First, SF problems (or any problem, for that matter) consist of a set of surface details and an underlying relational structure. SF systems all adhere to the same structure: If the inflow exceeds the outflow, the stock increases and vice versa. Even though the SF structure is simple, "seeing" it is not, but is nevertheless crucial for problem-solving. Because local processing means searching for details, whereas global processing means searching for structural relations (Förster, 2009; Love et al., 1999), we expect global processing to be beneficial for detecting the SF structure and thus for problem solving.
Second, global processing was found to be connected to more superordinate category-use (Förster \& Dannenberg, 2010). Because processing in concrete and narrow categories (e.g., "In minute five, eight people enter, and in minute six, two people enter") represents an erroneous strategy, whereas processing in abstract and broad categories (e.g., "Overall, more people enter than leave") represents a helpful strategy for making inferences about the overall system behavior such as the stock, we expect global processing to be beneficial for problem solving.
The typical SF paradigm may arguably have primed local perceptual processing, however, because local features such as specific numbers of people were highly salient (Fig. 1). Participants might therefore get the impression that exact numbers need to be retrieved and worked with, thus using local processing. In our reasoning, however, it should be beneficial to induce the impression that specific numbers are merely constituent elements, and that the overall figure, the gist of the display needs to be perceived. Since in the Navon-letter-task, it was found that manipulating the relative salience of the local versus the global form triggered local versus global perceptual processing (see Kimchi, 1992, for a review), we expect a task format highlighting surface
elements (local format) to induce local processing and therefore to be detrimental, and a task format highlighting structure (global format) to induce global processing and therefore to be beneficial for SF performance.

Figure 1. Original department store task format as used in Cronin, Gonzalez and Sterman (2009).

In sum, we expect a connection between global-local processing and stock-flow reasoning. Our test of this assumption is threefold:

1. Task format hypothesis: A global task format should enhance solution rates compared to a local task format. We use the same SF problem (department store task) and vary the relative salience of local versus global features.
2. Individual differences hypothesis: Individual more global perceptual processing should be connected to higher solution rates to SF problems. We measure global-local perceptual processing style using a variant of the Navon-letter task, the Kimchi-Palmer figures task (Förster \& Dannenberg, 2010) and correlate participants' mean score with SF problem-solving performance.
3. Priming hypothesis: Priming global perceptual processing should induce a transfer-appropriate, whereas local perceptual processing should induce a transfer-inappropriate shift on subsequent problemsolving. That is, we except induced global perceptual processing to shift to global conceptual processing, resulting in high solution rates in SF problems, and vice versa. We will experimentally induce different perceptual processing styles in participants using the
maps task (Förster, 2005; 2009), and test their effect on solution rates in the department store task.

## Experiment

Participants. A total of 148 participants ( 80 female, 67 male, 1 unknown) with a mean age of 34.9 years ( $S D=12$, range $=18-64$ ) took part in the experiment via Internet. All participants were residents of the US and had completed at least High School, 33\% had a 4 -year college degree in a range of different fields, the largest groups being Business (10\%), Psychology (7\%) and English (3\%).

Materials. A 3(priming: global vs. local vs. control) x 2(task format: global vs. local) mixed design was used, with priming as the between-, and task format as the withinsubjects factor. To procedurally prime participants with a processing style (global vs. local vs. control), the maps task was used (see Förster, 2005; Förster et al., 2009). For each of seven trials, participants were presented with a state map displayed on the screen. In the global condition, participants were instructed to attend to the map in its entity in order to be able to describe its overall shape in one sentence. In the local condition, participants were instructed to attend to only the respective capital marked on the screen in order to be able to describe its location in one sentence. In the control group, participants were instructed to think about an item that characterizes the respective state in order to name it in one sentence. For all three conditions, participants subsequently typed one sentence into an input field while the respective map was still presented on the screen.
To test effects of task formats, the department store task was used in a global and a local format. The local format was very similar to the original format used, thus arguably highlighting local surface features, whereas the global format was designed to highlight global structure of the problem. For both task formats, the original introductory sentence and task display depicting in- and outflows was used (see Fig.1), but the answer options cannot be determined were replaced with 7-point Likert scales assessing subjective confidence: How confident are you in your answer? $0=$ Not confident at all and $7=$ very confident. This was done to assess whether participants have a reliable feeling for correctness as a function of the task format. In the local format, participants answered the following questions:

1. During which minute did the most people enter the store?
2. During which minute did the most people leave the store?
3. During which minute were the most people in the store?
4. During which minute were the fewest people in the store? In the global format, participants answered the following questions:
5. How are the people entering related to the people leaving the store between time periods 1 to 14 ? (a) More people entering than leaving (b) More people leaving than entering (c) Same amount of people entering and leaving.
6. How are the people entering related to the people leaving the store between time periods 14 to 30 ? (a) More people
entering than leaving (b) More people leaving than entering (c) Same amount of people entering and leaving.
7. How would you best describe the accumulation of the number of people in the store between time periods 1 to 14 ? (a) Increasing (b) Decreasing (c) Stable.
8. How would you best describe the accumulation of the number of people in the store between time periods 14 to 30 ? (a) Increasing (b) Decreasing (c) Stable.
To measure individual global-local processing styles, we used the Kimchi-Palmer-figures task (Förster \& Dannenberg, 2010). Participants were presented with triangles and squares that are made up of smaller triangles and squares. Participants indicated for each of 16 trials whether a target figure (e.g., a global square made up of local squares) was more similar to a sample figure that matched its global form or its local form. Display of the figures was counterbalanced with respect to the global (local) match appearing on the left (right). Mean ratings were then conducted for each participant, ranging from 0 (completely local processing style) to 1 (completely global processing style).
Since a bi-directional link exists between good versus bad mood and a global versus local processing style (Gasper \& Clore, 2002), and, in turn, mood is connected to problemsolving (Spering, Wagener \& Funke, 2005), we controlled for mood effects using two 7-point Likert-scales: How do you feel right now? $0=$ Very good and $7=$ very bad; $0=$ Very sad and $7=$ Very happy.
Procedure. Participants were told that they were going to take part in two tasks, one about visual perception, and one about problem solving. Participants first completed one of three randomly assigned between-subjects procedural priming treatments (maps task): global vs. local vs. neutral. Second, participants answered both the local and the global version of the department store task, in random order. Please note that being able to answer the first version correctly (say, the global) was no prerequisite for being able to answer the second version correctly (say, the local). Third, participants completed the Kimchi-Palmer-Figures-task and, as a final set of answers, they answered the mood questions.

## Results

Task format hypothesis. To test whether a global task format improves SF performance relative to a local task format, we compared solutions rates to SF tasks in both formats. For both SF questions 3 and 4, solution rates in the global format were higher than in the local task format (see Table 1). Moreover, mean confidence ratings in the local tasks were not connected to performance in the local tasks, $r$ $=.004$, $p=.48$, but confidence ratings in the global tasks were connected to performance in the global tasks, $r=.37$, $p$ $<.001$.
In sum, the task format hypothesis was confirmed: As expected, mean solution to the SF tasks were higher when a global relative to a local task format was used. Confidence ratings in both format might indicate, moreover, that participants are merely guessing in the local tasks, whereas
they have insight into the problem structure, and therefore a reliable feeling for correctness, in the global tasks.

Table 1. Percentage of participants who answered each of the two SF questions (questions 3 and question 4) correctly as a function of task format (global vs. local).

| Task format | Question 3 | Question 4 | $\chi^{2}$ |
| :--- | :--- | :--- | :---: |
| Local <br> $(\mathrm{n}=148)$ | $20 \%$ | $16 \%$ | $42.3^{* * *}$ |
| Global <br> (n=147) | $57 \%$ | $77 \%$ | $109.3^{* * *}$ |

Note. Local question 3 (4): "During which minute were the most (fewest) people in the store?". Global question 3 (4): "How would you best describe the accumulation of the number of people in the store between time periods 1 to 14 (14 to 30 )?". $* * * p<.001$

Individual differences hypothesis. To test whether globallocal processing styles affect SF-reasoning, processing style was correlated with mean correct solutions to all four SF tasks as a function of priming. After global priming, globallocal processing styles were not connected to mean SF solution, $r(50)=-.05, p=.37$; processing styles were connected to mean SF solutions, however, after local and no priming, $r(99)=.21, p=.02$. A median split was performed to directly compare SF solutions from participants with more global vs. more local processing styles. After no priming (control), and even more so after local priming, participants with a more global processing style performed better than participants with a more local processing style (Table 2).
In sum, the individual differences hypothesis was supported: As long as global priming did not induce a global processing style anyway, participants profited from a preexisting more global processing style when solving SF problems and achieved higher mean solutions than participants with a more local processing style.

Table 2. Mean solution (SD) rates to all four SF tasks as a function of processing style (local vs. global) and priming (local vs. global vs. control).

| Priming | Local <br> processing | Global <br> processing | $t$ |
| :--- | :--- | :--- | :--- |
| Global <br> Priming <br> $(\mathrm{n}=51)$ | $.44(.29)$ | $.43(.28)$ | -.10 |
| Control <br> $(\mathrm{n}=43)$ | $.37(.51)$ | $.52(.27)$ | $-1.85^{*}$ |
| Local Priming <br> $(\mathrm{n}=53)$ | $.31(.26)$ | $.46(.18)$ | $-2.44^{* *}$ |

Note. Local question 3 (4): "During which minute were the most (fewest) people in the store?". Global question 3 (4):
"How would you best describe the accumulation of the number of people in the store between time periods 1 to 14 (14 to 30 )?". ${ }^{*} p<.05,{ }^{* *} p<.01$

Priming hypothesis. To test the effect of priming on solution rates to SF tasks, local and no priming conditions were collapsed, since they did not produce any significant differences in either of the four SF tasks ( $p>.05$ ). To test differences in the number of correct solutions in SF tasks after global priming, two-sample z-tests were conducted. If participants answered the global SF tasks first, global priming had no effect on solution rates, $z=1.04, p=0.15 ; z$ $=0.89, p=0.19 ; z=0.46, p=0.36$ and $z=0.33, p=0.37$ (for the local question 3 and 4 , and the global question 3 and 4 , respectively). However, if participants answered the local questions first, global priming enhanced solution rates in the local SF question compared to local or no priming for question 3 ( $M=24 \%$ vs. $M=12 \%$ ) and 4 ( $M=18 \%$ vs. $M=$ $7 \%$ ), yielding marginal significance of $z=1.44, p=0.07$ and $z=0.33, p=0.06$, respectively. Global priming did not enhance solutions rates to the global tasks 3 ( $M=77 \%$ vs. $M=68 \%)$ and $4(M=88 \%$ vs. $M=87 \%)$, yielding $z=0.8, p$ $=0.21$ and $z=0.33, p=0.23$, respectively.
To control for mood-effects, we compared participants' mean mood in the three priming conditions. Results showed that participants' mood in the global priming condition ( $M=$ 5.8, $S D=1.8$ ) was not different from the local or no priming condition $(M=6.3, S D=1.8), t(149)=-1.58, p=.12$, indicating that the effect of global priming on problemsolving performance was not simply due to mood effects.
In sum, the priming hypothesis was marginally supported: Inducing a global processing style enhanced solutions to the local, but not the global SF questions. An additional priming effect on the local SF tasks did not occur, however, if global SF tasks were answered first, indicating that answering the global SF questions first served as a prime in itself.

## Discussion and Conclusion

The present experiment investigated the cognitive mechanisms underlying SF failure. We proposed globallocal processing as a fundamental, cognitive explanation and tested this notion using three different approaches: Global versus local task formats, individual differences in global-local processing and procedurally priming local versus global processing. Results generally supported our notion of global-local processing to affect SF performance.
In the department store task, participants profited immensely from a global task format highlighting structural relations between the system parts compared to the original local format highlighting features of the constituent parts. Specifically, solution rates in the global format were twice (question 3) or even more than four times as high (question 4) compared to the local format. One might argue, however, that the higher solution rates in the global task format were merely due to the greater amount of information since only the global task format referred to "time periods 1 to 14 " and "time periods 14 to 30 ", respectively. However, the global
task format was specifically designed to unveil the structure of the problem, so that a greater amount of information was inherent in the design of the task format. We would even suspect, moreover, that if questions 3 and 4 left out information about time periods, the global task format would still achieve higher solution rates, simply because questions 1 and 2 already allow participants to detect the problem structure. This, however, is for further research to decide.
As a further result, there was a connection between globallocal processing style and mean solutions to all SF tasks in the control group and the local priming group. Specifically, in line with our expectation, participants using overall global processing were better able to infer the overall behavior of the SF system, as measured by tasks testing an understanding of how the stock reacts to given in- and outflow progressions. Moreover, global processing could be procedurally primed in participants with the map task, resulting in (marginally significant) higher solution rates compared to local processing and the control group. This connection was only present for the local tasks, however, suggesting that participants do not profit from global processing and thus a search for structure, when the task format highlights structure in the first place. In sum, these results point towards global-local processing as a first explanation of the cognitive mechanisms involved in SFreasoning and SF failure.
The present results contribute to an understanding of how people deal with dynamic complexity. Our results merge to the conclusion that less successful participants seem to approach the problem in a piecemeal and concrete manner, whereas successful participants seem to approach the problem in a holistic and abstract manner. Interestingly, locally processing participants tend to stick more closely to the literal information given, whereas globally processing participants tend to go beyond the given information (Friedman \& Förster, 2001). With respect to SF systems, such literal use of information might result in lowest level, categorical representations (e.g., "the inflow is five"), whereas going beyond the information given might result in ordinal (e.g., "in minute 5, the inflow is smaller than the outflow") and increasingly higher-order representations (e.g., "overall, the inflow is bigger than the outflow"). Similarly, fuzzy-trace theory holds that people store two fundamentally different kinds of representations in memory: superficial verbatim representations such as exact numbers and meaning-based gist representations such as the "substance" of information (Reyna, 2012). Based on the present results, it seems plausible to speculate that, after local versus global processing of the task, participants hold fundamentally different representations of the task in memory. This, however, is for future research to decide.
In order to enhance people's ability to deal with SF systems, a range of strategies can be deduced from the present results. For example, it might be helpful to apply the principles of Gestalt psychology for pattern recognition to SF problem displays. With help of the law of good Gestalt,
for example, the constituent elements of SF problems could be grouped to imply global structure and regularity. In a different vein, one could try to enable people to process dynamic problems globally, for example by teaching strategies of abstraction, pattern recognition and induction of higher-order representations. Making use of the finding that a Gestalt view is helpful for dealing with SF problems, one could even try to make computers "see" the patterns in simple SF systems in order to regulate them.
It seems interesting to speculate in how far the benefit of a global, Gestalt view applies to complex systems in general. Systems containing a range of interacting variables can hardly be regulated using analytical strategies, because of limited cognitive capacities of the problem-solver, and because information in real-life is mostly fuzzy in nature. For both reasons, form-generating Gestalt principles could be helpful: They enable the problem-solver both to conceive of the system in its most economic form and to recognize basic similarities and therefore to re-use previously successful regulation strategies. Thus, recognizing patterns in systems might enable one to recognize and use similarities in a noisy world.

# Grammatical Aspect influences Event Duration Estimations: Evidence from Dutch 

Monique Flecken (m.flecken@donders.ru.nl)<br>Donders Centre for Cognition, Radboud University, PO Box 9104, 6500 HE Nijmegen, the Netherlands

Johannes Gerwien (jo.gerwien@uni-heidelberg.de)<br>Institut für Deutsch als Fremdsprachenphilologie, Heidelberg University Plöck 55, 69117 Heidelberg, Germany

#### Abstract

This study investigates the effect of grammatical aspect marking in Dutch sentences, on speakers' estimations of the duration of highly familiar, everyday events. We first established the 'inherent' or natural duration of different events (Exp. 1). This was then used for the manipulation of aspect (Exp. 2). Participants dragged a slider across the computer screen to estimate the duration of progressive and non-progressive event descriptions. Findings show how the progressive form extends duration estimations for short events, whereas it shortens the perceived duration of inherently medium and long events. We interpret this as psycholinguistic evidence for the function of aspect in Dutch, i.e., giving an 'inside' view of the event and focusing a specific internal time span of the event.

Keywords: grammatical aspect, event representation, Dutch.

## Introduction

Time is an important domain of human experience. For example, most people are able to roughly estimate how long it takes to open a window, to prepare a certain meal or to watch a movie, given normal circumstances. This information about the time course of events is part of world knowledge and our experience with different events and situations. When people talk about events (in finite sentences) the grammar of the language they speak may require them to make specific distinctions which relate to time explicit. They may be required to provide information on whether an event is taking place in the present, or took place in the past (grammatical category of tense). People may also need to specify whether an event has just begun, is in progression, or has reached a state of completion (grammatical category of aspect). However, it is not clear, in what ways world knowledge about temporal features of events and the distinctions provided by the language system interact: how do specific linguistic structures influence the way people represent events? In this study we address this question, and ask specifically how the use of aspectual verb forms in a sentence context affects people's general knowledge about the temporal contours of events, i.e., the duration of events.

## Background

Linguistic theories on grammatical aspect (also viewpoint or verbal aspect) state that the function of progressive aspect is
to modulate the inherent temporal contours of an event, thereby defocusing its boundaries (e.g., Comrie, 1976; Dahl, 2000). Specifically, it expresses a particular perspective on an event in that it is represented as a specific 'ongoing' instance of an event: For example, the semantic difference between 'he passes the ball' and 'he is passing the ball'. The progressive defocuses the boundaries of the event, to give an 'inside' view of a situation and thus 'highlight' its intermediate phases (e.g., Comrie, 1976). It is important to note that event descriptions that mark information regarding tense or aspect ('finite' expressions) do not directly refer to the time span defined by inherent temporal features of an event. With regard to aspect, Klein (1994) for example, distinguishes two temporal layers in language and describes aspect as denoting the relation between the linguistically unspecified time of an event (Time of Situation, TSit), and the specific time span that is being talked about (Topic Time, TT). The function of progressive aspect is to express that this time span (TT) falls within the boundaries of the event (Figure 1). This means that the time span at issue will be viewed as having extended duration (event marked as in progress), but it will be shorter than that of the entire event, as the time span in question does not include the boundary phases. Events not marked for progressive aspect, on the other hand, are unspecific in this regard and can include the entire event ('passes the ball'), thus highlighting a qualitatively different time span compared to events marked for progressive aspect.

Figure 1: Time-relational analysis of progressive aspect (cf. Klein, 1994)

The present study addresses the psycholinguistic reality of the above claims on the function of aspect in a sentence context: how exactly does this grammatical structure influence the way in which events, as expressed by verbal
predicates, are perceived? We focus on potential modulations of the perceived inherent or natural duration of events.

Initial steps in understanding the role of grammatical aspect in event conceptualization have been made from a psycholinguistic perspective in production and comprehension studies. A production study, comparing mono-/bilingual speakers of aspect and non-aspect languages, has looked at event descriptions and patterns in gaze allocation (measured with eye tracking), while subjects were preparing to speak about causative events (which involve an agent acting on an object, e.g., a person knitting a scarf) (Flecken, 2011a). Speakers who used progressive aspect to describe the events (English, Dutch), predominantly allocated gaze to features of the ongoing action (the knitting), and less to the agent of the event (which was the German pattern, non-aspect language). Progressive aspect thus focuses visual attention to ongoing aspects of an event, online, in production.

Comprehension studies have focused on the role of grammatical aspect for our understanding of situations or events, and the relations between different events. Magliano and Schleich (2000), for example, show how grammatical aspect constrains mental models of situations, when connected within a narrative structure. In their comparison of readers' comprehension of sentences marked for progressive and perfective aspect in the past tense, and embedded in a stretch of discourse, they found differences between comprehenders' conceptions of events, despite use of the same lexical information. When reading 'Betty was delivering a baby' versus 'Betty delivered a baby' two different mental representations of the event were formed with consequences for the way in which further contextual information was understood. Using a question-answer paradigm, they explicitly asked whether the critical events were finished or not, at specific points in the story line. In one experiment, they addressed the question whether 'general knowledge' on the duration of events interacted with aspect marking. They included events with a long and a short duration (long duration: ranging from 'watching a movie' to 'writing a novel'; short duration: ranging from 'scratching your nose' to 'packing a suitcase'). Likelihood scores indicated that 'long' events, marked as in progress by means of progressive aspect, were still perceived as ongoing at later sentence positions, in contrast to 'short' events. As they used a rather course measure (yes/no questions), we cannot be sure how exact this difference for aspect marking between short and long events is. Furthermore, the events within each category showed a great range in duration ratings, and included events that may not be familiar to all participants (such as 'giving birth'). A person's lack of experience with a situation or action may result in a less precise mental model of the event. Their findings may be interpreted as showing that the duration of the event described with progressive aspect is interpreted as prolonged, in comparison to the same event described by non-progressive verb forms.

Madden \& Zwaan (2003) also show how verbal aspect constrains speakers' representations of events. In a sentence picture matching task, with pictures showing events at different phases, they found that sentences marked with progressive aspect (in the past tense) elicit an equal amount of choices for pictures showing a completed or an incompleted event. The authors interpret this as showing that speakers can represent different phases of an event as in progression.

Bergen \& Wheeler (2010) also study the effect of aspect on 'mental simulation'. They find that speakers mentally simulate the nucleus of an action, when described in English sentences marked with progressive aspect, in contrast to sentences with perfective aspect.

In, e.g., Anderson et al. (2008) a different methodology was adopted, aiming to get a closer look at online processing of aspectually marked event sentences. They used a mouse tracking paradigm, in which speakers were asked to place a figure on a path, on its way to an endpoint, when listening to sentences describing motion events with and without progressive aspect in the past tense ('was walking to school' versus 'walked to school'). Figures were placed closer to the goal of the motion in the non-aspect condition, indicating that the past progressive focuses attention on internal phases of the past event.

These experiments provide important insights, as they reveal more clearly how aspect influences the processing of event structure. Important questions remain, however: For example, how does progressive aspect modulate event duration estimations for different event types?

In the present study, we take Dutch as our test case, as there is the advantage that this language allows use of sentences describing events in the present tense, both with and without morphological marking of progressive aspect. Production studies on Dutch have shown how progressive aspect is used frequently, but not for all event types. Unlike in English, use is not obligatory in any context (von Stutterheim, Carroll \& Klein, 2009; see for acceptability judgements of progressive and non-progressive event descriptions, Flecken, 2011b). With the investigation of a language other than English, we set out to explore whether the temporal relations described above for progressive aspect (Comrie, 1976; Klein, 1994) apply when Dutch speakers use the progressive aan het construction. In linguistic terms, progressives in different languages will follow the same temporal logic; but do speakers' responses reflect their role so as to modulate their perception of the internal phases of a dynamic situation when estimating event duration? Dutch is a language in which use of progressive aspect is not fully grammaticalized in contrast to English, for example. A comparison with English would have to be carried out on the basis of the same stimuli, however. We thus take first steps in exploring the influence of aspect marking on event duration in Dutch.

## Aims of the present study

In the present study, we draw a distinction between the 'inherent' duration of an event (i.e., the infinite and unspecified time interval or duration of an event, as expressed by bare (infinite) verb phrases, for example 'to write a paper'), which relates to world knowledge about the normal course of an event, and the finite expression of event duration by means of finite sentences or verb phrases, relating to a specific situation ('finite’ event duration). Finite expressions of event duration can include a verbal marker of progressive aspect, or not.

We ask whether speakers of Dutch perceive the duration of an event differently, depending on the specific type of verb form used (progressive or non-progressive) in a sentence context. An example is 'Wij zijn een artikel aan het schrijven' (lit.: we are a paper at-the-write; 'we are writing a paper', progressive verb) versus 'Wij schrijven een artikel' (we write a paper, non-progressive verb form). In Dutch, both instances relate to a specific event, taking place in the here and now.

Dutch speakers estimate the duration of events of different types, described in written sentences, by dragging a slider across a computer screen, using the mouse. Previous studies show how performance on a spatial task may accurately capture speakers' conceptions of temporal dimensions, such as duration (Casasanto \& Boroditsky, 2008). Event sentences will be presented twice, once in a progressive and once in a non-progressive condition. To prevent participants from memorizing the estimated duration of an event, as each is repeated, participants will estimate duration in the absence of a concrete time scale. Sentences will be presented in pairs, which remain the same in both conditions, meaning that the 'pair partner' of an event is thus the main point of reference for duration estimation, rather than an absolute time line. Estimations in minutes/seconds may be more susceptible to memory effects, and may overrule subtle effects of (non-) aspect marking.

We aim to find out how aspect interacts with the 'natural' or inherent duration of events, as judged by speakers on bare verb phrases describing actions and events.

## Experiment 1: 'Inherent' event duration

In experiment 1 native speakers of Dutch were asked to rate all kinds of everyday events and actions described by bare (non-finite) verb phrases (e.g., 'to walk the dog'). Three different samples were asked to rate their familiarity with the events, in how far they are imaginable (to what extent is the event likely to occur in the real world?) and the inherent duration of the events or actions. All ratings were carried out on a five-point scale.

## Method

Participants In total, 30 native speakers of Dutch took part in the experiment, consisting of three parts. They were $(\mathrm{PhD})$ students and postdoctoral researchers at Radboud

University Nijmegen (age range 19-35, balanced for gender).

Materials Stimuli used were written infinite action phrases (bare VPs) relating to everyday actions and events, and described with infinite verb phrases, e.g., 'to peel an apple', 'to open a can', 'to watch a football game'. Sentences were placed in an online questionnaire in a randomized order, and speakers were asked to give online ratings, and specify their age and gender. In total, there were 150 different events/actions.

Procedure Three different samples of 10 native speakers of Dutch took part in three different short experiments, designed as web questionnaires. First of all, the infinite action phrases were rated for familiarity ('how familiar are you with this type of action?') on a scale from 1 (highly unfamiliar) to 5 (highly familiar). Only highly familiar events were selected (ratings of 4 and 5) for Experiment 2. A second sample rated the phrases as to what extent the action was imaginable (rating 1: not imaginable at all, rating 5: highly imaginable). Furthermore, another sample of 10 speakers rated the duration of the infinite action phrases in relation to a 'standardized' event, i.e., to boil pasta, which was specified as lasting for about 7-8 minutes (rating 1 : much shorter than boiling pasta, rating 5: much longer than boiling pasta). This latter rating was conducted to ensure homogeneity of inherent event duration estimations.

## Results

The three rating tasks in Experiment 1 resulted in the selection of 78 different events. All other items were discarded due to a low degree of familiarity, the fact that they were not imaginable, or whether duration ratings showed a high degree of heterogeneity. All in all, 72 items were discarded. The 78 events were divided into three categories of inherent event duration (26 items in each category), on the basis of the duration ratings obtained: short (e.g., 'to turn a key', 'to light a candle'), medium (e.g., 'to set the table'; 'to polish a shoe') and long (e.g., 'to watch a dvd', 'to wash a car'). Items with an average rating of between 1 and 2 were characterized as 'short' events (range of ratings: $1-1.67$ ). Items with an average rating of between 4 and 5 were classified as 'long' events (range of ratings: $4.11-5$ ). Medium events were items with an average rating of between 1.67 and 4.11 .
The 78 items with homogeneously-rated inherent event duration, categorized in three groups (short, medium and long), were used as materials for Experiment 2.

## Experiment 2: 'Finite' event duration

In Experiment 2 we asked native speakers of Dutch to estimate the duration of events, as described in whole sentences, marked with or without progressive aspect.

## Method

Participants In the present study 27 native speakers of Dutch took part, who were all students at Radboud University (age range: 18-32, 16 female, 11 male), and did not have an advanced level of proficiency in a second (or third) language. This was established on the basis of their answers in a language background questionnaire. Students, who reported a stay of over three months in a foreign language country, were excluded from participation.

Materials Stimuli consisted of written sentences describing everyday situations and events. There were in total 78 items, describing 78 different events. Each item was used for a progressive and non-progressive sentence and paired with an item with matching inherent event duration. There were thus 13 pairs in each duration category (short-short pairs, medium-medium pairs, long-long pairs). For the pairings, care was taken to avoid any thematic or semantic relatedness between the two items. Sentences were presented as pairs to provide a kind of reference point for the duration estimations, within each trial. Pairs were always presented in the same aspect (either progressive or non-progressive). The agents of all actions (the subjects of the sentences) were described with two specific names, 'Jan' and 'Paul' in all cases.

Procedure Before subjects came to the lab, they were asked to carry out the same online familiarity rating task as in Experiment 1, dealing with all 78 bare event phrases. Ratings were again made on a scale from 1 to 5 . In the lab, subjects were told that on each trial they would read two sentences describing the situations in which two specific persons, i.e., 'Jan' and 'Paul' were involved right now. They were asked to imagine the situations of both Jan and Paul, and to estimate how long the two agents would be engaged in the activities described. Numbered sentences appeared below each other on a computer screen in a centred position. Within trials, sentences were of approximately the same length, to avoid any visual bias. Lower down, two sliders were presented and subjects were instructed to use the mouse to drag the sliders from left to right, starting with the top one, to estimate duration (Figure 2).

Figure 2: computer screen with sliders dragged slightly to the right (progressive aspect condition, 'long' events: 'John
is telling a fairytale', 'Paul is cleaning the bathroom')

Subjects were instructed that the further they dragged the mouse to the right, the longer they estimated the agent to be engaged in the activity. Furthermore, it was explicitly stated that if they dragged the slider to the right only slightly, this would mean that Jan or Paul are engaged in the activity for a very short time. If they dragged the slider to the utmost right, this would mean that Jan or Paul are performing the activity for a long period of time. The particular part of the slider that was dragged, turned red. Subjects were able to adjust their estimations. After estimating the duration of both sentences, they proceeded to the next trial by clicking a button.

In order to ensure that participants were actually aware of the surface sentence structure, and did not only focus on the bare event characteristics, a question relating to the contents of one of the preceding sentences appeared randomly. Subjects were asked to decide whether they had read that sentence before, by clicking yes or no on a button box. The question sentences were correct half of the time, and the other half contained errors with regard to the type of object described (e.g., for sentence 2 above: Paul is cleaning the kitchen) or the type of aspect used (e.g., for sentence 2: Paul cleans the bathroom). Each sentence pair appeared twice, once in the non-progressive condition, and once in the progressive condition. All trials were pseudo-randomized, so that each repeated item appeared in the second half of the experiment (the second set of 39 trials), to ensure enough distance between repeated items. The occurrence of progressive or non-progressive sentence pairs in the first or second half of the experiment was varied between subjects.

After filling out a sociolinguistic questionnaire, subjects were asked to estimate the precise duration of the different events (described in bare VPs) in minutes (pencil-and-paper test). This was done to double-check, whether the events were rated as belonging to the same duration categories as those established in Experiment 1.

## Results

a) Familiarity ratings All 78 event phrases were rated as familiar (4) to highly familiar (5), replicating the results from experiment 1.
b) Online event duration estimations of sentences For the analysis, we focused on the values of the x-coordinates on the computer screen only, equalling the distance the mouse was dragged towards the right side of the screen. We analyzed our data using mixed effects models ( R , lme4 package). Our goal was to fit a model that would explain the estimations made by the subjects as the result of the impact of various variables, i.e. fixed and random effects. Our fixed effects were 'inherent duration' ('dur') (long, medium, short) and 'aspect' (progressive, non-progressive). The variables were coded as follows: for 'dur', the short event category was coded as the base level ( -1 short, 0 long, 1 medium) and for 'aspect' we coded the non-progressive verb form as the base level ( -1 non progressive form, 1 aan het form). We also aimed at controlling further influences
caused by the experimental design, by taking into account random effects in our model.
The random factors we originally considered were subject, item, and pair. For 'subject' we included by-subject random intercepts, as well as a by-subject random slope, which allowed the predictions for 'inherent duration' to shift by a fixed amount for each subject ${ }^{1}$. With respect to the random factor 'item', two things are important. First, every item (event) belongs to one and only one event duration category. Item is thus a nested random factor. We incorporated this by adding a variable which covered the 'item:dur' interrelationship; this term was also included as a random factor. Second, subjects always rated event pairs and not single events. The pairing of items remained fixed throughout the experiment, for each subject. We thus did not add pair as a separate random factor, as the nested 'item:dur' term would sufficiently capture the variance stemming from random item selection. In general, we follow an approach by Barr et al. (2012) in which the authors argue for a maximal approach, that is, "valid statistical inferences using LMEMs require maximal random-effects structures wherever possible ..."(p.1).

We log-transformed and centred all duration estimations (see Footnote 1 for the formula in R).

