D I$ set. The other half started with the $D I$ set. The value of $R$ ranged from $\$ 1500$ to $\$ 525$, with increments of $\$ 25$. The probability to lose this amount $P=$ $75 \%$, and $S=\$ 750$. The total amount of choices was 238 . After completion of the sequential risky choice task, the students participated in a short money-free version of the balloon analogue risk task (BART), (Lejuez et al., 2002).

Stimulus/Apparatus All stimuli were variations of the example in Figure 2, and contained the values for $P, R$, and $S$. In total, 40 different values of $R$ (ranging from $\$ 525$ to $\$ 1500$ with increments of $\$ 25$ ) were presented either on the left side of the screen, with the value of $S$ on the right, or vice versa. The stimuli were presented on an iMac, and a cordless computer mouse (Apple Inc. ${ }^{2}$ ) was used to select the choices, both were run using PsychToolbox software (Brainard, 1997). The BART stimuli were presented on a different computer monitor ( $\mathrm{Dell}^{\mathrm{TM}}$ ) and responses made using a standard computer mouse (Logitech ${ }^{\mathrm{TM}}$ ) were recorded using BART software made available online.

Procedure Participants provided their written consent and received instructions about the sequential risky choice task. Participants were seated in front of the computer screen that displayed the various choices and were instructed to indicate their choice preferences using the mouse. After completion of the sequential choice task, participants received instruction about the BART. They again sat in front of a computer screen on which the stimuli were displayed and were instructed to respond using the mouse.

## Results

Choice outcomes of one-fourth ( $22 \%$ ) of the participants showed no change at all. This is consistent with an earlier experiment with a smaller range of risk in $R$ (from \$725$\$ 1175$ ), in which $27 \%$ of the participants showed no change.

Figure 3: Model changes between choices for $R$ and $S$. Critical change is defined as the situation where a participant switches from $S(R)$ to $R(S)$ for the same amount

[^240]of risk in the first and second half of an $I D$ or $D I$ sequence. Hysteresis is defined as the situation where a participant switches from $S(R)$ to $R(S)$ later in the second half on an $I D$ or $D I$ sequence. Reversed hysteresis is defined as the situation where a participant switches from $S(R)$ to $R(S)$ earlier in the first half on an $I D$ or $D I$ sequence.

The remaining 28 participants switched between riskseeking and risk-averse choices at least once per sequence ( $M=3.8$ fluctuations ${ }^{3}, S D=3.4$ ). Using an automated search algorithm, two switch-points ${ }^{4}$ per $I D$ and $D I$ sequence were determined for each participant. Based on the locations of the switch-points, most participants (48\%) showed critical change, followed by reversed hysteresis (39\%), and hysteresis (13\%), see Figure 3 for details. The average value of the risk in $R$ for switches from $R$ to $S$ was $\$ 1000(S D=\$ 215)$, and from $S$ to $R, \$ 941(S D=\$ 174)$ indicating that overall, participants were risk-averse ( $p<$ $0.0001)$. The distance between the two switch-points for the $D I$ and $I D$ sequences was significantly larger compared to the random sequences $t(27)=3.61, p=.001, d=.95$.

## Switching under time-constraint

$22-27 \%$ of participants in a sequential risky choice task do not show any change at all. A closer look revealed that all of these participants were presented with the $D I$ sequence first, and consistently chose $R$. One explanation could be that for about one-fourth of participants, the attractor for $S$ is nonexistent. Another explanation is that the initial conditions strengthen the attractor for $R$ relative to $S$ such that the changing constraints provide too little perturbation to the system. A small follow-up study $(N=16)$ was therefore conducted with the only difference being that participants were instructed to decide as quickly as possible while still using the available information on the screen. It was hypothesized that this speed manipulation would destabilize the initial strength of the attractor for $R$. All 16 participants switched at least once between $S$ and $R(M=10.8$ fluctuations, $S D=12.5$ ), and the relation between the speed manipulation and the absence of 'no change' participants is significant, $\chi(1, N=52)=4.20, p=.04$. The speed manipulation increased variability and caused participants to be more sensitive to changing risk constraints. This is consistent with observations that time pressure influences decision-makers' strategy selection (see Edland \& Svenson, 1993 for a review).

[^241]
## Varying increments of $\mathbf{R}$

Increasing the value of $R$ in increments of $\$ 25$ results in a high predictability of the choices in the $D I$ and $I D$ sequences. This could have mediated the amount of reversed hysteresis in our sample. A follow-up study was therefore conducted in which the increments were sampled from an $N(25,1), N(25,2), N(25,4), N(25,8)$, and $N(25,26)$ distribution respectively. The maximum and minimum values of $R$ ( $\$ 525$ and $\$ 1500$ ) were maintained. Figure 4 shows the distribution of types of choice behavior for the fixed increments ( $N=36$ ), and varying increments ( $N=50$; 10 each).

Figure 4: Distribution of types of choice behavior for varying increments of the value of $R$.

There is a main effect of sequence type (ID or $D I ; p<.001$ ), and order ( $D I$ or $I D$ first, $\mathrm{p}<.001$ ) on the difference between the two switch-points, but not of the amount of variability. However, the distribution of the four types of change behavior did differ by the amount of variation in the increments of $R, \chi^{2}(12, N=171)=28.09, p<.01$, with a positive trend for the amount of participants that showed hysteresis and reversed hysteresis.

## Nonlinear Dynamical Modeling

Multi-stability in switching behavior is problematic for most linear models but can be accounted for by a nonlinear dynamical system (e.g. Cho, Jones, Braver, Holmes, \& Cohen, 2002; Roxin \& Ledberg, 2008). A dynamical system is a mathematical concept where the time dependence of a state variable (a variable that describes a certain quantity of a system that we are interested in, like position or concentration) is described using a fixed rule. In a nonlinear dynamical system, this fixed rule is nonlinear, and the system therefore does not satisfy the additivity and homogeneity properties that are necessary for linearity.

Examples of applications of (nonlinear) dynamical modeling to human behavior are vision (for example Fürstenau, 2006), speech (Kelso, Saltzman, \& Tuller, 1986; Tuller et al., 1994), language (for example Spivey, Grosjean, \& Knoblich, 2005), motor and neural dynamics (Haken, Kelso, \& Bunz, 1985; Schöner \& Kelso, 1988, Kelso, et al., 1992), and cognition (Bressler \& Kelso, 2001). Applications of dynamical models to decision-making under uncertainty have focused on either micro-level or macro-
level behavioral observations. For example Brown \& Holmes (2001) modeled a simple choice task using a dynamical model of firing rates of neurons. On a macrolevel, we find examples of dynamical models of multi-agent decision-making processes (for a brief overview, see Lu, Chen \& Yu, 2011).

## A One-Dimensional Model of Multi-Stability and Hysteresis in Risky Choice

To model the observed switching between $R$ and $S$, we propose a nonlinear dynamical system that has previously been applied to other cases in which individuals switched between two different behaviors, and where nonlinear phenomena like hysteresis and reversed hysteresis informed the use of a nonlinear dynamical model (e.g., Tuller et al., 1994). Equation 1 gives the potential function of the onedimensional model.

$$
\begin{equation*}
V(x)=k x-\frac{x^{2}}{2}-\frac{x^{4}}{4}+\xi \tag{1}
\end{equation*}
$$

where $x$ is the observed choice, $k$ the control parameter, and a noise term $\xi$ is added to each choice.
A potential function is the integral of the differential equation describing the evolution of the state variable $x$ (in our case, the observed choice), which means that a minimum or maximum of the potential function corresponds to a stable state of the system. Our system's potential function therefore reveals the attractor and repeller states, to which the system is attracted to or repelled from (see Kelso, 1995 and Strogatz, 2000 for more background on dynamical systems). The behavior of our dynamical system is driven by a control parameter $k$.

Figure 5: Potential landscape for five different values of $k$. Depending on the direction of change, a phase transition occurs between the two possible attractors for a critical value of $k, \pm k_{c}$.

Figure 5 shows some examples of the shape of the potential function, or attractor landscape, for different values of $k$. For a critical value of $k$, a bifurcation occurs (for both $k=k_{c}$, and $k=-k_{c}$ ), causing a phase transition between risk-seeking and risk-avoiding choices or vice versa. A phase transition occurs for a different value of $k$, depending on the direction of change, which explains hysteresis. By defining the two attractor states as the choice for $R$ and $S$ respectively, this model thus explains switches
between risk-seeking and risk-avoiding choices, as well as multi-stability through hysteresis (although not reversed hysteresis; see below for a more detailed discussion of reversed hysteresis).

Parameter Selection and Optimization The potential function offers a way to simulate sequential choice data. The key to modeling the risky choice phenomena is the control parameter $k$, which has to reflect the changing risk in $R$. We propose $k$ as a simple linear function of the risk in $R$ at choice $j$ and a baseline individual value, $k_{0}$, such that

$$
\begin{equation*}
k_{j}=k_{0}-R_{j}, \tag{2}
\end{equation*}
$$

By sampling $k_{0}$ from a uniform distribution spanning all possible values of $k$ between two extremes, and using Eq.
(1) and (2), we simulated an entire range of possible choice data. The lower boundary for $k_{0}$ corresponds to the case where only the attractor for $S$ exists, regardless of the value of the risk in $R$, and the upper boundary corresponds with only one attractor for $S$. Using a bootstrapped optimization with respect to the difference between the simulated and empirical choices on the $D I$ and $I D$ sequences of our main experiment (no variability in step-size, no speed manipulation), we were able simulate $86 \%$ of the observed choices. The differences in switch-points for reversed hysteresis are relatively small compared to the total range of values for $R(M=\$ 170.45, S D=\$ 183.08)$. This explains that, although the model does not account for reversed hysteresis, it generates a high proportion of correct choices.

Individual Risk Sensitivity A frequently reported result in research on decision-making under uncertainty is that people have relatively static personality characteristics that determine their risk-taking behavior (e.g. Mishra \& Lalumière, 2011). Accordingly, we hypothesize that $k_{0}$, the individual baseline value of the control parameter $k$ reflects risk sensitivity or propensity, and should therefore closely relate to participants' BART scores. Correlation between the participants' BART scores and the optimal values of $k_{0}$ however is very low, $r(33)=-.15, p=.36$ for the $I D$ sequences, and $r(33)=-.04, p=.81$ for the $D I$ sequences.

Modeling Reversed Hysteresis The current model does not account for reversed hysteresis, while up to $42 \%$ of participants show reversed hysteresis in their choice behavior. Lopresti-Goodman, Turvey, \& Frank (2012) provide a way to extend nonlinear dynamical models that includes reversed hysteresis using an auto-regulated control parameter. Negative auto-regulation forces the dynamical system to remain close to the bifurcation line and may reflect habituation to the amount of risk presented in the choices; rendering the choice for $S$ or $R$ unstable. This would also explain why the amount of hysteresis relative to reversed hysteresis increases with more variability in the increments of $R$ (Figure 4). Larger variability interferes with
the habituation and diminishes the effect of negative autoregulation.

## Discussion

There are many models of risky choice (see Glöckner \& Pachur, 2012 for a review). However, in order to account for multi-stability, nonlinearity is a necessary assumption. The results presented here show multi-stability in risky choice, for which we have provided a basic nonlinear dynamical model. The model provides a way to explain decisionmaking under uncertainty within the framework of complexity theory; a relative newcomer to the social sciences that offers a promising new perspective on human cognition (Van Orden, Holden, \& Turvey, 2003). Although the current model does not explain reversed hysteresis, it does provide a blueprint for a nonlinear dynamical model that can capture the entire range of observed choice behavior.

The aim of modeling was to provide a formal description of the observed decision-making behavior. Moreover, our hope is that identifying the right kind of nonlinear models will eventually lead to insights into the underlying processes or mechanisms. One of the strengths of the model is that multi-stability is an inherent behavior of the nonlinear dynamical system, pre-empting the need for weight functions or exceptions. The model also provides a starting point for theorizing about the psychological processes underlying the behavior. The control parameter is a single parameter that captures the switching between risk-seeking and risk-averse choices. Unexpectedly, however, there was no correlation between participants' BART scores and the baseline value of the control parameter, $k_{0}$. Upon reflection, this result is not as surprising after all. Nonlinear dynamical systems are especially useful in capturing change and the phenomena that are associated with change, like hysteresis. The BART however assumes individual risk preference is a temporarily static personality trait. The current results therefore indicate that risk preference is a highly complex and multi-dimensional construct and that the dynamics of subsequent risky choice behavior cannot be captured in a single measure of risk sensitivity.