Let us turn directly to the fixed effects section in our model (Table 1 below: asp. 1 is aan het condition; dur. 0 is long, dur. 1 is medium event type)

Table 1: Fixed effects in the mixed model

|  | Estimate | Std. Error | t value | p value |
| :--- | :--- | :--- | :--- | :--- |
| Intercept | -0.96918 | 0.10877 | -8.910 |  |
| dur.0 | 1.90106 | 0.12323 | 15.427 | $<.001^{* *}$ |
| dur.1 | 1.00654 | 0.09792 | 10.279 | $<.001^{* *}$ |
| asp.1 | 0.04819 | 0.02364 | 2.039 | $.041^{*}$ |
| dur.0:asp.1 | -0.07118 | 0.03343 | -2.129 | $.033^{*}$ |
| dur.1:asp.1 | -0.06721 | 0.03341 | -2.012 | $.044^{*}$ |

As predicted, for 'inherent duration' ('dur') we find high tvalues (long events $t=15.43$; medium events $\mathrm{t}=10.28$ ), showing that, in contrast to the base level (short events), the two other event types are estimated as significantly longer. There was a significant main effect of 'aspect' $(\mathrm{p}=.041)^{2}$, meaning that short events were estimated as having a longer duration in sentences marked with the aan het form, when compared to the same events described with nonprogressive verbs. Looking at the interaction effects, we find that, compared to our base level, medium and long events marked with the progressive form are estimated as significantly shorter (both p values > .05).

[^264]To exclude the possibility that the above pattern of results is due to the presence of outliers, 32 extreme values (. $008 \%$ ), with a standardized residual at a distance greater than 3 standard deviations from zero, were removed from the data, and the model was refitted.

Table 2: Fixed effects in the mixed model on trimmed data

|  | Estimate | Std. Error | t value | p value |
| :--- | :--- | :--- | :--- | :--- |
| Intercept | -0.97638 | 0.10859 | -8.991 |  |
| dur.0 | 1.93245 | 0.12593 | 15.345 | $<.001^{* *}$ |
| dur.1 | 1.03100 | 0.09883 | 10.432 | $<.001^{* *}$ |
| asp.1 | 0.04781 | 0.02157 | 2.217 | $.027^{*}$ |
| dur.0:asp.1 | -0.06942 | 0.03056 | -2.272 | $.023^{*}$ |
| dur.1:asp.1 | -0.08131 | 0.03052 | -2.665 | $.008^{*}$ |

The trimmed model (Table 2) shows the same significant results for the predictors and their interactions. We conclude that the statistical inferences made in the original model are not confounded by extreme values in the data set.
c) Inherent event duration estimations (bare VPs) Table 3 below displays the average and SD of the duration estimations for the infinite event phrases; these estimations were carried out after the actual experiment. The numbers displayed are duration estimations in minutes.

Table 3: Inherent duration estimations, in minutes

|  | Short | Medium | Long |
| :--- | :--- | :--- | :--- |
| Average | 2.25 | 11.20 | 80.24 |
| SD | 1.52 | 11.27 | 50.52 |
| Lower | 1 | 2 | 14.50 |
| Upper | 6.01 | 58.67 | 206.38 |

The absolute duration estimations support the division into the three categories of inherent event duration, based on Experiment 1.

## General discussion

In Experiment 1, we established three categories of highly familiar, everyday events of different 'inherent' duration (short, medium, long events), on the basis of three rating tasks. In Experiment 2, we used those items and specifically assessed the effect of aspect marking on subjects' duration estimations of the three event types, by means of the 'drag-the-slider-technique'.

First of all, with respect to the different 'inherent' event duration categories, the findings indicate that the method is valid; medium and long events were estimated as lasting significantly longer than short events. The duration estimations made by subjects using a slider on the computer screen, without a fixed time scale, reflect the time spans which are inherently part of the conceptual representation of events, showing that spatial tasks are informative about people's thinking about time (Casasanto \& Boroditsky, 2008).

Second, we find a significant interaction between aspect marking and inherent event duration, suggesting that aspect affects the perceived duration of events described in sentences in a specific way: In Dutch, short events are estimated as having a longer duration when described in the progressive aan het form, whereas medium and long events are estimated as having a shorter duration, when compared to estimations of the same events described by nonprogressive verb forms.

The mechanism underlying the patterns found is explained by a time-relational analysis of aspect: As described above (Klein 1994), progressive aspect marks that the time span being talked about (TT) is placed within the total event time (TSit) whereas unmarked (non-progressive) verb forms are unspecific in this regard. With the progressive, an internal time span is focused and explicitly viewed as 'in progress'. Short events inherently have a short TSit, which can include a transition phase or change in state ('to open a bottle': from 'not open bottle' to 'open bottle'). If language users describe such an event with progressive aspect, the time span at issue is located within the event time (Tsit), and attention is thus directed to the transition phase. Language users experience this as stretching and prolonging the duration of the event in their mental model. For medium/long events, the temporal boundaries (beginning and end) lie further apart (TSit is longer). There are also phases with changes of state with the event 'to repair a bicycle', for example, but it will typically have longer duration. When events are described with progressive verbs, attention is directed to a specific time interval that lies in between the beginning and end of TSit, and, crucially, it does not extend over the entire event. The duration of the event will thus be perceived as shorter, compared to the total time span for the entire event (TSit), as expressed in non-progressive sentences.

World-knowledge about a specific event seems to play a role for the interpretation of aspect - and both layers of duration interact in our subjects' mental models of the events. In general, we provide further evidence that grammatical aspect influences people's representations of events or situations (e.g., Anderson et al., 2008; Madden \& Zwaan, 2003).

## Conclusions

In this study we investigated in how far grammatical aspect has an influence on how people mentally represent the duration of everyday, highly familiar events, described in Dutch sentences. We distinguish between two 'layers' of event duration, which are packaged together in sentences, and which both contribute to the perceived duration of an event. The first 'layer' consists of the 'inherent' duration of an event, which is based on world knowledge. The second layer consists of 'finite' temporal information, expressed by tense and aspect. Our results imply that the inherent duration of events is shared among speakers of a language/culture. This inherent event duration is modulated
by grammatical aspect (aan het in Dutch; previous studies show this for the -ing form in English).
We find psycholinguistic evidence for the function of grammatical aspect in Dutch. By means of progressive aspect, speakers take an 'inside' perspective on an event, by selecting a time interval that falls within the total time period of the event - leading to a complex interaction between aspect marking and the inherent duration of events.

#### Abstract

The TIME IS SPACE metaphor consists in the use of a spatial mental time line (either left-right or front-back) to represent time. One of the issues still to be resolved is whether these space-time mappings can be automatically activated independently from the goals of the task. Prior attempts to settle this issue have failed to match adequately the temporally relevant and irrelevant tasks. In the present study we presented Spanish verbs and nonverbs conjugated in past and future forms in both a time judgment and a lexical decision task. Results showed that the left-right space-time mapping is only active when the task requires temporal discrimination, speaking against an automatic activation of the mental time line.

Keywords: time; space; mental time line; automaticity; flexibility; embodied cognition; conceptual metaphor.

## Introduction

As a response to the symbol grounding problem (Harnad, 1990), the Embodied and Grounded Cognition view (e.g., Barsalou, 1999; Gibbs, 2006; Lakoff \& Johnson, 1987) suggests that abstract concepts need to be grounded on concrete domains (i.e., those more directly based on sensory-motor experiences) in order to gain meaning. Under this view, language processing elicits an embodied simulation which is carried on by the very same neural systems used by perception, emotion and action (Barsalou, 2008; Gallese, 2008; Glenberg \& Gallese, 2011; Glenberg et al, 2008). When abstract concepts are referred to, such simulation follows the guide of stored mappings between abstract and concrete concepts. One line of support for this idea comes from empirical studies on the abstract domain of TIME, which seems to be grounded on the concrete domain of SPACE. Response time studies have reported interactions between the processing of the temporal reference of words and sentences and a variety of response mappings: lateralized key presses, forward-backward manual movements, vocal responses (e.g., Boroditsky, 2001; Ouellet et al, 2010b; Santiago et al, 2007; Sell \& Kaschack, 2011; Torralbo et al, 2006; Ulrich \& Maienborn, 2010; Ulrich et al, 2012).
Space-time congruency effects are part of a wide family of studies that manipulate concrete and abstract dimensions in tasks that require elaborating and responding to aspects of the abstract dimension. In this context, modulations due to task-irrelevant concrete dimensions are often found on the processing of the abstract, task-relevant dimension. The resulting
metaphoric congruency effect has been interpreted as the index of the use of underlying concrete representations to organize the abstract dimension, as i.e. in the SNARC effect (Dehaene et al, 1993).
Conceptual Metaphor Theory, which has a longstanding support from linguistics and psychological studies (e.g., Boroditsky, 2000; Clark, 1973; Lakoff \& Johnson, 1980, 1999; Núñez \& Sweetser, 2006; Talmy, 2000), pointed out that our vocabulary about abstract concepts has concrete roots. But one of the most interesting consequences of the empirical findings on conceptual metaphors has been the discovery of the existence of metaphoric mappings not explicitly attested in language (for a review, see Santiago et al 2011). In the last years, the most studied example has been one TIME IS SPACE metaphor, which maps temporal reference onto the left-right horizontal spatial axis. In contrast to the mapping of time onto the frontback axis, which is explicitly attested in many languages (e.g., Sell \& Kaschack, 2011; Torralbo et al, 2006; Ulrich et al, 2012), in his review of cross-linguistic space-time metaphors Radden (2004) observed a total lack of linguistic conventions directly referring in speech to a horizontal left-right time dimension. However, we are all used to conventional associations of time as flowing from left to right (or right to left) along a horizontal axis in written language, graphs, and in many types of graphic devices (e.g., comic strips, calendars, etc.).
The interpretation of conceptual congruency effects as indexes of stable semantic memory mappings has been clearly contradicted by recent experimental results. There is evidence in the literature of different degrees of flexibility/automaticity depending on the abstract dimension studied, the task and materials used, the kind of mappings which are evaluated (Santiago et al, 2011). Nowadays, there seems to be a well-motivated support to the idea that conceptual congruency effects could be of a very contextual nature (e.g., Torralbo et al, 2006; Santiago et al, 2008; Santiago et al, 2012; Lakens et al, 2012).
One of the strongest cases of automatic activation has been observed for the mapping of affective evaluation to front-back responses: participants are faster in responding to positive and negative items by pulling and pushing a lever, respectively (e.g., Chen \& Bargh, 1999). This occurs not only when the decision is based on the valence of the stimuli, but also when performing a lexical decision task (Wentura et al, 2000) and even a stimulus detection task (Chen \& Bargh, 1999), which minimize the taskrelevance of the evaluative dimension. In contrast, space-
time mappings do not seem to be activated so automatically. Recently, two studies extending prior findings with temporal words (e.g., Santiago et al, 2007) to full sentences have tried to address the question of whether it is possible to observe an automatic activation of the mental time-line in an implicit task, investigating both the left-right (Ulrich \& Maienborn, 2010) and the front-back (Ulrich et al, 2012) axes. These studies asked participants to carry out both an explicit temporal judgment task and a sensicality judgment task, observing space-time congruency effects only on the former.
The findings of Ulrich \& Maienborn (2010) on the leftright mental time line left open the possibility that participants did not need to process the temporal reference of sentences in the sensicality judgment task. The nonsensical sentences were constructed by matching an agent and an object that do not fulfill the meaning restrictions of the verb (i.e, as in the past sentence "The fir trees have put on their coat while bathing", or in the future sentence "On next Sunday, the town-hall will marry the pea"). In order to judge whether these sentences are sensible or not, participants might have only assessed whether the action mentioned by the verb can be done by the actor (with the object) on the patient. In other words, whether the arguments fulfill the meaning constraints imposed by the verb. In order to control for this possibility, in their study on the front-back mental time line, Ulrich et al (2012) asked participants in the sensicality task to also perform a time judgment for each sentence at the end of the trial. Again, they failed to observe any interaction between response direction and temporal reference.
Several possibilities are left open by these two studies. A first one is that participants split their judgments into two sequential phases: they first focused on assessing meaning consistency, started response, and then assessed whether the sentence referred to a past or future event (in which case, the effect of temporal reference would be missed by the latency measure). A second, and very interesting possibility is that meaning access at sentence level is less automatic than at the word level, because the meaning of the sequence of words needs to be composed into the overall sentence meaning. Finally, it might be the case that the activation of the front-back time line is not automatic, but we cannot still be certain whether this is also the case for the left-right mental time line (due to the methodological concerns discussed above). A more automatic left-right time line would be consistent with findings of automatic activation of left-right space in tasks that required the processing of ordinal sequences (either learned on the spot or previously known) when the order dimension was completely irrelevant for the task (e.g., Gevers et al, 2004; Previtali et al, 2010), as well as with the well-known SNARC effect in parity tasks (Dehaene et al, 1993). It is clear that the issue of automatic activation of the mental time line is still far from being solved.
In our study we wanted to address simultaneously several of these possibilities. We focused on the processing of time-related single words with left and right responding (thereby testing the activation of the left-right
mental time line) in both time-relevant and time-irrelevant tasks.
To create our materials, we selected isolated Spanish verbs with an intransitive reading (e.g., "dormir" - to sleep). As Spanish is a pronoun drop language, when these verbs are conjugated in past or future tense, they represent a full sentence (e.g., "durmió" means "He slept"). However, their meaning is acquired in a single fixation and through the activation of a single lexical item. So, the chances of a slower, more compositional comprehension strategy are lower. In order to create the nonwords, we modified the set of verbs by changing only one letter in their morphological stem. Therefore, the nonverbs did not pop out as such (e.g., "dormir" was changed to "dorpir"). Moreover, the nonverbs were also inflected in past and future ("durpió"). In this way, we made sure that in order to distinguish the existing from the non-existing verbs, participants had to pay close attention and deeply elaborate the stimulus. We presented these stimuli in a temporal judgment task (decide whether the stimulus refers to the past or the future; Experiment 1) and in a lexical decision task (decide whether the stimulus is a word or a nonword; Experiment 2) with lateralized manual responses. If the left-right space-time mapping can be activated automatically, both experiments should render significant space-time congruency effects. Otherwise, they should arise only in Experiment 1.

## Experiment 1

Experiment 1 used centrally presented Spanish tensed verbs (technically corresponding to full sentences) and nonverbs in an explicit temporal judgment task. Responses were given by means of bimanual lateralized key presses.

## Method

Participants 24 Psychology students from the University of Granada (5 males; age range 19-26 y.; 2 left-handed by self-report) participated for course credit. All participants had normal or corrected-to-normal vision and were naive as to the purposes of the experiment.

Materials We selected 148 Spanish verbs which are intransitive verbs, or at least allow a (very common) intransitive use. Such a kind of verbs was chosen because Spanish is a pro-drop language, so the subject of a verb can be dropped from the sentence. Thus, single conjugated intransitive verbs as used here can stand as full, grammatically correct and sensible sentences. In order to create the nonword set, each verb was modified by changing one letter in its stem, with the constraint of resulting in pronounceable phoneme sequences in Spanish.
The 148 verbs and 148 nonverbs were then conjugated in both the simple past perfect indicative and the simple future indicative (all six possible grammatical persons were more or less equally represented over the set). This resulted in 592 experimental stimuli of four types: past and future verbs, and past and future nonverbs. This total set was randomly divided into four lists of 148 stimuli
each, avoiding item repetition. For example, from the item "faltar/falbar" the following four third person singular tensed versions were created: "faltó" (past verb), "faltará" (future verb), "falbó" (past nonverb), "falbará" (future nonverb), and each of them was randomly assigned to one of the four different lists. Each list was then composed of 37 items of each of the four stimulus types.

Procedure Stimuli were presented centered on a computer screen (Courier New font, 38 points, lower case), black printed on white background. Participants sat at a distance of 60 cm from the computer screen, and placed their left index finger on the Q key and their right index finger on the 9 key of the numerical keyboard in a standard QWERTY keyboard. The distance between response keys was 32 cm . Each trial began with the presentation of a central fixation cross ( 500 ms ) followed by the target verb, that remained on screen until a response was made. Incorrect trials were followed by a 500 ms red uppercase X at the same location of the stimulus. Each incorrect trial was then followed by a 1000 ms blank screen. Correct trials were followed by a 1500 ms blank screen. Participants were instructed to decide whether the presented verb or nonverb referred to either the past or the future.

The experiment was divided into two blocks of 148 trials (separated by a two minutes break) in which the same list of stimuli were responded to using two different mappings of responses (past/future) to keys (left/right). The order of presentation of the two mappings was counterbalanced over participants. We did not control for factors known to affect word recognition times, such as frequency, length, or age of acquisition, because the theoretically interesting effect is the interaction between temporal reference and response hand when participants process the very same list of stimuli using the two possible response-key mappings. Each block was preceded by a short 4 trials training block using different stimuli. The experiment was programmed and run using E-prime 2.0.

Design and Analysis Data were analyzed using a mixed factorial ANOVA with the within-subjects factors Lexical status (word vs. nonword) x Temporal reference (past vs. future) x Key (left vs. right). Counterbalance was included in the design as a between-subjects factor in order to reduce noise, but because it is of no theoretical relevance, its main effect or interactions are not reported here.

## Results

Errors occurred in $6.43 \%$ of trials and were analyzed independently. Reaction times (RTs) exceeding 2 standard deviations from each participant's mean were excluded from the analysis, leading to the removal of an additional $12.01 \%$ of data.

The ANOVA on RTs revealed a significant main effect of the factor Lexical status $(F(1,22)=36.55, M S e=$ 18071.56, $p<.001$ ), due to longer latencies for nonwords ( 1106 ms ) than words ( 989 ms ). This result is completely in line with the psycholinguistic literature about the
lexicality effect (e.g., Kinoshita el al., 2004; Pagliuca et al, 2010) and shows that participants were unable to focus only on the verb inflection in order to give their responses. There was also a Lexical status x Temporal reference interaction $(F(1,44)=13.25, M S e=3451.7, p<.01)$, due to past words being faster than future words ( 982 ms vs. 996 ms , respectively), whereas future nonwords were faster than past nonwords ( 1130 ms vs. 1083 ms , respectively). Finally, and most relevant to current concerns, there was also a significant interaction between Temporal reference and $\operatorname{Key}(F(1,44)=12.03, M S e=$ 16640.96, $p<.01$ ), which showed faster responses to past verbs and nonverbs with the left than with the right hand $(1027 \mathrm{~ms}$ vs. 1085 ms , respectively; Newman-Keuls $p$ $<.05$ ) and to future verbs and nonverbs with the right than with the left hand ( 1004 ms vs. 1075 ms , respectively; Newman-Keuls $p<.05$ ). This interaction was not modulated by Lexical status $(F(1,44)=1.03, M S e=$ 7707.96, $p=.32$; Word: Past verbs - left hand $M=943 \mathrm{~ms}$, Past verbs - right hand $M=1022 \mathrm{~ms}$, Future verbs - left hand $M=1035 \mathrm{~ms}$, Future verbs - right hand $M=958 \mathrm{~ms}$; Nonword: Past verbs - left hand $M=1111 \mathrm{~ms}$, Past verbs right hand $M=1150 \mathrm{~ms}$, Future verbs - left hand $M=$ 1116 ms , Future verbs - right hand $M=1050 \mathrm{~ms}$ ).

The analyses of accuracy revealed only a main effect of Lexical status $(F(1,22)=6.03, M S e=2.43, p<.05)$, which confirmed a greater easiness for participants in processing and responding to words than nonwords (2.1 vs. 2.7 mean errors, respectively).

No other main effects or interactions were significant.

Figure 1. Mean latencies for the factors Temporal reference and Key in Experiment 1.

## Discussion

Experiment 1 found a significant interaction between temporal reference of the stimulus and side of response, taking the form of a standard left-right space-time congruency effect: responses to past sentences were faster with the left hand and responses to future sentences were faster with the right hand, independently of their lexicality. These results replicate and extend prior findings in the literature (e.g., Torralbo el al., 2006; Santiago el al., 2007; Ulrich \& Maienborn, 2010), suggesting, firstly, that a left-to-right mental time-line have been activated in this task, and secondly, that lexical status does not modulate its activation. In other words, the mental time line is used to process the temporal reference of both meaningful and
meaningless words (which are also simple sentences in Spanish).

## Experiment 2

Experiment 2 only differed from the prior experiment in the task instructions: participants were asked to decide whether the stimuli were real Spanish verbs or not. Thus, they carried out a lexical decision task for which temporal reference is irrelevant. The design of the experimental materials made sure that temporal reference information was equally present and salient in both the words and the nonwords.

## Method

Participants 24 Psychology students from the University of Granada (1 male; age range 20-25 y.; 4 left-handed by self-report) participated for course credit. All participants had normal or corrected-to-normal vision and were naive as to the purposes of the experiment.

Materials and procedure Everything was identical to Experiment 1, with the only exception of the instructions: participants decided whether the stimuli were real Spanish verbs or not.

## Design and Analysis

The data were analyzed using a mixed factorial ANOVA with the same factors as in Experiment 1: Lexical status (word vs. nonword) x Temporal reference (past vs. future) x Key (left vs. right) x Counterbalance (not reported further).

## Results

Errors occurred in $5.19 \%$ of trials and were analyzed independently. Reaction times (RTs) exceeding 2 standard deviations from each participant's mean were excluded from the analysis, leading to the removal of an additional $9.56 \%$ of data.
The ANOVA on RTs reported two significant main effects. First, as expected, there was a main effect of Lexical status $(F(1,22)=64.84, M S e=4141.01, p<.001)$ : latencies for nonwords ( 883 ms ) were longer than for words ( 808 ms ) as in Experiment 1. Second, the factor Temporal reference $(F(1,22)=26.22, M S e=2464.2, p$ <.001) was also significant, indicating shorter latencies for past ( 828 ms ) than for future verbs ( 864 ms ). No other main effects or interactions were significant in the RTs analyses. Thus, the lexical decision task failed to replicate the Temporal reference x Key interaction obtained in Experiment $1(F<1$; Past verbs - left hand $M=831 \mathrm{~ms}$, Past verbs - right hand $M=824 \mathrm{~ms}$, Future verbs - left hand $M=866 \mathrm{~ms}$, Future verbs - right hand $M=862 \mathrm{~ms}$ ).
An omnibus ANOVA pooling together both experiments with the between-subjects factor Task (temporal vs. lexical) and the same within-subjects factors mentioned above revealed a significant three-way interaction between Task x Temporal reference x $\operatorname{Key}(F(1,46)=$ 12.59, $M S e=8342.15, p<.001$ ). This confirmed that the two tasks generated different patterns of results.

In the analyses of accuracy there was a main effect of Lexical status $(F(1,22)=10.28, M S e=2.85, p<.01)$, which indicated again that words were easier to process than non-words ( 1.5 vs. 2.3 mean errors, respectively).
No other main effect or interactions were significant.

Figure 2. Mean latencies for the factors Temporal reference and Key in Experiment 2.

## Discussion

The central observation of Experiment 2 was the absence of interaction between left-right responses and temporal reference. This null result occurred in the context of a very clear and sizeable interaction obtained in Experiment 1 using the same stimuli, procedures and participant population. Therefore, it seems that even when specially designed stimuli are used to make sure that temporal reference is processed, the emergence of a congruency effect between left-right space and time is strongly mediated by the context and the goal of the task: the effect can only be found when temporal processing is taskrelevant.

## General Discussion

The present study addressed the question of the automaticity of the activation of the left-right mental timeline. In line with prior findings (e.g., Torralbo et al, 2006; Ulrich \& Maienborn 2010; Ulrich et al, 2012) there is flexibility, not automaticity, in the activation of the mental time-line(s). Short, single words and nonwords especially designed to secure a deep processing generated a strong space-time congruency effect when participants judged their temporal reference, but failed to do it in a lexical decision task. This result agrees well with the conclusions obtained by Ulrich et al (2012) regarding the front-back time line with longer sentences in German, and corroborates those by Ulrich and Maienborn (2010) regarding the left-right time line without some of their potential confoundings.
Present results are also consistent with the view that, all other factors being equal, only the conceptual mappings that are required to carry out the task are set up in working memory (Santiago et al, 2011). It also agrees well with the flexibility observed in the literature on the automaticity of affordance effects (e.g., Borghi et al, 2012; Natraj et al, 2013).

Obviously, present results leave open many future lines of inquiry, and the issue of the automaticity (or lack thereof) of the activation of the mental time line is still not
closed. An important remaining question is whether it is possible to observe the activation of the mental time line in time-irrelevant tasks using different conditions. One interesting possibility has to do with the use of temporal stimuli which have a more direct link to temporal reference, such as dates, months or weekdays. Another possibility is that a more sensitive measure might be able to find the effects (e.g., mouse trajectories). Data are currently being collected about this latter possibility
If the activation of the mental time line remains taskdependent, then there raises the question of why. Other conceptual mappings on the spatial dimension have been shown to be activated automatically at least under certain conditions (e.g., evaluation with approach-avoidance responses, Chen \& Barg, 1999; or number magnitude, Dehaene et al, 1993). Space and time seem to be intrinsically linked from the initial stages in development (Piaget, 1969) and the influence of space on temporal judgments in psychophysics tasks remains until the adult age (Casasanto \& Boroditsky, 2008; Casasanto et al, 2010). Why then participants do not activate the spatial dimension automatically when processing linguistic stimuli with a temporal reference? Future research needs to address this question.
In conclusion, present results corroborate that the leftright space-time congruency effect is strongly mediated by the context and goal of the task, such that it only arises when the task explicitly requires judging temporal reference.

# Surprise! You've Got Some Explaining to Do... 

Meadhbh I. Foster (meadhbh.foster@ucdconnect.ie) Mark T. Keane (mark.keane@ucd.ie)<br>Department of Computer Science \& Informatics, University College Dublin Belfield, Dublin 4, Ireland

#### Abstract

Why are some events more surprising than others? We propose that events that are more difficult to explain are those that are more surprising. The two experiments reported here test the impact of different event outcomes (Outcome-Type) and task demands (Task) on ratings of surprise for simple story scenarios. For the Outcome-Type variable, participants saw outcomes that were either known or less-known surprising outcomes for each scenario. For the Task variable, participants either answered comprehension questions or provided an explanation of the outcome. Outcome-Type reliably affected surprise judgments; known outcomes were rated as less surprising than less-known outcomes. Task also reliably affected surprise judgments; when people provided an explanation it lowered surprise judgments relative to simply answering comprehension questions. Both experiments thus provide evidence on this less-explored explanation aspect of surprise, specifically showing that ease of explanation is a key factor in determining the level of surprise experienced.

Keywords: Surprise; explanation; comprehension, coherence

## Introduction

Life is full of surprises, from bumping into a friend from home while on holidays, to arriving at a surprise party, to opening an amazing birthday gift, or hitting paydirt on that 100-1 racehorse. Surprise has been researched since Darwin's time, perhaps because it involves an interesting mixture of emotion and cognition. Originally, it was conceived of as a "basic emotion" (see Darwin, 1872; Ekman \& Friesan, 1971; Izard, 1977; Plutchik, 1991; Tomkins, 1962), though more recently it has been reappraised as a cognitive state (Kahneman \& Miller, 1986; Maguire, Maguire \& Keane, 2011) because, unlike most emotions, it can either be positively or negatively valenced (Ortony \& Turner, 1990). Although surprise clearly involves an emotional reaction (often accompanied by a startle response) it may also serve a strategic, cognitive goal, as it directs attention to explaining why the surprising event occurred and to learning for the future (see e.g., Maguire et al., 2011; Ranganath \& Rainer, 2003). Accordingly, in Artificial Intelligence (AI), surprise is seen as a candidate mechanism for identifying learning events in agent architectures (Bae \& Young, 2008, 2009; Macedo \& Cardoso, 2001; Macedo, Reisenzein \& Cardoso, 2004).

Imagine that you walk into your house and the walls have changed color from the color they were this morning. If you have no explanation for this turn of events then you would
probably be surprised by this outcome ${ }^{1}$. Many outcomes are surprising, the question is why? Our answer is that outcomes are surprising when they are hard to explain. Specifically, that surprise is a meta-cognitive sense of the amount of explanatory, mental work that was carried out to establish coherence between unfolding events in the world.

To illustrate the point, consider different scenarios for the "re-decoration surprising outcome". If I had left a team of decorators in my house that morning, I would clearly be less surprised by my walls being re-painted, because I had planned for that to occur. If no decorators were contracted, then I would be really surprised at this outcome, because no obvious explanation is forthcoming. However, if my wife and friends have been smirking at me for weeks (the way they do when they throw surprise parties) I would be less surprised because I can explain it as a prank. The experience of surprise will gradually increase across these scenarios as they move from being thoroughly-explainable (contracted decorators) to potentially explainable (smirking friends) to thoroughly-unexplainable (no decorators or smirking) because people have to carry out more explanatory, mental work to establish the coherence of these unfolding events.

In theories of surprise, one group of theorists have focussed on the properties of surprising outcomes, characterising them as low-probability events, disconfirmed expectations or schema-discrepant events (e.g., Meyer, Reisenzein \& Schützwohl, 1997; Reisenzein \& Studtmann, 2007; Schützwohl \& Reisenzein, 1999). Another group of theorists have stressed the importance of (often retrospective) sense-making and the integration of the surprising outcome to make it cohere with previous events (Kahneman \& Miller, 1986; Maguire \& Keane, 2006; Maguire et al., 2011). Theoretically, we are more aligned with the latter than with the former group; the main novelty in our approach being its emphasis on the meta-cognitive, explanatory aspects of the sense-making process. Adopting this meta-cognitive, explanatory approach suggests that experienced surprise may differ (a) for different classes of surprising outcomes (i.e., known versus less-known outcomes) and (b) under different task demands (i.e., being explicitly asked to explain a surprising outcome or not).

[^265]
## Classes of Surprising Outcomes

Viewing surprise from an explanation-perspective, suggests that outcomes may vary in their surprisingness because some are more well-known (directly or vicariously) than others. Intuitively, losing your wallet and losing your belt (that you put on your jeans this morning) are outcomes that could both surprise you during your day. We could call "losing your wallet" a known surprising outcome as it is an experience that people often discuss with one another, suggesting that most people have several "ready-made" explanations for it (see also Schank, 1986); that I left it in a shop, that I dropped it or that I was pickpocketed. In contrast, "losing your belt" is a less-known surprising outcome, suggesting perhaps that there are few or no "ready-made" explanations for $\mathrm{it}^{2}$. We predict that differences in the explanation spaces for these different classes of outcomes will result in different amounts of mental work to make them coherent and, thus, result in different levels of experienced surprise. Traditional probabilistic accounts would recast this known/less-known dimension as some variation of subjective probability, making parallel predictions about levels of surprise. However, obviously, we do not think that subjective probability is the key predictor of behaviour; indeed, in related work where it has been explicitly assessed, it has been shown not to accurately predict levels of surprise (see Maguire et al., 2011, Experiment 1).

## Explanation Task

Viewing surprise as a meta-cognitive effect suggests that if we ask people to explicitly explain the surprising outcome, they will be less surprised than if they receive task demands that are less directed toward explanation (e.g., comprehension questions about the scenario). If people are in "explanation mode" then clearly they should expend less mental effort in explaining the surprising event and hence, other things being equal, should experience less surprise relative to being in some "non-explanation mode". Should such explanation-effects occur, they can probably be explained in some ad hoc fashion by probabilistic accounts; however, we cannot see how a probabilistic account would lead one to perform such a test.

## Experiment 1

To test these predictions, we asked people to make surprise ratings about the outcomes of simple story scenarios describing everyday events. Some outcomes were known surprising outcomes, others were less-known surprising outcomes (see operational definitions in Materials). The task demands were varied by asking participants to either produce the answer to two short comprehension questions about that story or to produce an explanation for why that outcome may have occurred. So, the experiment involved a $2 \times 2$ design with Task (explanation vs. comprehension) as a

[^266]between-subjects variable and Outcome-Type (known vs. less-known) as a within-subjects variable. The questions asked for the comprehension task were very simple, using information clearly and unambiguously presented in the text given to participants (e.g., "Where is [character's name]?").

First, it was predicted that scenarios involving known surprising outcomes would be rated as less surprising than those with the less-known surprising outcomes; as explanations (or partial explanations) for the former would be available for use in making the outcome cohere with the rest of the scenario. Second, it was also predicted that the task demand to find an explanation would result in lower surprise ratings for outcomes, relative to the task demand of answering comprehension questions on the same stories. We made no specific predictions about whether these two variables would interact.

## Method

Participants and Design Forty UCD students (12 male, 28 female) with a mean age of 21.2 years ( $S D=2.07$, range $=$ 19-29) took part voluntarily in this study. Informed consent was obtained prior to the experiment. Participants were randomly assigned to one of two conditions in a 2 (betweensubjects; Task: explanation versus comprehension) x 2 (within-subjects; Outcome-Type: known versus less-known) mixed-measures design.

Materials A material set was created consisting of simple story scenarios with outcomes that were designed to involve known or less-known surprising outcomes (see Table 1). The type of outcome was operationally defined using (a) a pre-test sorting task by an independent group of raters and (b) Latent Semantic Analysis (LSA) scores of coherence.

For the sorting task definition, 20 story scenarios were presented in a pre-test to independent raters $(N=10)$. The raters were assigned to two groups: one group received half the scenarios with a known surprising outcome and the other half of the scenarios with a less-known surprising outcome, and the second group received the opposite. Each rater saw only one outcome for a given scenario. They were asked to determine if a given scenario has an outcome that "falls within the range of reasonable outcomes to the scenario" (i.e., known surprising outcome) or whether it "falls less within the range of reasonable outcomes to the scenario" (i.e., less-known surprising outcome). Of the 20 stories, the raters consistently deemed 9 stories to have separable known and less-known surprising outcomes (Fleiss' kappa showed substantial agreement, $\kappa=.68$, Landis \& Koch, 1977).

For the coherence-score definition, the known and lessknown variants of these 9 stories were scored using LSA. In discourse research (cf., Graesser \& McNamara, 2011), the explanatory coherence of texts is often operationalized by using latent semantic analysis (LSA) scores, where higher LSA scores indicate that the one text is more coherent than another (Landauer \& Dumas, 1996, 1997). For the selected 9 stories used in the experiment, the scenarios with the
known outcomes were scored higher ( $M=.62, S D=.2$ ) than their matched counterparts with less-known outcomes ( $M=$ $.53, S D=.21$ ), a difference that was statistically reliable, $F(1,8)=9.47, p=.015, \eta_{\mathrm{p}}^{2}=.54$.

Four material sets were created. Each of these comprised all nine scenarios, with either four scenarios with known surprising outcomes and five with less-known surprising outcomes, or five scenarios with known surprising outcomes and four with less-known surprising outcomes. As expected, the four material sets used proved to have no effect on subsequent surprise judgments, so these results are not reported in the following analyses ( $p>.12$ )

The order of presentation of these stories was randomised for each participant. Stories were presented on separate pages of a booklet, which began with the appropriate task instructions (explanation or comprehension). Each story was presented on a separate page with the scenario setting on the top of the page, followed by the outcome (known/lessknown), the statement of the task (comprehension or explanation) and a 7 -point scale on which to rate the suprisingness of the outcome (1: not surprised to 7 : very surprised).

Procedure and Scoring Participants were asked to read nine stories and to judge the surprisingness of their outcomes (see Table 1). For the Task variable, the participants in the explanation condition were asked to produce the first explanation they could think of for why the outcome may have occurred, before rating it for surprise; in the comprehension condition the participants were asked to answer two simple comprehension questions about the scenario, before rating it for surprise. For each story, the first question was about the story setting, and the second question was about the outcome.

| Setting | Rebecca is on the beach. <br> She goes for a swim in the water. |  |
| :--- | :---: | :---: |
| Outcome | Known <br> After she dries <br> herself off she <br> notices that her skin <br> has turned red. | Less-known <br> After she dries <br> herself off she <br> notices that her skin <br> has turned turquoise. |

Prior to the experiment, we conducted a pre-test $(N=4)$ to verify that there was no significant difference in the average time taken to produce an explanation compared to that taken to answer the two short comprehension questions; time taken to do one task or the other were not reliably different $(t(2)=-1.41, p=.29$, explanation $M=6.5$ minutes; comprehension $M=7.5$ minutes). Two measures were recorded: (a) the 7 -point scale rating of surprise, and (b) the explanations produced by participants for each scenario in the explanation group. Finally, prior to data analysis one
participant ( $2.5 \%$ of the data) was discarded because they failed to follow the instructions given.

## Results and Discussion

Overall, the results confirmed the predictions that OutcomeType and Task both impact people's perceptions of surprise. The intuition that known outcomes are less surprising than less-known outcomes was confirmed, as was the prediction that instructions to explain the outcome would reduce the overall perception of surprise. So, for example, though both outcomes were deemed to be surprising, the lost-wallet type of scenario was found to be less surprising than the lost-belt type of scenario. No reliable interaction was found between the two variables.

Surprise Judgments A two-way ANOVA confirmed that participants judged stories with known outcomes ( $M=3.92$, $S D=1.18$ ) to be less surprising than those with less-known outcomes ( $M=5.73, S D=0.95$ ), $F(1,37)=128.82, p<$ $.001, \eta_{p}^{2}=.78$, see Figure 1. We maintain that this Outcome-Type effect occurs because known outcomes have associated "ready-made" explanations that are recruited quickly and easily to explain the outcome, lowering surprise ratings. In contrast, stories with less-known outcomes have few "ready-made" explanations to be recruited, so the outcome is harder to explain, resulting in relatively higher surprise ratings.

There was also a significant main effect of Task, $F(1,37)$ $=10.18, p=.003, \eta_{\mathrm{p}}{ }^{2}=.22$, indicating that the explanation group judged the outcomes to be less surprising ( $M=4.40$, $S D=1.03$ ) than the comprehension group ( $M=5.27, S D=$ 0.62 ). This effect occurs because in 'explanation mode' participants find explanations more easily and, hence, for meta-cognitive reasons, their perception of surprise decreases. No interaction between the two variables was found, $F(1,37)=0.00, p=.98, \eta_{\mathrm{p}}^{2}<.001$.

Figure 1: Mean surprise ratings for both levels of Outcome-
Type (known vs. less-known) and Task (explanation vs. comprehension) in Experiment 1

Explanations The explanations provided by the participants in the explanation group provide a key piece of converging
evidence for the view that known outcomes differ from lessknown outcomes. Participants' explanations for each scenario were recorded and classified to identify the most common or dominant explanation for a given scenario. We then carried out a by-materials analysis of the scenarios using the frequency of this dominant explanation as the dependent measure. The ANOVA revealed a main effect of Outcome-Type, in which dominant explanations were found to be more frequently produced to known outcomes ( $M=$ $5.44, S D=1.59)$ than less-known outcomes $(M=4, S D=$ 1.32), $F(1,8)=6.76, p=.03, \eta_{\mathrm{p}}^{2}=.46$. So, participants agree more about the explanations for known outcomes than they do for less-known outcomes, showing that the explanation spaces for these classes of outcomes differ.

## Experiment 2

Our second experiment attempted to replicate the effects found for Outcome-Type and Task, while adding a manipulation to the setting (Setting-Type) designed to elicit counterfactuals, to test another potential aspect of surprise.

Kahneman \& Tversky (1982; Kahneman \& Miller, 1986) proposed that "abnormal events" (our "surprising outcomes") will seem more abnormal if contrasting counterfactual alternatives are highly available; that is, the abnormal event (i.e., losing your wallet) will appear more abnormal if the contrasting counterfactual (i.e., the normal event of "having your wallet") is highly available. Kahneman \& Miller also propose that the availability of the normal event (the counterfactual) can provide an explanation for the abnormal event (the factual one), as people often use the difference between the two events to find an explanation. So, in theory, the elicitation of such counterfactuals could reduce the perceived surprise of an outcome, as it could provide a "quick and dirty" explanation of the surprising outcome. However, this prediction assumes that the counterfactual-inspired explanation is always used (which may not be a given). The literature on counterfactuals (Byrne, 2002; Kahneman \& Tversky, 1982) shows that they tend to be elicited when scenarios mention non-routine events (e.g., if you are told Jack had a car crash when he did not take his usual route home, people naturally draw on the counterfactual scenario of Jack taking his usual route home to find an explanation), though this is not always the case (e.g., Dixon \& Byrne, 2011). So, in this experiment, in addition to the original settings used in Experiment 1 (none), to elicit counterfactuals we changed the setting in the scenarios to stress that the event was either routine (usual) or non-routine (exceptional; see Table 2) for the actor involved.

So, the final design for this experiment manipulated Task (comprehension versus explanation), Outcome-Type (known versus less-known) and Setting-Type (none, usual or exceptional).

## Method

Participants and design Sixty UCD students (27 male, 33 female) with a mean age of 20.95 years ( $S D=4.228$, range
$=18-44)$ took part voluntarily in this study. Informed consent was obtained prior to the experiment. Participants were randomly assigned to one of two conditions in a 2 (between-subjects; Task: comprehension versus explanation) x 2 (within-subjects; Outcome-type: known versus less-known) x 3 (within-subjects; Setting-Type: none, usual, exceptional) mixed-measures design.

Procedure and Scoring As in Experiment 1, participants were asked to read nine stories and to judge the surprisingness of their outcomes. Rather than asking participants how surprised they would be "if this event occurred" (as they were in Experiment 1), they were asked to judge how surprised they would be by the event "if they were the character described". For the Setting-Type variable, the events in the story setting (a) gave no hint as to whether they were routine or not (none), (b) were said to be regular or routine (usual), or (c) said to be non-usual or nonroutine (exceptional). For the Outcome-Type variable, the participants saw either a known or less-known surprising outcome for each story; only one outcome and one setting was seen by each participant for each story (see Table 2 for an example of the materials used). The LSA scores for the three variants of the setting, none, usual and exceptional showed no main effect of this Setting-Type variable ( $p>$ .59).

Table 2: Sample scenario used in Experiment 2

|  | None | Usual | Exceptional |
| :--- | :---: | :---: | :---: |
| Sentence 1 | Lorna is in <br> an ethnic <br> restaurant. | Lorna is in her <br> favourite ethnic <br> restaurant that <br> she has often <br> gone to before. | Lorna is in a <br> new ethnic <br> restaurant that <br> she has never <br> gone to before. |
| Sentence 2 | She has ordered her food and, after a while, the |  |  |
| waiter brings it to her. |  |  |  |

Six material sets were created. Each of these comprised all 9 scenarios, with three variants of each setting type (none, usual, exceptional). Of these, either four scenarios were presented with known surprising outcomes and five with less-known surprising outcomes, or five scenarios with known surprising outcomes and four with less-known surprising outcomes. As expected, the six material sets had no effect on subsequent surprise judgments, so were not included as a variable in the reported analyses ( $p>.5$ ).

The order of presentation of these stories was randomised anew for each participant. Stories were presented sentence by sentence on a desktop computer-screen as participants pressed the spacebar, with each sentence appearing below the preceding one on the screen, until the outcome was presented. At this point, the participants in the explanation condition were instructed to "type in the first explanation you can think of for why this outcome may have occurred:"
and the participants in the comprehension condition saw and answered sequentially two simple comprehension questions about the story. One of these questions was about the information provided in the setting, and the other was about information provided in the outcome. Neither of these questions drew the participants' attention to the SettingType variable, per se. Initially, the participants in this condition saw the first question and, after providing an answer, they pressed the return key, this first question disappeared and the second question appeared. After the explanation/comprehension step, all participants pressed the return key and the question "If you were [character's name], how surprised would you be by this outcome?" On presentation of this question, participants indicated on a 7point scale their surprise judgment (1: not surprised, to 7: very surprised). Three measures were recorded: (a) the 7point rating of surprise, (b) the response time from the time of seeing the outcome sentence to the time in which the surprise judgment was made ${ }^{3}$, and (c) the explanations produced by each participant for each scenario. Finally, prior to data analysis, four participants ( $6.7 \%$ of the data) was discarded for failing to follow the instructions given.

## Results and Discussion

Overall, the results confirmed the predictions that known surprising outcomes and the adoption of an "explanationmode" decreased the perception of surprise; however, there was no strong evidence for a counterfactual effect.

Surprise Judgments A three-way ANOVA confirmed that participants judged known outcomes to be less surprising ( $M=4.51, S D=1.11$ ) than less-known outcomes $(M=6.21$, $S D=.75)$, showing a main effect of Outcome-Type, $F(1,54)$ $=92.46, p<.001, \eta_{\mathrm{p}}^{2}=.63$. There was also a significant main effect of Task, $F(1,54)=4.64, p=.036, \eta_{\mathrm{p}}^{2}=.08$. indicating that participants judged the outcomes of scenarios to be more surprising when they had answering comprehension questions, $(M=5.56, S D=.63)$ as opposed to providing explanations for them $(M=5.09, S D=.85$; see Figure 2). However, there was no main effect of SettingType, $F(2,108)=.002, p=.998, \eta_{\mathrm{p}}^{2}<.001$, no interaction between Outcome-Type and Setting-Type, $F(2,108)=2.78$, $p=.07, \eta_{\mathrm{p}}^{2}=.05$, and no reliable 2-way interactions between the variables (all $F \mathrm{~s}<1$ ).

Explanations Again the frequency with which the most dominant explanation was chosen by the explanation group was calculated for each scenario. A two-way, by-materials ANOVA showed a main effect of Outcome-Type, in which participants were more likely to produce the same dominant explanation for a known surprising outcome ( $M=7.89$, $S D$ $=3.26$ ) than for a less-known outcome ( $M=5.22, S D=$ 2.63), $F(1,8)=6.09, p=.039, \eta_{\mathrm{p}}^{2}=.43$. So, again, participants seem to have a greater degree of shared knowledge in the explanation of known outcomes than they

[^267]do for less-known outcomes, showing that the explanation spaces for these classes of outcomes differ.

Figure 2: Mean surprise ratings for both levels of OutcomeType (known vs. less-known) and Task (explanation vs. comprehension) in Experiment 2

## General Discussion

Overall, the experiments showed that known surprising outcomes are perceived as less surprising than less-known outcomes for the same scenarios, presumably because they are easier to explain. The task of explaining itself was also found to significantly reduce surprise ratings relative to answering comprehension questions in both experiments, again demonstrating how explanation may be the key factor in determining the level of surprise experienced. Finally, the explanations produced by participants were found to be more homogeneous for known outcomes than for lessknown outcomes; that is, there seems to be a shared dominant explanation used to explain known outcomes, that is less present in the case of less-known outcomes. We believe that these results provide converging evidence for an explanation-based account of surprise. Indeed, taken together, the combined effects on surprise found here strongly suggests that surprise may be a metacognitive effect (see Müller \& Stahlberg, 2007; Sanna \& Lundberg, 2012; Touroutoglou \& Efklides, 2010), with perceived surprise reflecting the ease or difficulty of explaining the surprising event.

However, little evidence was found for the counterfactual effect tested for in Experiment 2 (see the Setting-type variable). Both Kahneman \& Miller's Norm Theory (1986) and Teigen \& Keren's Contrast Hypothesis (2003) seem to predict that the ready availability of counterfactuals may influence the degree of surprise experienced; norm theory proposes that counterfactuals are used to explain why the event occurred, while the contrast hypothesis proposes that what was expected to occur (the events these counterfactuals elicit) is contrasted with the outcome to determine the level of surprise. There are several possible reasons for this prediction failure; it could be that our manipulation was not notable enough to elicit counterfactuals (though prior research would suggest
otherwise), or it could be that counterfactuals were generated but not used for explanation, or not considered as good-enough explanations. Of course, it could also be the case that the prediction is just wrong.

The current work also has implications for AI approaches to agent architectures, where it has been proposed that surprise might be used to identify learning events (e.g, Macedo \& Cardoso, 2001; Macedo, Reisenzein \& Cardoso, 2004). This proposal looks like it could be useful, once it is tempered by some consideration of the degree of surprise entailed and the ease of producing an explanation. The current work suggests that both of these aspects of the surprise process can differ considerably and, as such, would deliver very different learning outcomes for an agent.

# Frequent Frames, Flexible Frames and the Noun-Verb Asymmetry 

Daniel Freudenthal, Julian Pine<br>School of Psychology, University of Liverpool<br>Gary Jones<br>School of Psychology, Nottingham Trent University<br>Fernand Gobet<br>School of Psychology, University of Liverpool

#### Abstract

In this paper we compare several mechanisms for using distributional statistics to derive word class information. We contrast three different ways of computing statistics for independent left and right neighbours with the notion of a frequent frame. We also investigate the role of utterance boundaries as context items and weighting of frequency information in terms of the successful simulation of the noun-verb asymmetry. It is argued that independent contexts can classify items with a higher degree of accuracy than frequent frames, a finding that is more pronounced for larger input sets. Frequent frames classify a larger number of items, but do so with lower accuracy. Utterance boundaries are useful for the development of a noun category, particularly at intermediate levels of frequency sensitivity.

Keywords: Word class derivation, independent contexts, frequent frames.

## Introduction

Several authors have shown that distributional statistics can provide powerful cues for acquiring syntactic categories; words that belong to the same syntactic category tend to be preceded and followed by the same words. Thus, nouns tend to be preceded by determiners and adjectives and followed by verbs. Redington, Chater and Finch (1998), building on work by Chater and Finch (1992), investigate several variants of the same basic principle: for any of a set of target words, a context vector was derived that contained (rank orders of) counts of the 150 most frequent words in the corpus, in positions preceding and following the target words. Redington et al. computed correlations between the context vectors of the target words, which were then used as input to a Hierarchical Cluster Analysis, and concluded that the resulting classes mapped closely onto broad syntactic classes. Redington et al. explore a number of variants of the basic mechanism, but get their best results by using a context of one preceding and one following word, and using a rank order correlation as their distance measure.

An alternative mechanism for acquiring syntactic categories has been proposed by Mintz (2003). Mintz introduces the notion of a frequent 'frame': two lexical items with one word intervening (e.g. He X to). Mintz argues that the (45) most frequent frames in the (English) corpora he analyses show high internal consistency in
terms of the grammatical category of the items that occur in the central position. The notion of a frequent frame is therefore thought to provide a powerful cue that children might employ in the acquisition of syntactic categories. More recent work has confirmed the utility of frequent frames for French (Chemla et al. 2009), but results have been less promising for languages with relatively free word order such as Dutch (Erkelens, 2009) and German (Stumper et al. 2011).

A major difference between the approaches of Redington et al. and Mintz is that the approach described by Redington is inherently graded and frequency sensitive in nature. Thus, in this approach, co-occurrence statistics are collected across all uses of a particular word. Depending on the exact implementation, the approach can also show varying degrees of frequency sensitivity with context vectors containing (rank orders of) word counts. Similarity is then expressed as a correlation-like measure across context vectors, which can be interpreted as a probability of two items being of the same class. This graded context-sensitivity is absent from Mintz's approach. Thus, while Mintz's analysis is restricted to the 45 most frequent frames, it clusters together all items that co-occur in one of these frames. The approach therefore ignores many contexts in which a word may occur, and instead clusters items on the basis of (potentially one) occurrence in specific high frequency contexts.
Typically, mechanisms for extracting grammatical categories are evaluated in terms of accuracy (the extent to which items that are clustered together belong to the same syntactic category) and completeness (the extent to all items within one syntactic category are clustered together). St. Clair et al. (2010), as well as Monaghan (2004), compared frames and independent contexts as used by Redington et al. in the context of connectionist simulations, and found that frames were accurate but resulted in low completeness while independent contexts performed similarly in terms of accuracy but outperformed frames in terms of completeness.
However, while high accuracy is clearly a desirable property of a mechanism that derives syntactic categories (children for instance make very few word class errors), it is less clear if high completeness is desirable, particularly if one is interested in modeling children's early linguistic abilities. Thus, while children ultimately develop
linguistic abilities that suggest the presence of relatively abstract linguistic categories, their early multi-word speech has been characterized as lexically specific. Moreover, completeness is often measured across word classes, when there appear to be developmental discontinuities in children's productive use of grammatical categories. Thus, children appear to be more prepared to produce novel nouns than novel verbs in familiar contexts (Akhtar \& Tomasello, 1997), a finding which has led to the suggestion that children may develop a productive noun category earlier than a productive verb category (Tomasello, 2000).

On the basis of these considerations, it would seem that a mechanism that is plausibly employed by language learning children is one that favours accuracy over completeness and favours the linking of high numbers of nouns over the linking of high numbers of verbs. One factor that might impact on the relative likelihood of linking nouns and verbs is the weighting of frequency information. Nouns for instance have a relatively high likelihood of being preceded by one of a small set of determiners. A second factor that is likely to affect the relative linking of nouns and verbs is the availability of utterance boundaries as framing elements. Nouns have a relatively high likelihood of occurring in utterance final position, and the utterance boundary is thus a potentially powerful cue for a noun category. Freudenthal et al. (2008), in the context of connectionist simulations, provide some evidence in support of this suggestion.

The main aims of this paper then are as follows: 1. To compare frequent frames and measures similar to those used by Redington et al. (1998) in terms of their ability to simulate the word classes apparent in children's early speech, 2. To investigate how different levels of frequency sensitivity as well as the availability of utterance boundaries may impact on these mechanisms.

## Similarity measures used

In the current paper we compare 4 different measures of similarity. We consider the frequent frames approach described by Mintz (2003), as well as 3 different implementations of the independent contexts approach described by Redington et al. (1998). In line with Redington et al., we considered as target words (i.e. words to be classified) the 1000 most frequent words in the corpus. The frequent frames approach closely followed the implementation by Mintz: we considered the target words that co-occurred in the 45 most frequent lexical frames within a corpus. The implementations of independent contexts closely followed the implementation of Redington et al. The context for a given word was encoded as a vector of length 300 consisting of counts of the 150 most frequent words in the corpus in the position directly preceding and following the target word. The actual similarity measures based on these vectors were: 1. Spearman rank order correlation (as used by Redington et al); 2. Cosine similarity based on raw frequency counts;
and 3. Cosine similarity based on the square root of frequency counts. These three different measures differ with respect to the weighting of frequency information, which is highest for cosine similarity based on raw counts and lowest for rank orders. Weighting of frequency information is even lower for frequent frames: this measure only considers whether or not target words cooccur within a given frame, not how often they co-occur.

## Corpora

The analyses were performed on the child-directed speech of the 12 children in the Manchester corpus (Theakston et al., 2001). The child-directed speech in the Manchester corpus is typically in the range of 25,000 to 30,000 utterances per child. Corpora were cleaned up minimally, and only multi-word utterances were analysed. For all corpora the following statistics were collected: for every word in the corpus, counts were collected for the items that preceded and followed it, as well as the frames (A X B) that surrounded them. Frame counts were then tallied across words to determine overall counts for (frequent) frames.

One additional manipulation involved the merging of the corpora for the 12 individual children into one large corpus. This manipulation was included to determine whether the mechanisms under investigation are differentially affected by changes in corpus size.

For the purpose of determining accuracy of derived word pairings, words were assigned their respective Part of Speech (POS) tag as employed on the \%mor coding tier of the corpus. POS tags in the Manchester corpus are relatively detailed and distinguish between main verbs and auxiliaries, as well as nouns, pronouns and proper nouns. The categories employed here are therefore similar to what Mintz terms 'expanded' labelling. Where multiple POS tags were used for one word form (e.g. forms that can be used as either noun or verb) the most frequently used POS tag was assigned. That is: words forms were assigned to the grammatical category in which they were used most frequently.

## Results

There are several ways in which one can evaluate the success of different similarity measures. Redington et al. (1998) performed a cluster analysis, and plotted accuracy and completeness as a function of the similarity level (or number of clusters extracted). While this is informative, it does raise a number of problems in interpreting the outcome. First, it is not immediately obvious at what similarity level one should compare different mechanisms, and second, the clustering process itself can be performed in different ways which have the potential to influence the results in terms of accuracy and completeness. For these reasons we opted to sidestep the clustering process, and perform a more direct evaluation of the similarity scores. This was done by extracting all possible word pairs, and computing the relevant similarity

Table 1: Accuracy and number of classified words for the four different distance measures.

metrics for every word pair. Where a similarity metric exceeded a certain threshold the word pair was considered to belong to the same category.

This procedure obviously raises the question of what threshold should be chosen for the different similarity metrics. Generally, higher values for the threshold will result in higher levels of accuracy and lower numbers of classified items, but these numbers may differ across metrics for a specific value of the threshold. For this reason, we decided to choose a different value for the threshold across metrics such that the resulting accuracy was always relatively high ( $\sim 90 \%$ ) and comparable across the metrics ${ }^{1}$, thus allowing for a meaningful interpretation of differences in completeness. Table 1 shows percentage accuracy as well as number of classified items for the 12 individual children in the Manchester corpus, the average for these children as well as scores for the merged Manchester corpus.

The concept of a threshold for classification is irrelevant for frequent frames (thus making it impossible to peg accuracy at $90 \%$ ), as the notion of a frame entails that two items that co-occur in one of the frequent frames are of the same word class. Table 1 therefore lists accuracy and number of classified items for all word pairs that co-occurred in one of the 45 most frequent frames in

[^268]the relevant corpus. Word pairs that co-occurred in multiple frames were counted only once.

Looking at the individual children and their average in Table 1, it is obvious that there are substantial differences between the different metrics. Frequent frames classify a large number of pairs, but do so at relatively low accuracy. Accuracy levels for frequent frames are lower than reported by Mintz (who reports a type accuracy of .91). This lower accuracy is at least partly caused by the fact that, for the current analyses, words were assigned to their most common category. While such a procedure makes sense for graded measures that collate statistics over different contexts, it may be less appropriate for the frame style analysis. Thus several words can be used as either a noun or a verb (e.g. pull, paint). In the corpora employed here, pull is overwhelmingly used as a verb, while paint is used as a noun more often than a verb (and as a consequence, is considered to belong to the noun class for the current analyses). The frequent frames analysis will classify these items together (resulting in a false alarm) because they co-occur in the frame you $X$ your.

For this reason we performed a second, contextual accuracy analysis on the frames analysis: for every word pair that co-occurred in one of the frequent frames, we considered the actual category of the word within the (most frequent) frame. This analysis resulted in accuracy scores (. 76 on average) that were higher than in the standard analysis, but still lower than those attained by the probabilistic measures.

A comparison of the probabilistic measures also reveals differences. Spearman rank-order and square root cosine similarity classify a similar number of items at similar levels of accuracy. Raw cosine similarity on the other
hand only classifies around a third of the number of items that the other probabilistic measures classify.
Looking at the results for the merged corpus, it becomes apparent that all four measures classify a larger number of items. The three probabilistic measures however, do so with slightly higher accuracy than for the individual children, while the frequent frames measure shows a decrease in accuracy ( $66 \%$ vs. $55 \%$, and $76 \%$ vs. $69 \%$ for the contextual score). Thus, it appears that the merged corpus contains additional information that can be successfully employed by the probabilistic measures but not the frequent frames measure. The increased information in the merged corpus is actually detrimental to the accuracy score for frequent frames. This latter finding appears to be caused by the fact that the frequent frames approach is overly sensitive to the occurrence of 'stray' words within the frequent frames. The fact that a word needs to occur only once within a specific frame to be clustered with all other words within that frame means that infrequent words that are atypical of a particular frame can potentially exert undue influence on overall accuracy scores. This problem becomes more pronounced in larger corpora. Such effects are less of a problem for the probabilistic measures.

## The noun-verb asymmetry

It was argued earlier that children are more willing to use novel nouns in known contexts than they are to use verbs. This finding has been taken as evidence that children develop a productive noun category earlier than they develop a verb category. In this section, we examine to what extent the different metrics show a preference for the clustering of nouns and verbs. This was done by examining the 'hits' from the data in Table 1, and counting the number of noun-noun and verb-verb pairs. The resulting data (proportion of noun-noun pairs relative to noun-noun + verb-verb pairs) are displayed in Table 2.
It is clear from Table 2 that the measures that are most frequency sensitive cluster the highest proportion of nouns. Thus, cosine similarity based on raw frequencies clusters a relatively low number of items but these items consist almost exclusively of nouns. Square Root Cosine similarity and rank order correlation are equally productive in terms of the number of items they classify, with the more frequency sensitive Cosine Similarity linking more nouns. Frequent frames on the other hand overwhelmingly link verbs. It is also apparent from Table 2 that, for frames, there is considerable variation in the proportion of noun-noun pairings: Aran's proportion is highest at $55 \%$, but half the children show a proportion of noun-noun pairings under $5 \%$.

Table 2: Proportion of noun-noun pairings relative to noun-noun plus verb-verb pairings (total N in parentheses), excluding utterance boundaries.

## The role of utterance boundaries

The analyses reported in Table 1 and 2 only considered 'lexical contexts'. That is, only words were considered as context items. The following set of analyses included the beginnings and ends of utterances as context items. Redington et al. (1998) do consider utterance boundaries as context items in one of their analyses (and conclude that they are potentially useful), but the non-parametric nature of their distance metric (rank order correlations) may underestimate the potential utility of utterance boundaries.
Mintz (2003) does not consider utterance boundaries, and it could be argued that there is little reason to consider them. Intuitively, the appealing feature of frames is that (because of their lexical nature) they are highly constraining and hence likely to result in relatively high accuracy. Allowing utterance boundaries in frames limits their constraining nature and may thus reduce accuracy levels. At the same time, however, frames including
utterance boundaries have the potential to capture large numbers of nouns (e.g. The X end\$) and thus might serve to counteract the verb bias apparent in Table 2. Table 3 shows the accuracy scores and number of word pairings for the analysis that include the utterance boundary as a framing element. The proportion of noun-noun pairings relative to noun-noun plus verb-verb pairings are shown in Table 4. For reasons of brevity, Tables 3 and 4 do not present data for the individual children in the Manchester corpus, but only the average and merged data across the 12 children.

Table 3: Proportion correct and number of word pairings including utterance boundaries.

|  | Cos-raw | Cos-Sqrt | Spearman | Frames |
| :---: | :---: | :---: | :---: | :---: |
| Average | .82 | .90 | .90 | .49 |
|  | $(862)$ | $(5739)$ | $(3163)$ | $(81351)$ |
|  |  |  |  |  |
| Merged | .85 | .91 | .92 | .28 |
|  | $(4098)$ | $(23271)$ | $(11271)$ | $(316651)$ |

It is evident from Table 3 that the probabilistic measures deal well with the addition of the utterance boundary as a framing element. Accuracy levels are comparable to those shown in Table 1, while the number of word pairings has increased by a factor 2 to 3 . Inspection of Table 4 furthermore indicates that the increase in completeness is largely the result of increased linking of noun pairs. This is particularly noticeable in the square root cosine similarity model, which links twice as many words as the rank order model. Thus, the average square root cosine similarity model links over 4700 noun-noun pairs, compared to $\sim 1900$ for the rank order model. This difference reflects the greater frequency sensitivity of the cosine model, and suggests that square root of raw frequency represents an optimum level of frequency sensitivity.

Table 4: Number of noun-noun pairings relative to noun-noun plus verb-verb pairings, including utterance boundaries.

## Conclusions

The main aim of this paper was to compare a mechanism for extracting syntactic categories based on independent contexts with Mintz style frequent frames in terms of their accuracy and ability to cluster nouns and verbs. A secondary aim was to investigate the role of frequency sensitivity and availability of utterance boundaries as framing elements.

The analyses presented here suggest that independent contexts result in better predictions than frequent frames. Frequent frames classify a larger number of words, but do so with lower overall accuracy.

Apart from being more accurate, the mechanisms based on independent contexts also cluster more nouns than verbs. This appears to be consistent with the suggestion that children form a productive noun category earlier than they form a verb category. The reverse is true of frequent frames: across the corpora frequent frames overwhelmingly cluster verbs rather than nouns, with noun-noun pairings making up under $5 \%$ of pairings for half the corpora.

When considering large input sets (i.e. the merged Manchester corpus), it becomes obvious that the mechanisms employing independent contexts are able to utilize the additional information contained in larger data sets to classify a larger number of items with similar levels of accuracy. The frequent frames mechanism also classifies a larger number of items when employed on a larger data set, but does so with lower accuracy. This result suggests that one of the strengths of frequent frames - its ability to quickly categorize a relatively large number of items on the basis of limited data - becomes a weakness when faced with larger datasets. Thus, the fact that the approach does not consider the frequency with which items occur in the target frames, results in it being relatively brittle and sensitive to noise and infrequent items in the input.

As an illustration, consider the frame You $X$ to, which is the most frequent frame for the corpus of Carl as well as the merged Manchester corpus. Within Carl's corpus this frame contains 22 unique words, of which 20 (or 91\%) are verbs. Across the Manchester corpus, the same frame contains a total of 89 unique words of which 67 (or $75 \%$ ) are verbs. This increase in non-verbs has a marked impact on the accuracy for the frame which drops from . 74 to .49 . Many of the non-verbs occurring in the frame are legitimate (but infrequent) fillers for the frame (e.g. back, off, down, happy, ready, anything, something, just, how, over, not, one), while others are slightly more exotic: that (from we brought you that to help you), tomorrow (from who's taking you tomorrow to playgroup) to somewhat bizarre: card (from a thank you card to give you).

Since noisiness is an inherent property of the speech signal, which contains frequent repetitions, retracings and restarts, this finding suggests that frequent frames may not be a suitable source of information for category extraction unless combined with some sort of 'clean-up mechanism' or probabilistic element. Such an addition, however, would considerably weaken the great strength of this approach: its ability to rapidly classify items on the basis of little information.

All three mechanisms that computed statistics over independent contexts were able to attain higher accuracy levels, though they classified fewer items. It was argued that the probabilistic nature of these mechanisms allows
them to utilize the additional information in larger corpora without suffering from the brittleness associated with frequent frames.

A similar pattern emerges when including utterance boundaries as context items. For independent contexts, the inclusion of utterance boundaries results in comparable levels of accuracy, coupled with greater levels of completeness. The inclusion of utterance boundaries in frequent frames results in a drop in performance, in particular when considering the merged corpus. Such a finding may not be surprising (and indeed may not be in the 'spirit' of frequent frames), since the inclusion of utterance boundaries leads to the measure being less constrained than the lexical frequent frames that were originally proposed by Mintz. It does, however, provide an additional indication that independent contexts are less brittle and better able to incorporate additional, potentially noisy information.