#### Abstract

Behavioral mimicry is the nonconscious copying of an interaction partner's behavior and is affected by social dynamics. Whereas it has been studied extensively in adults, little is known about the development of mimicry. The aims of this study were twofold, first to identify whether young children demonstrate mimicry and, second, to investigate whether young children's mimicry displays sensitivity to social dynamics. Using a video-based paradigm, 40-monthold children observed six types of behaviors (i.e. yawning, laughing, frowning, cheek-scratching, mouth-rubbing and head-wiggling) performed by a model which they had previously seen either helping or hindering another model. Results indicate that children carried out five of the six behaviors more often while watching the behavior videos than during baseline. However, no differences were found between the two social manipulations. We conclude that young children demonstrate mimicry like that reported in adults and discuss the possible causes of the absence of a social effect.

Keywords: behavioral mimicry; development; action; social dynamics; social interaction.

## Introduction

An often unnoticed component of social interactions is behavioral mimicry. Mimicry can be defined as nonconsciously adopting the behaviors of an interaction partner (van Baaren et al., 2009). In one of the first comprehensive studies of mimicry, participants were exposed to foot-shaking or face-rubbing confederates with smiles or neutral expressions on their faces. Chartrand and Bargh (1999) showed that participants were more likely to carry out the modeled behaviors and expressions than the non-modeled behaviors and expressions. Importantly, replicating these behaviors occurred outside of the participants' awareness (Chartrand \& Bargh, 1999).

In contrast to the extensive adult literature on mimicry (for a review see Chartrand \& van Baaren, 2009), exceptionally few studies have investigated the development
of mimicry. Some authors have documented neonatal imitation (e.g. Meltzoff \& Moore, 1977; Meltzoff \& Moore, 1983). Others, however, note the lack of breadth of these behaviors and have been unable to replicate original findings with older infants and young children (e.g. Anisfeld, 1996; Jones, 2007). Additionally, in such studies, infants and young children are encouraged to replicate modeled behaviors (e.g. Jones 2007), which stands in contrast to the uninstructed mimicry reported in adults. In one study that did not give replication instructions, children saw video stimuli in which someone often yawned, but children under the age of five did not demonstrate instances of yawning (Anderson \& Meno, 2003). In a live paradigm, only three out of 40 children under the age of four demonstrated contagious yawning (Helt et al., 2010). Similarly, Over and Carpenter (2009) report that, in a pilot study, 5-year-old children who interacted with an adult who repetitively touched her face failed to mimic this behavior. Notably, the authors posited that there was little evidence to suggest that children under the age of five exhibit mimicry of the sort found in adults (Over \& Carpenter, 2009).

Not only do adult studies indicate the uninstructed nature of mimicry, but they also bring to light its sensitivity to social dynamics. For example, liking one's interaction partner has been shown to increase mimicry rates, both when liking was preexistent and manipulated (Likowski et al., 2008; McIntosh, 2006). Although there is no evidence of uninstructed mimicry in young children, a form of imitation has been shown to be affected by social dynamics. Overimitation (also called affiliative imitation) is the replication of actions shown during a task demonstration that are unrelated to achieving the desired end-state of the task (Over \& Carpenter, 2012). In a conceptual replication of an adult study by Lakin, Chartrand and Arkin (2008) which showed that being socially excluded lead to higher mimicry rates, Over and Carpenter (2009) found that priming 5-year-olds with social exclusion increased overimitation rates (Over \& Carpenter, 2009), indicating
that non-mimicry forms of behavior replication are sensitive to social factors in young children.

Children's sensitivity to social dynamics is also manifest in other behavioral measures. One study showed that 3-yearolds helped helpful adults more than destructive adults (Vaish, Carpenter, \& Tomasello, 2010). Kenward and Dahl (2011) demonstrated that, when given an uneven number of biscuits, 4.5-year-olds distributed more biscuits to puppets they saw helping another puppet than to puppets they saw violently hindering the other puppet. Three-year-olds did not distinguish in their biscuit-distribution but the authors suggest this was because they were shocked by the violent nature of the events and were not sure which puppet was which (Kenward \& Dahl, 2011).

Thus far, no studies have reliably found uninstructed mimicry during early childhood, and it is hence also unknown if children's mimicry is affected by social dynamics. In the present study, we first aimed to identify whether young children demonstrate mimicry like that found in adults. Importantly, we incorporated a range of behaviors, such as facial expressions and manual behaviors, to investigate the generality of young children's mimicry. Also, as past adult studies have successfully used videos to elicit mimicry (e.g. Lakin \& Chartrand, 2003; Platek et al., 2003), we chose to present the stimuli as videos to ensure that all children saw identical behaviors. Moreover, this provided the children with a 'task', namely to watch TV, which is in line with the contention of van Baaren and colleagues (2009) that during mimicry experiments the focus should not be on the behaviors specifically. We incorporated a baseline measure so as to compare natural behavior rates with those elicited by observation within participants, because past studies indicate that individual differences influence mimicry rates (e.g. Chartrand \& Bargh, 1999; Platek et al., 2003; Sonnby-Borgström, 2002). We hypothesized that children would demonstrate the behaviors at greater frequencies while watching the behavior videos than during baseline.

The second aim was to address whether mimicry is sensitive to social dynamics at three years of age. As past studies demonstrated that children around three and four years of age show differential treatment of helpers versus hinderers (Kenward \& Dahl, 2011; Vaish et al., 2010), we used a similar paradigm to manipulate the social dynamics. We designed the models’ interactions such that the helper would come across as a nice individual whereas the hinderer would be seen as a mean but not violent individual. In this manner, we aimed to implement a similar effect as in the manipulated-liking designs of adult mimicry studies (Likowski et al., 2008; McIntosh, 2006). Due to possible carry-over effects from previous interactions (e.g. Lakin \& Chartrand, 2003), we used this social manipulation as a between-participants factor, such that half of the children were randomly assigned to the helper condition and half to the hinderer condition. We hypothesized that children would mimic helpers more than hinderers, replicating the pattern of higher mimicry rates for liked individuals in adult studies.

## Methods

## Participants

Participants were recruited through the database of volunteer families of the Baby Research Center Nijmegen. Signed consent was obtained from parents beforehand. Thirty-three children participated in this study (mean age: 39.7 months, range: 39.2-40.2; 23 girls). Seven children were excluded due to not wanting to watch the videos ( $\mathrm{N}=1$ ), technical error ( $\mathrm{N}=1$ ), and not meeting the inclusion criteria of having attended to at least $40 \%$ of the behavior videos ( $\mathrm{N}=3$ ) or having watched each behavior video at least once ( $\mathrm{N}=2$ ). Thus, the final sample consisted of 26 children (19 girls).

## Stimuli

The stimulus videos for the experiment were made using a digital video camera (Sony Handycam, DCR-SR190E) and were digitally muted. Two types of videos were recorded, social manipulation videos and behavior videos.

Figure 1.2 shows the final scene of the helper video, and gives an indication of the scene composition used in the social manipulation videos. In both the helper and hinderer videos, a stuffed animal was initially positioned in the left, front corner of the table, and the helper or hinderer (H) walked in from the left and the neutral model ( N ) from the right, each sitting down at their respective sides of the table. After N failed to reach the stuffed animal from her position, H reached over to get the stuffed animal and held it out to N who reached for it. At this point the videos differed; in the helper videos, H passed the stuffed animal to N who held it as in Figure 1.2, whereas in the hinderer videos, H pulled the stuffed animal back and held it to her chest.

Three adult female models were used. Two models were used for H (i.e. H 1 and H 2 ), who each played both the helper and the hinderer in order to control for possible idiosyncrasies of each model. The model for $H$ was kept consistent within participants, such that children who saw H 1 during the social manipulation video also saw the behavior videos of H 1 , and the same for H 2 . The H models wore a colored shirt to aid subsequent identification while N wore black. Since N never reappeared in the behavior videos, only one model played her role.

Six different behavior videos were made. The first, yawning, was selected for its contagious qualities (Figure 1.3; Platek et al., 2003). Two emotional facial expressions, laughing and frowning (i.e. a sad facial expression), were used as they have successfully elicited mimicry in adult studies (Lakin \& Chartrand, 2003; Moody \& McIntosh, 2011; Sonnby-Borgström, 2002) and recently also in schoolaged children (Deschamps et al., 2012). Two manual behaviors were loosely based on those used in interactive adult studies (e.g. Chartrand \& Bargh, 1999; Lakin \& Chartrand, 2003), namely using the fingertips to scratch the cheek (i.e. cheek-scratching) and rubbing the fingertips back and forth across sealed lips (i.e. mouth-rubbing; Figure 1.5). Finally, in the head-wiggling clip the model moved her head
from side to side while looking forwards. Each behavior video showed the model in a neutral position for the first and last 500 milliseconds. Pilot data indicated that children of this age were capable of replicating all behaviors.

Figure 1: Experimental design.

## Design

This experiment consisted of three types of stimuli: the baseline, the social manipulation and the behavior videos. For the baseline, a non-social video ( 73.7 sec .) from an unrelated experiment was shown displaying a single racecar driving through a racetrack (Figure 1.1; Immens, 2011). Next, the social manipulation video (average duration 23sec.), depending on the condition the participant was assigned to, was shown twice (Figure 1.2). The behavior videos (average duration 7 sec .) were presented after the social manipulation videos (Figure 1.3 and 1.5). Each of the six behaviors was presented five times, resulting in 30 behavior videos in total, and after every 5 behavior videos an attention grabber video ( 2 sec .) was shown. After half of the behavior videos were played, the same social manipulation video was shown a third time (Figure 1.4) and was announced via a recording of a voice saying in Dutch, "Look! Again this video." Children’s behavior during the third repetition of the social manipulation video was not included in the behavior rate calculations. Together, the baseline, the three repetitions of the social manipulation video and the 30 behavior videos lasted approximately six minutes. At the end of the experiment, the experimenter asked the children if they remembered the social manipulation video, if they could describe what had happened and whether the model was nice or mean, as well as whether the child remembered copying the model's behaviors.

Randomization and counterbalancing. The (pseudo)randomizations were done using Mix (van Casteren \& Davis, 2006). Participants were randomly assigned to one of the two conditions (i.e. helper or hinderer) and one of the two models (i.e. H1 or H2); hence there were four groups, one for every combination of condition and model. For each
group there were two presentation orders of behavior videos (i.e. eight in total), which were constrained such that at least three different behavior types had to be presented before the same behavior could be shown again, and these presentation orders were counterbalanced across participants.

## Procedure

Following a short play session, the child and parent were led to the experiment room. Children were seated in front of an eye-tracker (T120, Tobii Technology, Stockholm, Sweden, Tobii Studio software) either alone or on their parent's lap. A video camera (Sony Handycam, DCR-SR190E) was positioned to the side of the child such that it was not in her direct visual field but still obtained the most frontal recording angle possible. The only instructions given were to watch the videos. Upon conclusion, the participants were allowed to select a storybook or were given 10 Euros for participating in the experiment.

## Coding and Reliability

The children's behavior was coded using ELAN Linguistic Annotator (4.3.3, http://tla.mpi.nl/tools/tla-tools/elan, Max Planck Institute for Psycholinguistics, Nijmegen, The Netherlands; Lausberg \& Sloetjes, 2009). The coder was blind to condition and the order of stimulus presentation.

Although the experiment was presented on an eye-tracker so that attention could be measured precisely, the percentage of looking time according to the output was often considerably lower than the amount of time that the child actually attended the screen (for comparable eye-tracking discrepancies, see Morgante, Zolfaghari, \& Johnson, 2012). For this reason, attention was coded by hand. If the child looked away for more than five seconds, turned to interact with the parent or experimenter, or was not clearly visible on the video, that duration was coded as not-attending.

Pilot data was used to create the coding scheme for the behaviors so as to accommodate how children carry out each behavior. If the child verbally labeled a behavior right before, during or after carrying it out, it was not coded as mimicry. Also, behaviors that started while the child was not attending were not coded as these might have been externally triggered. The exact coding scheme is available from the first author, with the required characteristics as follows. Yawns were coded when the lips were parted forming an O-shape. For laughing, the corners of the mouth needed to be turned upwards (i.e. smiles were also counted) while for frowns they needed to be turned downwards. A cheek scratch was coded if the child brought her hand to her cheek or forehead and made scratching movements with her fingers. If the child rubbed her fingers over her mouth or chin it was coded as a mouth rub. Lastly, the head-wiggle was coded when the child tilted her head to the left or right and then to the other side at least once.

To ensure coding-reliability, a random sample of 20 percent of the participant videos was re-coded. The mean intraclass correlation coefficient between behavior rates of the first and second coding was $\mathrm{r}=.98$.

## Behavioral Measures

The timing of all events (e.g. onset and offset times of stimuli and the participant's behaviors) were synchronized and rounded to the nearest 100 milliseconds. The baseline and behavior videos period were separated; the baseline consisted of the duration of the racecar animation and the behavior videos period was defined as starting when the first behavior video started and ending after the last behavior video, but with the social manipulation video in between excluded. Participant's behaviors that occurred during the behavior videos period but before the first attended behavior video of that type were excluded.