The increased flexibility of independent contexts is further underscored by the analyses relating to the nounverb asymmetry. Empirical work has suggested that children are more likely to substitute novel nouns in familiar contexts than they are to substitute novel verbs. (Akhtar \& Tomasello, 1997; Tomasello, 2000). If the number of classified nouns versus verbs is an indication of such a tendency, frequent frames would appear to result in levels of verb-richness that are overly high. Thus, when excluding utterance boundaries, noun pairs make up on average only $28 \%$ of noun and verb pairs for frequent frames, compared to approximately $80 \%$ for independent contexts. While the inclusion of utterance boundaries leads to higher levels of noun pairs in the frequent frames approach, the results from Table 2 suggest that this is achieved at the expense of accuracy. For independent contexts, accuracy and noun richness remain high, whilst completeness is improved relative to the condition without utterance boundaries.

Some differences were also apparent within the different implementations of independent contexts. The present paper compared three different measures that differed primarily in terms of the weighting of frequency information. Within the constraints employed (which included a threshold value that results in an average accuracy level of approximately $90 \%$ ), it was apparent that a similarity measure based on raw frequency counts results in relatively low completeness, while completeness for square root cosine similarity and rank order correlations perform at similar levels of completeness, with the square root cosine similarity measure showing more of a noun advantage than the less frequency sensitive rank order correlation. Overall, the inclusion of utterance boundaries leads to higher levels of noun-richness, suggesting it is a useful source of information. The size of this effect of noun-richness however was dependent upon frequency sensitivity: while noun-richness increased for all probabilistic measures, this was most pronounced for the square root cosine
similarity, suggesting that this represents an optimum level of frequency sensitivity.

# Emotional Speech Processing and Language Knowledge 

Conor I. Frye (cifrye@cogsci.ucsd.edu)<br>Department of Cognitive Science, UC San Diego, 9500 Gilman Dr. M/S 0515<br>La Jolla, CA 92093 USA<br>Sarah C. Creel (creel@cogsci.ucsd.edu)<br>Department of Cognitive Science, UC San Diego, 9500 Gilman Dr. M/S 0515<br>La Jolla, CA 92093 USA

#### Abstract

How does language knowledge affect processing of paralinguistic information-vocal properties that are not directly related to understanding words? This study investigates links between a listener's native language, any other languages they may have experience in, and the ability to identify vocal emotional information in those languages. The study focuses on two particular classes of languages: those with lexical tone, such as Mandarin Chinese, which use pitch properties to distinguish otherwise-identical words; and those without lexical tone, such as English. English listeners and bilingual Mandarin-English listeners listened to sentences and categorized the emotional content of English and Mandarin sentences. Half of the sentences were presented normally; the other half were low-pass filtered to remove all but prosodic cues (pitch and timing). English listeners were better at identifying emotions in English sentences, while bilinguals were equally good at identifying emotions in both languages. This indicates better overall emotion recognition from prosody alone for listeners more familiar with a language. It may point to a connection between tone language experience and augmented paralinguistic processing capabilities.

Keywords: speech perception; paralinguistic perception; voice; language background; individual differences; bilingualism

## Introduction

Spoken language as a medium is not just a symbol system of discrete speech sounds; it is also replete with cues to the talker's identity, region of origin, and emotional state. Although much research has been devoted to understanding how exposure to a language affects speech sound identification (Kuhl, 1994), almost no one has asked how language knowledge affects processing of paralinguistic information-vocal properties that are not directly related to understanding words like speech rate and pitch changes (see Thompson \& Ballkwill, 2006, for an exception). Emotion in the voice is thought to be conveyed by these paralinguistic cues. Though differing languages seem to use similar vocal acoustic cues for the "basic emotions" in non-speech vocalizations such as laughter and crying, it is not clear how readily listeners perceive these emotional cues crosslinguistically when only presented with the auditory signal (Sauter et al., 2010).

## Language-specific recognition of vocal affect

One likely set of cues that listeners use to identify vocal emotion is prosody: pitch and timing information. Happy speech, for instance, typically has more variable pitch and volume, higher overall pitch level, and a faster speaking rate, whereas sad speech sounds exhibit lower average pitch, attenuated loudness and pitch variation, and a slower pace of speech (Morton \& Trehub, 2001). Previous work demonstrates that humans use paralinguistic cues during speech to alert co-communicators to their current emotional state (Kehrein, 2002). However, this ability to attribute certain paralinguistic cues to particular emotional states may not be fully present at birth, but may require learning through lengthy exposure to one's native language.

One indication of the learned nature of paralinguistic processing is that children experience difficulty in identifying vocal emotional cues (Morton \& Trehub, 2001); for instance, 6-year-olds who hear "my mommy gave me a treat" with "sad" emotional prosody will report that the speaker sounded happy, suggesting that they are still learning the mapping between particular speech patterns and emotional states. Further research suggests that these learned aspects may be language-specific (Thompson \& Balkwill, 2006), though those authors do not pinpoint particular cues that may be relevant, nor do they offer a hypothesis as to what level of fluency one needs to access the learned aspects of emotional speech. In a related area, speaker recognition shows some language specificity in infants (Johnson et al., 2011) and adults (Bregman \& Creel, 2012). If encoding of vocal emotional information works similarly to encoding of voices, then good emotional recognition within a language may be dependent on lengthy language experience, and may not generalize to emotion recognition in other languages.

## General ability to recognize vocal emotion

On the other hand, there is evidence that expertise in processing the cues that communicate vocal emotion may generalize widely across domains. This implies that better attention to or encoding of pitch for another purpose or in another domain may lead to better perception of vocal emotion. For example, certain types of languages have been claimed to boost pitch perception abilities: Speakers of tone languages such as Mandarin are better at making relative
pitch distinctions in musical stimuli (Pfordresher \& Brown, 2009). Conversely, musicians are better than non-musicians at brain encoding of linguistic pitch changes (Wong et al, 2007). These studies suggest that facility with pitch processing generalizes even across domains. This implies that good linguistic pitch processing should facilitate pitch processing generally, which would thereby facilitate perception of pitch-related vocal-emotional information, even outside one's native language. The novel prediction for vocal affect detection is that, over and above languagespecific knowledge, tone-language speakers may excel at perceiving vocal-emotional information due to their language background.

## The current study

The current study focuses on two hypotheses about processing of vocal affect. First, the language-specificity hypothesis suggests that listeners are best at identifying vocal affect in their native language, due to lengthy perceptual learning of vocal correlates of emotional states specific only to that language. This also assumes any second language that the speakers are fluent or near-fluent at will also experience this emotional state comprehension. Crucially, a listener who is not a fluent speaker of a language will have difficulty identifying emotion in that language relative to fluent speakers. Second, the tonelanguage benefit hypothesis posits that listeners with a history of speaking tone languages will show good identification of vocal affect even in non-native languages because tone languages generally facilitate listeners' processing of pitch information, and pitch information is one important cue to affect.

To investigate how language background affects emotional speech processing, we asked speakers of Mandarin Chinese (a tonal language) who also spoke English, and speakers of American English (a non-tonal language) to identify emotion in utterances produced in Mandarin and English. Participants' abilities to identify emotions in their own language were compared to their ability to identify emotions in languages unfamiliar to them.

## Methods

## Participants

Thirty-six undergraduates from the University of California, San Diego participated in this study for class credit. Eighteen of the participants were native English speakers who did not speak Mandarin Chinese, and the remaining eighteen were native speakers of Mandarin Chinese who also spoke English fluently as a second language. English was a second language for each of the 18 Mandarin speaking participants, who acquired English at a mean age of 8 years (range: 0-17).

## Stimuli

Eight speakers recorded 96 sentences each in their native language. Four speakers (2 male, 2 female) were native
speakers of English, and the other four (2 male, 2 female) were native speakers of Mandarin Chinese. The speakers' ages ranged from 19 to 26 , with a mean age of 21.75 .

Sentences spanned six different emotional states: anger, disgust, fear, happiness, sadness, and surprise. Sentence semantic content was created to elicit the intended emotion, to make the task of emotional speech production more naturalistic for our speakers. The 16 sentences for each emotion were originally written in English and translated to Mandarin Chinese. Each sentence contained five syllables in the English version. The translation was retranslated separately by all four Mandarin speakers to ensure a good content match with the original English sentences.

Sentences were recorded in a sound-attenuated booth and saved as .wav files. Files were edited so that each sentence had its own sound file. Two types of sound files were created for each sentence. One type of stimulus (Figure 1a) reflected the original recording, complete with naturalistic emotional sentence semantic content. The other (Figure 1b) was low-pass filtered at 500 Hz using Praat software (Boersma \& Weenink, 2011). Low-pass filtering removes high-frequency information including cues to consonants and vowels, while retaining low-frequency information in the speech signal. The result is a muffled, unintelligible sound that preserves fundamental frequency variability, including lexical tone (Mandarin only), prosody, and speech rate. This manipulation allowed for the measurement of prosody recognition without the confound of languagespecific semantic content. Each file was set to an average loudness of 60 decibels.
(a)

Figure 1. Spectrogram of an (a) unfiltered and (2) low-pass filtered angry sentence.

## Procedure

Each participant listened to 384 total sentences, counterbalanced across two conditions so no participant heard the same sentence from the same speaker or in the same language or in the same filter condition twice. Of the 384 sentences, half each were English and Mandarin; crossed with this, half were unfiltered and half were filtered. Participants were asked to identify the emotional state of each sentence as it was presented through Sennheiser HD 280 Pro headphones. The computer monitor displayed the six possible emotions and a number that corresponded to each emotion. Participants pressed the number key that they
thought matched the emotion of the sentence. Perceived emotional responses and reaction times were recorded in Matlab using the Psychtoolbox3 (Brainard, 1997; Pelli, 1997).

## Results

For the current experiment, the language-specificity hypothesis and the tone-language hypothesis make similar predictions regarding the participants due to the fact that our tone language speakers were fluent bilinguals. If listeners showed native language specificity of emotion recognition, then accuracy should be higher for English listeners in English. Mandarin-English bilinguals should perform equally well in both languages-either due to knowledge of both languages, or due to enhanced abilities as tonelanguage speakers. This may vary by degree of language fluency, as assessed by age of English acquisition. Importantly, this pattern should still hold for filtered speech, which crucially does not contain any semantic language information. That is, if listeners are using language-specific acoustic cues to vocal emotion, they should still be more accurate at recognizing emotion in a familiar language even when lexical cues are removed.

To test this hypothesis, we performed a mixed ANOVA on recognition accuracy with Listener Language (English, Mandarin) as a between-participants variable, and Stimulus Language (English, Mandarin) and Intelligibility (unfiltered, filtered) as within-participants variables. The three-way interaction between these variables was significant ( $\mathrm{F}(1,34)=121.70, \mathrm{p}<.0001$ ). This interaction qualified all lower-level effects and interactions.

Figure 2. Accuracy for unfiltered sentences with standard errors. The dotted line represents chance performance

Therefore, we broke the data out into filtered and unfiltered data to better highlight interactions at that level. For unfiltered sentences, with full naturalistic verbal content, there was a significant interaction between Listener Language and Stimulus Language ( $\mathrm{F}(1,34)=325.58$, $\mathrm{p}<.0001$ ), indicating that participants were better able to comprehend emotional affect in languages they spoke highly fluently, which is supportive of our languagespecificity hypothesis. This result is also important as a control for the stimuli used, and demonstrated that the sentences provided ample emotional content clues. When presented with unfiltered speech, English speakers were significantly more accurate with English speech ( $\mathrm{t}(17)=63.706, \mathrm{p}>.0001$ ) whereas Mandarin speakers were equally proficient at identifying emotional affect in both languages $(\mathrm{t}(17)=.891, \mathrm{p}=.385)$ as would be expected from their language background.

Considering the filtered stimuli, which contained only prosodic cues, we again found an interaction of Listener Language and Stimulus Language ( $\mathrm{F}(1,34)=46.278$, $\mathrm{p}<.0001$ ), indicating that even when there was a lack of verbal information, participants were significantly more capable to parse emotional affect when presented with languages they spoke fluently. Considering each listener language group individually, English speakers were significantly more accurate in identifying the intended emotion when given filtered English speech than filtered Mandarin speech $(t(17)=9.949, p<.001)$. Mandarin speakers, however, showed good performance on filtered speech in both languages with no significant differences in accuracy $(t(17)=1.923, p=.0714)$.

Figure 3. Accuracy for filtered (prosody only) sentences with standard errors. The dotted line represents chance performance

Finally, we assessed whether English performance was affected by degree of English fluency by calculating the correlation between bilinguals' English accuracy on filtered speech and their age of English acquisition. This correlation was not significant $(r(16)=-.2176, p=.3856)$, suggesting that somewhat surprisingly, age of second language acquisition was unrelated to ability to process semantic-information-free speech.

## Discussion

Previous work has demonstrated a link between tonal language background and enhancements of abilities in other perceptual domains such as music (Pfordresher \& Brown, 2009), but the link between language background and vocal emotion had been underexplored. The current study explored the relationship between language background and vocal affect identification, focusing on hypotheses of a language-specific benefit and a tone-language benefit in vocal affect identification.

In support of these hypotheses, we showed that listeners are better at discerning emotional content in speech for all languages they have achieved fluency in, even when highfrequency lexical cues are removed. This is important, because the lack of high frequency information removes any clues as to the specific language being presented. This means that all performances on filtered speech represent the participant's processing of the low frequency emotional pitches and tonal changes without the influence of any clues to the actual language. This implies that any responses are based entirely on pitch processing, and any benefits can only come from validation of one of the two hypotheses presented. The data demonstrate, specifically, that English monolinguals identified emotions more accurately in English than in Mandarin, whereas Mandarin-English bilinguals showed equivalent performance in both languages. This is consistent with the language-specificity hypothesis: that listeners are better at discerning cues to emotion in their native language. However, due to the design of the current study, it is also consistent with the tone-language facilitation hypothesis: that tone-language speakers, due to lengthy experience attending to finegrained pitch characteristics of language, have a general advantage at recognizing vocal emotion. That is, Mandarin listeners performed at above-chance levels in both languages because they are tone-language speakers, not only because they also speak English. This would predict that Mandarin listeners would also be superior at emotion recognition in a completely unfamiliar language, a hypothesis we are currently testing. Further study is currently being performed to address these design limitations, and will alleviate the current confound of the tonal language speaking subjects being fluent in the languages of all the presented stimuli

Nevertheless, in the current study, discussion of the implications of both hypotheses is warranted by the data. In regards to the first hypothesis, the language-specific hypothesis, our data are consistent with the expectation that
monolingual listeners perform better in identifying vocal emotion from prosodic cues in their native language. Listeners familiar with two languages (Mandarin and English) performed comparably in both languages. It is possible more subtle effects were also present in the data regarding the bilingual speakers' performances. For instance, if the emotional-speech processing capabilities are affected by the "sensitive period" demonstrated for phonology, then early-exposed speakers of a second language should show native-level abilities in emotional speech processing, and those who acquired their second language later should not. When a Pearson's productmoment correlation was run on the data, however, the correlation suggested no link between a subject's age of acquisition and performance on filtered speech processing. If age of acquisition does not play a correlational role, some other aspect of the subjects' background must be dictating their abilities.

This leaves the possibility that a general benefit for tonelanguage speakers better accounts for the results. The current results, although consistent with a language specific (or familiar-language) benefit, are also consistent with the tone-language benefit hypothesis; speakers of tonal languages performed equally well at identifying vocal affect in both languages presented. However, the data described here cannot distinguish whether bilinguals' good performance in both languages resulted from their tonelanguage background, or simply being fluent in both languages present in the stimuli. Further study will present these subject groups with tonal and non-tonal languages with which they are not familiar.

If there is a general tone-language advantage, Mandarin speakers should outperform English speakers on all unfamiliar languages. This would indicate that a tonal language background affords the speaker with a type of emotional prosody processing training, and that there are aspects of tonal languages that improve the processing capabilities of individuals in emotional speech. This might be true if there are universal pitch characteristics that can be found in all languages, but are very subtle and difficult to pick up on if the listener does not have sufficient training in either that specific language or excellent awareness in pitch perception in general.

There could even be a specific tone-language advantage, such that tone-language speakers would outperform nontone language speakers only for unfamiliar tone languages. This data pattern might hold if tone languages use devices to convey vocal emotion that are similar across a range of tone languages, but different than non-tone languages. We are currently testing these possibilities regarding the tonelanguage advantage with English speakers and MandarinEnglish bilinguals and four languages (English; Mandarin; Dutch [unfamiliar non-tone language]; Vietnamese [unfamiliar tone language]).

The present data demonstrate that there is emotional affect information present even without higher frequency information. It also provides evidence that speakers are
capable of picking up on this information without relying on distinct linguistic information in languages that they are familiar with. The current study provides a tantalizing peek into the emotional affect processing provided by language background, and with further study already in process, moves our understanding of vocal emotional affect processing forward.

#### Abstract

Cooperation among children can appear haphazard, a finding often attributed to deficient social skills and moral reasoning. Here we took a game theoretical approach to understand development of cooperation, using the prisoner's dilemma to test an alternative source of age-differences in cooperative behavior-how children and adults represent the numerical magnitudes of payoffs for cooperating versus not. We found that as incentives increased solely in numerical magnitude, speed of incentive comparisons decreased and cooperation increased. Further, though children tended to be more cooperative than adults, effect of age on cooperation was moderated by speed of incentive comparison. We conclude that representations of numeric value constrain how economic rewards affect cooperation and that children's greater cooperativeness may be attributed to a poor sense of numerical value.

Keywords: Cooperation; Numerical Cognition; Cognitive Development.

## Introduction

Development of cooperation-how it begins, how it changes over time, and what factors promote it-has invited speculation for at least 350 years. According to Rousseau (1754/2007), cooperation is our birthright, society breeds competition; according to Hobbes (1651/2008), we are naturally competitive, society promotes cooperation. Although scientists champion neither position, nearly all look to the same factors-social constructs-to explain development of cooperation (Miles, Hare \& Tomasello, 2006; Warneken \& Tomasello, 2006; 2007; Warneken, Chen \& Tomasello, 2006). Research on the role of social constructs (i.e., theory of mind, communication, fairness norms, trust, social tolerance) on development of cooperation finds support for both views-development breeds either competition or cooperation, depending on the context (i.e., Damon, 1975; Lane \& Coon, 1972; Piaget, 1932; Warneken \& Tomasello, 2006; 2007; Warneken, Chen \& Tomasello, 2006).

One possible way to explain the role of context on development of cooperation is to consider that cooperation may result, not only from developing social skills, but also from how cooperative incentives are mentally represented (Furlong \& Opfer, 2009). This role for incentive structure has been explored by game theory, which predicts circumstances under which organisms are likely to cooperate and tests these predictions using games such as

Prisoner's Dilemma (PD). Following this approach, we propose a novel and surprising influence on cooperationhow children represent numeric value. In the following sections we: (1) follow Hobbes' lead and provide a game theoretical analysis linking incentive structure to cooperative behavior, (2) explain how developing representations of number affect representation of incentive structures, and (3) show how this analysis accurately predicts Rousseau's claim that cooperation would decrease with age and experience.

## Game Theory Links Incentives to Cooperation

Insight into why cooperation depends heavily on contextual factors comes from game theory, which makes predictions about the incentive structures under which organisms are likely to cooperate. Incentive structures in which small immediate costs of cooperation are offset by large immediate benefits, known as mutualisms, commonly lead to cooperation. Even simple organisms-such as fish and ants-readily engage in cooperation under mutualist incentive structures (Bronstein, 2001; Mesterton-Gibbons \& Dugatkin, 1992; Trivers, 1971).

While cooperative mutualisms occur readily throughout the animal kingdom, reciprocity--in which short-term costs of cooperation are exchanged in expectation of long-term benefits--is relatively scarce. Indeed, in many cases, these exchanges can be explained by simpler mechanisms such as kin selection, where cooperation does not occur in expectation of any future exchange (i.e., Maynard-Smith, 1965; Trivers, 1971; Stevens et al, 2005).

Biologists typically account for high mutualism rates and low reciprocity rates by arguing that mutualism poses relatively few risks (costs are immediate and relatively low and benefits are immediate and relatively high), whereas the additional temporal element of reciprocity makes it fairly risky (costs are immediate and high and future large benefits are tenuous and may never realize; Maynard-Smith, 1965; Stevens et al, 2005; Trivers, 1971). The likelihood of cooperation depends, therefore, on the relation between benefits and costs-in other words, its incentive structure.

How incentive structure can affect cooperative behavior is often examined using the prisoner's dilemma game (Clements \& Stephens, 1995; Noe, 2006; Rapoport \& Chammah, 1965; Valev \& Chater, 2006). The prisoner's dilemma can be conceptualized in this way: Suppose two children, Bonnie and Clyde, have agreed to charge $\$ 3$ per
glass in competing lemonade stands. If Bonnie cooperates and charges $\$ 3$, she'll earn $\$ 3$; however, if she reneges and drops her price, she may be able to sell more lemonade for a cheaper price (say, 2 cups for $\$ 2.50$ each yielding $\$ 5$ ). If both renege, their prices will drop until they sell lemonade at cost-\$1 per cup. If Clyde drops his price, but Bonnie does not, Bonnie will lose her clients to Clyde and earn nothing (Figure 1a).

Generally, if players meet only once, they maximize rewards by defecting; however, if players interact repeatedly, they maximize rewards by cooperating (Axelrod \& Hamilton, 1981; Rapoport \& Chammah, 1965). Sadly, even in iterated dilemmas, people and animals tend to defect (i.e., Baker \& Rachlin, 2002; Dawes \& Thaler, 1998). However, reciprocal dilemmas can elicit mutualistic behavior simply by manipulating incentives-for example, by changing the reward for mutual cooperation from $\$ 3$ to $\$ 6$ and the temptation to defect from $\$ 5$ to $\$ 8$, cooperation rates increase (Figure 1b; Rapoport \& Chammah, 1965; Valev \& Chater, 2006).

## Representation of Incentive Structure Depends on Representation of Numeric Value

Why manipulating incentives results in mutualistic behavior might be explained by how the brain represents numeric quantity. Specifically, as numeric values increase, discriminability decreases; thus, while participants quickly determine that $5>3$, they are slower to determine that $8>6$ (Moyer \& Landauer, 1967; Starkey \& Cooper, 1980).

This numeric size effect fits into a broader literature suggesting non-symbolic numeric quantities may be represented logarithmically: that the brain overestimates differences among small quantities and compresses differences among large quantities (Dehaene, 1997; Nieder \& Miller, 2003). Therefore, the difference between 3 and 5 feels larger than the difference between 6 and 8 .

The suggestion that subjective incentives in the brain may be quite different than objective incentives in the real world
is not new. This is the chief insight of prospect theory (Kahneman \& Tversky, 1979): choices and framing of incentives may affect their subjective value. As Bernoulli (1738/1954) famously observed, "a gain of 2000 ducats is more significant to a pauper than to a rich man though both gain the same amount." The framing of incentives-in this case, the initial endowment-may affect decisions about those incentives.

Although most theories of decision-making rely on prospect theory, in which economic value is subject to size effects (Kahneman \& Tversky, 1979), we argue that numeric value, independent of economic value, can affect cooperative behavior. This hypothesis leads to an interesting implication-namely, converting a reciprocal dilemma into a mutualism may not require manipulating economic values of incentives; rather, it may be accomplished by manipulating numeric values alone.

Figure 2: Payoff matrices used by Furlong \& Opfer (2009).
This surprising hypothesis was recently tested in a series of experiments in which adult participants played one of four prisoner's dilemma games, identical except for incentive structure (Figure 2; Furlong \& Opfer, 2009). As observed in previous studies, subjects in the baseline (\$1) condition showed relatively high rates of defection and low rates of cooperation. When rewards were increased a hundred-fold to $\$ 100$, however, subjects showed the opposite behavior-low rates of defection and high rates of cooperation. This finding could be explained by the standard economic value model-perhaps subjects cooperated more in the $\$ 100$ condition simply because there was more at stake. On the other hand, subjects may have cooperated more simply because 100 is a larger number than 1 . In support of the latter explanation, subjects playing for $100 \phi$, which is economically equivalent to playing for $\$ 1$ and numerically equivalent to playing for $\$ 100$, showed identical behavior to those playing for $\$ 100$. Similarly, subjects in the $1 \phi$ condition behaved identically to those in the $\$ 1$ condition, even though the increase from $1 \phi$ to $\$ 1$
represents a one hundred fold increase in economic value. Thus, cooperative behavior changed in response to numeric value, but not in response to economic value.

These numeric-magnitude effects are consistent with the idea that numbers associated with payoff values are represented logarithmically. That is, the linear model predicts defection whenever the ratio between the reward for mutual cooperation and the temptation to defect is less than 1 , and because $300 \phi / 500 \phi$ equals $\$ 3 / \$ 5$, changing numeric values would not matter. This preservation of ratio information does not obtain if numeric values are scaled logarithmically, as $\ln (300) / \ln (500)$ is approximately 1 (i.e., temptation to defect and cooperate are nearly equal), whereas $\ln (3) / \ln (5)$ is approximately .68 (i.e., temptation to defect is higher than temptation to cooperate).

## Hypothesized Effects of Developing Number Representations on Cooperation

In Furlong and Opfer's (2009) work, big numbers increased cooperation-a finding predicted by the way the mind represents non-symbolic quantities to increase logarithmically with actual value. When representing symbolic quantities, however, important developmental differences emerge (see Opfer \& Siegler, 2012, for review). For young preschoolers, numeric symbols are meaningless stimuli. For example, 2- and 3-year-olds who count flawlessly from $1-10$ have no idea that the number 6 is greater than the number 4 , nor do children of these ages know how many objects to give an adult who asks for 4 or more (Le Corre et al., 2006; Opfer, Thompson, \& Furlong, 2009; Sarnecka \& Carey, 2008). As young children gain experience with the symbols in a given numerical range and associate them with non-verbal quantities in that range, they initially map them to a logarithmically-compressed mental number line (Berteletti et al., 2010; Booth \& Siegler, 2006; Opfer, Thompson, \& Furlong, 2010; Siegler \& Booth, 2004; Siegler \& Opfer, 2003; Thompson \& Opfer, 2010). Over a period that typically lasts $1-3$ years for a given numerical range $(0-10,0-100$, or $0-1000)$, their mapping changes from a logarithmically compressed form to a linear form, in which subjective and objective numerical values increase in a 1:1 fashion. Use of linear magnitude representations occurs earliest for the numerals that are most frequent in the environment, that is the smallest whole numbers, and it gradually is applied to increasingly large numbers.

The logarithmic-to-linear shift in children's representations of symbolic quantities expands children's quantitative thinking profoundly. It improves (1) children's ability to estimate the positions of numbers on number lines (Siegler, Thompson, \& Opfer, 2010), (2) to estimate the measurements of continuous and discrete quantities (Booth \& Siegler, 2006; Laski \& Siegler, 2007; Thompson \& Siegler, 2010), (3) to categorize numbers according to size
(Laski \& Siegler, 2007; Opfer \& Thompson, 2008), (4) to remember numbers that they have encountered (Thompson \& Siegler, 2010), and (5) to estimate and learn the answers to arithmetic problems (Booth \& Siegler, 2006). All of these abilities also have important educational roles, leading to use of linear representations of number being highly correlated with mathematics achievement and a broadly effective target of instructional interventions. Thus, children's representations of symbolic quantities-like those used in the payoff matrices of prisoner's dilemma games-change dramatically with age and experience.

Developmental differences in representations of symbolic magnitudes have important implications for how children and adults are likely to respond to economic incentives. That is, if representations of numeric quantity affect cooperative decisions, adults--who are least likely to use logarithmic representations of symbolic quantity-should show the smallest effect of numeric value on cooperative behavior, whereas young children-who are most likely to use logarithmic representations-should show the largest effect of numeric value on cooperative behavior. This is a somewhat surprising and counter-intuitive prediction: because behavioral variability typically decreases with age, effect sizes generally increase with age. To test this hypothesis, we explored the effects of numeric and unit changes on cooperation in third-grade children, fifth-grade children and adults engaged in a prisoner's dilemma game.

## Method

## Participants

Undergraduate students ( 23 males, 25 females; $\mathrm{M}=19.58$ years of age, $s=1.43$ ), third-grade students ( 19 males, 29 females; $\mathrm{M}=9.33$ years of age, $\mathrm{s}=.33$ ) and fifth-grade students ( 25 males, 23 females; $M=11.06$ years of age, $\mathrm{s}=.43$ ) from largely middle-class schools were randomly assigned to play one of four iterated prisoner's dilemma games (IPDs) identical except for payoff structure (Figure 2). All participants received a sticker (children) or course credit (adults) for participating.

## Design and Procedure

Participants played IPDs against computers using a "Tit-forTat" (TFT) strategy - initially cooperating and thereafter mirroring the participant's behavior on the preceding trial. Participants received no instruction on strategy but were told they were going to play a game called "rock/paper" in which they could earn pretend money (rock was defect and paper cooperate). They were further instructed that the goal was to earn as much money as possible, and that the amount of money they earned depended on how they and the computer played the game. Participants could click on an

Figure 3. Cooperation in adults, 5th graders and 3rd graders in the prisoner's dilemma game.
icon of a piece of paper (cooperate) or a hand in a fist (defect) to make their choice. Once they made their choice the computer's 'choice' was presented as well as a running total of each player's score. Each participant was allowed as much time as they wanted to complete each of 45 trials.

The design was a 2 (unit: dollars or cents) X 2 (number: 1 or 100) factorial design resulting in four games, identical except for payoff structure (Figure 2) - a numerically small dollars condition (\$1), a numerically large cents condition ( $100 \phi$ ), a numerically small cents condition (1申), and a numerically large dollars condition (\$100).

We measured four indices of cooperative behaviorindividual cooperation (total number of trials in which the participant cooperated), mutual cooperation (number of trials in which participant and computer engaged in cooperation together), mutual defection (number of trials in which participant and computer defected together) and forgiveness, a measure of number of trials to cooperate after the computer's first defection.

To ensure children understood the monetary conversion, children were asked, "how many pennies are in a dollar?" Only one child (a third-grader) answered this question incorrectly; his data were excluded from analyses.

Additionally, subjects participated in a computerized number discrimination task in which they were presented with two numbers (i.e., 3 and 5) and asked to press one of two keys to indicate which was the larger as quickly and accurately as possible. Combinations of the numeric values presented to participants in the numeric discrimination task were identical to the prisoner's dilemma task.

## Results and Discussion

First, we explored effects of number, unit and value on cooperative behavior in all three age groups. This analysis is followed by an exploration of the magnitude of the effect of numeric value on cooperation across ages. Finally, we explore the relation between numeric representation in the number comparison task with cooperative behavior in the prisoner's dilemma task.

Two (units: dollars, cents) by two (number: 1, 100) MANOVAs were conducted on the four indices of cooperation. No age groups showed a main effect of unit,
nor did any age group show an interaction of unit with number on their cooperative behavior. Further, no age group showed an effect of economic value ( $1 \phi, \$ 1$ or $\$ 100$ ) on cooperative behavior.

Cooperation in all three groups, however, varied with number (Figure 3; Adults: $F[4,41]=2.66, p=.046$; 5th graders: $F[4,41]=5.09, p=.002$; 3rd graders: $F[4,41]=3.89$, $p=.009$ ). Specifically, numerically greater rewards increased individual cooperation (Adults: $\mathrm{F}[1,44]=10.06, \mathrm{p}=.003$; 5th graders: $\mathrm{F}[1,44]=10.42, \mathrm{p}=.002$; 3rd graders: $\mathrm{F}[1$, $44]=13.49, \mathrm{p}=.001$ ) such that changing rewards from $3 \phi$ to $300 \varnothing$ increased cooperation rates, but an economically identical change from $3 \phi$ to $\$ 3$ did not. The same pattern was evident in rates of mutual cooperation, where numerically large rewards elicited more mutual cooperation than numerically small rewards (Adults: $F[1,44]=7.18$, $p=.01$; 5th graders: $F[1,44]=9.46, p=.004 ; 3$ rd graders: $\mathrm{F}[1$, $44]=8.49, p=.006$ ). Further, numerically large rewards elicited less mutual defection than numerically small ones (Adults: $F[1,44]=9.18, p=.004 ; 5$ th graders: $F[1,44]=6.05$, $p=.02$; 3rd graders: $F[1,44]=9.75, p=.003$ ). While no effect of number was observed for forgiveness in adults and 5th graders, 3rd graders did show an effect of number on forgiveness ( $F[1,44]=5.94, p=.02$ ), requiring fewer trials to 'forgive' their partner for large numeric values than for small numeric values.

A 3 (age: 3rd grade, 5th grade, adult) X 2 (number: 1, 100) MANOVA also revealed main effects of age ( $F[8$, $272]=5.92, p<.001)$ and number $(F[4,135]=8.30, p<.001)$ on cooperation. This effect was observed for individual cooperation $(F[2,138]=9.57, p<.001)$ and mutual defection ( $F[2,138]=19.05, p<.001$ ). Results for mutual cooperation $(F[2,138]=2.18, p=.11)$ and forgiveness $F[2,138]=2.41$, $p=.09)$ trended toward significance. Post-hoc tests revealed 3rd graders had more individual cooperation than both 5th graders and adults ( $p \mathrm{~s}<.01$ ). This pattern held true for mutual defection (5th graders: $\mathrm{p}=.001$; adults: $\mathrm{p}<.001$ ). Fifth graders and adults did not differ from each other on individual cooperation $(p=.82)$ but they trended to differ on mutual defection $(p=.06)$. No differences were found between the groups on mutual cooperation or forgiveness.

Figure 4: 3rd graders showed larger effects of number on individual and mutual cooperation and forgiveness than 5th graders and adults.

We next compared values of Cohen's $d$, a measure of effect size, for each of the four indices of cooperation in each of the three age groups. We expected to find a larger effect of number (a larger value of $d$ ) in third-grade children than in fifth-grade children and adults. This predicted pattern was indeed observed for three of our four measures of cooperation: 3rd graders showed a larger effect of numeric value on individual cooperation ( $d=1.08$ ), mutual cooperation ( $d=1.12$ ) and forgiveness ( $d=0.70$ ) than 5th graders (individual cooperation: $d=0.95$; mutual cooperation: $d=0.90$; forgiveness: $d=0.31$ ) or adults (individual cooperation: $d=0.93$; mutual cooperation: $d=0.78$; forgiveness: $d=0.30$ ). Effect sizes for mutual defection were roughly equal across all three groups (3rd: $d=0.92$; 5th: $d=0.73$; adults: $d=0.88$; Figure 4).

We hypothesized that the age related increases in effect size were due to number representations, and that the 5th graders were already demonstrating adult-like number cognition. Data from individual participants were analysed to determine whether their reaction times in the number discrimination task were best fit using a linear difference between the two comparison numerals (i.e., $5-3$ ) or a logarithmic difference (i.e., $\ln [5]-\ln [3]$ ). This allowed us to classify participants are relying on a more linear or more logarithmic representation.

As predicted, as age increased reliance on a linear representation increased as well ( $\chi 2(2)=4.88, \mathrm{p}=.08) ; 57 \%$ of 3rd graders were best fit by the linear model; $69 \%$ of 5 th graders and $77 \%$ of adults were best fit by the linear model. A 2 (representation type: logarithmic or linear) X 2 (number: 1 or 100) MANOVA on cooperation revealed a significant effect of representation type on cooperation ( $F[4$, 96] $=2.78, p=.03$ ) such that participants best fit by the logarithmic model showed greater individual cooperation ( $F$ $(1,104)=3.41, p=.06)$ and mutual defection $(F$ (1, $104)=7.40, p<.01$ ) than participants best fit by the linear model.

## Conclusion

What is the nature of human cooperation? Are we Rousseauian, naturally cooperative, or are we Hobbesian, naturally competitive? The answer may be Both: we start life cooperative (a la Rousseau), but become competitive with age and experience (a la Hobbes). Our cooperative decisions may be shaped, however, not just by changing social influences, but also by developing numeric representations.

Consistent with this perspective, adults--who represent numbers relatively precisely--showed more individual and mutual cooperation and less mutual defection in response to large numbers, not large economic values. Not only did third- and fifth-grade children also demonstrate this pattern, but age related changes in number representation were associated with changes in cooperation: 3rd graders showed a larger effect of number than the older children and adults in individual cooperation, mutual defection and forgiveness.

Further, numerical representations predicted individual cooperation, mutual cooperation, defection and forgiveness rates; subjects who relied more on logarithmic representations demonstrated higher rates of individual and mutual cooperation, lower rates of mutual defection, and took less time to forgive their partner than subjects who relied more on linear representations. These results suggest that logarithmic representations may make it harder to discriminate incentives, resulting in them being treated more like a cooperative mutualism than a reciprocity.

Our results may be able to shed light on previous findings that children appear Hobbesian or Rousseauian depending on the context (Damon, 1975; Lane \& Coon, 1972; Piaget, 1932; Warneken \& Tomasello, 2006, 2007; Warneken, Chen \& Tomasello, 2006). Perhaps these inconsistencies in cooperation can be explained by how costs and benefits are represented in the minds of children. Children may be more likely to cooperate in tasks in which they perceive the costs to be minimal and/or the benefits large (e.g., holding a door open for a stranger), but may be less likely to cooperate in tasks in which they perceive the costs to be large and the benefits minimal (e.g., providing another child with a reward out of one's own stock).

Thus, while it may not be possible to definitively resolve the Hobbes-Rousseau debate, the combination of game theory and psychology of number may make it possible to predict which circumstances incentive cooperation. Put simply, children may be more Rousseauian when costs and benefits are hard to discriminate, but more Hobbesian when they are easily discriminable.

#### Abstract

We tested the computational feasibility of the proposal that open-ended cultural evolution was made possible by two cognitive transitions: (1) onset of the capacity to chain thoughts together, followed by (2) onset of contextual focus (CF): the capacity to shift between a divergent mode of thought conducive to 'breaking out of a rut' and a convergent mode of thought conducive to minor modifications. These transitions were simulated in EVOC, an agent-based model of cultural evolution, in which the fitness of agents' actions increases as agents invent ideas for new actions, and imitate the fittest of their neighbors' actions. Both mean fitness and diversity of actions across the society increased with chaining, and even more so with CF, as hypothesized. CF was only effective when the fitness function changed, which supports its hypothesized role in generating and refining ideas.

Keywords: Agent-based model, CF, convergent though, creativity, cultural evolution, divergent thought, dual process, recursive retrieval, stream of thought.

## Introduction

Humans are unique with respect to the ability to generate accumulative, adaptive cultural evolution, a phenomenon referred to as the ratchet effect (Tomasello, Kruger, \& Ratner, 1993). Gaining insight into the origins of the capacity for complex culture is difficult, since all that is left of our prehistoric ancestors are bones and artifacts such as stone tools that resist the passage of time. Although methods for analyzing these remains are becoming increasingly sophisticated, they cannot always distinguish amongst competing theories. Thus, formal models provide valuable reconstructive tools for testing the feasibility of theories concerning the origins of the cognitive mechanisms that have transformed our planet.

Several cognitive mechanisms have been implicated in the ability to evolve culture. One is the capacity to chain thoughts together to generate a sequence of actions or stream of thought (Donald, 1991). Another is contextual focus (hereafter referred to as CF): the capacity to shift between analytic and associative modes of thought (Gabora, 2003). Mathematical models of both have been developed (Gabora \& Aerts, 2009; Gabora \& Kitto, 2012; Veloz et al., 2011). Incorporating chaining into a computational model of cultural evolution increased the fitness and diversity of cultural outputs, as well as the effectiveness of learning (Gabora \& Saberi, 2011). Incorporating CF into a portrait painting computer program
generated artworks that humans preferred over those generated without CF (DiPaola \& Gabora, 2009). However, the portrait painting program did not allow investigation of the effect of CF on the evolution of ideas through cultural interaction. The goal of the work presented here was to understand the relationship between chaining and CF. Specifically, we investigate the feasibility of the hypothesis that RR is broadly useful for improving cultural outputs, while CF is specifically useful for overcoming a new or sudden challenge.

## Early Signs of Human Creativity

The minds of our earliest ancestors, Homo habilis, are referred to as episodic because there is no evidence that their experience deviated from the present moment of concrete sensory perceptions (Donald, 1991). They encoded perceptions of events in memory, but had little voluntary access to them without cues. They were therefore unable to voluntarily shape, modify, or practice skills and actions, and could not invent or refine complex actions, gestures, or vocalizations.

Homo habilis was eventually replaced by Homo erectus, which lived between approximately 1.8 and 0.3 million years ago. This period is considered the beginning of human cultural evolution. Homo erectus exhibited signs of enhanced intelligence, creativity, and adaptability. They made sophisticated task-specific stone hand axes, had complex stable seasonal home bases, and there is evidence of long-distance hunting strategies involving large game, and migration out of Africa (Leakey 1984). It is widely believed that these early signs of creative culture reflect an underlying transition in cognitive or social abilities. The cranial capacity of the Homo erectus brain was approximately $1,000 \mathrm{cc}$, which is about $25 \%$ larger than that of Homo habilis, and at least twice as large as that of living great apes, and $75 \%$ that of modern humans (Aiello, 1996 ).

Some have suggested that these abilities are due to the onset of a theory of mind (Mithen, 1998) or the capacity to imitate (Dugatkin, 2001). However, there is evidence that nonhuman primates also possess theory of mind (Heyes, 1998) and the capacity to imitate (Dugatkin, 2001), yet their cultural complexity do not compare with humans'. Evolutionary psychologists have suggested that our unique abilities were due to the onset of massive modularity (Barkow, Cosmides,
\& Tooby, 1992). However, although the mind exhibits an intermediate degree of functional and anatomical modularity, neuroscience has not revealed vast numbers of hardwired, encapsulated, task-specific modules; indeed, the brain is more subject to environmental influence than was previously believed (Buller, 2005; Byrne, 2000; Wexler, 2006).

Donald (1991) proposed that with the enlarged cranial capacity of Homo erectus, the human mind underwent a transition characterized by a shift from an episodic to a mimetic mode of cognitive functioning, made possible by onset of the capacity to voluntarily retrieve memories independent of environmental cues and chain them into sequences. Donald refers to the cognitive architecture underlying this capacity as a self-triggered recall and rehearsal loop. It enabled information to be processed recursively, and from different perspectives. Voluntary access to memories made it possible to act out ${ }^{1}$ events that occurred in the past or that might occur in the future. Thus not only could the mimetic mind temporarily escape the here and now, but by miming or gesture it could communicate similar escapes to other minds. The capacity to mime thus brought forth what is referred to as a mimetic form of cognition, and allowed for the onset of culture. The selftriggered recall and rehearsal loop also enabled our ancestors to engage in a stream of thought, in which one thought or idea evokes another, and so forth recursively. In this way, attention can be directed away from the external world toward one's internal model of it. Finally, self-triggered recall allowed for voluntary rehearsal and refinement of actions, enabling systematic evaluation and improvement of skills and motor acts.

## An Explosion of Creative Cultural Change

The European archaeological record indicates that an unparalleled cultural transition occurred between 60,000 and 30,000 years ago, at the onset of the Upper Paleolithic. Considering it "evidence of the modern human mind at work," Leakey (1984:93-94) describes this period as "unlike previous eras, when stasis dominated, ... [with] change being measured in millennia rather than hundreds of millennia." Similarly, Mithen (1998) refers to the Upper Paleaolithic as the 'big bang' of human culture, exhibiting more innovation than in the previous six million years of human evolution. It marks the beginnings of traits considered diagnostic of behavioral modernity, including a more organized, strategic, season-specific style of hunting involving specific animals at specific sites, elaborate burial sites indicative of ritual and religion, evidence of dance, magic, and totemism, colonization of Australia, and replacement of Levallois tool technology by blade cores in the Near East. In Europe, complex hearths and many forms of art appeared, including cave paintings of animals, decorated tools and pottery, bone and antler tools with engraved designs, ivory statues of animals and sea shells, and personal decoration such as beads, pendants, and perforated animal teeth, many of which may have indicated social status.

[^269]Whether this period was a genuine revolution culminating in behavioral modernity is hotly debated because claims to this effect are based on the European Palaeolithic record, and largely exclude the African record (McBrearty \& Brooks, 2000). However the dominant view is that modern behavior appeared in Africa between 40,000 and 50,000 years ago, and spread, resulting in displacement of the Neanderthals in Europe (Klein, 1999). From this point on there was only one hominid species: modern Homo sapien, and despite a lack of overall increase in cranial capacity, their prefrontal cortex, and more particularly the orbitofrontal region, increased significantly in size (Dunbar, 1993). in what was most likely a time of major neural reorganization (Klein, 1999). Given that the Middle/Upper Palaeolithic was a period of unprecedented creativity, what kind of cognitive processes were involved?

It is widely believed that a divergent or associative mode of thought predominates during idea generation, while a convergent or analytic mode predominates during the refinement, implementation, and testing of an idea (Finke, Ward, \& Smith, 1992). It has been proposed that the Paleolithic transition reflects fine-tuning of the biochemical mechanisms underlying the capacity to subconsciously shift between these modes, depending on the situation, by varying the specificity of the activated cognitive receptive field (Gabora, 2003; Gabora Kaufman, 2010). This is referred to as contextual fo$\operatorname{cus}^{2}$ (CF) because it requires the ability to focus or defocus attention in response to the context or situation one is in. Defocused attention, by diffusely activating a broad region of memory, is conducive to divergent thought; it enables obscure (but potentially relevant) aspects of the situation to come into play. Focused attention is conducive to convergent thought; memory activation is constrained enough to hone in and perform logical mental operations on the most clearly relevant aspects.

## The Computational Model

We reviewed the evidence for two hypotheses: (1) the earliest signs of culture were due to the onset of the capacity to chain representations together, and (2) the cultural explosion of the Middle-Upper Paleolithic was due to the onset of CF. We investigated these hypotheses using an agent-based model of cultural evolution referred to as "EVOlution of Culture", abbreviated EVOC. EVOC uses neural network based agents that (1) invent new ideas, (2) imitate actions implemented by neighbors, (3) evaluate ideas, and (4) implement successful ideas as actions. EVOC is an elaboration of Meme and Variations, or MAV (Gabora, 1995), the earliest computer program to our knowledge to model not just cultural transmission but cumulative, adaptive, cultural evolution. ${ }^{3}$ It was inspired by the genetic algorithm, a search technique that finds solutions

[^270]to complex problems by generating a 'population' of candidate solutions through processes akin to mutation, selecting the best, and repeating until a satisfactory solution is found (Holland, 1975). The goal behind MAV, and also behind EVOC, was to distil the underlying logic of not biological evolution but cultural evolution. Agents do not evolve in a biological sense-they neither die nor have offspring-but do in a cultural sense, by adaptively modifying each others' ideas for actions. We summarize the architecture of EVOC in sufficient detail to explain our results; for details we refer the reader to previous publications (e.g., Gabora, 1995; Gabora \& Saberi, 2011; Leijnen \& Gabora, 2009).

## Agents

Agents consist of (1) a neural network, which encodes ideas for actions and detects trends in what constitutes a fit action, (2) a 'perceptual system', which carries out the evaluation and imitation of neighbours' actions, and (3) a body, consisting of six body parts which implement actions. The neural network is composed of six input nodes and six corresponding output nodes that represent concepts of body parts (LEFT ARM, RIGHT ARM, LEFT LEG, RIGHT LEG, HEAD, and HIPS), as well as hidden nodes that represent more abstract concepts (LEFT, RIGHT, ARM, LEG, SYMMETRY, OPPOSITE, and MOVEMENT). Input nodes and output nodes are connected to hidden nodes of which they are instances (e.g., LEFT ARM is connected to LEFT.) Activation of any input node activates the MOVEMENT node. Same-direction activation of symmetrical input nodes (e.g., upward motion-of both arms) activates the SYMMETRY node.

## Invention

An idea for a new action is a pattern consisting of six elements that dictate the placement of the six body parts. Agents generate new actions by modifying their initial action or an action that has been invented previously or acquired through imitation. During invention, the pattern of activation on the output nodes is fed back to the input nodes, and invention is biased according to the activations of the SYMMETRY and MOVEMENT hidden nodes. (Were this not the case there would be no benefit to using a neural network.) To invent a new idea, for each node of the idea currently represented on the input layer of the neural network, the agent makes a probabilistic decision as to whether the position of that body part will change, and if it does, the direction of change is stochastically biased according to the learning rate. If the new idea has a higher fitness than the currently implemented idea, the agent learns and implements the action specified by that idea.

## Imitation

The process of finding a neighbour to imitate works through a form of lazy (non-greedy) search. The imitating agent randomly scans its neighbours, and adopts the first action that is fitter than the action it is currently implementing. If it does not find a neighbour that is executing a fitter action than its own current action, it continues to execute the current action.

Table 1: Definition table.

| Term | Definition | Example |
| :--- | :--- | :--- |
| Body <br> Part | Component of agent <br> other than neural net- <br> work. | Left Arm (LA) |
| Sub- <br> action | Set of six components <br> that indicates position of <br> 6 body parts. Each can be <br> in a neutral (0), up (1), or <br> down (-1) position. | RA:-1, LL:1, LA: <br> RL:0, HP:-1; <br> This sub-action <br> is abbreviated <br> $01-110-1$ |
| Action | One or more sequential <br> sub-actions. | $01001-1, \quad-10-1-$ <br> 111 |
| Template | Abstract or prototypical <br> format for a sub-action. <br> Position of a body part <br> can be unspecified (*). | HD:0, LA:*, <br> RA:1, LL:*, <br> RL:1, HP:-1 |

Table 2: Partial set of the templates used in the first fitness function. (The rest are omitted due to lack of space.)

$$
\begin{array}{|l|l|}
\hline T^{1}=\{0, *, *, *, *, *\} & T^{24}=\{1, *, *, 1,1, *\} \\
\hline T^{2}=\{*, 0, *, *, *, *\} & T^{25}=\{1, *, 1, *, 1, *\} \\
\hline T^{3}=\{*, *, 0, *, *, *\} & T^{26}=\{1, *, 1,1, *, *\} \\
\hline
\end{array}
$$

## Evaluation: The Fitness Function

Fitness was evaluated using an adaptation of the Royal Roads fitness function (Forrest \& Mitchell, 1993). Midway through a run the fitness function was changed to test the effectiveness of chaining and CF for adapting to a sudden change in the task constraints or the environment. Definitions of terms used to accomplish this are provided in Table One.

The first fitness function is determined by 45 templates, six of which are shown in Table Two. The second (not shown) is constructed analogously, with different sub-actions. The templates can be thought of as defining the cultural significance of types of sub-actions (such as dance steps). Each template $T^{i}$ consists of six components, one for each body part (i.e., $T^{i}=t_{j}^{i} ; j=1 . .6$ ). Each body part can be in a neutral position (0), up (1), down (-1), or an unspecified position (*). For example, in template $T^{i}=*, 1,-1, *, *, 0$, the left arm is up (LA:1), the right arm is down (RA:-1), the hips are in the neutral position (HP:0), and the positions of other body parts is unspecified (HD:*, LL:*, and RL:*). The templates provide constraints, as well as flexibility with respect to what constitutes a fit action. For example, in an optimally fit action, the head must be in the neutral position (in $T^{1}$ the first component is 0 ) but the positions of other body parts can vary). The optimal sub-actions are $\{0,1,-1,1,-1,1\},\{0,1,-1,1,-1,-1\}$, $\{0,-1,1,-1,1,1\}$, and $\{0,-1,1,-1,1,-1\}$.

Assume that D is a sub-action (i.e., $D=d_{j} ; j=1 . .6$ ) and $T^{i}$ is the $i^{t h}$ template (i.e., $T^{i}=t_{j}^{i} ; j=1 . .6$ ). Thus, $d_{j}$ represents the position of the $j^{\text {th }}$ body part and the value of $d_{j}$ can be either 0 (neutral), 1 (up), or -1 (down). Likewise, the value of
$t_{j}^{i}$ can be $0,1,-1$, or * (unspecified). Accordingly, the fitness of sub-action $D$ is obtained as per Eq. 1 .

$$
\begin{equation*}
F(D)=\sum_{i=1}^{19} \Phi\left(T^{i}, D\right) \times \Omega\left(T^{i}\right) \tag{1}
\end{equation*}
$$

As shown in Eq. 1, fitness is a function of template weight $\left(\Phi\left(T^{i}, D\right)\right)$ and template order $\left(\Omega\left(T^{i}\right)\right)$.
Template Weight $\Phi\left(T^{i}, D\right)$ is a function that determines the weight of sub-action $D$ by comparing it with template $T^{i}$. This weight is set to one if each component of the sub-action (i.e., $d_{j} ; j=1 . .6$ ) either matches the corresponding component of the template (i.e., $t_{j}^{i} ; j=1 . .6$ ) or if the corresponding components of the template is unspecified (i.e., $t_{j}^{i}=*$ ):

$$
\Phi\left(T^{i}, D\right)=\left\{\begin{array}{cc}
1 & \text { if } \forall t_{j}^{i} \in T^{i}: t_{j}^{i}=d_{j} \text { or } *  \tag{2}\\
0 & \text { otherwise }
\end{array}\right.
$$

Template Order $\Omega\left(T^{i}\right)$ computes the order of the template $T^{i}$ by counting the number of components that have a specified value (i.e., $t_{j}^{i} \neq *$ ).

$$
\begin{equation*}
\Omega\left(T^{i}\right)=\sum_{j=1, t_{j}^{i} \neq *}^{6} t_{j}^{i} \tag{3}
\end{equation*}
$$

The fitness functions are difficult to solve because they are rugged; is to have multiple milestones, or fitness peaks, that agents must achieve before reaching the plateau. For example, consider the fitness function given in Table 2. The action $0,0,0,0,0,0$ has a fitness of 6 . An agent may move on from this action to find an actions that fits the third order templates with a fitness of 31 , e.g., $F(D):\{1,1,1,1,1,0\}=$ $3+3+3+3+3+3+3+3+3+3+1=31$.

## Learning

Invention makes use of the ability to learn, and respond adaptively to trends. Knowledge acquired through the evaluation of actions is translated into educated guesses about how to invent fit actions. For example, an agent may learn that symmetrical movement tends to be either beneficial or detrimental, and bias the generation of new actions accordingly.

## A Typical Run

Fitness and diversity of actions are initially low because all agents are initially immobile, implementing the same action, with all body parts in the neutral position. Soon some agent invents an action that has a higher fitness than immobility, and this action gets imitated, so fitness increases. Fitness increases further as other ideas get invented, assessed, implemented as actions, and spread through imitation. The diversity of actions increases due to the proliferation of new ideas, and then decreases as agents hone in on the fittest actions. Thus, over successive rounds of invention and imitation, the agents' actions improve. EVOC thereby models how "descent with modification" occurs in a purely cultural context.

## Method

## Modeling Chaining

The chaining algorithm is illustrated schematically in Figure 1b. Chaining gives agents the opportunity to execute multistep actions. The agent can keep adding a new sub-action to its current action so long as the most recently-added subaction is both novel and successful. A sub-action D is considered novel if at least one of its components is different from that of the previous sub-action. It is considered successful if there exists a template $T^{i}$ such that $\Phi\left(T^{i}, D\right)$ is one.

$$
\operatorname{successful}(D)=\left\{\begin{array}{lc}
\text { true } & \text { if } \exists T^{i}: \Phi\left(T^{i}, D\right)=1  \tag{4}\\
\text { false } & \text { otherwise }
\end{array}\right.
$$

The fitness of an action consisting of more than one subaction is obtained by adding the number of sub-actions to the fitness of the last sub-action in the sequence. For example, if the last sub-action of an action is $D=[0,1,-1,1,-1,1]$ and the number of sub-actions is seven, the fitness of the action is $F(D)+7=14+7=21$. Thus where $c$ is 'with chaining', $w$ is 'without chaining', n is the number of chained sub-actions, the fitness of a chained action, $F_{c}$, is calculated as follows:

$$
\begin{equation*}
F_{c}=F_{w}+n \tag{5}
\end{equation*}
$$

An agent can execute an arbitrarily long action so long as it continues to invent successful new sub-actions. In general, the more sub-actions the fitter the action. This is admittedly a simple algorithm of simulating the capacity for chaining, but we were not interested in the impact of this action per se. The goal here was simply to test hypotheses about how chaining at the individual level affects dynamics at the societal level, by providing agents with a means of implementing multistep actions such that the optimal way of going about one step depends on how one went about the previous step.

## Modeling Contextual Focus

The CF algorithm is illustrated schematically in Figure 1c. In the convergent mode, the current action is only slightly modified to create a new action. In the divergent mode, the current action is substantial modified to create a new action. An agent switches between these modes by modifying its rate of creative change ( RCC ). If the fitness of its current action is low relative to previous actions, RCC increases, causing the agent to shift to a more divergent processing mode conducive to large leaps through the space of possibilities. If action fitness is high relative to that of previous actions, RCC decreases, and the agent shifts to a more convergent mode conducive to minor adjustments. With CF turned off, RCC stays constant throughout the run at $1 / 6$ (i.e., a new action involves change to one of the six body parts). The equation to modify RCC is shown in Eq. 6 where $a$ is a negative value. Since at the start of a run previous fitness is undefined, RCC in this case is a function of the current fitness as per Eq. 7, where $0<b<1$.

$$
\begin{equation*}
\Delta R C C=a\left(F_{\text {new }}-F_{\text {old }}\right) \tag{6}
\end{equation*}
$$

Figure 1: Schematic illustration of (a) neither chaining nor CF, (b) chaining only, and (c) both. Chaining operates within a generation whereas CF operates between generations.

$$
\begin{equation*}
R C C_{\text {initial }}=b^{F_{\text {current }}} \tag{7}
\end{equation*}
$$

In the results shown here $a$ and $b$ were initialized to -0.005 and 0.8 respectively.

## Results

The results of introducing chaining and CF on the mean fitness and diversity (total number of different actions) of actions across all agents in the society are shown in Figures 2 and 3 respectively. All graphs show means of 500 runs. Chaining and CF both significantly increased mean fitness of actions. Without chaining, mean fitness quickly reached a plateau; with chaining it could increase indefinitely. While chaining increased mean fitness throughout the run, CF only increased mean fitness following initial exposure to a new fitness function, i.e., at the beginning of the run, and when the second fitness function was introduced at iteration 50.

Chaining also significantly increased the diversity of actions. Although inspection reveals that there is always convergence on optimal actions, without chained actions, this set is a static (thus mean fitness plateaus) whereas with chained actions the set of optimal actions changes, as increasingly fit actions continue to be found. When agents were first exposed to a fitness function, CF increased both the rate at which new possibilities were generated, and the rate of convergence on the fittest of these, although this effect is more pronounced for the first fitness function than the second. As with fitness, CF exerted no noticeable effect on diversity once the agents had fit actions.

Figure 2: Mean fitness of cultural outputs across the society with both chaining and CF (red line), chaining only (dashed blue line), and neither chaining nor CF (dotted green line).

Figure 3: Diversity of cultural outputs across the society with both chaining and CF (red line), chaining only (dashed blue line), and neither chaining nor CF (dotted green line).

## Discussion

This paper provides valuable insights into the mechanisms underlying the uniquely human capacity for collectively generated, open-ended, adaptive cultural evolution. Our results suggest that once humans became able to sequence thoughts together to generate increasingly complex and refined cultural outputs, they would have found themselves at a significant adaptive advantage. Similarly, our results suggest that once humans became able to employ an exploratory, divergent processing mode when stuck, followed by a shift to a more constrained convergent processing mode to fine-tune their cultural outputs, they would have been capable of generating significantly more valuable cultural outputs. We suggest that a mechanism akin to CF is what makes possible the cumulative creativity exhibited by successful computational models of language evolution (e.g., Kirby, 2001). A potential downfall of processing in a divergent mode is that since effort is devoted to the re-processing of previously learned material, less effort may be devoted to being on the lookout for danger and simply carrying out practical tasks. Since divergent thought carries a high cognitive load, it would not have been useful to think divergently until there was a means to shift back to a convergent mode. Although these results do not prove that onset of the capacity to chain thoughts together into sequences, and to shift between divergent modes of thought through CF, are responsible for our cultural complexity, it shows that they provide a computationally feasible
explanation. We know of no other cognitive mechanisms implicated in the evolution of complex culture for which openended, adaptive cultural change has been demonstrated.

Both chaining and CF were implemented in a simple manner. Future investigations will focus on developing more realistic implementations of chaining and CF. Chaining will use associative recall to reconsider an item from multiple potentially relevant 'perspectives', and the divergent mode of CF will use a sophisticated mathematical model of concepts to facilitate the generation of new concept combinations.

#### Abstract

Under conditions where an object is inside another object and only a single face is visible, is there a bias to assume smooth continuation of the surface straight back into the object? To examine the ability to estimate how features progress into a volume, participants viewed 16 pictures of everyday objects (rocks, food, wood) presented with only a single face visible (see Figure 1). Participants reported whether a highlighted region of a picture was present on the surface or extended into the object. If they perceived the region as extending in, they positioned a rod to indicate the angle. Surface responses were rare and instead participants' readily perceived 3D forms from 2D views. Inspection of frequency histograms revealed a systematic bias to estimate the angle of extension in the $80-110^{\circ}$ range. This type of completion process suggests constraints on models of visual completion and has implications for STEM education, in particular, how students deal with ambiguity.

Keywords: perception of 3d volumes, amodal continuation, penetrative thinking.

## Introduction

How does the visual system estimate 3-dimensional (3D) forms of objects embedded in other objects? While this question has received very little empirical attention (Chariker, Naaz, \& Pani, 2011; Hegarty, Keehner, Cohen, Montello, \& Lippa, 2007), we believe it is central to our understanding of amodal completion. Take for example the image shown in Figure 1. There is little doubt that the dark brown region (cinnamon swirl) is 3D and extends into the object, however from this 2-dimensional (2D) view or crosssection, the 3D shape is unknowable (note even if you knew the true 3D shape the answer would still be ambiguous within a mirror reflection because the image could come from either side of a cut). In order to infer the 3D shape of the region, one would have to have a view of the region from another side. Inferring shape from partial information is particularly important for disciplines that rely on 3D visualization (e.g., astronomy, neuroscience, geosciences). However, a common sentiment echoed by geoscientists and noted by Kali \& Orion (1996) for geological stimuli, is that students neglect the ambiguity inherent in a single 2D view and instead are biased to assume that surface boundaries extend perpendicularly into solids.

The goal of this paper was twofold: 1) to examine whether people recognize that the 3D form of an object is unknowable from a single 2D view and 2) to examine whether participants do indeed exhibit a bias to assume smooth continuation of a surface straight back into the solid as suggested by the anecdotal reports of geoscience educators.
To answer this question we showed undergraduate psychology majors pictures of everyday objects such as food, rocks and wood. For each picture, a region was indicated with a colored line, as shown in Figure 1 top. Students indicated if the highlighted region was visible only on the surface or whether it extended into the object. Note that the answer to this question is in fact unknowable. While some of the objects are familiar to viewers (kiwi, bread, etc) and thus the overall shape of the object can be inferred, one cannot know how the cut was made or for unfamiliar objects, whether the indicated region continues into the object or is present only on the surface. To infer the 3D shape one would have to see more than one 2D crosssection of the object. If students saw the indicated region as extending in, they used a rod attached to an inclinometer to indicate the angle at which the region continued into the object (the correct answer for the bread is shown in Figure 1 bottom). We predicted that participants would have a strong sense that the indicated regions were 3D and would exhibit a bias to see the regions as extending back at a $90^{\circ}$ angle relative to the ground surface.

Figure 1: The bread stimulus. Top: Participants indicated if the region highlighted by the red line, was present on the surface or extend into the solid. Bottom: Red line shows the angle at which the swirl extends into the bread. Note participants never saw this view.

## Method

Participants. Participants were 30 Temple University Undergraduates.

Stimuli. The stimuli consisted of 17 color photographs of common objects such as food, wood and rocks. There was one practice image and 16 experimental images. For each picture we selected a specific region of the picture to ask participants about. As shown in Figure 1, this region was indicated with a red line. In each image the area represented a region where a plane might intersect the visible surface. For example in Figure 1, the plane defined by the cinnamon layer between two regions of dough is indicated. Images when presented on the screen were approximately $25 \times 18$ cm.

These categories of images were chosen with two constraints: 1) that we were physically able to slice each object and measure the angle at which each highlighted region extended into the object and 2) that we sample a range of objects that might be familiar to participants.

Our stimuli fell into six broad categories defined by their internal structure: 1) rocks (granite slab), 2) wood (tree ring and a knot), 3) fruits (pineapple, papaya, kiwi), 4) vegetable (onion), 5) animals (fish and beef) and 6) food products that were originally liquid and are now solid (blue cheese, chocolate with almonds and cinnamon bread). These categories were selected because the internal structure ranged from highly structured and constrained by the environment (e.g., wood grain) to relatively unconstrained (e.g., minerals in rock) and thus the orientation is either knowable within a certain range or completely unknowable.

For example, the internal structure of wood is constrained by the environment. As tree structures are generally concentric cylinders, the extension into a slice is a function of the angle of the cut relative to the cylinders. For the fruit stimuli we selected fruits with radial symmetry and thus the internal structure is also structured. An onion although somewhat irregular in shape, has an organized internal structure. For the fish and beef stimuli we asked about how regions of fat extend in. Fat deposits are structured in complex ways by the surrounding muscles and thus organized but not to the same degree as wood, or fruit. The internal composition of rocks can be structured, but the orientation of a mineral's surface relative to the cutting plane is essentially arbitrary.

Apparatus. Stimuli were presented on a 20 -inch Dell monitor. As shown in Figure 2, the monitor was positioned parallel to the ground.

Figure 2: The display used in the experiment. Participants used the black rod to indicate the orientation at which the highlighted region extended into the object.