Behavior rates. Per participant, it was counted how often each behavior was carried out, and rates were calculated separately for the baseline and behavior videos period. Total behavior rates were calculated by dividing the total behavior count by the duration in minutes that the screen was attended. Similarly, behavior rates were calculated per behavior type using the count of just one behavior. For these separate behavior rates, the duration attended in minutes for the behavior videos period was adjusted to start from the beginning of the first behavior video of that behavior type, resulting in the separate behavior rates being lower than the overall behavior rate. Hence, per participant, per baseline or behavior videos period, seven behavior rates (i.e. behaviors per minute attended) were calculated: the overall rate and one rate for each of the six behavior types.

## Analysis

Several comparisons were run to check that the models and the presentation orders did not have an effect on behavior rates during the behavior videos period and were run separately for the two conditions. The helper condition consisted of 12 participants, five of whom saw the videos of model H 1 , while the hinderer condition had 14 participants, 7 of whom saw model H1. Independent-samples $t$-tests and Mann-Whitney U-tests compared the effect of model (e.g. H1 or H2) on total behavior rates and separate behavior rates, respectively, and Kruskal-Wallis H-tests compared the effect of the presentation orders on both total behavior rates and separate behavior rates. There were no effects of model or presentation orders for total or separate behavior rates in either condition (all ps >.1). Therefore, the models and presentation orders were collapsed in the subsequent analyses. Additionally, Mann-Whitney U-tests revealed no differences in behavior rates between children sitting on their parents' laps and those sitting alone on the chair during either the baseline or the behavior videos period (all $p s>.2$ ).

## Results

Out of the 26 participants, 25 participants demonstrated at least one of the six behaviors during either the baseline or the behavior videos period, and 23 participants carried out the behaviors more often while watching the behavior videos than during baseline.

Since it first needed to be investigated whether the two conditions (i.e. groups of participants) differed, the hypothesized difference between the helper and hinderer condition during the behavior videos period was tested. However, a Mann-Whitney U-test revealed no significant difference in total behavior rates between conditions ( $p>.4$ ). Hence, for the subsequent comparisons the participant groups were collapsed across conditions.

To investigate whether behavior rates differed between baseline and the behavior videos period, a paired-samples $t$ test was used to compare total behavior rates. Children carried out the behaviors significantly more often during the behavior videos period ( $M=2.38$ behaviors per minute, $S E=0.24$ ) than during the baseline ( $M=0.92$ behaviors per minute, $S E=0.33$; $t(25)=-4.3, p<.001, r=.65)$.

Subsequently, each separate behavior was investigated using Wilcoxon signed-rank tests, and alpha was corrected for multiple comparisons using a Bonferroni correction ${ }^{1}$ (Figure 2). During the behavior videos, the rates of yawning, frowning, mouth-rubbing and head-wiggling, were significantly higher than the baseline rates of yawning ( $z=3.18, r=.44$ ), frowning ( $z=2.74, r=.38$ ), mouth-rubbing ( $z=2.61, r=.36$ ) and head-wiggling ( $z=2.93, r=.41$; all $p s<.008$ ), respectively. Cheek-scratching occurred more often during the behavior videos period than during the baseline at a level of marginal significance ( $p=.011$ ). Laughing did not differ significantly between the two periods.

Figure 2: Mean behavior rates of each behavior type for the baseline and behavior videos period. Error bars indicate one standard error above the mean; ${ }^{* *} p<.008,{ }^{*} p=.011$.

For the five behaviors with significant and marginally significant effects, it was investigated post hoc whether any one behavior was more likely to be replicated than the other behaviors. A Friedman's ANOVA was used to compare the difference in behavior rates between baseline and behavior videos period (i.e. behavior videos period behavior rate

[^242]minus baseline behavior rate) between the behaviors. No differences between the behaviors were found (all ps>.7).

A Mann-Whitney U-test showed that the children's answers to the question of whether they consciously replicated the model's behaviors were not predictive of their behavior rates during the behavior videos period ( $p>.6$ ).

## Discussion and Conclusion

This study aimed to identify and investigate mimicry in 40-month-old children. We found that children carried out the behaviors significantly more often while watching the behavior videos than while watching the baseline video. This was evident across individuals, as 23 out of 26 participants showed higher behavior rates during the behavior videos period than during baseline, and across behavior types, as five of the six behaviors were mimicked. Yawning, frowning, mouth-rubbing, and head-wiggling all occurred at significantly greater rates during the behavior videos than during baseline and cheek-scratching showed this effect at a level of marginal significance. Of the mimicked behaviors, no one behavior was more likely to be mimicked than others, while controlling for baseline rates.

Mimicry of these behavior types have, to the best of our knowledge, not been tested during early childhood before, with the exception of yawning. Helt and colleagues (2010) report very low rates of yawning in live paradigms under the age of four and Anderson and Meno (2003) did not find any instances of yawning during video watching in three-yearolds. In their video-based study, children were instructed to clap whenever they saw a yawn; as also suggested by Helt and colleagues (2010), the disparity between their findings and ours may be a result of the assigned tasks, since our simple instructions to watch the videos better resemble the uninstructed nature of adult mimicry studies. Indeed, the behavior rates during the behavior videos period of our study are similar to the behavior rates measured during live interactions in adults. For example, Chartrand and Bargh (1999) found an average rate of .57 face-rubs per minute, which closely corresponds to the children's average behavior rate of .51 for mouth-rubs.

The only behavior that did not demonstrate a mimicry effect in the current study was laughing. This was likely caused by the children's enjoyment of the baseline video, as average laughing rates during the baseline far exceeded those of the other behaviors' baseline rates. Although the baseline video was selected for its neutrality and non-social nature, the animation still needed to be, and in fact was, attractive enough for children to attend to it.

An important characteristic of mimicry is that it occurs outside of the awareness of both the individual mimicking and the individual being mimicked (Chartrand \& van Baaren, 2009). Children were asked at the end of the experiment whether they copied the model while watching the behavior videos, and their answers were not related to their actual mimicry rates. Additionally, during a pilot study children were instructed to copy the behaviors, but it became apparent that they found it unusual to consciously
replicate the behaviors of a non-responsive model, even when encouraged by their parents. Furthermore, our coding scheme ensured that the few cases in which children verbally labeled a carried-out behavior, indicating that they were focusing on doing that behavior, were not counted as mimicked behaviors. Anecdotally, several parents remarked that they were surprised to see their child replicate the behaviors seemingly automatically. Altogether, there is sufficient evidence to indicate that the children nonconsciously replicated the behaviors, in line with the definition of behavioral mimicry.

This study further investigated whether children's mimicry is sensitive to social dynamics. To influence the social dynamics, a helper-hinderer manipulation was used in a between-participants design. However, no significant differences between the conditions were found. Given that past studies have linked mimicry with social perspective taking skills (e.g. Chartrand \& Bargh, 1999; Platek et al., 2003), it might be that the sensitivity of mimicry to social factors gradually develops during childhood as an effect of increasing social cognition and experience. However, it should be considered whether the social manipulation could have been ineffective. A limitation of the present study was that the social manipulation and behaviors were recorded as separate video clips with different background settings. Since Kenward and Dahl (2011) reported that their participants had difficulty later identifying the puppets, we allocated the helper and hinderer models a colored shirt to aid later identification. Nonetheless, the different setting of the two video types may have prevented children from making the link between the model in the social manipulation video and the model in the behavior videos. More support for this notion comes from recent pilot data with $51 / 2$-year-olds, which indicated that children older than those in this study often failed to relate the model in the behavior videos to the model in the social manipulation video seen before. A similar limitation was that video presentation prevented participants from actually affiliating with the model, thereby possibly preventing an affiliationdriven social effect, as suggested by Over and Carpenter (2012) regarding an overimitation study by Nielsen, Simcock and Jenkins (2008).

The findings of this study highlight avenues for further research into the neural and cognitive underpinnings of mimicry. Whereas a perception-action matching system founded in imitation research has been suggested to also underlie mimicry (Chartrand \& van Baaren, 2009), it is unclear whether neural differences exist between nonconscious mimicry and instances of conscious motor observation and replication. Additionally, cognitive mechanisms have been suggested to contribute to imitative behaviors (e.g. Meltzoff, 2007; Woodward et al., 2009), and future studies should investigate whether similar mechanisms, and the development thereof, are involved in mimicry's reported social sensitivity.

In conclusion, this study is the first to identify uninstructed behavioral mimicry in 40-month-old children.

The spectrum of behaviors for which this was the case reflects the repertoire of mimicked behaviors in the adult literature (Chartrand \& van Baaren, 2009), and provides a basis for future research investigating the underlying neural and cognitive processes. It is unclear whether the lack of social modulation of mimicry was a result of experimental design or an effect of social-cognitive development, and this posits further investigation.

#### Abstract

How do people coordinate actions with others? We tested the hypothesis that pairs of participants strategically reduce the variability of their action performance to achieve synchronicity in the absence of visual feedback about each other's actions. Consistent with this prediction, participants moved faster and less variably in a condition where they could not see their task partner's movements compared to a condition in which visual information was available. The accuracy of the resulting coordination was the same in both conditions. These findings are interpreted as evidence for general strategic adaptation in the service of real-time action coordination when only minimal perceptual information is available.

Keywords: Joint action; coordination strategy; cooperation; social cognition.

## Introduction

Whenever people coordinate their actions with other people, they are engaged in a 'joint action' (Clark, 1996; Marsh et al., 2009; Sebanz, Bekkering, \& Knoblich, 2006). Depending on the specific task and the presence or absence of an explicit joint action goal, different mechanisms and processes will make coordination of multiple people's actions possible. For instance, a couple might discuss through verbal or non-verbal communication who is responsible for preparing dinner and who will set the table (Clark \& Wilkes-Gibbs, 1986). Or a group of friends might help push-start a car by using perceptual cues and haptic information to predict when everyone else will push (van der Wel, Knoblich, \& Sebanz, 2011; Wilson \& Knoblich, 2005). In yet other cases, coordination might arise without prior planning as when two strangers unintentionally walk in synchrony (van Ulzen et al., 2008).

While people in these and many other everyday examples make use of visual, auditory or haptic information to guide their joint efforts, this is not always possible. Sometimes coordination is required in contexts where only little or even
nothing is known about the coordination partner and how or when the partner will perform a particular action. In these cases, all that might be represented is one's own action part ('ME'), the fact that someone will take care of another action part (' X ') required to achieve the joint goal and the joint action goal ('ME +X ') achieved by combining the individual action parts (Vesper et al., 2010). Thus, a precise representation about the partner's task might not be available. We claim that in these cases, coordination is supported by very general mechanisms and processes that are not required to the same extent if more information about a task partner is available. The present study addressed the mechanisms and processes allowing people to achieve coordination in this kind of minimal joint action situation.

More specifically, we investigated whether people who intend to coordinate their actions under real-time constraints and with no access to visual information about a task partner's actions adapt their own actions in a way that will make interpersonal coordination most likely. Such a coordination strategy (Vesper et al., 2010) reliably simplifies coordination in a general way, i.e. it is a modulation of one's own behavior that does not directly depend on how a task partner's particular action will unfold.

One example of strategic adaptation is to behave in a way that will make one's own actions predictable. When timing is not critical, this could involve relying on shared or conventional knowledge (Clark, 1996). For example, someone might decide to wait at the Brandenburg Gate to meet a friend in Berlin when they forgot to agree on a precise meeting point in advance (Schelling, 1960). Similarly, if each member of a group has to guess a number such that the sum of all numbers matches a randomly selected target number, providing consistent and therefore predictable guesses can be beneficial to achieve the desired group outcome (Roberts \& Goldstone, 2011).

In situations in which actions need to be coordinated in real-time, making actions predictable can involve mini-
mizing the variability of one's own performance. Recent empirical evidence for this claim is provided by a study in which pairs of participants performed a simple two alternative forced choice (2-AFC) reaction time task next to each other with the goal of synchronizing the timing of their response button presses (Vesper et al., 2011). An analysis of mean reaction times and the trial-by-trial variability of reaction times indicated that participants responded faster and with less variability in joint action compared to individual baseline performance. This in turn positively affected coordination such that pairs whose members responded fast and with little variability were on average better synchronized.

Critically, the study showed that it was the reduction in variability that predicted how successful coordination was, as demonstrated by a correlation of variability and asynchrony that persisted when controlling for the potential effects of mean reaction time. Thus, the more predictable actions were, the more successful interpersonal coordination was. Given that performing tasks at higher speed tends to reduce temporal variability (Wagenmakers \& Brown, 2007), participants most likely used speeding as a means to reduce their action variability. A second experiment demonstrated that speeding and predictability were only correlated with asynchrony when task partners intended to synchronize their button presses, but not in an experimental condition where the two people merely performed the task next to each other without a coordination goal. This suggests that the coordination strategy of making oneself predictable is used specifically to achieve intentional joint action coordination.