Procedure. Participants were tested individually. They viewed each picture while standing with their nose over the center of the monitor. Participants were told that we were interested in their opinions of how regions of images continue in 3 -dimensions. They were told that sometimes they would see pictures where they might have a strong sense that a region continued and sometimes they might have a sense that something was present only on the surface. To illustrate these cases, students were shown a picture of a Swiss roll and crayon marks on paper. All students reported seeing the layers of the Swiss roll as extending into the object while the crayon marks were present on the surface.

Participants were shown 16 pictures. For each, their task was to indicate whether the region indicated with the red line was present only on the surface or extended into the object. If they thought it extended into the object, they used a stainless steel rod with an inclinometer (angle measure) attached to indicate the orientation of continuation. Participants placed the edge of the rod on the red line and then moved the rod up and down to indicate the angle. The $0^{\circ}$ was defined relative to the ground plane (i.e. if positioned the rod to indicate straight down, as shown in Figure 2, the angle measurement was $90^{\circ}$ ). After they estimated the angle, they reported their confidence in their response on a 5-point scale. Prior to viewing the 16 pictures participants practiced using the angle measurement device on the image of the Swiss roll. To be sure that there were not differences in the estimates based on the orientation of the picture, after viewing all the pictures and making their responses participants were shown the 16 pictures again but this time the images were rotated 180 degrees. This allowed us to calculate any bias due to their body position relative to the image. Finally, participants were shown the pictures a third time and asked to identify each picture. For any response with a confidence rating of 0 or 1 , we further probed their uncertainty. Participants were asked to select which of the following reasons best described why they were uncertain in their response: 1) they have no idea what it could be, 2) the answer is unknowable 3) there could have been a range of possible angles. Additionally, for the pictures that they
selected surface for, we told them that the region did extend in and asked them if they could make a guess about its orientation using the rod (note these estimates were not included in any analyses). After this, participants completed the Geologic Block Slicing Test (a measure of inferring internal spatial structures from views of multiple sides; Ormand et al, 2011), Spatial Orientation Test (Kozhevnikov \& Hegarty, 2001) and the Mental Rotations Test (Shepard \& Metzler, 1971). Data for these spatial tests are not presented in this paper.

## Results

Although the single 2D view is insufficient to define a 3D shape, participants reported that the answer was unknowable on only $1 \%$ of the trials (12 times out of 960 trials), suggesting that participants do not recognize the need for multiple views to solve the intersection of constraints problem. Consistent with this, participants were confident in their angle estimates. The mean confidence was 3.2 (SD $=1.1$ ) on a 5-point scale. Participants did perceive some of the highlighted regions as being only on the surface, but this was the case on only $26 \%$ of the trials, suggesting that participants tended to perceive the highlighted regions as extending into the object in three dimensions.

In order to calculate the participant's unbiased estimate for each picture, the two estimates were combined by calculating the average of the first estimate and $180^{\circ}$ minus the second estimate. By presenting each picture in two orientations, we could remove any bias that a participant had to orient the rod towards (or away from) their body. For example, consider a case where the estimate for the first view and the second view (when the picture was rotated $180^{\circ}$ ) of a picture was $80^{\circ}$. If the participant were truly responding with an unbiased estimate, this would mean that if the estimate for the first view was $80^{\circ}$, the estimate for the second view should have been $100^{\circ}$. Thus, by subtracting the second estimate from 180, we can avoid any systematic bias (overall participants exhibited an $\sim 4$ degree bias towards their body).

Figure 3 shows the mean angle estimate without bias for each picture along with the $95 \%$ confidence interval for that picture. Inspection of the figure reveals that mean estimates tended to be biased towards $90^{\circ}$. Fifteen of the 16 pictures have mean estimates that are not significantly different from $90^{\circ}$ (the red line denotes $90^{\circ}$ ). The only picture that has a mean estimate significantly greater than $90^{\circ}$ was the "onion" picture.

Figure 3: Mean estimate for each picture. Error bars show $95 \%$ confidence interval for each mean.

Next we examine whether the distribution of responses for each picture was random or whether there was a preferred direction for the distribution. Surface responses were excluded from this analysis. Thus the N for each picture varies based on the number of estimates for that picture. To examine the structure of the distributions we conducted the Rayleigh test (Zar, 1999) using the EZ Rose program (Baas, 2000). The null hypothesis is that the distribution of responses are randomly distributed around a semicircle. If the null is rejected then the distribution of responses has a preferred direction. To examine whether the null is accepted or rejected one compares R (mean vector length) for each picture to the critical value of the test statistic $R_{0.05}$ (see Baas, 2000 equation 10). If $R$ is greater than $\mathrm{R}_{0.05}$ then the distribution of responses has a preferred direction (i.e. is not random). As can be seen in Table 1 the Rayleigh test was rejected for 14 of the 16 pictures. For the "Tree Knot" and Papaya pictures, participants tended to perceive the region as on the surface ( $44 \%$ and $58 \%$ were judged to be "on surface," respectively). Thus the number of estimates was less than the 15 recommend for this test (Baas, 2000). However, an inspection of the frequency distributions (see below) reveals that when estimates were made, they centered around $90^{\circ}$.

## Table 1: Results of the Rayleigh Test.

| Picture | R | $\mathrm{R}_{0.05}$ | $\mathrm{H}_{0}$ |
| :---: | :---: | :---: | :---: |
| Chocolate | 0.91 | 0.38 | rejected |
| Tree Knot | - | - | - |
| Pineapple | 0.97 | 0.43 | rejected |
| Blue Cheese | 0.94 | 0.43 | rejected |
| Salmon | 0.87 | 0.32 | rejected |
| Granite 4 | 0.84 | 0.38 | rejected |
| Wood 1 | 0.97 | 0.45 | rejected |
| Steak 2 | 0.82 | 0.33 | rejected |
| Bread | 0.92 | 0.33 | rejected |
| Kiwi | 0.85 | 0.33 | rejected |
| Steak 1 | 0.80 | 0.36 | rejected |
| Granite 3 | 0.79 | 0.37 | rejected |
| Granite 2 | 0.85 | 0.39 | rejected |
| Granite 1 | 0.85 | 0.43 | rejected |
| Onion | 0.89 | 0.37 | rejected |
| Papaya | - | - | - |

Finally, we examined whether the mean estimates centered around $90^{\circ}$ because some participants estimated the angle at $10^{\circ}$ and others at $170^{\circ}$ and this averaged out to $90^{\circ}$ or whether there was consistency among estimates for all participants. Figure 4 shows the frequency distribution for response for each of the 16 pictures grouped by category. As can be seen in the figure, the distributions are fairly uniform. There are certain pictures, for example the papaya, where participants on averaged perceived the indicated region to be on the surface (thus number of estimates is smaller). However, there were other pictures, like the kiwi and bread where participants agreed the region extended in. Also evident in the distributions is the limited spread. Mean estimates did not encompass the entire $0-180^{\circ}$ spectrum; instead on average they were concentrated around 90.

## Discussion

Two conclusions can be drawn from this work. The first is that participants failed to recognize that one cannot know the orientation of a 3D structure from a single 2D view. Instead of recognizing that this situation is ambiguous, participants tended to have consistent intuitions about how regions of pictures extend in 3D into the object. The second conclusion that can be drawn from these findings is that participant's estimates tended to be clustered around $90^{\circ}$, suggesting that estimates were biased to assume that the surface continues straight back into the object. These findings 1) suggest possible constraints on models of amodal completion processes and 2) have implications for STEM education, in particular, challenges that arise when students do not recognize ambiguity. We consider each of these in turn.

In developing our understanding of how the visual system estimates the 3D form of objects, there are important completion phenomena that should constrain computational models. Here we describe a completion phenomenon that to our knowledge has not been recognized -- participants readily perceived 3D forms from 2D views (of both familiar and unfamiliar objects) and the perception is that surface boundaries extend perpendicularly into a solid.

This bias may be informative about the filling out process that occur under conditions where the 3D completion of surfaces can not occur because the edges of an object are not aligned in the 2D projection on the retina (see Tse, 1999). The bias evident in this study may be a product of the way the visual system handles a more common instance of having partial information about an object - when viewed head-on. Normally, if one can only see a single side of an object, it is a result of your current viewpoint (the line-ofsight is perpendicular to the front face). So, the visual system may represent the portions of the occluded object using past experience (i.e. knowledge about cinnamon swirl bread) or some properties of the front face. This process becomes evident when the object (the cinnamon swirl) is surrounded by an opaque region (more bread) and thus other sides are not visible to the observer. The visual system is not flummoxed by this situation but instead rapidly extrapolates from the available single surface to represent an extended 3D structure. Under these conditions, the completion process reflects the assumption that edges on the surface project straight into the object.

Our observations suggest the existence of a visual process that uses available visual information to extend form representations into regions where the form is not visible. Models of visual completion argue that completion processes reflect the system's attempt to construct a representation of the most likely 3D form. An ongoing debate in the literature has examined whether completion processes occur as a result of extrapolation (filling out) or interpolation (filling in). Here, where only one face of a 3D
form is visible, the completion processes must be based on extrapolation - filling out from available visual information (Shipley \& Kellman, 2003) - rather than interpolation between defined regions. Extrapolation occurs in both amodal (Kanizsa, 1979) and modal displays (Shipley \& Kellman, 2003), but previous demonstrations have been extrapolation of planes or edges, not 3D volumes.

In addition to informing our understanding of visual completion processes, these results have important implications for STEM education. Consider a field geology student examining a rock face and trying to make inferences about its 3D structure, or an anatomy student learning where best to make an incision during dissection or surgery. Both of these tasks require inferences about a 3D form from a 2D view. What is critical in both these cases is that an accurate estimate of the orientation of the 3D form requires more information - either in the form of looking at another angle of the rock to see how features penetrate in, or knowing something about the true 3D shape and using that to constrain the estimate of orientation of how the region extends into the volume. There are aspects of the world that might place constraints on the probable internal structure (i.e. grains in wood has a cylindrical structure), however students must recognize the need to seek out additional information in order to make inferences about the 3D structure.

An extensive body of research has examined decisionmaking regarding uncertain events (Kahnamen, \& Tversky 1982), however to our knowledge work in this area has not examined uncertain perceptual situations and their relationships to confusion in the classroom. We believe this is an interesting area to pursue in future research. How best to convey to students that information in an image may appear to determinant, but is in fact ambiguous.

Our aim in this paper is threefold: first, examine 3D completion from 2D views and to bring this type of process to the attention of the research community. By making researchers aware of completion processes in the "wild", we hope to begin a dialogue that may move completion research forward into new domains. Second, to expand the phenomena considered by any model of visual completion. Third, we wish to illustrate the importance of scaffolding student's ability to recognize ambiguity and the necessity to seek out additional information for solving a problem.

# Computational exploration of task and attention modulation on holistic processing and left side bias effects in face recognition: the case of face drawing experts. 

Bruno Galmar (brunogal@hku.hk)<br>Janet Hui-wen Hsiao (jhsiao@hku.hk)<br>Department of Psychology, University of Hong Kong<br>Pokfulam Road, Hong Kong SAR

#### Abstract

Drawing artists and non-drawers are like any adult both experts at face recognition. Yet, artists have a richer learning experience with faces: they were trained in rapid sketching of faces. Zhou, Cheng, Zhang and Wong (2011) found that drawing experts showed less holistic processing (HP) for face recognition than non-drawers. Using a computational model of face recognition that did not implement motor processing, we examined whether engagement of local attention and nature of the learning task could account for the reduced HP in drawers without the influence from motor experience. We showed that compared with the non-drawer model that had a global face input (i.e., Hsiao, Shieh \& Cottrell, 2008), a drawer model that incorporated both global face and local facial parts (eyes and mouth) in the input showed reduced HP, suggesting the modulation of local attention engagement. In contrast, the other drawer model that used only global face input but learned to perform an additional face part identification task did not show the reduced HP effect. In addition, both drawer models demonstrated stronger left side (right hemisphere) bias than the non-drawer model. Our data thus suggest that engagement of local attention is sufficient to account for the reduced HP in drawers, and that HP and left side bias effects can be differentially modulated by visual attention or task requirements.

Keywords: Model of face recognition; Holistic processing; Hemispheric lateralization; Visual expertise.

## Introduction

Visual expertise in subordinate-level discrimination has been extensively studied (e.g., Bukach, Gauthier, \& Tarr, 2006), such as our expertise in recognizing individual faces. Several behavioral markers of visual expertise have been identified, including holistic processing (HP), which refers to the phenomenon of viewing faces as a whole instead of various parts (Bukach et al., 2006; although some argue that HP is specific to face recognition; e.g., McKone, Kanwisher, \& Duchaine, 2007). Subsequent studies suggest a correlation between an increase in HP and expertise in subordinate-level individualization, as opposed to expertise in basic-level categorization (e.g., Wong, Palmeri, \& Gauthier (2009)). For example, Wong et al. (2009) trained two participant groups to recognize an artificial object type (Ziggerins) with different training tasks: one group learned to rapidly individualize Ziggerins at the subordinate level, whereas the other group learned rapid sequential categorization at the basic level. The results showed that only the individuation experts showed an increase in HP, even though the two groups had the same amount of
exposure to Ziggerins. This suggests that qualitatively different expertise processing can arise depending on the nature of the training task.

Such a qualitative difference of expertise processing resulting from different learning and training experience has been recently observed for face recognition. Zhou, Cheng, Zhang and Wong (2011) studied two groups: (a) an experimental group was composed of art students who had extensive formal training in sketching and drawing portraits, and (b) a control student group of non-drawers - i.e. who had no prior drawing background or education-. Hence, the two groups had different learning experience in processing faces. Non-drawers would show the typical face expertise any adult is endowed with: being able to recognize at least a thousand of faces. In contrast, art students would have internally assimilated an ordered procedure for rendering faces on a 2D surface (Balas \& Sinha, 2007; Willenbrink \& Willenbrink, 2012), for example: a) sketch the basic head proportion, b) sketch the overall head form and basic lines for features, c) place the brows and lips, and so on. Such a fine-grained procedure relies upon a mix of global and local processing, and featural and configural processing. Art students would not ignore face details which are critical to render a vivid portrait of an individual. Hence, art students are used to scrutinize a face and could be less engaged in HP than non-drawers. This educative guess is supported by eye-tracking studies (Miall \& Tchalenko, 2001; Tchalenko et al. 2003) of eye movements of a skilled artist. Miall and Tchalenko (2001) proposed as an account of the visual encoding of the studied artist Ho: "The capture of visual information detail by detail, rather than in a more holistic manner, is reflected in the way the drawing or painting is built up. Each detail and each element is of intrinsic importance." Using the complete composite paradigm of face recognition, Zhou et al. (2011) found less HP for art students than for non-drawers. Reduced HP with drawing expertise is not an isolate case. Previously, Hsiao and Cottrell (2009) found reduced HP for Chinese readers - who were experts at recognizing Chinese characters - compared with novice Chinese readers. Tso, Au, and Hsiao (2011) further showed that the reduction in HP found in expert Chinese readers depended on their writing rather than reading experience of Chinese characters, since proficient readers who had limited writing experience (i.e. Limitedwriters) showed increased HP as compared with novices, in contrast to the reduced HP observed in Chinese readers who could read and write fluently (i.e., Writers; Tso, 2012).

In the present study, we aimed to examine the underlying mechanism accounting for the results in Zhou et al. (2011) through computational modeling and simulations. Computational modeling is an insightful tool to test ideas on the nature of cognition difficult to test with human subjects (McClelland, 2009). Motor experience, visual attention, and nature of the learning task are all potential factors that may account for drawers' reduced HP in face recognition. These factors may be difficult to disentangle within drawers so that the separate contribution of each to HP is not easily amenable to experimental study. Here, we aimed at testing two simplified models of drawing expertise that did not implement motor processing and to compare them with our previous model of face recognition (i.e., the intermediate convergence model in Hsiao, Shieh, \& Cottrell, 2008), which is to serve as a non-drawer model, in order to examine whether visual attention and nature of the learning task can account for the reduced HP in drawers without the influence from motor experience. Through these two models, we postulated two hypotheses concerning how art students having developed expertise in the task of drawing faces could demonstrate reduced HP in face recognition compared with non-drawers.

The non-drawer model - called base model thereafter shown in Figure 1 is trained to map face images to whole face identity. This global task is intended to reflect ordinary face recognition by non-drawers. The models of drawing expertise are not as purely global as the base model. They embed local processing in addition to the global face identification.

## Rationale behind the first model of drawing expertise

Our first model of drawing expertise shown in Figure 2 is trained to map face, eyes and mouth images to whole face identity. Modeling the encoding of visual information from facial parts such as eyes and mouth to serve the task of whole face identity reflects the engagement by artists in local attention. Using eye-tracking, Tchalenko, DempereMarco, Hu, and Yang (2003) reported that artists do process individually facial parts and even scrutinize faces for informative details: "[...] the experienced painter differed from the novice in his ability to repeatedly target saccades onto a small detail of the model's face, and to lock on to that detail in a steady fixation." Consistently, Zhou et al. (2011) showed that artists had slower response times (RT) compared with non-drawers. This could be because of the additional engagement of local attention on facial parts. The nature of this more local and prolonged visual engagement is translated in the first model of drawing expertise by a larger input layer compared with the base model. A drawing expert may manipulate more encoded visual inputs - as suggested by the expertise literature (Bransford, 2000) - but would still perform the same global identification task than the normal face recognizer. Because of the selective encoding of eyes and mouth in addition of global encoding of the face image, this model reflects engagement of both global and local attention at the encoding stage of visual processing.

## Rationale behind the second model of drawing expertise

Our second model of drawing expertise shown in Figure 3 is trained to map face images to both whole face identity and cluster identities for mouth and eyes. Hence, the rationale is that artists use the same global attentional resources - i.e. the model has the same global input layer as the base model- but artists engage in a more analytical face recognition task. Here, given a face input, the model tries to recognize in addition to face identity, a mouth prototype (a kind of mouth) and a pair of eyes prototype (a kind of eyes). Such partitioning of eyes and mouth in kinds reflects that artists would engage in clustering facial features. This hypothesis is not only sound but also well-grounded. In his Treatise on Painting, the Renaissance genius Leornardo Da Vinci exposes some technical insights on how to develop the skills necessary to a portraitist (Rigaud, 1877). For example, in the section of "How to remember the Form of a Face", Da Vinci mentioned: "If you wish to retain with facility the general look of a face, you must first learn how to draw well several faces, mouths, eyes, noses, chins, [...], all those principal parts which distinguish one man from another." Then, we read: "[...] noses are of ten different sorts: straight, bunched, concave, [...]." In another section entitled "Observations on drawing Portraits", we read: "The uniting of the nose with the brows is in two ways [...]. The forehead has three different forms."

Details on the implementation of these models are given in the next section. We trained the three models to either the same performance level in the whole face identification task or the same amount of epochs, and examined their difference in HP and lateralization. Face processing has been shown to involve right hemisphere (RH) lateralization, as indicated by the left side bias effect: a chimeric face made from two left half faces from the viewer's perspective is usually judged more similar to the original face than one made from two right half faces (Gilbert \& Bakan, 1973). It is commonly assumed that HP is associated with RH lateralization. However, some experimental and computational studies (Hsiao \& Cottrell, 2009; Hsiao \& Cheung, 2011) showed the possibility of increased engagement of RH whereas decreased HP is measured. Another work on Chinese reading expertise (Tso, 2012) revealed a reduced HP for Chinese Writers as compared with Limited-writers; however there was no difference in left side bias between them. Our modeling work is hoped to also shed additional light on this issue.

Figure 1: Base Model

## Modeling Implementation

## Base model for non-drawers

Face recognition by non-drawers is modeled by Hsiao et al.'s (2008) intermediate convergence model of face recognition. This model (Figure 1) incorporated several known observations about visual anatomy and neural computation. Hsiao et al.'s (2008) used Gabor responses over the input images to simulate neural responses of cells in the early visual area, and Principal Component Analysis (PCA) to simulate possible information extraction processes beyond the early visual area. They then used this PCA representation as the input to a two-layer neural network. In addition, they implemented a theory of hemispheric asymmetry in perception, Double Filtering by Frequency theory (DFF, Ivry \& Robertson, 1997) in the model. The theory posits that visual information coming into the brain goes through two frequency-filtering stages. The first stage involves attentional selection of a task-relevant frequency range. At the second stage, the LH amplifies high spatial frequency (HSF) information, while the RH amplifies low spatial frequency (LSF) information. This differential frequency bias in the two hemispheres was implemented in the model by using two sigmoid functions assigning different weights to the Gabor responses in the two hemispheres. In the present implementation, the face input ( $100 \times 135$ pixels) was first filtered with a grid $(6 \times 6)$ of overlapping 2D Gabor filters in quadrature pairs at five scales and eight orientations. The five scales corresponded to 2 to 32 cycles per face (the task-relevant frequency range, depending on the image size. The maximum frequency should not exceed 2 pixels per cycle; the 6th scale, $2^{6}=64$ cycles per image exceeds the maximum frequency of the images, $100 / 2=50$ cycles per image). The resulting Gabor vector representation of the face was split into left and right halves. The perceptual representation of each half was compressed into a 50-element representation. After PCA, each principal component was z-scored to equalize the contribution of each component in the model. The PCA representation was then fed to a feedforward network with one hidden layer of 50 nodes. The number of nodes was determined empirically to allow efficient training of the network of all the three models of the present study. The output layer of the neural network has one output for each of the 53 faces of the testing set. Face images were taken from the CAlifornia Facial Expressions dataset (CAFÉ; Dailey, Cottrell, \& Reilly, 2001). We used two different neutral images for each face to constitute the training and testing sets. The neural network was trained with gradient descent with adaptive learning rate backpropagation from the MATLAB ${ }^{\circledR}$ Neural Network Toolbox (Version 7.0.3). All the networks were trained for both 400 epochs and 150 epochs. 400 epochs is enough for all the models to reach perfect recognition rates on the training sets and near perfect accuracy on testing sets. Training with only 150 epochs offers another viewpoint on the behavior of the three models by decreasing the ceiling effects observed with 400 epochs.

## Implementation of model I of drawing expertise

Our first hypothesis states that drawing experts engage in local attention on specific facial features at the encoding stage in addition to the global encoding process shared with non-drawers. Hence, in addition to the face input, model I includes isolated mouth and isolated eyes as local inputs. We filtered mouth images ( $50 \times 20$ pixels) and eyes images ( $74 \times 18$ pixels) by a bank of Gabor filters of three scales and eight orientations. The three scales corresponded to 2 to 8 cycles per face (The maximum frequency should not exceed 2 pixels per cycle; the 4 th scale, $2^{4}=16$ cycles per image exceeds the maximum frequency of the images, 18/2 $=9$ cycles per image for eyes and $20 / 2=10$ cycles per image for mouth). The size of the filtering grid ( $6 \times 6$ ) was the same for each kind of three - face, mouth and eyes inputs reflecting the engagement of the same resources for processing the global face or anyone of the two local parts. The choice of eyes as a facial feature was motivated by Tchalenko et al.'s (2003) finding that artists primarily focused on eyes. We added also a bottom facial feature: mouth, richly informative for artists. After Gabor filtering, the vector representations of mouth and eyes followed the same scheme of splitting, weighting and compressing as the one for face input. Hence, the neural network of model I was fed with an input layer of length 300 , with 100 PCA values for each of the three inputs. The model I of drawing expertise executes the same classification task as the base model. Hence, the two models have an identical output layer.

Figure 2: Model I of drawing expertise

Figure 3: Model II of drawing expertise

## Implementation of model II of drawing expertise

The second model of a drawing expert in Figure 3 is modified from the base model by adding at the classification stage of the neural network level two tasks. Namely, the model has to map the mouth and the eyes in the face input to respectively a "mouth cluster" and an "eyes cluster". This
second model shares the same input layer with the base model. This means that both models use the same attentional or perceptual resources to encode the input face. However, the expert model is trained with a more analytic task than mere face identification. It has to perform a cluster mapping operation for mouth and eyes. Four eyes and four mouth clusters were defined based on a set of features for eyes and mouth mentioned in textbooks on drawing portraits. This clustering ${ }^{1}$ yielded high recognition rates (> 98\%) for mouth and eyes on both training and testing sets for both training durations.

## Model of the composite task and measure of holistic processing

In human studies, HP is usually assessed through the composite paradigm (Young, Hellawell, \& Hay, 1987). In this paradigm, two stimuli are presented briefly, either sequentially or simultaneously. Participants attend to either the top or bottom halves of the stimuli and judge whether they are the same or different. In congruent trials, the attended and irrelevant halves lead to the same response, whereas in incongruent trials, they lead to different responses. HP is indicated by interference from the irrelevant halves in matching the attended halves; it can be assessed by the performance difference between the congruent and the incongruent trials.

The holistic face processing effect has been accounted for by computational models. For example, Cottrell, Branson, and Calder (2002) trained a computational model to perform a face identification task and an expression judgment task, and showed that the model was able to account for HP effects in both tasks. Richler, Mach, Gauthier, and Palmeri (2007) also used a variant of Cottrell et al.'s (2002) model to account for the HP effect in face recognition. To assess HP in our three models, we applied the method used by Hsiao and Cheung (2011), which was derived from Richler et al. (2007). After training we attenuated the Gabor responses of either the top or bottom half of the images in the test set by multiplying a factor of 0.125 to simulate directing the models' attention to the bottom or top half of the images respectively. For the first model of drawing expertise, for mouth and eyes inputs, only the unattended part was attenuated (eyes are in the top half, mouth is in the bottom half; see Figure 5(a)). The complete composite design was used; it has been shown to be more robust than the partial composite paradigm (Richler, Cheung, \& Gauthier, 2011). We created 4 types of stimulus pairs corresponding to the 4 conditions in Figure 4. Twenty pairs of images in each condition were randomly selected to form the materials (80 pairs in total). We calculated the correlation of the hidden layer representations in each pair as the similarity measure between them.

[^271]

Figure 4: Design of the composite task, with top halves attended.
A threshold was set to be the midpoint between the mean correlation of the "same" stimulus pairs and that of the "different" stimulus pairs. We assumed that the model responded "same" when the correlation of a pair was higher than the threshold, and responded "different" when the correlation was lower than the threshold. The HP effect was indicated by the discrimination performance difference between the congruent and incongruent trials measured by $\mathrm{d}^{\prime}$.

## Measuring hemispheric lateralization effect

The left side (RH) bias was assessed by the accuracy difference between recognizing a left-lateralized stimulus (carrying RH/LSF information) as the original stimulus and recognizing a right-lateralized stimulus (carrying LH/HSF information) as the original one. We defined RH lateralization (RH/LSF preference, Hsiao et al., 2008; Hsiao \& Lam, in press) as the left side bias measured in the biased condition minus that measured in the baseline condition. For the first model of drawing expertise with additional mouth and eyes inputs, lateralized stimuli were also used following the scheme applied to the face input (see Figure 5 (b)).

Figure 5: (a) Illustrative example of a Congruent Same pair for the composite task where bottom half is attenuated. (b) Example of a left-lateralized stimulus for measuring lateralization effects. For (a) and (b), eyes and mouth parts were only used in Model I of drawing expertise.

## Results

## Model I of drawing expertise (Experiment 1)

As shown in Figure 6, the model I of expertise with an input layer completed with mouth and eyes local inputs demonstrated less HP than the base model after either 150 or 400 epochs of training. For the 400 epochs case (the perfect accuracy case on the training set), a directional t-test revealed that model I was statistically significantly less holistic than the base model, $\mathrm{t}(798)=-1.76, \mathrm{p}=.04$, confirming our hypothesis. The mean value of $\Delta \mathrm{d}^{\prime}$ (Congruent d' - Incongruent d') for model I was smaller by a magnitude of 4 than the base model. This could be the result of a stronger ceiling effect. When decreasing the number of training epochs from 400 to $150, \Delta d^{\prime}$ for model I was increased from 0.006 to 0.023 , whereas $\Delta \mathrm{d}^{\prime}$ for the base
model increased from 0.026 to 0.063 . Decreasing the number of epochs did not change the significantly lower amount of HP for model I compared to the base model, $\mathrm{t}(798)=-2.29, \mathrm{p}=.011$. Model I with its increased size of the input layer initially generalized better than the base model. For 150 epochs, model I outperformed the base model ( $98 \%$ versus $91 \%$ recognition rates on the testing sets). However, by 400 epochs, the base model caught up with model I, and both models had equally perfect recognition rates.

Concerning RH lateralization (see Figure 7), a t-test indicated that model I was significantly more subject to a left side bias than the base model, $\mathrm{t}(798)=9, \mathrm{p}<.001$. For 150 epochs, the left side bias was further more accentuated for model I compared with the base model, $\mathrm{t}(798)=16.03$, p <. 001 .

Figure 6: Experiment 1. Holistic Processing

Figure 7: Experiment 1. RH Lateralization
Together the results indicated that our first model of drawing expertise compared with the base model of nondrawers is less holistic as measured by $\Delta \mathrm{d}$ ' and is characterized by a stronger left side (RH) bias effect. This finding of more RH lateralization for the model of drawing expertise was somewhat unexpected: drawers by focusing on parts in addition to global processing could have engaged in more LH/HSF processing than non-drawers. However, the main result here is the replication of Zhou et al. (2011)'s finding of less HP for drawing experts compared with nondrawers.

## Model II of drawing expertise (Experiment 2)

The model II of drawing expertise trained to recognize faces and to map mouths and eyes to respective clusters did
not demonstrate less HP than the base model (see Figure 8). Statistical analysis showed that the expert model was as holistic as the base model for both 400 and 150 epochs, $(\mathrm{t}(798)=-0.38, \mathrm{p}=.35$; $\mathrm{t}(798)=-1.12, \mathrm{p}=.13)$. We expected model II to behave less holistically than the base model but it did not.

Concerning the left side (RH) bias, a t-test showed that model II was significantly more RH lateralized than the base model for both 400 and 150 epochs, $(t(798)=4.56, \mathrm{p}$ $<.001$; $\mathrm{t}(798)=3.17, \mathrm{p}<.001)$. Again, this finding of more RH lateralization for the model of drawing expertise is somewhat unexpected: forcing the model to map eyes and mouth to cluster identities could have favored instead more LH/HSF processing (e.g., Hsiao \& Lam, in press).

Figure 9: Experiment 2. RH Lateralization

## Discussion \& Conclusion

Through computational modeling, we explored the nature of drawing expertise and aimed at accounting for Zhou et al. (2011)'s finding of less HP for drawing experts compared to non-drawers. Our first model of drawing expertise relied on engagement of local attention on face parts at the encoding stage in addition to the mere global face encoding in the case of the base model. This model of drawing expertise was successful in accounting for a lesser amount of HP compared with the base model. In the second model of drawing expertise, we kept the input layer of the base model but added to the face identification task, a mapping task of eyes and mouth to cluster identities. This second model was as holistic as the base model. Our modeling idea of an enriched input layer of both local and global information for experts in model I is supported by eye-tracking studies
(Miall \& Tchalenko, 2001; Tchalenko et al. 2003) of artists showing richer and more selective visual encoding by drawing experts compared with non-drawers.

Our findings of the two models of drawing expertise being more RH lateralized than the base model are congruent with the results of Hsiao and Cottrell (2009) on Chinese reading expertise. They found that Chinese character recognition experts have increased RH lateralization but reduced HP compared with novices. Like their results, our finding of increased RH lateralization but reduced HP for the first model of drawing expertise suggests that HP and RH lateralization may be separate processes that do not always go together, depending on the task requirement (Hsiao \& Cheung, 2011). Our finding also provides a testable hypothesis that face drawers may exhibit stronger left side bias in face perception than non-drawers.

Tso (2012) showed that Chinese Writers and Limitedwriters differed in HP but not in left side bias of Chinese characters. Drawers at first sight resemble Chinese Writers in that both achieved expertise through sharpening their motor and visual attention skills by eye-hand coordination while practicing their domain task. Nonetheless, the two groups may also differ in the following way. Chinese Writers were reinforced in a rote motor behavior while learning and copying the sequence of strokes for each character. However, drawers are not only challenged with each face's genuine and instantaneous uniqueness but critically have to render this uniqueness by capturing its gist in the details of the face. Hence, writing Chinese involves more rote motor learning than drawing faces; in contrast, drawers may develop better/finer visual attention skills than Chinese writers. Future work will examine whether our model can also account for Tso's (2012) finding in Chinese Writers and Limited-writers.

Our models of drawing expertise did not embed any motor component to represent motor drawing skills of experts. Hence, we showed that drawing experts and nondrawers could be sufficiently differentiated in terms of the nature (merely global versus both local and global) of attention during visual encoding of faces. We paved a first step in accounting for the nature of drawing expertise. It remains to be investigated what could be the contribution of motor expertise in drawing experts on the amount of HP they engage in.

# A Joint Interference Effect in Picture Naming 

Chiara Gambi (c.gambi@sms.ed.ac.uk)<br>Department of Psychology, 7 George Square Edinburgh, EH8 9JZ U.K.