The aim of the present study was to extend these earlier findings (Vesper et al., 2011) by addressing three predictions following from the concept of a coordination strategy (Vesper et al., 2010) - generalizability, specificity, and independence. The first prediction was that the link between response speed, response variability, and asynchrony of task partners' actions would also be useful for coordination of more complex, temporally extended joint actions. Therefore, we instructed pairs of participants to each use a computer mouse to move a cursor on a screen from a start location towards a target with the joint goal of reaching the target at the same time (Figure 1). Thus, the task required two people to synchronize the endpoints of two-dimensional aiming movements. When they reached the target auditory feedback informed participants about their coordination accuracy.

The second prediction was that a coordination strategy will predominantly be used in situations in which no or only little information about a task partner's actions is available. In this 'minimal' case, all someone can do is to adapt his or her own actions in a general way to make coordination most likely. In contrast, when task or perceptual information is available, other mechanisms and processes will support coordination. For instance, co-actors can monitor (Malfait et al., 2009; Schuch \& Tipper, 2007) or predict (Graf et al., 2007; Knoblich \& Jordan, 2003) when and how another person will perform a particular action. Consequently, in
many situations, perceptual information is beneficial for joint action coordination. As an example, when two people build a toy model together such that one person (the director) verbally instructs another person (the builder) which parts to assemble, coordination is more successful if the director can see what the builder is doing (KrychAppelbaum et al., 2007). Similarly, two people who jointly search a shared workspace for a target object are more efficient in their search if they receive information about where each of them is currently looking at (Brennan et al., 2008). To test the specificity of coordination strategies, we compared an experimental condition in which co-actors did not receive visual information about each other (Other Hidden) with one in which they could see each other and each other's ongoing action performance (Other Visible). We hypothesized that a speeding and predictability strategy would predominantly be employed in the Other Hidden condition, whereas for Other Visible, we expected that the additional perceptual information would allow co-actors to use a different mechanism for coordination. This could involve monitoring and anticipating the partner's computer mouse movements. Therefore, we expected reaction times and movement variability to be smaller in Other Hidden compared to Other Visible. Given that perceptual information often positively influences coordination, we also hypothesized that asynchronies between co-actors' actions in Other Visible would be smaller, indicating better coordination accuracy when more information is available.

The third prediction was that a coordination strategy is used in a general way, independently of how the task partner actually performs an action. This means that the partner's particular action performance is not directly relevant for one's own strategic adaptation. In contrast, when other mechanisms such as monitoring and prediction are used, one's own action performance should be directly related to the task partner's action performance. One way to address this prediction is to compare the actually measured asynchronies between task partners' actions with asynchronies that are calculated after co-actors' reaction times have been shuffled and randomly matched. This method effectively treats the data as if each person's actions were not targeted towards a corresponding action of the co-actor because their actions now come from different trials. We hypothesized that this procedure would affect coordination in Other Hidden to a lesser extent than in Other Visible, indicating that co-actors in the former case adapt in a general way that is independent of the task partner's particular action performance, whereas in the latter case, co-actors make use of the given perceptual information and take into account how the partner's action unfolds on a trial-by-trial basis.

## Method

## Participants

Twenty-four students (14 women) participated in pairs. They were between 19 and 25 years old (mean 21.1 years)
and right-handed. They gave prior informed consent and received monetary compensation for their participation.

## Material and Apparatus

A "space mission" scene was created on two computer screens placed next to each other (Figure 1). The scene contained three elements presented on a dark blue background. First, close to the outer margin of each screen, a yellow "spaceship" was drawn (ca. $2.5 \mathrm{~cm} \times 1.9 \mathrm{~cm}$; position centrally on the vertical axis), indicating the starting position for each trial. Second, on the inner margin of each screen, a blue half circle was drawn on one of three possible locations, indicating a "planet" as the target (radius ca. 2.0 cm or 3.8 cm ; position at $20 \%$, $50 \%$ or $80 \%$ from the upper screen margin). When both screens were visible (Other Visible), the two half circles together formed a complete "planet". Finally, centrally between "spaceship" and "planet", on one of five possible locations, an array of small differently-sized white dots was drawn to represent an "asteroid belt" (ca. $1.9 \mathrm{~cm} \times 9.3 \mathrm{~cm}$; position at $20 \%$, $35 \%$, $50 \%, 65 \%$ or $80 \%$ from upper screen margin). It served as a potential obstacle between start and target locations.

Figure 1: The "space mission" scene (example layouts). A) In Other Hidden, each participant only saw one half of the scene due to an occluder placed between the participants. B) In Other Visible, both participants saw the complete scene.

The stimuli were presented on two 17 "-screens (resolution $1280 \times 1024$ pixel, refresh rate 60 Hz ). In individual baselines and in Other Hidden, a black card board (70 x 100 cm ) was set up between the two participants and between the two screens. The experiment was run on two Dell OptiPlex computers that were connected through a nullmodem cable to allow online data exchange. For data
collection, two special gaming computer mice (Logitech G500) were used that were sampled at 100 Hz and that had automatic acceleration turned off. Matlab version 2012a was used for controlling the experiment and for data analysis.

## Procedure

There were four experimental parts: the Other Hidden condition (Figure 1A), the Other Visible condition (Figure 1B) and two individual baselines. Each participant first performed four practice trials and then the first individual baseline, while the task partner waited in another room. After both participants had finished their first individual parts, they performed the two joint conditions together. The order of Other Hidden and Other Visible was counterbalanced. Finally, each participant separately performed another individual baseline. Each of the four parts consisted of six experimental blocks à 16 trials with short breaks in between. The overall duration of the experiment was about 1.5 hours.

At the beginning of a trial, the start location ("spaceship") was presented for 600 ms . Next, the target ("planet") and obstacle ("asteroid belt") appeared at a location that was randomly chosen from the possible locations. The frequency of target and obstacle locations and the target size were counterbalanced within each block. The relation of target and obstacle locations determined whether the direct path between start and target location was blocked by the obstacle or not. At the same time when target and obstacle appeared, the spaceship briefly flashed for 200 ms by showing flames at the rear engine. The purpose was to redirect participants' attention to the start location where a mouse cursor (a yellow circle) was now visible.

Participants were instructed to move the mouse cursor to the target without moving over the obstacle. A short feedback tone ( 100 ms ) was played as soon as they moved into the target area, i.e. no button press was required. The feedback tones for the left-seated and the right-seated participants differed in frequency so that they could be distinguished ( $1100 \mathrm{~Hz}, 1320 \mathrm{~Hz}$ ). Additionally, visual feedback about the accuracy of the trial was given: The planet turned red indicating negative task performance 1) if participants' movements were too slow (movement onset > 600 ms or reaction time > 1600 ms ), 2) if they moved over the obstacle area, 3) if the task partner had made any of these mistakes or 4) if co-actors did not reach the target synchronously (absolute asynchrony $>400 \mathrm{~ms})^{1}$. In all other cases, trials were successful and the planet turned into a bright green. Participants then returned to the start position and the next trial started.

Participants were told to think of the task as a space contest that requires securing planets from an alien nation by landing on a planet before them. According to this background story, in some areas of the universe (individual baselines), this could be achieved alone, whereas in other

[^243]areas of the universe (Other Hidden, Other Visible), they would have to arrive at the planet at the same time as the task partner in order to win. Thus, task instructions explicitly mentioned that participants should be as fast and as accurate as possible, while strongly focusing on arriving at the same time. Co-actors were not allowed to talk.

## Results

For the purpose of the present paper, we only report analyses of mean reaction times (RT; measured as the time from the start signal until the target was reached), standard deviation of reaction times (STD) and absolute asynchrony between participants' reaction times (ASYNC) ${ }^{2}$. These dependent variables were acquired by averaging over all trial types within a condition, i.e. we did not differentiate between different target and obstacle locations or target sizes. All trials in which participants' own RT was slower than 1600 ms or in which they moved over the obstacle area were excluded from further analyses (1.1 \% in Other Hidden, 0.7 \% in Other Visible).

Figure 2: Results. A) Mean RT. B) Mean trial-by-trial variability measured as STD. The dotted lines show individual baseline performance before (upper line) and after joint action (lower line). Error bars display withinsubject confidence intervals (Loftus \& Masson, 1994).

We first tested whether participants made use of a coordination strategy predominantly in the case where they did not receive visual information about the task partner's action. Confirming this hypothesis, RTs in Other Hidden were significantly faster, $F(1,23)=14.01, p<.01$ (Figure 2A) and less variable, $F(1,23)=5.36, p<.05$ (Figure 2B) than in Other Visible. Moreover, as described in more detail below, coordination between co-actors was equally good in the two conditions.

To investigate the hypothesized relation of RT, STD and ASYNC, we performed zero-order and partial correlations.

[^244]For Other Hidden, these analyses indicated that both RT and STD significantly influenced ASYNC such that shorter and less variable RTs led to better coordination between coactors (for exact results, see Figure 3A). Crucially, however, when controlling for RT in a partial correlation, STD still predicted ASYNC, whereas when controlling for STD, the relation between RT and ASYNC did not persist. Thus, as predicted, participants' response variability was critical in determining how well coordinated co-actors were when no online perceptual information about the task partner's actions was available. In contrast, in Other Visible, RT and STD did not predict ASYNC, although RT and STD were correlated (for exact results, see Figure 3B).

Figure 3: Zero-order and partial (in parentheses) correlations for A) Other Hidden and B) Other Visible. The thick arrow in A indicates that the relation between STD and ASYNC still holds when controlling for the influence of RT with a partial correlation. * $p<.05$, ** $p<.01$, *** $p<.001$.

Finally, we tested the hypothesis that the speeding and predictability strategy in Other Hidden is general in the sense that it depends only to a certain extent on how the task partner actually performed his or her actions. In contrast, coactors in Other Visible should take the other person's actual movements into account by monitoring and predicting the other's action. Based on this reasoning, we hypothesized that the coordination outcome from a general strategy should depend less on a trial-by-trial match of task partners' actions, whereas when using perceptual information this should be relevant. To test this prediction, we compared the originally measured asynchronies with asynchronies in which the specific trial-by-trial relation between co-actors’ actions was destroyed by randomly shuffling the order of trials from one member in each pair (separately for the different trial types) and re-calculating the asynchrony between the two persons' response times.

In line with our hypothesis, a comparison of original and shuffled asynchronies in the two conditions indicated an unequal effect of the shuffling: Although asynchronies increased in both conditions, shuffling co-actors' trial order had a significantly stronger effect for Other Visible than for Other Hidden. This was demonstrated statistically by an interaction of the factors Condition (Other Hidden, Other

Visible) and Trial Order (original, shuffled), $F(1,23)=$ 10.59, $p<.01$ (Figure 4). There was also a main effect of Trial Order, $F(1,23)=16.88, p<.001$, but no significant effect of Condition, $F(1,23)=.01, p>.9$. Thus, co-actors reached the same level of coordination performance in the two conditions.

Figure 4: Asynchrony measured (original) and re-calculated after randomly matching different trials from the members within a pair (shuffled). Error bars display within-subject confidence intervals (Loftus \& Masson, 1994).

## Discussion

The aim of the present study was to systematically test predictions following from the hypothesis that people strategically increase the speed and predictability of their actions to achieve real-time coordination with another person given only minimal perceptual information (Vesper et al., 2010, 2011). Pairs of participants performed mouse movements towards a target displayed on a computer screen. The joint goal was to reach the target at the same time as the task partner. Short feedback tones when arriving at the target informed participants about the accuracy of their joint coordination.

The present results confirm our hypothesis that co-actors strategically reduced the variability of their movements through speeding (Wagenmakers \& Brown, 2007) whereby action variability contributed directly to the coordination outcome. In particular, when controlling for the impact of reaction times, response variability still predicted asynchrony, whereas when controlling for the impact of response variability, there was no longer a correlation between reaction time and asynchrony. This not only replicates earlier findings (Vesper et al., 2011) but also demonstrates that this coordination strategy can support coordination in complex, temporally extended actions.

Furthermore, the present study shows that the predictability strategy is predominantly used in situations in which little or no information about the task partner is available. To test this hypothesis, we compared an experimental condition in which co-actors could not see each other (Other Hidden) with one in which visual
information was available (Other Visible). Consistent with our predictions, participants' movements were significantly faster and less variable without visual information and the relation between reaction time, variability, and coordination accuracy was present only in the Other Hidden condition. This confirms that coordination strategies are specific such that they are predominantly employed when other mechanisms like monitoring and predicting another's actions cannot be used.

A third hypothesis was that the employment of strategic behavior modulations would not depend on how the task partner actually performs his or her actions. Therefore, we compared two types of asynchronies: One that we had actually measured (original) and one that we calculated after shuffling the order of task partners' reaction times and randomly matching them again (shuffled). This resulted in a measure of how much each person's action was related to the task partner's actual action performance. Confirming our hypothesis, shuffling the trial order affected coordination significantly less in Other Hidden compared to Other Visible. Thus, when making oneself predictable one's own actions do not or only to a small extent depend on how exactly the task partner performs his or her action.

A possibly surprising result of the current study is that coactors were on average equally well-coordinated in the two joint conditions. Although perceptual information is often beneficial for joint action (e.g. Brennan et al., 2008; Knoblich \& Jordan, 2003; Krych-Appelbaum et al., 2007), this suggests that using a coordination strategy can compensate for a lack of perceptual information. Moreover, given that participants' actions were overall faster and less variable when no perceptual information was available, one might even argue that action performance was better without visual feedback. This is consistent with other evidence that having 'redundant' information potentially impairs joint action coordination. Specifically, when two people who jointly search a workspace not only receive visual information about each other's looking behavior, but can also talk to each other about the task, their search is considerably less efficient than when verbal communication is restricted (Brennan et al., 2008). As an alternative, the present findings might indicate that taking away perceptual information requires co-actors to put in extra effort in order to achieve the same degree of coordination.

How then did co-actors approach the task in the Other Visible condition? Although investigating this in detail is beyond the scope of the present paper, participants most likely used the available visual information to guide their actions either reactively (monitoring the task partner's action, then acting oneself) or predictively (anticipating when the task partner will reach the target and acting in accordance with this prediction). Further experiments could distinguish these two cases, e.g., by measuring participants’ eye movements to determine at what time during the interaction they track their task partner's movements.

The present study has implications beyond human joint action. For instance, an important research topic in the
cognitive sciences is how to implement real-time interaction of a robot and a human user. To that end, mechanisms observed in human social interaction are currently being transferred to robot platforms, including natural-language discourse (Salem et al., 2010), action prediction (Bicho et al., 2011; Dindo, Zambuto, \& Pezzulo, 2011) and continuous movement synchronization (Mörtl et al., 2012). Considering also general strategic behavioral adaptions for human-robot interaction can be beneficial for this endeavor. First, human users might employ a strategy such as making oneself predictable also when interacting with a robot so that coordination would improve if the robot used the same strategy. Second, human users might expect the robot to adapt its movements strategically so that robots that do so would appear more 'human-like' and thereby are more easily accepted as an interaction partner.

Taken together, this study provides evidence that general strategic adaptations of one's own actions can effectively support coordination with other people in situations in which precise representations about the partner's task might not be available. The concept of a coordination strategy therefore complements other approaches towards joint action like those focusing on communication (Clark, 1996), action prediction (Wilson \& Knoblich, 2005) or dynamic perception-action coupling (Marsh et al., 2009).

## Acknowledgments

The research reported in this manuscript was supported by the ESF program EuroUnderstanding. We thank Veronika Herendy for her help in collecting the data.

#### Abstract

Based on the unique traits of biological motion perception, the existence of a "life detector", a special sensitivity to perceiving motion patterns typical for animals, seems to be plausible (Johnson, 2006). Showing motion displays upsidedown or with changes in global structure is known to disturb processing in different ways, but not much is known yet about how inversion affects attention and incidental processing. To examine the perception of upright and inverted point-light walkers regarding incidental processing, we used a flanker paradigm (Eriksen \& Eriksen, 1974) adapted for biological motion (Thornton \& Vuong, 2004), and extended it to include inverted and scrambled figures. Results show that inverted walkers do not evoke incidental processing and they allow high accuracy in performance only when attentional capacities are not diminished. An asymmetrical interaction between upright and inverted figures is found which alludes to qualitatively different pathways of processing.

Keywords: biological motion perception; point-light walker; incidental processing; inversion effect; life detector

## Introduction

An important feature of the visual processing of the dynamic human gestalt in point-light displays is the "automatic" nature of the perceptions. As Johansson (1973) points out, "... we have found that it seems to be a highly mechanical, automatic type of visual data treatment that is most important." While Johansson's use of the term "automatic" points more to the early processes involved in establishing hierarchies of locally rigid perceptual units, there is a case to be made for the automatic processing of biological motion at a higher cognitive level under favorable circumstances, i.e., given an appropriate task. Phenomenally, Johansson's own demonstrations point to the immediateness and vividness of viewing point-light displays of biological motion. Observers are fast and accurate in their identifications when not disrupted by dynamic masking. They appear to have direct access to a level of meaning that facilitates the identification and recognition of actions depicted in the point-light displays. In contrast to upright displays, inverted point-light displays lead to impaired recognition, identification, detection and priming (e.g.,

Bertenthal \& Pinto, 1994; Daems \& Verfaillie, 1999; Hemeren, 2008; Shiffrar \& Pinto, 2002; Troje, 2003).

Previous results have also shown that point-light walkers (PLWs) trigger attention mechanisms (Thornton \& Vuong, 2004). Using a flanker paradigm, Thornton and Vuong (2004) demonstrated incidental processing of upright oriented PLW flankers during judgments of the walking direction of the displays. Upright point-light walkers can elicit incidental processing while static, scrambled or chimeric ones cannot, but in these studies they did not address the question of inversion. Incidental processing was indicated by an increase in the time it took to make direction judgments when the direction of the flankers was incongruent with the direction of the target. The task irrelevant flankers interfered with the visual processing of the target.

Recently, Shi et al. (2010) reported effects of upright PLWs on the accuracy of reporting the perceived direction of a Gabor patch. Accuracy was significantly lower when the walking direction of an upright PLW was incongruent with the orientation of the Gabor patch. Importantly, no such effect was found for inverted PLWs. This suggests the existence of a perceptual cue that triggers reflexive attentional orienting for upright, but not for inverted, PLWs. This is consistent with previous results regarding a general inversion effect and evidence for a "life detector" (see e.g., Johnson, 2006; Troje \& Westhoff, 2006).

In our study, we investigate the differential effects of the orientation of PLWs within the framework of Hochstein and Ahissar's Reverse Hierarchy Theory (2002). The idea here is that the visual quality of biological motion perception for upright displays is indicative of global processing as well as quick access to semantic level representations. Consistent with Hochstein and Ahissar (2002), the perception of inverted displays could be characterized as an example of illusory conjunctions. The perception of inverted displays could be said to demonstrate the effects of top-down processing in the sense that the default value is an upright orientation and this creates false conjunctions in the perception of inverted displays.

This line of reasoning is consistent with the reasoning in Shiffrar, Lichtey \& Heptulla Chatterjee (1997) where they show that global processes are involved in the perception of
upright biological motion displays across apertures but that this global processing is impaired when inverted biological motion displays are viewed across apertures. Their findings show that global processing is associated with viewing upright displays and that local processing is associated with viewing inverted displays.

Given this, we suggest that upright PLWs are incidentally processed on the basis of initial explicit perception as 'vision at a glance,' and it also reflects the activity of large receptive fields of high cortical areas and spread attention of initial perception (Hochstein \& Ahissar, 2002). At the other (low-level) end of the processing continuum, inverted PLWs constitute 'vision with scrutiny' which involves focused attention and the activation of small receptive fields in lower cortical areas.

By extending the flanker paradigm in Thornton and Vuong (2004) to include inverted walkers, we can further address the issue of incidental processing of flankers while performing a direct visual task on a central target. It may be the case that inverted walkers can be incidentally processed when the target is also an inverted walker. This condition can be directly contrasted with upright flankers and an upright target, for which there is already evidence of incidental processing (Thornton \& Vuong, 2004). This study will therefore include a replication of those results. Directional congruence will also be included in this study in order to assess the potential interference or facilitation effects of similar or different walking directions of the targets and flankers.

Here we can investigate the orthogonal pattern of interaction between upright and inverted displays under conditions of orientation congruence and direction congruence. This allows us to potentially see asymmetrical interactions in the way upright and inverted flankers modulate the visual processing of upright and inverted targets.

One obvious prediction from previous findings of the inversion effect is that inverted flankers will have no effect on reaction time or accuracy in detecting the walking direction of an upright target. This is due to the relatively fast and automatic processing of an upright and biologically relevant moving human. The structure of the information in the inverted flankers is not sufficient to modulate the processing of an upright target.

The potential effect of inverted flankers on inverted targets is less obvious to predict. Previous evidence (Hemeren, 2008) shows that inverted PLWs can prime (repetition priming) themselves as well as other inverted point-light actions. Given this evidence, inverted flankers may be incidentally processed because the visual system is active in scanning the available information for clues to resolve the conflicts (false conjunctions) in the inverted targets. This, however, entails that the information in the inverted flankers is relevant. If there is no relevant information, then there will be no incidental processing of inverted displays.

Since upright flankers convey biologically relevant information and are visually processed relatively automatically, we expect them to be incidentally processed when presented with an inverted target. This incidental processing will likely lead to significant interference when judging the walking direction of an inverted target.

The effect of upright flankers on upright targets will likely depend on the congruence of walking direction for the target. Based on results from Thornton and Vuong (2004) we expect the incidental processing of upright flankers to interfere with upright targets when they are walking in different directions (directional incongruence). When they are walking in the same direction (directional congruence), the question is whether the incidental processing of upright flankers will speed up (facilitate) the ability to correctly detect the walking direction of the target in relation to inverted flankers or whether there will be no difference between the effects of upright and inverted flanker on detection time for upright targets.

## Methods

## Participants

Ten right-handed subjects (5 male and 5 female, aged 20 to 49 years, $\mathrm{M}=28.9$, with normal or corrected-to-normal vision) participated in the experiment. Participants were selected from colleagues and the student population of the University of Skövde. All participants were naive to the purpose of the experiment and only the students received monetary compensation (approximately \$15). Participants provided written informed consent. Experiment protocol conformed to Swedish law and the World Medical Association Declaration of Helsinki.

## Stimuli

The stimuli consisted of the target walker $\left(1.26^{\circ} \times 0.74^{\circ}\right)$ displayed in the center surrounded by five distractors evenly placed at a fixed distance from the target $\left(1.89^{\circ}\right)$ with a randomly defined angular offset for the five flankers together. To compensate for the smaller cortical representation of peripheral stimuli, flankers were scaled by a cortical magnification factor (Goolkasian, 1997), thus having the size of $2^{\circ} \times 1.17^{\circ}$. The total size for the whole display was $5.78^{\circ}$. Figures were depicted in profile by 13 dots based on the 3-dimensional coordinates of the action "Walk" from a stimulus set of human point-light actions created by Vanrie \& Verfaillie (2004). For presentation of the stimuli and recording of the answers MatLab R2010a was used on an HP EliteBook 8440p laptop computer. An HP L2245wg monitor ( $1440 \times 900$ pixels, 60 Hz ) displayed the stimuli at 100 cm viewing distance.

In every condition the same figure was mirrored so that there were two possible directions of translation (left and right) and two possible orientations (right-side-up and upside-down). In addition to these four variations, scrambled flankers were created for control by mixing dots randomly chosen from the four conditions and displaying
them with random starting positions, while the total size of the figure was kept equal to the regular flankers. This way, scrambled flankers as a whole did not contain directional or orientation information, while the local motion patterns of the dots remained the same as in the globally intact figures. The four variations of the target and five variations of the flankers resulted in twenty conditions in total (see examples in Figure 1).

Figure 1: Upright target with translation to left and inverted flankers with translation to right (panel A); Inverted target with translation to right and scrambled flankers (panel B).

## Procedure

Participants were informed about that they would see a centrally located PLW (target) either upright or inverted and that flankers would surround the target. They were instructed to just focus on the target and to indicate the walking direction of the target by pressing one of two keys.

Left or right responses were given by key presses with the corresponding index fingers, indicating the direction of translation of the target regardless of its orientation. Participants were instructed as to the importance of the speed and accuracy of their responses. Stimuli were played from a randomly chosen starting frame (randomized between figures as well) in a continuous loop at 30 FPS (stride frequency: 2/s) until the participant responded. Every trial was preceded by an ISI of $500-800 \mathrm{~ms}$, during which a fixation cross $\left(0.23^{\circ}\right)$ marked the center of the display.

Each participant started with a training session of 32 trials. After that, 1440 trials were recorded, divided by arbitrary breaks into three sessions of 480 trials. In one session out of the three, $50 \%$ of the trials contained the scrambled conditions, while the other two sessions were made up of only non-scrambled trials. The order of the sessions varied between participants. This design was necessary to avoid a possible novelty effect of scrambled trials, since their total number was less than the total number of non-scrambled trials. Altogether, 1200 nonscrambled and 240 scrambled trials were completed by each subject, which means 75 trials per each non-scrambled condition and 60 trials per each scrambled condition.

The design of this experiment consisted of four independent variables; Target orientation (upright vs.
inverted), Flanker orientation (upright vs. inverted), Target direction (left vs. right) and Flanker direction (left vs. right). In addition, four conditions of scrambled flankers were created by pairing scrambled flankers with levels of target orientation and direction. Dependent variables are reaction time and accuracy.