#### Abstract

In two experiments we provided evidence for a joint interference effect in picture naming. Participants took longer to name pictures when they believed that their partner concurrently named pictures than when they believed their partner was silent (Experiment 1) or concurrently categorized the pictures as being from the same or from different semantic categories (Experiment 2). However, picture naming latencies were not affected by beliefs about what one's partner said. These findings are consistent with the idea that speakers represent whether another speaker is preparing to speak, but not what they are preparing to say.

Keywords: joint task; co-representation; agent-conflict; language production; picture naming.

In this paper we report results from two experiments that, for the first time, combined a highly constrained language task (picture naming), with a manipulation of the context in which the task is performed (i.e., whether the participant speaks concurrently with her partner or on her own). A similar rationale has been used by researchers who compared solo and joint SR compatibility effects (see Knoblich, Butterfill, \& Sebanz, 2011 for a review), but it has never been applied to picture naming.

A well-known SR compatibility effect is the Simon effect. People are faster responding to "right" stimuli with their right hand and to "left" stimuli with their left hand (congruent trials) than they are responding to "right" stimuli with their left hand and to "left" stimuli with their right hand (incongruent trials). For example, people respond more quickly to the color of a stimulus when the stimulus (e.g., the photograph of a hand) is pointing towards the response hand than when the stimulus is pointing away from the response hand (Sebanz, Knoblich, \& Prinz, 2003).

A similar effect occurs when participants respond only with one hand, but they take turns with another participant who is seated next to them (i.e., they are slower when the pictured hand points towards the other participant than when it points towards themselves). This joint interference effect is interesting because the Simon effect is not observed (or is
reduced) if participants respond with one hand and they perform the task on their own.

The joint Simon effect has been interpreted as evidence that participants represent their partner's potential response and that this representation interferes with their own response on incongruent trials (because the two responses are incompatible, in the same way as a response with one's right hand is incompatible with a response given with one's left hand). We refer to this as the co-representation account of joint interference effects. Interestingly, joint compatibility effects were found when participants sat alone but were led to believe another person performed the task with them. This occurred even when no feedback was available (Atmaca, Sebanz, \& Knoblich, 2011).

The co-representation account has been challenged. Here we are particularly interested in an alternative account put forward by Wenke et al. (2011), the agent-conflict account. According to this account, representing that one's partner is (potentially) about to respond on the current trial interferes with one's own response. However, this occurs because there is a conflict regarding whose turn it is to respond, rather than because of incompatibility between one's own and one's partner's response. In fact, congruent responses should lead to similar amounts of interference as incongruent responses.

Joint interference effects have been almost exclusively investigated in manual tasks (e.g., Simon task, Flanker task, SNARC task), with only two studies using verbal responses (Philipp \& Prinz, 2010; Pickering \& MacLean, 2013) and none looking at picture-naming responses. Importantly, picture-naming responses are subject to varying degrees of congruency. For example, if one participant names the picture of an apple, her partner could either concurrently produce the same word (i.e., apple), or they could concurrently produce an unrelated word (e.g., blouse), or a related word (e.g., banana).

These different degrees of congruency do matter in solo tasks, as shown by several picture-word interference studies. Speakers who name pictures while ignoring distractor words are fastest when the distractor word is the picture's name.

They are slower when the distractor is a different word and slowest when it is a different but semantically related word. The difference in naming latencies between trials with unrelated distractors and trials with related distractors is due to interference between co-activated lexical representations (Levelt, Roelofs, \& Meyer, 1999).

In our study, participants saw pairs of pictures rather than picture-word pairs. When distractor words are replaced by distractor pictures, semantic interference effects generally disappear (Damian \& Bowers, 2003), possibly because distractor picture names are not routinely retrieved or their activation is too weak to out-weight facilitatory effects at the conceptual level. We therefore asked participants to name both pictures in a pair, a task that is subject to semantic interference effects (Aristei, Zwitserlood, \& Abdel Rahman, 2012).We asked whether the time they took to respond might be affected by a representation of their partner's concurrent response.

## Experiment 1

In Experiment 1, a red and a blue picture were simultaneously displayed to two participants seated in different rooms. Before the pictures appeared, an instruction screen showed the names of the two participants accompanied by the words red, blue, or no. Red and blue corresponded to "go" trials: the participant was instructed to name the picture presented in the given color first, and then also name the other picture. No corresponded to "no-go" trials: The participant was instructed to give no response.

We varied the order in which the other participant (the partner) was concurrently naming the pictures (Partner's task), as follows. On trials on which the two participants were assigned the same color, they named the pictures in the same order, therefore producing the same verbal response (SAME condition). On trials on which the two participants were assigned different colors, they named the pictures in reversed order, therefore producing different verbal responses (DIFF condition). Finally, when either of the participants was assigned a "no-go" cue, one participant named the pictures while their partner produced no response (NO condition). See Figure 1 (top) for examples (with apple in blue, blouse in red).

In addition, we introduced a second manipulation, orthogonal to Partner's task. Participants saw either two semantically related (e.g., apple - banana) or two unrelated pictures (e.g., apple - blouse). This served two purposes. The first was to provide a manipulation check. When two semantically related lexical items are activated concurrently (e.g., when speakers are asked to say "apple" and "banana" in close proximity), they interfere with one another (Aristei, et al., 2012). We therefore expected longer latencies when participants named two related than when they named two unrelated pictures (a main effect of semantic relatedness).

Most importantly, we expected Partner's task to affect naming latencies. Specifically, if the co-representation
account can be extended to naming responses, it could be taken to predict that speakers represent the content of their partner's response and activate the corresponding lexical representations.

Figure 1: Sample trial (top) and hypothesized effects according to the three accounts.

Note that, because the speakers always named both pictures, their utterances always contained the same lexical items. However, when the order differed, the picture that the speaker named second was the picture that their partner named first.
Therefore, in the DIFF condition the representation of the partner's response might enhance the activation of the second picture's name. This would in turn result in greater competition between the two pictures' names. Instead, when the order is the same, the first picture's name was the word that one's partner also named first. Therefore, its activation level might be raised and competition with the second picture's name could be reduced. Overall, we should find longer naming latencies in the DIFF condition than in the SAME condition.

This scenario is presented in Figure 1 (panel A). The nodes represent lemmas in Mary's mental lexicon. On the right is a snapshot of the activation level of the nodes apple and blouse just before the onset of the word "apple" when Mary is preparing to utter "apple blouse" (unrelated case), under the different conditions. The degree of activation is indicated by the thickness of the circles. Pointed arrows are excitatory connections, rounded arrows are inhibitory connections.

In addition, the degree of relatedness might also matter (and this was the second purpose of the relatedness manipulation). Specifically, if other-representations are content-specific, the semantic interference effect could be enhanced in the DIFF compared to the SAME condition.

Alternatively, speakers might not represent the content of their partner's response, but they might represent whether their partner responds on the current trial or not (agentconflict account). If so, the relationship between self- and other-representations would not affect processing, and hence naming latencies would be comparable in the SAME and DIFF conditions. For the same reason, there should be no interaction between Relatedness and Partner's task. However, naming latencies should be longer in the SAME and DIFF conditions than in the NO condition. This scenario is presented in Figure 1 (panel B).

Finally, people might not represent other people's responses. Note that our participants could not interact: They named pictures alongside each other, but could not hear each other. Whereas several studies have shown that non-interacting participants display joint interference effects (see above), they all used manual responses. We do not know whether the same would be true for verbal responses, particularly because language is perhaps more tightly linked to communicative situations compared to manual actions. If the Partner's task manipulation has no effect (i.e., no difference between the SAME, DIFF, and NO conditions), we would conclude that another person's utterances are not represented under the conditions tested in our experiment. This scenario is presented in Figure 1 (panel C) as the norepresentation account.

## Method

Participants Twelve pairs of previously unacquainted participants were recruited from the University of Edinburgh student community. All reported to be native English speakers and had no speaking or reading difficulties. They were paid $£ 6$ in return for participation.

Materials Fifty line drawings of everyday objects and animals were paired twice to yield 50 picture-picture pairs ( 25 semantically related, 25 semantically unrelated).

Design and Procedure Partner's task (henceforth, Partner; SAME vs. DIFF vs. NO) and Relatedness (unrelated vs. related) were manipulated within participants and within
items. An item was defined in terms of the first named picture (so apple-blouse and blouse-apple counted as different items). Partner varied on a trial-by-trial basis.

Each participant named a given item once per condition. Pictures were presented into 4 different blocks of 100 trials each. Each block comprised an equal number of trials in each condition for both participants. The order of presentation was pseudo-randomized, separately for each pair and for each block, with the constraint that the same picture never appeared on two consecutive trials. (The order of blocks was counterbalanced across pairs). In addition, we counterbalanced within each block and for each participant the color of the first named picture (blue or red) and the position of the cue (top or bottom half of the screen).

Participants were tested in adjacent soundproof booths. They were seated in front of computer monitors connected to the same machine in the control room (so stimulus presentation was simultaneous). There was a window between the two rooms, but participants could perceive each other only peripherally when facing the monitors.

Upon entering the lab, participants were introduced to one another and taken into the booths. After learning the picture names individually, they were told that they would "work together"; instructions were delivered to both participants at the same time in the control room. Participants then returned to the booths and, after performing 20 practice trials, began the experimental phase. A sample trial is shown in Figure 1 (top). A session lasted about 1 hour.

Recording and Data Analysis An inaudible beep marked stimulus presentation and was recorded together with the participants' responses (on three separate channels), using a multi-channel M-Audio FireWire 1814 device (inMusic, Cumberland, RI, www.m-audio.com) and Adobe Audition (Version 4.0; sampling rate: 48000 Hz ). Beep onsets were automatically tagged using Audacity (Version 1.2.5). Recordings were pre-processed to reduce background noise. Speech onsets were tagged using the Silence finder algorithm in Audacity and manually checked (for lip smacks, etc.). Naming latencies were defined as the time from beep onset to the onset of the participant's response.

The data were analyzed using Generalized Linear mixedeffects models (Bayeen, Davidson, \& Bates, 2008) in R (Version 2.7.2) with a logistic link function for categorical data (Jaeger, 2008). All predictors were contrast-coded. For Partner, we defined two planned contrasts: naming vs. no compared the DIFF and SAME conditions against the NO condition; same vs. different compared the SAME against the DIFF condition.

Fixed and random effects were selected using backward selection. If the model with full random structure did not converge we simplified it by removing higher order terms (first by subjects, then by items). The alpha-level for
likelihood-ratio tests was set to .05 for fixed effects, to .1 for random effects ${ }^{1}$.

Latencies were analyzed only if both pictures were named correctly. Incorrect responses included: naming errors (the wrong name was used), disfluencies, order errors (the name of the second picture was uttered first and vice versa), missing responses. Latencies longer than 3000 or shorter than 300 ms were considered outliers and excluded. Latencies more than 3 standard deviations from the byparticipant mean ( $1.5 \%$ ) were replaced with the cut-off value.

## Results

Accuracy Speakers produced (marginally) fewer incorrect responses when naming related than unrelated pictures ( $\left.\chi^{2}(1)=3.54, p=.06\right)$.

Table 1: \% incorrect in Exp. 1.

|  | DIFF | SAME | NO |
| :--- | :--- | :--- | :--- |
| Unrelated | $7.9 \%$ | $6.8 \%$ | $6.3 \%$ |
| Related | $8.1 \%$ | $5.3 \%$ | $4.9 \%$ |

Table 2: Best fit for accuracy data in Exp. 1.

| Predictor | Estimate | SE | Z |
| :--- | :---: | :---: | ---: |
| Intercept | -3.10 | .18 | -16.97 |
| naming vs. no | .24 | .11 | 2.23 |
| same vs. different | -.23 | .08 | -2.75 |
| related vs. unrelated | -.31 | .15 | -2.05 |
| Random effect | Explained variance estimate |  |  |
| Subjects: intercept | .48 |  |  |
| Items: intercept | .48 |  |  |
| Items: Relatedness | .56 |  |  |

Interestingly, the likelihood of producing an incorrect response was affected by $\operatorname{Partner}\left(\chi^{2}(2)=13.10, \mathrm{p}<.01\right)$ : They produced more incorrect response when their partner was naming than when their partner was silent and also fewer incorrect responses in the SAME than in the DIFF condition (see Table 1 and 2).

Naming latencies Participants took longer to name semantically related than unrelated pictures $\left(\chi^{2}(1)=11.32\right.$, $\mathrm{p}<.001$ ). Crucially, Partner affected naming latencies ( $\chi^{2}(2)$ $=7.80, \mathrm{p}<.05)$ : Latencies were longer when the partner was naming than when he was silent. However, the DIFF and SAME conditions did not differ. Finally, Relatedness and Partner did not interact (see Table 3 and 4).

[^272]Table 3: Mean latencies in Exp. 1.

|  | DIFF | SAME | NO | Tot |
| :--- | ---: | :--- | ---: | :---: |

## Discussion

Experiment 1 showed that beliefs about another's task can affect the latency of picture-naming responses, and are thus not consistent with the no-representation account. We take this as evidence that speakers represented that their partner was about to speak. More precisely, our results do not support the co-representation account. Though participants made more errors when their partner prepared an incongruent (DIFF) than a congruent (SAME) response, this pattern was not confirmed by latency data. In addition, while there was a clear semantic interference effect, which replicated previous findings (Aristei, et al., 2012), the effect was no greater in the DIFF ( 12 ms ) than in the SAME condition ( 17 ms ). These results are consistent with the agent-conflict account, as participants took longer to respond when they believed their partner also prepared to respond.

However, we must consider alternative explanations. Note that the slowest conditions (SAME and DIFF) are the ones in which two "go" instructions are displayed on the screen. Participants might be distracted by their partner's instruction more if it is a "go" instruction than if it is a "no-go" instruction, perhaps because "go" instructions are more similar to each other than they are to "no-go" instructions. This might cause interference between memory representations for one's own and the partner's instructions. Participants rarely performed their partner's task by mistake, which seems to suggest that they had little trouble remembering instructions. However, this occurred more often in the DIFF (on $2.3 \%$ of trials speakers named the pictures in their partner's order) than in the NO condition (on $1.2 \%$ of trials speakers gave no response). But more importantly, this explanation cannot account for the fact that latencies were equally long in the SAME as in the DIFF
condition (as in SAME instructions were identical). We return to this issue after Experiment 2.

We conclude that participants experienced interference whenever their partner responded concurrently, because they represented whether it was their partner's turn to respond. But what sort of mechanism could be responsible for this interference effect? The process of "imagining" that one's partner is about to respond might draw away attentional resources from the picture-naming task. If this is the case, "imagining" one's partner performing any task should slow down latencies to the same extent as "imagining" them naming.

However, it is also possible that interference arises because the same mechanisms (i.e., language production mechanisms) are used to represent one's partner naming response and to prepare one's own naming response. If this is the case, we predict less interference when one's partner is preparing a different (non-naming) task than when one's partner is preparing a naming response. Experiment 2 was designed to decide between these alternative explanations.

## Experiment 2

In Experiment 2 we replaced "no-go" trials with a semantic categorization (CAT) task. The SAME and DIFF conditions were exactly the same as in Experiment 1. In the CAT condition, partners were instructed to judge whether the two pictures belonged to the same semantic category or to different semantic categories. They responded by saying "yes" or "no" into the microphone.

Thus, all trials required a response from both participants. If imagining one's partner performing any task was driving the effect we observed in Experiment 1, we should now find no difference between the SAME, DIFF and CAT conditions. Note that both the CAT task and the naming task involve visual processing of the pictures and retrieval of the concepts associated with the depicted entities from memory. In addition, both tasks require articulation of an overt verbal response.

Crucially, however, only the naming task engages language production mechanisms (and specifically the retrieval of the picture's name). Therefore, if the interference effect in Experiment 1 is due to a representation that one's partner is preparing a naming task, we should replicate it in Experiment 2.

## Method

Sixteen new participants from the University of Edinburgh student community were recruited. Materials, design and procedure were as in Experiment 1, except that the CAT condition replaced the NO condition. For the semantic categorization task, participants were told that when they saw the word question (which replaced the word no) next to their name, they were to respond to the following question: "Are the two pictures from the same category?" Data were
analyzed as in Experiment 1; latencies exceeding the 3SDthreshold amounted to $1.7 \%$ of the data.

## Results and Discussion

Categorization Task Participants responded correctly on $94.7 \%$ of the unrelated trials and on $93.6 \%$ of the related trials (a non-significant difference).

Accuracy Speakers produced (marginally) more incorrect naming responses to related than unrelated pictures $\left(\chi^{2}(1)=\right.$ $2.98, \mathrm{p}=.08$ ). More importantly, Partner did not affect the likelihood of producing an incorrect response (see Table 5).

Table 5: \% incorrect in Exp. 2.

|  | DIFF | SAME | CAT |
| :--- | :--- | :--- | :--- |
| Unrelated | $5.6 \%$ | $6.3 \%$ | $6.0 \%$ |
| Related | $7.2 \%$ | $7.1 \%$ | $5.8 \%$ |

Naming latencies Participants took longer to name semantically related than unrelated pictures $(\chi 2(1)=11.04$, $\mathrm{p}<.001$ ). As in Experiment 1, Partner affected latencies $(\chi 2(2)=6.54, p<.05)$ : They were longer when participants believed their partner named pictures than when they believed their partner categorized the pictures. However, the DIFF and SAME conditions did not differ and Relatedness and Partner did not interact (see Table 6 and 7).

Table 6: Mean latencies in Exp. 2.

|  | DIFF | SAME | NO | Tot |
| :--- | ---: | :--- | :--- | :--- |
| Unrelated | 881 | 879 | 874 | 878 |
| Related | 898 | 907 | 885 | 897 |
| Tot | 889 | 893 | 880 |  |
| Semantic |  |  |  |  |
| interference | -17 | -28 | -11 | -19 |

Note that in Experiment 2 two "go" instructions were displayed on every trial, including in the CAT condition; therefore, interference could not have been due to greater interference between memory representations for more similar instructions.
The results of Experiment 2 are not consistent with the co-representation account. As in Experiment 1, naming latencies were very similar in the DIFF and SAME condition. In addition, and unlike in Experiment 1, the likelihood of incorrect responses was very similar in the two conditions (and did not differ significantly from the CAT condition, either). Finally, the semantic interference effect was not larger in the DIFF than in the SAME condition.

Table 7: Model for naming latencies in Exp. 2

| Predictor | Estimate | SE | t |
| :--- | :---: | ---: | ---: |
| Intercept | 884 | 24 | 36.77 |
| naming vs. no | 12 | 5 | 2.47 |
| same vs. different | 3 | 4 | .70 |
| related vs. unrelated | 19 | 5 | 3.48 |
| Random effect | Explained variance estimate |  |  |
| Subjects: intercept | 16490 |  |  |
| Subjects: Size ${ }^{2}$ | 13080 |  |  |
| Items: intercept | 46670 |  |  |
| Items: Relatedness | 4380 |  |  |

Most importantly, we found that naming latencies are longer when speakers believe that their partner is also naming a picture than when they believe their partner is performing a semantic categorization task. Given that the two tasks share all processing stages except lexical retrieval, we conclude that the process of naming pictures is inhibited by the belief that another speaker is concurrently retrieving the pictures' names.

## Conclusion

We showed that people represent their partner's task in a joint picture-naming task. The evidence is not consistent with the co-representation account of joint task effects. Participants did not form content-specific representations of their partner's response. It is possible that this finding is limited to the conditions tested in this study. Interlocutors might form content-specific representations when engaged in a conversation (when they rarely speak at the same time). In addition, the amount of practice and repetition that characterizes picture naming experiments could have masked content-specific effects (perhaps because activation was already at ceiling). Future studies should consider these limitations.

However, our results are consistent with a version of the agent-conflict account, in which interference in naming responses is due (at least partly) to the belief that one's partner is preparing a naming response (as opposed to any response). This is consistent with the idea that people represent others' utterances using some of the mechanisms they use in preparing their own utterances (i.e., language production mechanisms; Pickering \& Garrod, in press).

# Semantic Ambiguity Resolution as a Decision Process 

Nicholas Gaylord (nlgaylord@utexas.edu)<br>Colin Bannard (bannard@utexas.edu)<br>Department of Linguistics, University of Texas at Austin<br>305 E. 23rd St. B5100, Austin, TX 78751 USA

#### Abstract

Resolution of the meaning of a semantically ambiguous word requires knowledge about the space of possible meanings of that word, and the selection of a meaning in the light of available evidence and given situational constraints. As such, ambiguity resolution bears many similarities to decision making scenarios more generally. We report on an experiment exploring this analogy by applying some standard manipulations from the decision making literature to a semantic disambiguation task. We explore two particular proposals: (1) that depth of semantic processing can be cast as strategy selection reflecting a risk-sensitive effort-accuracy tradeoff, and (2) that thresholds for inference about meaning in context are situationally flexible and learnable via feedback. One robust property of decision making is people's ability to use feedback in order to adjust responses to maximize payoffs. Participants completed a semantic entailment judgment task in which they received trial-by-trial feedback, and payoff matrices and decision thresholds were manipulated across conditions. We find an effect of risk, with participants employing different comprehension strategies depending on relative gains and losses. We also find that participants were in fact sensitive to varying decision thresholds and accurately adjusted their behavior to match the constraints on what qualified as a true conclusion in different conditions. We take these findings as preliminary evidence that ambiguity resolution in language can be modeled, at least in part, as involving more general decision processes.

Keywords: Speed-Accuracy Tradeoff, risk, decision thresholds, decision making, sentence processing, word meaning, ambiguity

## Introduction

Semantic ambiguity is a widespread phenomenon in natural language, whereby a single word can have more than one interpretation depending on its use. The resolution of semantic ambiguity requires knowledge of the range of possible meanings of an ambiguous word, and the consideration of those possibilities in light of available contextual evidence and given certain situational constraints (such as how strict or precise an interpretation is required). Characterized as such, semantic ambiguity resolution bears many similarities to other scenarios that are studied in research on human decision making. However, the connection between decision making and semantic processing is as yet underexplored.

One robust property of human decision making in other domains is the ability to use feedback in order to adjust responses to maximize benefits (increasing material rewards and/or minimizing cognitive costs). In this paper we look at whether the same behavior might be observed for a semantic disambiguation task. Two particular manipulations were employed, parallel to manipulations in other decision tasks: a) changes to the decision threshold, which separated correct "true" or "false" responses concerning the meaning of a word in context, and $b$ ) changes to the degree of risk (possible material losses) in the decision situation. Such factors
have useful analogues in language understanding. Decision threshold changes are implicated in that different situations call for more (or less) restrictive assumptions as to what can be safely concluded from a potentially ambiguous utterance. Risk is implicated via the potential negative consequences of misinterpretation, which is greater in some cases than others - for example, a failure of interpretation is likely more consequential in a job interview than in a casual conversation.

## Background

Semantic ambiguity has been extensively studied from a variety of perspectives including linguistic theory and psycholinguistics. One important finding from this work is that not all cases of semantic ambiguity are the same - Apresjan (1974) argues that different senses (or uses) of a word can vary in how semantically similar they are, and most psycholinguistic research into the representation of semantic ambiguity arrives at a similar conclusion (Brown, 2008; Frazier \& Rayner, 1990; Klepousniotou, Titone, \& Romero, 2008; Pickering \& Frisson, 2001; Williams, 1992). This position is further supported by various offline judgment tasks (Erk, McCarthy \& Gaylord 2009, To Appear; Gaylord, 2011). In short, there is a growing body of evidence that word meanings are graded - the meanings of individual occurrences of a word can vary quite subtly, and the extent to which word senses apply to a given occurrence varies in a graded fashion as well.

A closely related question is that of how we use the information available in our lexical representations to determine a contextually-appropriate meaning. McElree, Murphy, and Ochoa (2006) and Gaylord, Goldwater, Bannard, and Erk (2012) both investigated the dynamics of this process using a Speed-Accuracy Tradeoff (SAT) design. McElree, Murphy, and Ochoa observed elevated false alarms after short processing delays with stimuli such as Water pistols - are dangerous and Gaylord et al. found the same effect with stimuli such as The dawn broke - Something shattered. In other words, both studies found evidence that when a word is encountered, a context-independent default meaning is activated prior to semantic integration, whether or not it is supported by the occurrence in question. It is likely that these default meanings correspond to those words' most frequent interpretations. There is a current debate as to how information-rich our lexical knowledge must be (cf. Elman 2011) and while evidence is accumulating that our semantic representations provide access to a great deal of richly informative world knowledge, results such as those just discussed also indicate that our knowledge of word meanings contains a more schematic layer that is more efficient to access.

One question that can be raised is why this more schematic level of semantic representation is present despite the fact that it can lead to errors of interpretation. A plausible answer is that sentence comprehension, like other cognitive processes, is subject to economic pressures, and that under many circumstances a shallower processing is sufficient (Barton \& Sanford, 1993; Bever, Sanz, \& Townsend, 1998; Ferreira \& Patson, 2007; Sturt, Sanford, Stewart, \& E Dawydiak, 2004; Swets, Desmet, Jr., \& Ferreira, 2008; Townsend \& Bever, 2001). We hypothesize that these default meanings, as they reflect a word's most likely interpretation, support a shallow semantic processing strategy.

A considerable amount of decision making research addresses the question of strategy selection (Beach \& Mitchell, 1978; Busemeyer, 1993; Gigerenzer, Todd, \& ABC Research Group, 1999; Johnson \& Payne, 1985; Payne, Bettman, \& Johnson, 1988). This work studies how people select more or less effortful decision making strategies in different situations, where increased effort tends to yield increased accuracy. The concept of an effort-accuracy tradeoff is central to strategy selection, and has been seen to be sensitive to risk. Semantic comprehension has been shown to be effortful, and we propose that depth of semantic processing can be cast as a strategy selection problem driven by a risksensitive effort-accuracy tradeoff. We explore this hypothesis through changes across conditions to the payoff matrix dictating potential gains and losses for correct and incorrect responses. We hypothesize that shallow processing strategies (marked by acceptance of default meanings in the absence of contextual support) will be more prevalent under decreased risk, and dispreferred when potential losses are high.

However, parallels with strategy selection are not the only similarity between semantic comprehension and decision making more generally. More generally, ambiguity resolution requires the selection of a possible interpretation of a word in light of available contextual evidence, and given situational constraints on interpretation. As discussed above, meaning-in-context appears to be a very graded phenomenon, and another question is whether people adapt their semantic comprehension behavior to meet situational demands. We explore this question as well by moving the threshold (corresponding to a property of the stimulus) at and above which a response of "true" will be counted as correct in different conditions, and providing trial-by-trial feedback on response accuracy. We hypothesize that participants will use their graded representations of word meanings in order to rapidly learn an optimal decision threshold.

## Experiment

Participants 131 undergraduate psychology students from the University of Texas at Austin completed the experiment in exchange for course credit. Participants received a cash payment of up to $\$ 3.00$ depending on their performance on the task. All participants were native English speakers.

Table 1: Example stimuli, with their associated truth norms. TS = true given context sentence; PS = plausible given context sentence; FS = false (but possible given a different sentence); FV = false given the verb (false regardless of context)

| Context | Probe | Norm | Type |
| :--- | :--- | :--- | :--- |
| The insult burned | Something was mean | 6.65 | TS |
| The insult burned | Something was true | 4.85 | PS |
| The insult burned | Something was warm | 1.30 | FS |
| The insult burned | Something was rolled | 1.30 | FV |
| The log burned | Something was warm | 6.55 | TS |
| The log burned | Something was dangerous | 4.55 | PS |
| The log burned | Something was mean | 1.10 | FS |
| The log burned | Something was fixed | 1.20 | FV |

Table 2: Summary of experimental conditions. Threshold is the truth norm at and above which items were counted as true.

| Condition | Gain/Loss | Threshold |
| :---: | :--- | :--- |
| A | $+5 /-1$ | 3.7 |
| B | $+1 /-5$ | 3.7 |
| C | $+5 /-5$ | 3.7 |
| D | $+5 /-5$ | 2 |
| E | $+5 /-5$ | 6 |

Materials The experiment, 240 trials in length, took the form of a semantic judgment task in which each trial consisted of a context sentence (e.g. The dawn broke) followed by a semantic probe (e.g. Something shattered) to be evaluated as true or false. Each context sentence was paired with a true probe, a plausible but not necessarily true probe, and two false probes: one which would be true under a different meaning of the context verb, and one which was false given any contextually-activated meaning of the verb. The truthfulness of each probe, given its context sentence, was measured via a separate offline norming task and the averages of these ratings established a truthfulness value for each stimulus. Further examples of stimuli are contained in Table 1.
Procedure Participants were told that the experiment would take the form of a game, in which points were gained or lost based on accuracy, and that those points were redeemable for cash at the end of the session. At the start of the experiment, participants were familiarized with the gains and losses associated with correct and incorrect responses, and after each trial they received feedback about their response accuracy (a smiling face for a correct response or a frowning face for an error) and associated gain or loss of points.

A schematic of an experimental trial is shown in Figure 1. The experiment contained 5 conditions (summarized in Table 2), across which we varied risk (via changes to payoff matrices, which were always symmetrical) and decision threshold.

Risk. In condition A participants could gain 5 points for a correct answer, but only lose 1 point for an incorrect answer.

Figure 1: A single trial, depicting a correct "false" response.

Hence the risk associated with giving an errorful response was minimal. In condition B, participants could gain only 1 point for a correct answer but could lose 5 points for an incorrect answer. In condition $C$ participants could gain 5 points for a correct answer and lose 5 points for an incorrect answer. Both conditions B and C are characterized by large potential losses, and are by extension higher in risk than condition A. While the difference between possible gain and loss on a trial is smaller in condition $B$ than in condition $C$, and is in fact exactly the same as in condition A, we know that people tend to evaluate risk relative to a status quo reference point and tend to be loss-averse (Kahneman \& Tversky, 1979). As such, condition B is the highest risk case overall, since possible gains are much smaller than possible losses.

Acceptance Threshold. Across conditions C-E we varied the acceptance threshold while holding risk constant. Acceptance threshold manipulations were accomplished relative to the mean truthfulness ratings that we independently gathered. Very high-rated stimuli were true across conditions, and very low-rated stimuli were consistently false, but stimuli with intermediate truthfulness ratings were counted as true in some conditions but false in others. The threshold for condition C was at median. The threshold for conditions D and E were lower and higher respectively. These thresholds determined the feedback we gave to participants on their responses.

## Results and Discussion

Participants' responses and response times were recorded on each trial. Participant responses of under 150 ms were excluded, as well as the $0.5 \%$ of slowest responses.

Effects of Risk. Risk was manipulated via changes to the study payoff matrix, such that in Condition A possible gains on each trial were large and possible losses small, while in Conditions B and C possible losses were greater. We hypothesized that participants would employ different response strategies in the higher-risk Conditions C (in which uninformed responding would yield a loss relative to the maximum points possible) and $B$ (in which uninformed respond-
ing would be expected to yield a loss relative to the starting point), relative to the low-risk Condition A (in which uninformed responding would be expected to yield a net gain).

We performed a series of multilevel logistic regression models, in which the outcome was the participants' response (true $=1$, false $=0$ ) and in which participant ID was included as a random effect on the model intercept. We first of all examined simple accuracy by looking at whether correct response was a good predictor of actual participant responses across the conditions. As discussed in Wright and London (2009) this is equivalent to a traditional d-prime analysis. A model containing an interaction between correct response and condition was found to give a significantly better fit to the data than a model containing only correct response $\left(\chi^{2}(4)=15.673, p\right.$ $<0.01$ ) and a model containing both terms but no interaction $\left(\chi^{2}(2)=11.172, \mathrm{p}<0.01\right)$. The coefficients revealed the increase in the likelihood of participants responding "true" if the correct response was "true" was significantly greater in both Conditions B and C than it was in condition A.

We next looked in more detail at how participants were making their decisions. In our norming study we obtained graded ratings as to whether the probe sentences were entailed by the context sentences. We assume that participants in our main study were able to utilize intuitions that corresponded to such scales. We first looked at whether our normed truth scale was predictive of response in a series of logistic regression models. A model including the truth norm rating as a predictor gave a better fit to the data than a model including the correct response as sole predictor. A model containing an interaction between truth norm rating and condition was a significantly better fit than a model containing only truth norm $\left(\chi^{2}(4)=17.794, p<0.01\right)$ or one containing both terms but no interaction $\left(\chi^{2}(2)=13.228, \mathrm{p}<0.01\right)$. The coefficients revealed the increase in the likelihood of participants responding "true" as a function of increases in the truth norm was significantly greater in both conditions B and C than in condition A. We next fit separate logistic regression models to the data from each of the conditions and looked at the predictive value of the truth norms in each case. Log Likelihood Ratio Indices (McFadden, 1974) revealed that the truth values had more predictive value in conditions B (0.458) and $\mathrm{C}(0.477)$ than in condition $\mathrm{A}(0.420)$. These data further support the finding that probe truthfulness is a stronger determinant of participant response under increased risk.