## Results

## Reaction Times

Reaction time (RT) data were analyzed only for correct responses, with all outliers exceeding 2 SDs above and below the mean eliminated. Errors (accounting for 2.42 \% of all answers) were analyzed separately. Means generated for each condition and subject were used in a repeatedmeasures ANOVA analysis. Individual conditions in relevant cases were compared with t-tests.

Since the task of the participants was to respond to targets and to ignore the flankers, the amount of influence of the flankers on RTs and accuracy can be accounted for incidental processing of these figures. This is expressed in the walker congruency effect (WCE, Thornton \& Vuong, 2004) which in our case is positive for upright flankers but missing when flankers are inverted, i.e., responses to all targets are faster $(t(9)=5.46, p=0.000)$ when upright flankers have congruent direction of translation ( $M=644.2$ $\mathrm{ms}, S D=79.10$ ) compared to responses on incongruent trials with upright flankers ( $M=683.75 \mathrm{~ms}, S D=76.61$ ), while this difference cannot be found ( $M_{\text {Congruent }}=650.05$, $S D=78.98 ; M_{\text {Incongruent }}=650.55, S D=78.38 ; t(9)=0.15, p=$ 0.886 ) when flankers are inverted (Figure 2).

Figure 2: Walker congruency effect. (RSU = right-side-up, INV $=$ inverted. Asterisks indicate significant differences at $\mathrm{p}<0.05$, error bars show $95 \%$ confidence intervals.)

Regarding the interaction between the processing of upright and inverted biological motion, the RT means for direction judgments as a function of direction congruence and orientation congruence between flankers and targets are presented in Figure 3.

The pattern of results shows that inverted flankers have no effect on reaction times to the target and that these responses are also similar to conditions where the target was surrounded by scrambled flankers (Figure 3).

A $2 \times 2 \times 2 \times 2$ repeated measures ANOVA was carried out on the means. The relevant differences here are between right-side-up and inverted targets, where the inversion effect leads to a significant increase in RTs. The main effect for target inversion was significant, $F(1,9)=40.90$, partial $\eta 2=$ $0.82, p<0.001$. In relation to the error rates displayed in Figure 4, this main effect was not accompanied by a difference in accuracy. Upright flankers had no effect on the accuracy of judging the direction of upright or inverted targets. The difference of flanker influence in this case is restricted to reaction time, not accuracy.

The effect of flanker orientation on reaction time is limited to upright flankers. These distractors show a highly significant interference on inverted targets when their directions are incongruent ( $M=728.30, S D=86.82 ; t(9)=$ $6.51, p<0.001$ ) compared to the effect of inverted flankers in the respective condition $(M=669.45, S D=81.10)$. This effect is smaller but still significant when comparing the same conditions ( $M_{R S U}$ flankers $=682.90, S D=88.41 ; M_{I N V}$ flankers $=670.25, S D=82.10$ ) with congruent direction $(t(9)=$ $2.42, p=0.039$ ).

The effect of upright flankers is different when targets are also upright. In this case we do not see any increase in reaction times even with incongruent directions $\left(M_{R S U}\right.$ ${ }_{\text {flankers }}=639.20, S D=69.60 ; M_{\text {INV flankers }}=631.65, S D=78.00$; $t(9)=1.55, p=0.156)$, although the higher error rates show that flankers are processed and they affect the accuracy of responses ( $M_{R S U}$ flankers $=3.71, S D=3.49 ; M_{I N V}$ flankers $=1.89$, $S D=2.87 ; t(9)=2.29, p=0.047)$. When directions are congruent however, the effect of upright flankers on upright targets becomes facilitative: RTs are significantly lowered compared to the corresponding condition with inverted flankers $\left(M_{R S U}\right.$ flankers $=605.50, S D=72.92 ; M_{I N V}$ flankers $=$ $629.85, S D=79.21 ; t(9)=7.90, p=0.000)$. This relative facilitation however does not appear when compared to the effect of scrambled flankers $\left(M_{\text {Scrambled flankers }}=624.45, S D=\right.$ $76.14 ; t(9)=1.45, p=0.182$ ). This shows that upright flankers are processed to an extent that seems to occur in parallel to the upright targets. This is only the case when the direction of upright flankers and targets is congruent.

In contrast to the reaction times, the error rates in the case of relative facilitation stayed unchanged ( $M_{R S U}$ flankers $=1.24$, $S D=1.79$ ), compared to conditions either with inverted ( $M$ $=1.29, S D=2.52 ; t(9)=0.14, p=0.89)$ or scrambled flankers $(M=1.58, S D=2.31 ; t(9)=0.65, p=0.533)$. Accuracy is therefore not affected by flankers when directions are congruent, only in incongruent conditions and with upright flankers.

Figure 3: Conditions across orientation and direction of translation. (RSU = right-side-up, INV = inverted, $\mathrm{Sc}=$ scrambled. Asterisks indicate significant differences at $\mathrm{p}<0.05$, error bars show $95 \%$ confidence intervals.)

Figure 4: Errors. (RSU = right-side-up, INV = inverted, Sc $=$ scrambled. Asterisks indicate significant differences at $\mathrm{p}<0.05$, error bars show $95 \%$ confidence intervals.)

## Discussion

Our results show that inverted biological motion does not elicit incidental processing and even more importantly, upright and inverted point-light walkers have substantially different attention demands. Subjects are only required to respond to targets, and thus the processing of flankers happens without active top-down control. Nevertheless, upright flankers have significant effects on the responses to targets, the effect of which is different depending on the
orientation of the target. When both the target and the flankers are upright, reflexive attention seems to be drawn to both, thus resulting in either a relative facilitation in RTs (seen in the case of congruent directions) or in interference leading to higher error rates (incongruent directions). This interference shows the processing of both the target and flankers reach the level of subtracting directional information by the starting of the response. However, this does not lead to higher RTs - which may be due to the reflexive manner of the response to the target as well, allowing the two processes to run in a parallel manner.

When targets are inverted, they require more top-down control, and there is no incidental processing which indicates that attention is directed to them in a reflexive manner. The amount of attention incidentally drawn by the upright flankers leads to faster processing of the distractors, thus always interfering with the processing of inverted targets and leading to higher RTs. Furthermore when the two processes involve handling incongruent direction between flankers and targets, error rates become higher as well.

In terms of Hochstein and Ahissar's RHT (2002), these results suggest that the visual processing of upright human point-light walkers is consistent with vision at a glance since upright flankers not only interfere with the visual processing of inverted displays but that they can also modulate the visual processing of upright centrally displayed targets. In addition to the results for the speed of visual processing (RT-results), this interpretation is strengthened by the increase in the error rate for upright targets when the direction of upright flankers is in conflict with the target.

It is important to emphasize that RHT is not restricted to perceptual learning as such but applies to perception in general (Ahissar \& Hochstein, 2004). PLWs are salient examples of dynamic gestalt figures, which also include other action categories (e.g., Hemeren, 2008). The original findings from Johansson (1973) demonstrate that when presented with a static form, people have difficulty in identifying the figure and action. However, once the figure starts to move, people see the action that the person is performing. Much previous research (see e.g., Shiffrar \& Pinto, 2002) demonstrates the holistic/global processing involved in the visual perception of point-light displays of biological motion. From a perceptual learning perspective, biological motion perception is an example of the Eureka effect (Ahissar \& Hochstein, 2004), in which learning is governed by top-down control and single exposures and has long-lasting effects.

In contrast to upright targets and flankers, the results for inverted flankers in relation to inverted and upright targets indicate visual processing consistent with vision with scrutiny. There appears to be no access to high-level perceptual meaning that would trigger reflexive attention and lead to incidental processing. Although there is evidence of perceptual learning for inverted displays of biological motion (Grossman, Blake \& Kim, 2004), learning
is relatively difficult in terms of time taken and the ability to discriminate between different action categories depicted in the point-light displays (Hemeren, 2008). Inverted displays are perceptually difficult to resolve, i.e., they have no perceptually obvious ecological relevance. When confronted with this situation, visual processing is guided down the processing hierarchy where more local processing of the stimulus is carried out in order to find a solution to the perceptual problem. This requires the activation of small receptive fields in lower cortical areas. This takes additional time and is also prone to an increase in perceptual errors. If incidental processing of upright PLWs is evidence of a life detector (Johnson, 2006; Troje \& Westhoff, 2006), then it also shows that it also occurs at a high cortical level.

Recently, Ikeda, Watanabe and Cavanagh (2013) used a horizontal flanking paradigm to investigate the effect of the distance of upright PLWs and scrambled PLWs to upright PLW targets. Consistent with our results, they found that direction discrimination became more difficult with smaller distances between the flankers and the target. It is important to note that the conditions in their experiment were all directionally incongruent between flankers and targets. Ikeda et al. (2013) assert that their results show that the "crowding" effect occurs at a high-level of motion perception since the effect was absent when scrambled flankers were used.

An additional perspective on our results can be seen in the work of Vicario and Kiritani (1999) where the issue can be described as a matter of a vertical organization of visual events, i.e., determining what rules apply if simultaneous stimuli are perceived as one object (integration) or as different objects (segregation). In our case the relevant traits of the point-lights influencing this judgment seem to be: the amount and direction of displacement, speed and acceleration patterns and the variability in distance from neighboring dots. These traits are comparable with the Gestalt principles; however, it is not clear how they can unequivocally explain the inversion effect. One possibility is through the congruency or incongruency between acceleration patterns of the dots presented and acceleration patterns normally determined by gravity (this approach is discussed in detail by Chang and Troje, 2009). Another possibility is that an additional Gestalt principle is playing a role here, which leads to an effortless and fast form-frommotion perception of human figures, when the emerging form matches the usual human body configuration (i.e. it is walking with the right side up). Presumably both mechanisms are important in the inversion effect with pointlight walkers (Hirai, Chang, Saunders \& Troje, 2011).

Our results suggest that people have implicit access to initial high-level meaning for upright PLWs and that this access can be reflexively triggered when a visual target is difficult to perceptually resolve or when simultaneously presented PLWs are incongruent with regard to a relevant visual task.

# The Role of Circadian Variations and Socially Distributed Thinking in Belief Perseverance 

Gaëlle Villejoubert (G.Villejoubert@kingston.ac.uk)<br>Madiha Khan (k0801532@kingston.ac.uk)<br>Frédéric Vallée-Tourangeau (F.Vallee-Tourangeau@kingston.ac.uk)<br>Department of Psychology, Penrhyn road<br>Kingston upon Thames, KT1 2EE United Kingdom

#### Abstract

From the moment they make up their mind, people are reluctant to change it. We tested the hypothesis that people disposing of more cognitive resources-through circadian variations or socially distributed thinking-would engage in deliberative thinking and would consequently be less likely to exhibit belief perseverance. Perseverance was measured by the change in judgments related to a suspect in a criminal case, following the presentation of an offender profile that was at odds with the suspect's description. Individuals tested at a compatible circadian time exhibited less perseverance in the face of contradictory evidence compared to individuals tested at an incongruent time. Individuals deliberating on their own also tended to show more belief perseverance compared to those who worked in groups. There was, however, no interaction effect between circadian timing and condition of deliberation on belief change. The implications for our understanding of the mechanisms that underpin belief perseverance are discussed.

Keywords: Belief perseverance; Dual-process accounts of cognition; Circadian variations; Socially distributed cognition.

## Introduction

Despite the public release of his birth certificate, a 2011 Gallup poll published by USA Today revealed that only $38 \%$ of Americans definitely believed President Obama was born in the US (Adams, 2011). Although the President was reportedly "puzzled" by the persistence of these rumors, this incident illustrates a well-established finding in psychological science: it is easier to get people to believe something new than to get them to abandon an existing belief even in the face of indisputable evidence to the contrary-a phenomenon known as belief perseverance (Ross, Lepper \& Hubbard, 1975).

Belief perseverance may concern beliefs about one's own skills and abilities, those of others, as well as naïve theories about stereotypical traits and behaviors (Anderson, 2007). In their seminal study of perseverance in social perception, Ross et al. (1975) presented a series of cards containing a real and a fictitious suicide note and asked participants to decide which note was written by a patient with suicidal ideation. Participants first received false feedback on their performance and were later debriefed on the arbitrary nature of the feedback they received. Yet, when participants were asked to reassess their performance after the thorough debriefing, those judgments remained strongly influenced by the initial spurious test results they had received.

A combination of three types of cognitive processes have been implicated in the perseverance of beliefs (Anderson \& Lindsay, 1998): the availability heuristic, its associated illusory correlation effect, and the anchoring and adjustment heuristic (Tversky \& Kahneman, 1974). Events such as a performance appraisal or the observation of a person's behavior are presumed to initiate the generation of a causal explanation (e.g., "I am (un)skilled at this task"). This new belief thereafter remains available in memory, independently of the inceptive evidence such that when the evidence is discredited, the belief remains intact (Anderson, Lepper, \& Ross, 1980).

Attempts to alleviate belief perseverance have been met with mitigated success. The most effective approach has been to encourage individuals to consider alternative causal explanations-counterexplanations-in an effort to reduce the influence of the inceptive belief (Anderson, 1982, 2007). Yet, considering alternatives may sometimes backfire. When individuals are given the opportunity to discount negative evidence, for example by plausibly discrediting it, the availability of counterexplanations no longer reduces belief perseverance (Vallée-Tourangeau, Beynon, \& James, 2000). Moreoever, perseverance is aggravated when evidence for the alternative explanation is difficult to elicit or when evidence for the target hypothesis is easily accessible (Nestler, 2010).

The mitigated success of the counterexplanation account, we wish to argue, can be best accounted for within a dualprocess framework. The dual-process view of cognition has gained considerable influence in the past decade in research examining judgment, decision-making or reasoning (e.g., see Darlow \& Sloman, 2010 for a review) but has yet to be applied to the study of belief perseverance. According to this view, two families of cognitive processes may underpin judgments and decisions: an intuitive mode of cognitive functioning-where judgments originate from rapid and automatic processes-and a second, more deliberate and effortful mode of thinking engaging processes which can either be at the origin of the judgment provided or simply monitor its quality (Kahneman, 2003). The type of heuristic processing that is taken to underpin belief perseverance is a trademark of the intuitive heuristic mode of thinking. This suggests that any situation either favoring deliberative thinking or augmenting deliberative thinking capacity should lead to a decrease in belief perseverance. We examine this possibility by investigating the role of two
variations in cognitive resources on belief perseverance: circadian preferences and socially distributed thinking.

Several studies have demonstrated that the efficiency of executive control-a key feature of deliberative thinkingis contingent upon the synchronicity between people's peak period of circadian arousal and the time of testing (for a review, see Schmidt, Collette, Cajochen, \& Peigneux, 2010). For example, West, Murphy, Armilio, Craik and Stuss (2002) used a choice reaction time task placing variable demands upon working memory: individuals were asked to identify and respond to the spatial location of a target presented in a previous display either with or without a distractor that they had to ignore. Time-of-day variations had an effect on performance, but only when more controlled processes were involved (e.g., when a distractor had to be inhibited); performance on simpler trials requiring automatic processes was unaffected by circadian variations. Schmidt et al. (2010) reviewed this and other studies pointing to similar results and concluded that cognitive functioning at nonoptimal time of day was typically associated with failure to clear or suppress irrelevant information and difficulties to resist predominant responses even if they are incorrect. For example, Bodenhausen (1990) showed that people were less likely to rely on stereotypic preconceptions when rendering judgments at a time of day that was congruent with their circadian preferences.

From a dual-process perspective, these results suggest that circadian congruence fosters the optimal deployment of cognitive resources, enabling people to engage in more effortful deliberative thinking. In turn, circadian incongruence encourages more heuristic and less effortful thinking, and hence lead people to unquestionably rely on established beliefs and stereotypic preconceptions. In light of the importance of circadian congruence for effortful deliberation, we hypothesized that belief change should be greater in a task where people are asked to revise a prior belief in light of new conflicting evidence at a time congruent with their circadian preference.

If depleted cognitive resources lead to belief perseverance, augmenting those resources may counteract the effect of circadian variations. We tested this possibility by examining the impact of socially distributed cognition on belief perseverance. From a distributed cognition perspective, cognitive functioning is conceived as taking place in a system including resources and operations that are distributed across time, material artefacts as well as people (Hollan, Hutchins, \& Kirsh, 2000; Villejoubert \& ValléeTourangeau, 2011). From this perspective, interactivity acts as a cognitive scaffold, resulting in improved performance. For example, we showed that when participants could interact with physical matchsticks in a matchstick algebra problem, they were more likely to achieve insight compared to those for whom matchsticks were drawn on paper (Weller, Villejoubert, \& Vallée-Tourangeau, 2011; see also Vallée-Tourangeau, Euden, \& Hearn, 2011).

Unlike material distribution, the contribution of socially distributed resources for performing a cognitive task remains debated, however; with wealth of evidence showing that performance may be both weakened or strengthened when cognition is shared in a group (Larson, 2010). Group performance may vary depending on the fit between members' cognitive resources and the cognitive demands of the task, how resources are distributed, and process costs arising from group interactions (Steiner, 1972). On the one hand, groups may benefit from the potential to generate a more diverse range of interpretations and counterexplanations than would individuals (Hutchins, 1991). For example, multiple-cue judgments were shown to be more accurate when they originated from dyads rather than individuals (Olsson, Juslin, \& Olsson, 2006). Yet, it is not clear that groups will always be in a better position to engage in deliberative thinking as the superiority of groups may also depend on the cognitive resources they have at their disposal (Hutchins, 1991). This suggests, for example, that groups composed of individuals with limited cognitive resources may function worse than individuals, exhibiting more heuristic thinking and "groupthink" (Janis, 1982) whereas groups composed of members at the peak of their cognitive functioning may outperform individuals.

Our study was therefore also designed to examine whether the amount of cognitive resources available to individuals in a group (manipulated through circadian variations) would affect group performance. We expected that groups would exhibit less belief perseverance than individuals when they were made of individuals tested at their best period of circadian arousal. Conversely, we expected belief perseverance to be more pronounced in groups than in individuals when groups were composed of individuals tested at an incongruent circadian time.

## The Present Study

The present study investigated the cognitive processes that underpin belief perseverance by examining the moderating role of circadian variations and socially distributed thinking. It used a forensic scenario where participants were asked to revise their initial judgment of the extent to which a stereotypical suspect was guilty of an offense, after being presented with counterevidence in the form of an atypical offender profile written by an expert profiler. Guilt judgments were produced either by small groups of three participants or by individual participants. Half of the individual participants and groups were tested at a time that was congruent with their optimal circadian preference; the rest were tested at an incongruent time. Building upon previous research on the role of circadian variations on thinking mode, we expected that people who were tested at an incongruent time would exhibit greater belief perseverance because their limited cognitive resources should favor a heuristic mode of thinking. We also explored the role of socially distributed thinking on belief perseverance and hypothesized that the relative performance of groups compared to individuals would depend on
whether or not groups were composed of members functioning at their optimal time of circadian arousal: groups of individuals tested at a congruent time were expected to revise their guilt judgment to a greater extent than individuals while groups of individuals tested at an incongruent time were expected to persevere more in their belief of guilt compared to individuals.

## Method

## Participants

A total of 129 students and administrative staff were recruited on the campus of Kingston University. They were either tested individually ( $N=32$, Mean age $=29$ years, $S D$ $=12.85,22$ women) or in one of 32 small groups made of three to four individuals (see Table 1 for group demographics).

Table 1: Group demographics.

| Group type | $N$ | Mean age $(S D)$ |
| :--- | ---: | :---: |
| Women only | 5 | $25(9.33)$ |
| Men only | 3 | $22(2.46)$ |
| Mixed $(2 \mathrm{~W} / 1 \mathrm{M})$ | 12 | $23(6.65)$ |
| Mixed $(1 \mathrm{~W} / 2 \mathrm{M})$ | 12 | $23(5.60)$ |
| Total | 32 | $23(6.48)$ |

## Design

The experiment used a $2 \times 2 \times 2$ mixed design. The between-subject independent variables were the time of testing (circadian-congruent or circadian-incongruent) and testing condition (individually or in small groups). The within-subject independent variable was the time of judgment (before or after the presentation of disconfirming information). Participants were randomly allocated to one of the resulting four conditions.

## Procedure

Participants were invited to take part in a study examining how jurors make decisions in various circumstances. Participants' circadian type was assessed using the abridged English Version of Morningness-Eveningness questionnaire (rH\&O, Chelminki et al., 2000). They were categorized as either Morning (M) types or Evening (E) types on the basis of a median split of their scores. M-types scored significantly higher on the Morningness-Eveningness dimension compared to E-types; $M_{\text {M-types }}=17.00(S D=$ 3.36), $N=34, M_{\mathrm{E}-\mathrm{types}}=11.57(S D=1.36), N=30, t(64)=$ 7.31, $p<.001$. All participants were then reconvened to complete a small questionnaire. Half of the participants were tested at a time that was congruent with their circadian preferences (M-types tested between 10am and 12noon and E-types tested between 1 pm and 5 pm ) while the remaining half was tested at an incongruent time. Participants were asked, on their own or in a small group, to read a brief description of a criminal case involving a series of sexual assaults against young girls, followed by a stereotypical
description of a suspected child molester (e.g., a 44-year-old white male, unemployed, lonely and morally deviant). Lastly, they read an atypical offender profile by a forensic expert, which listed characteristics informed by actual statistics for this kind of offender although at odds with the stereotypical suspect description (e.g., "In most crimes of this nature the offender is employed in some form of skilled or office job"; see Marshall and Alison, 2007, for the complete descriptions). Participants tested in groups were invited to read the case information on their own and thereafter discuss the case between themselves before reporting a unique group estimate for each of the variables measured.

## Measures

Participants were asked to consider the case and rate the degree to which the suspect may be guilty and the degree to which they felt confident that their judgment was correct ( $1=$ not at all, $10=$ completely ) both before and after the presentation of the atypical profile. Finally, participants were asked to rate their level of involvement in the case ( $1=$ none, $10=$ greatly) and how difficult it was to make a decision ( $1=$ not at all, $10=$ very ) before they were debriefed and thanked for their participation.

## Results

## Manipulation Checks

Participants tested at a congruent circadian time reported a slightly higher level of involvement in the task, $M_{\text {congruent }}=6.55, S D=2.36$ vs. $M_{\text {incongruent }}=5.88, S D=2.56$, as well as higher levels of difficulty, $M_{\text {congruent }}=6.23$, $S D=2.35$ vs. $M_{\text {incongruent }}=5.74, S D=2.21$. Possibly due to lack of statistical power, however, neither difference reached statistical significance; $t(62)=1.08, p=.14$, onetailed, Cohen's $d=0.27$ for involvement, and $t(62)=0.87, p$ $=.19$, one-tailed, Cohen's $d=0.22$ for difficulty.

## Guilt Judgments

The theoretically important patterns in these data are (i) the effect of time of judgment (before or after the presentation of the profile), which captured the degree to which participants, regardless of circadian congruence or grouping, changed their guilt ratings after seeing the atypical offender profile; (ii) the interaction between circadian congruence and time of ratings (see Fig. 1); (iii) the interaction between group and time of ratings (see Fig. 2); and finally (iv) the interaction between circadian congruence and group (see Fig. 3).

Guilt judgment data were analyzed with a 2 (circadiancongruent vs. circadian-incongruent) $\times 2$ (individual vs. group) $\times 2$ (before vs. after the atypical profile presentation) mixed analysis of variance (ANOVA). The main effect of time of testing (congruent or incongruent with circadian preferences) was not significant, $F<1$, nor was the main effect of testing condition (individually or in small group), $F(1,60)=1.25$. However, there was a significant main
effect of the time of judgment, $M_{\text {before }}=7.26(S D=1.52) \mathrm{vs}$. $M_{\text {after }}=5.44(S D=2.07), F(1,60)=47.23, M S E=2.35, p<$ $.001, \eta_{\mathrm{p}}^{2}=.44$. There was also a significant interaction between circadian time of testing and the time of judgment, as Figure 1 illustrates, $F(1,60)=4.65, p=.04, \eta_{\mathrm{p}}^{2}=.07$. Guilt judgments were significantly revised downwards both at circadian-congruent times, $t(29)=6.02, p<.001$, and at circadian-incongruent times, $t(33)=3.46, p=.002$. However, as anticipated, the difference in pre- and postprofile judgments was significantly smaller, indicative of more belief perseverance, under circadian-incongruent time of testing, $t(62)=-2.13, p=.02$, one-tailed.

Figure 1: Mean judgments of the extent to which the suspect may be guilty before and after the presentation of the atypical offender profile, as a function of time of testing (circadian congruent or incongruent)

Figure 2: Mean judgments of the extent to which the suspect may be guilty before and after the presentation of the atypical offender profile, as a function of testing condition (individual or group)

The interaction between time of judgment (before or after the presentation of the profile) and testing condition was also marginally significant, $F(1,60)=3.44, p=.07, \eta_{\mathrm{p}}^{2}=$ .05. Both judgments made by individuals, $t(31)=3.20, p=$ .003 , and those made by groups, $t(31)=6.36, p<.001$, were significantly revised downwards after the presentation of the atypical profile (see Fig. 2). However, the amount of belief revision was larger in group judgments, $t(62)=1.81, p=$ .04, one-tailed.

Of less theoretical interest, the effect of testing condition on guilt judgments collapsed across time of testing was also moderated by circadian congruency, $F(1,60)=4.50, M S E=$ $3.89, p=.04, \eta_{p}^{2}=.07$ (see Fig. 3). Unplanned post-hoc tests (with a Bonferroni-corrected $\alpha$ set at .0125) revealed that testing condition did not affect overall guilt judgments when participants were tested at a congruent time, $t(28)=-$ .61. However, guilt judgments made individually were significantly higher than those made in groups when participants were tested at an incongruent time, $t(32)=2.72$. These results show that individual and group guilt judgments collapsed across time of testing were indistinguishable when produced at circadian congruent times whereas individual judgments of guilt were more pronounced than group judgments at incongruent circadian times.

Figure 3: Mean overall judgments of the extent to which the suspect may be guilty as a function of time of testing and testing condition

Finally, the three-way interaction term was not significant, $F<1$. As Figure 4 illustrates, the effect of circadian time congruency on belief revision was the same for individuals and for groups, albeit groups tended to revise their judgments to a greater extent compared to individuals, in line with the findings reported above.

Figure 4: Mean proportion of belief change as a function of time of testing and testing condition

## Discussion

This study aimed to shed new light on the mitigated success of the counterexplanation approach to reduce belief perseverance. We proposed that belief perseverance originated from a heuristic mode of cognitive processing whereas belief revision demanded an effortful, deliberative processing of the task information, more taxing in cognitive resources. This assumption led us to hypothesize that belief perseverance would be less likely to occur in situations where cognitive resources were unconstrained. We examined two such situations: times when individuals' period of circadian arousal was at its peak and situations when individuals' cognitive resources may be augmented by socially distributed thinking.

Our findings confirmed that the degree of belief persistence in the suspect's guilt after the profile presentation was moderated by circadian congruency: when tested at a congruent time, participants exhibited less belief persistence-that is, they revised their guilt judgment to a greater extent-than when they were tested at an incongruent time. Contrary to what one might expect from the groupthink perspective, but in line with predictions from the distributed cognition perspective, group judgments tended to exhibit less belief perseverance in the suspect's guilt after presentation of the atypical profile-judgments made in groups were revised more substantially than individual judgments. There was, however, no interaction between circadian time of testing and testing condition: group judgments exhibited less belief perseverance than individual judgments, both at congruent and incongruent circadian times of testing.

These findings contribute to our understanding of the cognitive mechanisms that may underpin belief perseverance. They suggest that belief perseverance is not only a consequence of the content of thought-for example, the availability of reasons for or against a target belief or a counterexplanation (Anderson, 1982, 2008)-but is also influenced by the cognitive resources available to individuals, which in turn determine the mode of thought they can apply to the task. As such, this study provides empirical support for the claim that belief perseverance arises from a heuristic mode of thinking since perseverance was more marked when cognitive resources were limited, thus inhibiting a more effortful and deliberative processing of the task. More importantly, simply increasing the pool of cognitive resources available to process the task-either by testing individuals at their peak circadian time or by allowing them to distribute cognitive resources in a social system-was sufficient to significantly reduce belief perseverance.

The fact that we found no evidence of "groupthink" when groups were tested at incongruent circadian times may suggest that the increased pool of cognitive resources offered by socially distributed thinking remained sufficient to counteract heuristic thinking. Distributed thinking enhances cognitive power by, notably, lowering the cost of sense making. According to Kirsh (2010), distributed
thinking involves three cost structures: the cost of mental operations, the cost of outer operations-in the present research, most typically exemplified by the speech acts (Austin, Urmson, \& Sbisà 1975) performed by the group members-and the coupling cost of coordinating these inner and outer processes. This suggests in turn, that the superior performance of groups tested at incongruent circadian times occurred because the benefits of socially distributing thinking continued to outweigh the cost of inner cognitive processes and the coupling costs. Future research may shed light on this possibility by increasing coupling costs. One strategy to do so could be to distribute the information about the suspect and the profile between group members as opposed to present all information to all members, as was the case in this study; this would require group members to engage in the coordination of evidence, and this added cost might eliminate the superior performance of groups in incongruent circadian conditions.

Finally, our findings also have implications for past accounts of belief perseverance. They suggest that instructions to consider counterexplanations may succeed by inviting deeper processing of the belief revision task and may fail when the cognitive cost of this type of processing is either too high or when individuals' cognitive resources are depleted. Alternative accounts (e.g., Nestler, 2010; Sanna, Schwarz, \& Stocker, 2002) have suggested that judgments are mediated by metacognitive feelings of difficulty. For instance, Nestler (2010) suggested that individuals infer the likelihood of the truth of an outcomebe it the target belief or the counterexplanation-from the difficulty they experience in generating many reasons for (or against) this outcome. This metacognitive explanation does not seem to be supported by our present results: if anything, individuals tended to perceive the task as more difficult when they were tested at congruent circadian times and yet, this was also when they exhibited less belief perseverance.

Future research may thus benefit from disentangling the respective impact of metacognitive feelings of difficulty and mode of thinking. Specifically, an alternative account of Nestler's (2010) findings could be made in terms of the cognitive demands of the task and their impact on the mode of thinking elicited. Prompting for a few reasons in favor of the target belief may be the least demanding and thus unlikely to engage a deliberative mode of thinking. Prompting for many reasons supporting the target belief or prompting for a few reasons supporting the alternative hypothesis might be sufficient to engage more deliberative processes and, as a result, reduce belief perseverance. But prompting for many reasons supporting the alternative explanation may be too taxing in cognitive resources: it entails holding both the target and alternative hypothesis in working memory while also exerting efforts to find a large amount of evidence for the alternative hypothesis. Unless they are motivated to do so, people will more naturally consider multiple evidence in support of one hypothesis rather than establishing the diagnostic value of a single
piece of information for two hypotheses (Villejoubert \& Vallée-Tourangeau, 2012). The increasing demand on cognitive resources in this instance could thus have led to cognitive overload, causing people to revert to a heuristic mode of thinking and, as a result, exhibit more belief perseverance.

To conclude, employing circadian congruence as a proxy for the cognitive resources available to perform a judgment task, this research suggests that belief perseverance results from an intuitive mode of thinking. Contrary to what might be anticipated by the groupthink perspective, however, depleted cognitive resources in a group setting did not affect belief perseverance. This suggests that socially distributed thinking may help to counteract the detrimental effect of cognitive depletion.

# How does emotional content affect lexical processing? 

David Vinson, Marta Ponari \& Gabriella Vigliocco<br>\{d.vinson, m.ponari, g.vigliocco\}@ucl.ac.uk<br>Cognitive, Perceptual and Brain Sciences, University College London<br>Gower Street, London WC1E 6BT United Kingdom

#### Abstract

It is now generally accepted that words' emotional content plays a role in lexical processing, but the literature offers incompatible findings concerning what this role may be. Here we use a large sample of lexical decision data (British Lexicon Project, Keuleers et al., 2012) and we carry out a series of analyses differing in the way emotional variables are treated. A variety of statistical approaches yielded common conclusions: when confounding variables are taken into account, emotional words, whether positive or negative, are processed faster than neutral words. This effect is categorical rather than graded; is not modulated by emotional arousal; and is not limited to words explicitly referring to emotions. We discuss this in terms of internally grounding words' meanings in emotional experience, akin to the manner in which concepts may be grounded in perception and action.

Keywords: emotion; valence; lexical decision.

## Introduction

In mainstream lexical processing studies, emotional content has been largely ignored, whether considered irrelevant to the core meanings of words, or as properties of narrowly defined sets of words explicitly referring to emotions (e.g. Altarriba \& Bauer, 2004). Recently, however, a number of studies of lexical processing effectively demonstrated that emotional content plays a role even in shallow tasks involving single words such as lexical decision (e.g. Estes \& Adelman 2008a,b; Kousta, Vinson \& Vigliocco, 2009; Kousta, et al., 2011; Larsen, et al., 2008).

As a result, language processing researchers have begun to acknowledge the interplay between emotion and language processing systems, discussing emotional effects in language processing as due to the embodied nature of linguistic representations (e.g. Kousta et al., 2011; Moseley, et al., 2012; Vigliocco et al., 2009), just as researchers in other domains of cognition have posited embodied emotional effects (e.g. Pistoia et al., 2010). However, precisely which mechanisms are involved in emotional processing is unclear at the present. This is because different studies of lexical processing have found different and apparently incompatible results even when the same task (e.g., lexical decision) is used.

It has been shown that previously reported effects of emotional valence (i.e. numeric ratings indicating the extent to which a word is positive, neutral or negative) can change dramatically once confounding variables such as length, frequency and orthographic neighbourhood size are taken into account (Larsen, Mercer \& Balota, 2006). However, even after controlling for non-emotional variables, results are conflicting. Estes \& Adelman (2008a,b) and Larsen et al (2008) reported slower lexical decision reaction times (RTs)
for negative than positive words. This has been interpreted in terms of attentional vigilance: heightened and/or extended attention to negative stimuli (e.g. Fox et al., 2001; Pratto \& John, 1991) which would slow any decision (such as lexical decisions) on other aspects of the stimuli. In contrast, Kousta et al. (2009) found a processing advantage for both negative and positive over neutral words, which they explain in terms of greater motivational relevance of emotionally loaded stimuli (e.g. Lang, Bradley \& Cuthbert, 1997). Kousta et al argued that the discrepancy in findings was due to the relative lack of neutral words in the data sets tested previously, but especially due to the lack of control of potentially confounding variables, such as ratings of familiarity and age of acquisition (AoA) in previous studies.

In addition, Larsen et al (2008) found that the effect of valence was modulated by the arousal of words such that a negative disadvantage was present for medium-low arousing words, but no effect was observed for highly arousing negative words, Estes and Adelman (2008b) argued for a far more constrained role of arousal, and Kousta et al. (2009) argued that valence effects could not be explained in terms of arousal (although these authors did not explicitly test for valence $\times$ arousal interactions).

All of these previous studies were conducted using lexical decision data from a single source: the English Lexicon Project (ELP, Balota et al., 2007), so in addition to questions about the different assumptions and approaches taken by previous authors, one may also wonder about the extent to which the findings may be related to quirks of that particular item set. Here we take advantage of an entirely independently obtained large-scale set of lexical decision data (British Lexicon Project (BLP): Keuleers, Lacey, Rastle \& Brysbaert, 2012), to try and resolve these questions. Our analyses compare models based on different a priori theoretical assumptions concerning the role of valence in word processing, controlling non-emotional variables known to affect lexical decision RTs. We begin by fitting baseline models in which all the non-emotional predictors mentioned above are taken into account, then add specific terms embedding different assumptions about the role of valence. Such an approach is essential in order to test theoretical accounts of emotion effects in lexical processing.

After assessing how well different measures of valence perform after taking baseline variables into account, we move on to evaluating the role of other aspects of emotional content besides just valence, assessing the extent to which valence effects may instead be explained or modulated in terms of arousal. Finally, we test whether the effects of emotional valence differ for words specifically referring to emotional experience, vs. words that are only valenced.

## Materials and methods

## Data

From the full set of words in the BLP, we selected those 1374 words for which valence ratings were available from ANEW (Bradley \& Lang, 1999), or from the additional ratings described in Kousta et al., 2009, 2011). Next, we filtered out those words for which BLP participants were extremely inaccurate on making lexical decisions: those with overall accuracy less than $67 \%$ in the BLP ( $n=56$, e.g. larkspur, dryad, godhead). This is an important step not employed in previous studies, as widely unfamiliar words are likely to elicit slow RTs, and to receive neutral valence ratings from participants. Finally, we removed five words for which concreteness and imageability ratings were not available, leaving 1313 words for analysis. Of these, 856 were in common with the set from the ELP which Kousta et al. (2009) analysed.

## Measures of emotional valence

We centred the scale of the original valence ratings which ranged from 1-9, so as to range from -4 (most negative) to +4 (most positive) with 0 reflecting neutrality. We then created the following measures that embed different theoretical assumptions concerning valence. The most essential distinction concerns the direction of valence effects as this differentiates between highly distinct accounts of emotion processing. If the crucial distinction is between negative words and other words, this would favour attentional vigilance or other negativity-bias accounts of emotion processing; but if instead the crucial distinction is between emotionally valenced and neutral words, it would favour motivational accounts of emotion processing.
In addition, we compare models in which valence is considered as a continuous measure, vs. models in which it is discretized, as a test of previous claims that effects of emotion should be considered all-or-nothing (e.g. Estes \& Adelman, 2008a,b).

Continuous valence These measures treat valence as a graded measure varying from most negative (-4) through neutral (0) to most positive ( +4 ).
Linear measure includes only the linear relationship between valence and RT. If negative words are slower than other words (e.g. Estes \& Adelman, 2008a,b; Larsen et al., 2008), we expect to find a negative slope (RTs decrease with increasing valence).
Polynomial measure includes linear and quadratic components of valence. ${ }^{1}$ If valenced words are faster than neutral words with no difference between positive and

[^245]negative (e.g. Kousta et al., 2009) we expect a negative quadratic coefficient while the linear coefficient would offer no further benefit.

Discrete valence These measures treat valence as categorical rather than continuous/graded.