We performed a final exploration by defining a simple model based on these truthfulness values and exploring how well it accounts for participants' responses. We assume that an idealized responder would say "true" for a given item with a probability equal to the mean truth rating provided (minus the minimum possible response, 1 ), divided by the difference between the minimum and maximum response (6). We look at the perplexity (an information theoretic measure of how surprised the model is by the data) of such a model when confronted with participant response data. Model perplexity is higher for condition $\mathrm{A}(2.328)$ than it is for conditions

B (2.213) and C (2.110). This indicates that participant responses in the riskier conditions are better described by probe truthfulness than are responses in the less risky conditions.

These analyses suggest that participants are making more sensitive semantic judgements in the riskier conditions. Because semantic comprehension is effortful, one explanation of this is that there is an effort-accuracy tradeoff at work. Participants should be more willing to expend this effort via deeper semantic processing when there is more at stake. A possible consequence of this would be an increase in the time taken to make decisions. This effect is in fact seen, though response times are not elevated across-the-board in the riskier conditions. Rather, stimuli with very high or very low truthfulness values are processed as quickly as in the low-risk condition, and extra time is spent precisely those items that warrant it items with intermediate truthfulness ratings.

Effects of Decision Threshold Placement. We next turn to the effect of changes to the decision threshold. In Conditions C-E, the same stimuli were used but the threshold value at and above which a probe was considered true was varied across conditions. Based on our above argument that word meaning in context is a graded phenomenon whose scales can be used flexibly in making decisions, we hypothesized that participants would adjust their responses to reflect these thresholds. Our norming study showed that people are able to reliably assign graded values as to whether our probe sentence was entailed by our context sentence. We assume that participants in our main experiment will have similar graded evaluations and that they will respond differently depending on our different conditions by inferring an optimal point on their scales at which to accept or reject probes. It is worth reiterating that this is not an arbitrary manipulation - different situations do indeed carry different constraints on meaning-in-context inference. A legal contract, for example, demands a very constrained interpretation of explicitly presented information, while innuendo demands much greater inference.

Acceptance probabilities (across participants) for all stimuli as a function of their truthfulness values are contained in Figure 2, in which it is clearly visible that participants do evaluate stimuli differently between conditions. This is particularly true for stimuli with intermediate (2-6) truthfulness ratings, which are evaluated differently depending on threshold placement. There is much less effect on the acceptance of very high- or very low-rated stimuli. The effect of threshold placement is further supported by the improved fit of a model with an interaction between item truth norm and condition, compared to a model with item truth norm as the only predictor $\left(\chi^{2}(4)=191.69, p<0.001\right)$. Our primary interest, however, is in how rapidly participants learn different decision thresholds. Figure 3 sheds light on this question, showing the changes over trials in the minimum truthfulness ratings for the items that are accepted and the maximum ratings for the items that are rejected for the three conditions. This shows how participants adjust these cutoffs over trials differ-

Figure 2: Acceptance probabilities for stimuli as a function of their truthfulness ratings in Conditions C-E. For each condition, the "true"/"false" threshold is indicated in red.
ently in line with the acceptance thresholds revealed to them via feedback. This is supported by model comparison - a model including a three-way interaction between item truth norm, condition, and trial number gives a significantly better fit ( $\left.\chi^{2}(6)=181.1, \mathrm{p}<0.001\right)$. We take this as evidence that people do dynamically adjust their judgments about meaning-in-context, specifically how broadly or conservatively they interpret meaning, in response to situational constraints.

## General Discussion

We found that participants dynamically adjust their assumptions regarding the conclusions that can be drawn from a given utterance in response to feedback. We also found that they employed different responding strategies depending on risk, and that the difference was not simply due to a speedaccuracy tradeoff. These results suggest that decision making behaviors that have been reported in other non-linguistic do-

Figure 3: Lowess smoothed values for the minimum ratings at which items were accepted (the lower line) and maximum ratings at which items were rejected (the upper line) by trial for our conditions C-E.
mains might reasonably be extended to sentence processing, and in particular to meaning-in-context resolution.

The finding that semantic ambiguity resolution is affected by economic considerations is timely given related developments in the literature. One is the appearance in the sentence processing literature of the so-called "Good Enough" approach (Ferreira \& Patson, 2007), along with other studies (discussed above) that have found people often only engage in shallow syntactic or semantic processing. To the best of our knowledge, the present work is the first to extend this line of inquiry to semantic processing at the lexical level, and the first study to explicitly predict semantic processing depth based on situational characteristics. The connection we make here with the decision making literature suggests further possibilities for studying the effect of situational pressures on language processing. Techniques from this literature, such as trial-by-trial feedback, are being adopted by other research in language processing as well (Lewis, Shvartsman, \& Singh, To Appear) . Another recent development, this time in the theoretical linguistic literature, has been the use of ideas from decision theory and game theory to discuss linguistic communication (Clark, 2012) and particularly pragmatics (Benz, Jager, \& Rooij, 2006). One of the main challenges in extending these accounts is the effective parameterization of utilities. Our findings suggest that standard techniques from the decision making literature might be useful in this regard.

We have argued here that participants' performance in the absence of risk reflects the use of default interpretations of the kind found by McElree et al. (2006) and Gaylord et al. (2012). Depending on the degree of situational risk, people might vary in how readily they will accept an initially-activated default interpretation of a word, presumably because under cer-
tain payoff schemes it is no longer worth the effort of computing a more precise interpretation to avoid a marginal potential loss. A related question to be explored in greater detail in future research is how this readiness to accept default interpretations is affected by the relative strength of the default meaning versus other potentially competing candidate interpretations (Kilgarriff, 2004), and in fact whether it is the case that only one default interpretation is activated.

Participants’ dynamic adjustment to different truthfulness thresholds is equally striking as it shows that in different situations they rapidly learned how conservative or permissive to be regarding the possible conclusions that can be drawn from given information. This is particularly relevant for the study of semantic ambiguity resolution due to the fact that contextualized meaning has long been tied to the set of conclusions that can be drawn from a sentence. While approaches such as that in Chierchia and McConnell-Ginet (2000) are more restrictive in that they characterize sentence meaning through entailments, which are necessarily true, as opposed to here where we also deal with plausible conclusions, the general sentiment of these approaches is nonetheless applicable. Additionally, manipulations of decision threshold such as those employed here may prove useful to the broader study of inference in experimental pragmatics.

An immediate next step is to observe the effects of simultaneously varying both risk and decision threshold. We have already seen that participants rapidly learn to approximate the threshold, and we have seen that participants become more deliberative under higher risk. These facts jointly predict that threshold learning will be both more rapid and more accurate under increased risk. Investigation of these questions is currently underway.

## Acknowledgments

This work was supported in part by a Carlota S. Smith Memorial Research Fellowship to the first author. We also wish to thank Arthur B. Markman for many very important insights as well as the use of his lab, and J. Grant Loomis for his invaluable assistance throughout the data collection process.

# Individual Differences, Imagery and the Visual Impedance Effect 

Lupita Estefania Gazzo Castañeda (Estefania.Gazzo@psychol.uni-giessen.de)<br>Justus-Liebig University, Experimental Psychology and Cognitive Science, Otto-Behaghel-Str. 10F, 35394 Giessen, Germany<br>Markus Knauff (Markus.Knauff@psychol.uni-giessen.de)<br>Justus-Liebig University, Experimental Psychology and Cognitive Science, Otto-Behaghel-Str. 10F, 35394 Giessen, Germany

#### Abstract

The visual impedance effect describes the fact that unnecessary visual information can impede reasoning (Knauff \& Johnson-Laird, 2002). We explored how this effect is modulated by individual differences in reasoning styles. The main hypothesis of the present work is that the magnitude of the impedance effect depends on the degree to which people use visual mental images during thinking. We conducted two experiments with participants with highly imagistic and highly verbal reasoning strategies. The relational inferences differed in how easily they could be visualized. Our results indicate that (1) verbalizers do not show the visual impedance effect, and (2) that people with a high preference for mental imagery try to imagine even non-visual information visually, always showing the strongest impedance by visualization.

Keywords: Reasoning, individual differences, cognitive styles, visual impedance effect

## Introduction

Many theories have been developed to explain human reasoning (Clark, 1969; Johnson-Laird \& Byrne, 1991; Oaksford \& Chater, 2009; Rips, 1994). A problem common to these theories is that they often exclude the possibility of individual differences in reasoning (Bacon, Handley, \& Newstead, 2003; Ford, 1995). If people are asked how they solve reasoning problems, they usually report different ways of reasoning. While some people report the use of visual imagery (e.g. Egan \& Grimes-Farrow, 1982; Richardson, 1977), others report more language based approaches like rehearsal (Polk \& Newell, 1995), and yet others to think in a more abstract manner (Egan \& Grimes-Farrow, 1982). Based on such observations, Richardson (1977) proposed the differentiation between verbalizers and visualizers. Both were conceptualized as the extremes of a continuum. Visualizers were described as people with high visual imagery, but with poor verbal abilities, and verbalizers were described with the reverse tendencies. Over the years this dichotomy was expanded in accordance with newer neurological findings, and visualizers were divided into object- and spatial- visualizers (e.g. Kozhevnikov, Kosslyn, \& Shepard, 2005). While object visualizers are described as being able to construct vivid, high resolution images, spatial visualizers are described as being especially good in the processing of spatial information (Blazhenkova \& Kozhevnikov, 2009). Such differences in cognitive styles are important because unlike strategies, cognitive styles should be understood as relatively stable and durable
(Blazhenkova \& Kozhevnikov, 2009; Riding \& Cheema, 1991).

The influence of cognitive styles on tasks like anagrams and mental rotation (e.g. Just \& Carpenter, 1985) has already been investigated. Also, individual differences in spatial abilities and mechanical reasoning have been examined (Hegarty \& Sims, 1994). Nevertheless, only few studies analyzed the influence of individual differences on deductive reasoning (e.g. Bacon et al., 2003; Ford, 1995; Sternberg \& Weil, 1980). With the help of verbal protocols, Ford (1995) and Bacon et al. (2003) argued that people resolve syllogisms in two different ways. Some of the participants used a "verbal" strategy and resolved the syllogism via substitution of the terms. Other participants used a "spatial" strategy and resolved the syllogism with the help of schematic drawings which closely resembled Euler circles. However, almost no differences in performance were found (Bacon et al., 2003). Sternberg and Weil (1980) trained their participants to use either visual or rule based strategies in resolving relational inferences. One group of participants received no training. They found an interaction between skill and strategy: the effectiveness of the strategy depended on the verbal or spatial skills of the participant. More importantly, in the same study Sternberg and Weil found that a rule-based strategy lead to the fastest response times. Beyond these initial results, the question of the influence of individual differences based on imagery on other reasoning tasks like relational reasoning problems still remains open. This is surprising, insofar as the role of visual imagery on relational reasoning has been a topic of much controversy (Knauff, 2013).

## The Visual Impedance Effect

For a long time, the role of visual imagery during reasoning was not clear. While some researchers reported imagery as a helpful tool for reasoning (Clement \& Falmagne, 1986; Shaver, Pierson, \& Lang, 1975), others reported opposite results (Johnson-Laird, Byrne, \& Tabossi, 1989; Richardson, 1987; for a detailed review see Knauff 2013; Knauff \& Johnson-Laird, 2002). In search of clarification, Knauff and Johnson-Laird (2002) postulated that these discrepancies are based on a confounding in the items. Many items which are called "visual" are visual as well as spatial. Thus, in order to investigate the role of imagery during reasoning, it is important to disentangle the visual
from the spatial features of a given reasoning problem. By doing this, Knauff and Johnson-Laird (2002) showed that unnecessary visual information is an unnecessary cognitive load in working memory that leads to longer reaction times. They called this effect the visual impedance effect. They adapted their findings to the Theory of Mental Models (Johnson Laird \& Byrne, 1991) and proposed that mental models are spatial and not visual, as other groups propose (e.g. De Soto, London, \& Andel, 1965; Huttenlocher, 1968). This visual impedance effect has been corroborated in experiments with blind persons (Knauff \& May, 2006).

The visual impedance effect and the existence of more or less imagery-based cognitive styles motivated us to assume that people with different abilities in imagery should also perform differently in logical reasoning. We expected that the magnitude of the visual impedance effect would depend on the ability to use imagery during reasoning. Thus, the visual impedance effect should be increased for people with high visual imagery compared to those without a special preference for visual imagery or with a more linguistic cognitive style. Because of their cognitive style, this last group should hardly be affected by unnecessary visual information in tasks and thus show a better performance in relational problems compared to people with high visual imagery, especially in items with unnecessary visual information. To investigate these assumptions we conducted two experiments. In both experiments participants with different preferences for imagery had to solve relational problems. The content of these problems was manipulated in such way that problems were easy or hard to visualize.

## Experiment 1

In the first experiment, we measured the differences in cognitive style with a German version of the VerbalizerVisualizer Questionnaire (VVQ) from Richardson (1977). In a pilot study, we administered a German Version of the VVQ to 120 undergraduate psychology students at the University of Giessen. Using cut-off points at 5 and 12 points we found clearly distinguishable groups of verbalizers and visualizers (the scale ranged from 0 to 15 points).

## Method

Participants 22 participants (18 female, 4 male) from the pilot study participated in the experiment. Half of them were visualizers, the other half were verbalizers. The mean age was 22.8 years $(S D=4.55)$ and they participated for academic credit points.
Materials and Design We created 32 relational inferences. All of them described the same relation (left-right), but the term was either easy (fruits, tools, cutlery or office implements) or hard (nonsense syllables) to visualize. Half of the problems had valid conclusions; the other half had invalid conclusions. Here is an example for an easily visualizable problem with a valid conclusion:

Premise 1: Apple left of Kiwi
Premise 2: Kiwi left of pear
Conclusion: Pear right of apple
The design was a $2 \times 2$ design. The cognitive style of the participants was treated as a between-subjects factor. The ease of visualization for the terms was treated as a withinsubjects factor.
Procedure The experiment took place on a computer in a quiet room, and was programed in Cedrus SuperLab ${ }^{\text {TM }}$. The participants were tested individually. Premises and conclusions were presented on separate slides. The premises were written in black while the conclusion was written in red. The background was white. By pressing the space bar, participants decided when to pass from one premise to the next premise or to the conclusion. The task for the participants was to decide whether the conclusion was valid or not. They gave their decision by pressing one of two keys for "correct" or "false". Between each item, the participants had the opportunity to take a break. Before starting the actual experiment, the participants practiced on four items. To avoid learning effects the terms of these problems were abstract (the letters A, B, C). Dependent measures were premise reading times (not reported here), the mean number of logically correct responses, and the decision times for conclusion-evaluations.

## Results and Discussion

We first analyzed the percentage of correct responses ${ }^{1}$. Examining the problems that were easy to visualize, verbalizers responded correctly to $95.75 \%(S D=5.39)$ of them, while visualizers responded correctly only to $90.91 \%$ ( $S D=11.65$ ) (U-Test, $z=-1.095, p=.273$ ). Examining the problems that were hard to visualize, verbalizers responded correctly to $95.15 \%$ ( $S D=7.94$ ), while visualizers scored 92.73\% ( $S D=9.17$ ) (U-Test, $z=-.643, p=.520$ ). The main effect did not reach statistical significance, which is in accordance with our pervious results (Knauff \& JohnsonLaird, 2002). In the second step, we analyzed the decision times for correct responses. The results are illustrated in figure 1. As expected, visualizers $(M=6212 \mathrm{~ms}, S D=$ 1550) needed more time to resolve problems that were easy to visualize compared to verbalizers ( $M=4917 \mathrm{~ms}, S D=$ 1769). This effect was marginally significant (U-Test, $z=-$ 1.937, $p=.053$ ). For the problems that were hard to visualize, verbalizers ( $M=5700 \mathrm{~ms}, S D=2310$ ) were not significantly faster than visualizers ( $M=6053 \mathrm{~ms}, S D=$ 1703), (U-Test, $z=-.624, p=.533$ ). But contrary to what is implied by the visual impedance effect, decision times for problems that were hard to visualize were no smaller than the ones for problems that were easy to visualize. On the contrary, verbalizers were significantly slower solving problems that were hard to visualize compared to those that were not (Wilcoxon test, $z=-1.956, p=.050$ ). Visualizers showed no difference between both types of problems

[^274](Wilcoxon test, $z=-.533, p=.594)$. So there was something like a visual impedance effect for verbalizers, but not for visualizers. This unexpected result can be explained in two ways. One possible reason might be that nonsense syllables are not only hard to visualize, but also unknown and therefore probably also hard to memorize. This difficulty in memorizing the terms may have led to more cognitive load in working memory and thus to longer decision times compared to items which are known. This would explain the sudden increase in decision time for verbalizers. However, another reason for this unexpected result can be found in the reports many participants made after the experiment. Visualizers in particular, reported visualizing even the nonsense syllables. They reported that the nonsense syllables were visualized as phantasy creatures or names of foreign persons. Obviously, visualizer are so strongly biased towards using visual imagery, that even in tasks where no such visual information is available they transform the given information in such a way that they can use their typical visual thinking style. If so, then visualizers should not show the typical visual impedance effect, but instead of it something like a visual impedance effect on the subjects level. Thus visualizers should always have problems with relational problems, because all problems would be treated as highly visual problems. To test this hypothesis, it is important to use problems with familiar terms which are known, but which are still not easy to visualize. Therefore, in the second study we used the original material from Knauff and Johnson-Laird (2002).

Figure 1: Mean decision times for the conclusion. Error bars represent standard errors.

## Experiment 2

In the second experiment, we decided to measure the differences in cognitive style with the German version of Blazhenkova and Kozhevnikov's (2009) Object-Spatial Imagery and Verbal Questionnaire (OSIVQ). This questionnaire has the benefit that it accounts for the difference between visual imagery and spatial imagery. Thus the OSIVQ makes the same distinctions as the items used by Knauff and Johnson-Laird (2002).

In a pilot study we administered the German Version of the OSIVQ to 148 students at the University of Giessen. We selected our participants on the basis of their scores on the three scales contained within the OSIVQ: the visual scale, the spatial scale, and the verbal scale. We considered a participant as belonging to one of the three cognitive styles, if she or he scored above the sample mean of one scale, but below the sample means of the other scales ${ }^{2}$. Participants with higher deviations were preferred over those with fewer deviations. We selected 13 object visualizers, 6 spatial visualizers and 10 verbalizers. Additionally to these three experimental groups, we also selected a control group, whose scores on the scales did not differ from the sample scale means. The control group consisted of 10 participants.

## Method

Participants All selected participants from the pilot study participated in the experiment. All object visualizers were female ( $n=13$ ), with a mean age of $M=22.54(S D=2.3)$. The group of the spatial visualizers consisted of 3 female and 3 male participants. Their mean age was $M=22.67$ ( $S D$ $=3.14$ ). The group of the verbalizers consisted of 9 female and 1 male participant. Their mean age was $M=22.8$ ( $S D=$ 8.16). Finally, the control group consisted of 7 female and 3 male participants. Their mean age was $M=22.6$ ( $S D=$ 2.59). The participants participated for academic credit points or candies.
Materials and Design We used the relational inferences from Knauff and Johnson-Laird (2002; see table 1). These relations have been evaluated empirically (Knauff \& Johnson-Laird, 2002) and differ in the relative degree to which they can be imagined either visually or spatially. Using these relational terms it is possible to create 32 items. All items consisted of the same terms (dog, cat, ape). Again, half of the problems had valid conclusions; the other half had invalid conclusions. An example for a valid visual problem is:

Premise 1: The dog is cleaner than the cat
Premise 2: The ape is dirtier than the cat
Conclusion: The ape is dirtier than the dog
The design was a $4 \times 4$ design. The cognitive style of the participants was treated as a between-subjects factor. The ease of visualization was treated as a within-subjects factor.

Additionally to the inference task, we also measured spatial, verbal and visual abilities of the participants. The idea was to validate the cognitive style of our participants. A similar procedure was also used by the developers of the OSIVQ (Blazhenkova \& Kozhevnikov, 2009). As a measure for visual abilities we used the Vividness of Visual Imagery Questionnaire (VVIQ: Marks, 1973). It consists of 16 items which examine how easily the participant is able to imagine, visually and vividly, different scenes with open and with closed eyes. As a measure of spatial ability we used a

[^275]mental rotation task, based on the one by Shepard and Metzler (1971). It consisted of the presentation of a target 3D figure, in combination with another similar figure which was either the same in one of six rotated degrees, or a rotated mirror image. The task for the participant was to decide whether both images were the same or not. This task consisted of 48 items. Finally, as a measure of verbal ability we used the subtest "Masselon" from the Berliner Intelligenzstruktur Test (BIS: Jäger, Süß, \& Beauducel, 1997). In this test the participant is confronted with three words (human, feeling, technology) and must then create as many sentences as they can with these three words. For better comparisons with experiment 1, we also administered a German Version of Richardson's (1977) VVQ.
Procedure The experiment always began with the relational inference task, which was programed in SuperLab ${ }^{\text {TM }}$. The procedure for the relational inference task was the same as experiment 1. After completing the relational task, the VVIQ tasks, the rotation task, and the Masselon tasks were presented in a random order. Finally, the participants answered the VVQ and provided written comments on how they believed they solved the tasks. Again, we measured the reading time for each premise (not reported here), the decision time for the conclusion, and whether the task was solved correctly or not.

Table 1: Relations used in Experiment 2, with a description of how easy they were to imagine either as a visual image or a spatial array (adapted from Knauff and Johnson-Laird (2002; p. 368)).

| Relations | Description |
| :---: | :---: |
| Visual |  |
| cleaner-dirtier fatter-thinner | Ease to envisage visually, but hard to envisage spatially |
| Control |  |
| better-worse smarter-dumber | Hard to envisage visually and spatially |
| Visuospatial above-below front-back | Easy to envisage visually and spatially |
| Spatial |  |
| north-south ancestor-descendant | Hard to envisage visually, but easy to envisage spatially |

## Results and Discussion

VVIQ, mental rotation, and verbal abilities The results from the three tasks indicate that our selection of the exponents of the different cognitive styles was successful. The VVIQ was computed in such a way that high scores (max. 80 points) indicated good visual abilities, whereas low scores (min. 16 points) indicated a lack of it. Object visualizers ( $M=51.08, S D=5.61$ ) reached a higher score than verbalizers ( $M=39.75, S D=8.72$ ) on the VVIQ (UTest, $z=-3.072, p=.002$ ). They also reached a higher score than spatial visualizers $(M=40.83, S D=13.45)$ and the control group ( $M=43.70, S D=6.87$ ), but these last two
differences did not reach the adjusted alpha level (U-Test, $z$ $=-1.931, p=.053$ for the comparison with spatial visualizers; U-Test, $z=-2.576, p=.01$ for the comparison with the control group).

Even if there was no significant main effect on the time needed to solve the items in the mental rotation task (Kruskal Wallis, $C h i^{2}=5.440, p=.142$ ), descriptively it was possible to see that, across all items, spatial visualizers ( $M=4.99 \mathrm{~s}, S D=1.88$ ) were faster than verbalizers $(M=$ $7.54 \mathrm{~s}, S D=3.87$ ), than object visualizers ( $M=8.15 \mathrm{~s}, S D=$ 2.85) and the control group ( $M=6.80 \mathrm{~s}, S D=3.41$ ). Poltrock and Brown (1984) proposed that the linear regression slopes of the latencies are an indicator of the rotation speed, in that the smaller the slope, the faster the rotation was performed. As expected, spatial visualizers rotated faster ( $b=29.55, S E=8.39$ ) than verbalizers $(b=$ 72.00, $S E=16.42$ ), object visualizers ( $b=55.79, S E=9.75$ ) and the control group ( $b=48.16, S E=16.77$ ). The groups did not differ in the amount of errors made (Kruskal Wallis, $C h i^{2}=2.641, p=.450$ ).

Our analysis of the Masselon test was based on the amount of written words in valid sentences. Verbalizers ( $M$ $=43.30, S D=11.37$ ) wrote significantly more words than object visualizers $(M=30.54, S D=7.93$; U-Test, $z=-2.86$, $p=.004$ ) and spatial visualizers ( $M=25.17 ; S D=7.11$; UTest, $z=-2.71, p=.007$ ), but they did not differ from the control group ( $M=34.70, S D=12.60$; U-Test, $z=-1.34, p$ $=.182$ ).
The VVQ The comparison of the scores on the VVQ showed that the VVQ is only able to differentiate correctly between verbalizers ( $M=7.20, S D=2.35$ ) and object visualizers ( $M=10.46, S D=2.22$; U-test, $z=-2.875, p=$ .004). Given that the VVQ does not consider spatial visualizers, spatial visualizers ( $M=7.67, S D=3.98$ ) scored similar to verbalizers (U-test, $z=-.174, p=.869$ ) on the VVQ.
Relational inferences Similar to Knauff and Johnson-Laird (2002), we encountered some problems with the spatial relations. On the one hand, several participants reported that they still imagined them in a visual way (e.g. as animals on maps). On the other hand, the spatial terms created "illogical" constellations (e.g. the dog is descendant of the cat), whose difficulty probably confounded the decision times. Therefore, the spatial relational terms were not purely spatial and had to be removed from our analysis. The reported results are based solely on the correct responses to the other three kinds of relational terms.

Based on the results of experiment 1, we assumed that people with a high preference for imagery would not only have difficulties in visual relational problems, but also in non-visual relational problems. Because of their cognitive style, object visualizers would try to imagine even non visual information visually, regardless of how difficult this is, and be impeded by this visualization. To analyze these hypotheses we first considered the percentage of errors made by our participants. As in experiment 1, there were no significant differences between the participants with
different cognitive styles in the percentage of correct answers (Kruskal Wallis, $C h i^{2}=2.060, p=.560$ ). However, there was a significant main effect in the response times when we compared the groups of object-visualizers, spatial visualizers, and verbalizers (Kruskal Wallis, $C h i^{2}=6.855, p$ $=.032$ ). Pairwise comparisons showed that, as expected, object visualizers ( $M=4608 \mathrm{~ms}, S D=2671$ ) took longer to resolve the tasks compared to verbalizers, ( $M=2777 \mathrm{~ms}$, $S D=645$ ). This difference was also significant (U-test, $z=-$ 2.481, $p=.012$ ). Object visualizers were not significantly slower than spatial visualizers ( $M=3857 \mathrm{~ms}, S D=1159$; Utest, $z=-0.614, p=.579$ ) and verbalizers still tended to answer faster than spatial visualizers (U-test, $z=-1.735, p=$ .093). As can be seen in figure 2, neither object visualizers nor verbalizers showed the classical visual impedance effect. In neither group a main effect on decision times for the different kinds of items could be found (Friedman Test, $C h i^{2}=1.077, p=.584$ for object visualizers; $C h i^{2}=.200, p$ $=.905$ for verbalizers). The only group that showed a pattern resembling the classical visual impedance effect were the spatial visualizers. However, because of the small sample size ( $n=6$ ), the main effect did not reach significance (Friedman Test, $C h i^{2}=3.000, p=.223$ ). This trend was not expected and should be investigated in further studies. Nevertheless, the missing visual impedance effect for verbalizers and the long decision times of object visualizers confirm our suppositions derived from experiment 1: while object visualizers do indeed try to visualize even nonvisual information, verbalizers never visualize anything. This leads to a lack of visual impedance effects on the item level, but instead causes visual impedance effects on the subject level.

Figure 2: Mean decision times for the conclusion. Error bars represent standard errors.

## General Discussion

Our findings indicate that, depending on their cognitive style and how easily they are able to use imagery during reasoning, people are influenced in different ways by the imageability of the content of reasoning problems: On the one hand, verbalizers are typically not impeded by visual
characteristics of reasoning problems. They seem to be immune to the visual impedance effect. On the other hand, people who tend to imagine the content of reasoning problems try to visualize even non-visual problems and therefore show a visual impedance effect on all problems, whether the problems are highly visual or not. These results notwithstanding, we are aware of the limitations of our study. In order to strengthen our results, it would be necessary to conduct studies with a greater sample size and to control for gender differences. An additional task for the future is to investigate during which phase of the inference individual differences take effect. Particularly, it remains unclear whether these individual differences play a role only during interpretation and encoding of the reasoning problem premises, or if the individual differences also have an effect on the reasoning process itself. Knauff (2009, 2013) proposes that relational reasoning problems are solved in three steps among which only the first step involves the construction of visual mental images and the other two steps comprise the "real" reasoning processes. However, in this work we did not distinguish between different cognitive styles and so it is still unclear how verbalizers solve such tasks. Do they also create such (irrelevant) initial picturelike representations? One approach that we took previously is to use functional brain imaging to study the neural basis of individual differences in reasoning (Ruff, Knauff, Fangmeier, \& Spreer, 2003). By testing people with different cognitive styles in the scanner it might be possible to see during which phases of the reasoning process these cognitive styles take effect. By doing this, it would also be possible to see to what extent the steps proposed by Knauff (2009, 2013) are generalizable to all cognitive styles. The same could be also done with other individual differences. For example, it might be of interest to investigate whether people with either a holistic or an analytic cognitive style (see Riding \& Cheema, 1991) differ in the construction of mental models.

Another task for the future is to replicate the present results using different formats of presentation. In both studies reported here our items were presented in written form. Considering that verbalizers are often described as having fun and being good at reading and language based tasks (see the relevant items of the VVQ and the OSIVQ), it seems possible that the superior performance of verbalizers resulted not only because they did not use imagery, but also because verbalizers might feel more comfortable with a task presented in their preferred format. Thus, in further studies it is important to present items in other formats, for example acoustically or in an iconic way.

In conclusion, our results support the visual impedance effect. Irrelevant visual details can be a nuisance in reasoning. However, the effect seems to be modulated by the different cognitive styles of individuals. Object visualizers are so profoundly driven by their visual thinking style that they try to visualize almost everything. Thus they show a visual impedance effect even for non-visual reasoning problems. Verbalizers, in contrast, are only
marginally affected by the visual characteristics of reasoning problems. They use more abstract reasoning styles and therefore have no problems with disruptive visual images. We were also able to identify differences between object visualizers and spatial visualizers. Comparing both groups, our findings indicate that the use of spatial representations and processes is the most effective way to solve relational reasoning problems. However, individuals using spatial layout models (Knauff, 2013) seem not to be immune to irrelevant and side-tracking visual details and can therefore be impaired in solving highly visual inference problems. We will continue to explore this effect more thoroughly. A final important corollary of our study is that effects found in general populations (without considering differences in cognitive style) do not necessarily apply to every single person: visual items do not always impede reasoning, they only impede if subjects represent visual features in their mental representation of the task. That is why it is important to incorporate individual differences into theories of reasoning and to highlight such differences in the predictions and assumptions of those theories. Disregarding these differences may lead to unjustified overgeneralizations.

# Playing for Us: The Influence of Joint Action on Planning in Three-year-olds 

Sarah A. Gerson (s.gerson@donders.ru.nl)<br>Sabine Hunnius (s.hunnius@donders.ru.nl)<br>Harold Bekkering (h.bekkering@donders.ru.nl)<br>Radboud University Nijmegen<br>Donders Institute for Brain, Cognition, and Behaviour, Montessorilaan 3<br>Nijmegen, 6500HE, The Netherlands

#### Abstract

Learning to plan sequences of actions and appropriately adapt our actions during interactions with others are both critical skills upon which much of human society is built. We know that children's joint action and planning skills are both undergoing development during the preschool years, but not much is known about how the joint action context influences young children's planning. In this study, we examined the effect of playing alone or with a joint partner on sequence planning during a problem-solving game in three-year-old children. We found that children were better at planning ahead in the individual than the joint condition of the game despite the joint condition requiring fewer actions on the part of the child. In contrast, children were equally good at problem-solving (i.e., correcting an error) in both conditions. The possible reasons for this difference and directions of future research are discussed.

Keywords: joint action; planning; cognitive development
Working together with others is important across a variety of everyday tasks, ranging from simple, mundane actions to considerably complex plans and action sequences. When we interact with a partner in a work or athletic setting, the complexity of coordinating our actions with another's is quite clear. In contrast, when we perform simple everyday actions such as passing a cup of milk to another person, we likely do this with ease and do not dwell on the coordination with the other or the expectations about the others' action. When acting with another person, planning our own actions requires coordinating our actions with another individual, whether this coordination is conscious and complex or seemingly automatic. Planning our actions when interacting with another is a task that spans many domains and is critical for much of cognitive and social development. Examining the developmental emergence of this skill can shed light on how and when the factors necessary to working with others are integrated.

When performing a task by ourselves, we can create a plan internally and carry out the task without interruption. When jointly acting with another, however, we need to take the other person's actions into account. According to Sebanz and Knoblich (2009), intentional coordination of actions with another requires representing both one's own and one's partner's roles in the task. They suggest that adults engaged in joint actions predict a partner's actions in a joint action task by representing the action of a partner and one's own actions in a functionally equivalent way. In fact,
incorporating a partner's task "affects one's own action planning and performance even when there is no need to take the other's part into account at all" (p. 357). One mechanism thought to underlie the representation and prediction of another's actions is simulation (Gallese \& Goldman, 1998). That is, when one perceives someone else acting in a goal-directed manner, one's own motor system is activated as if one was performing the action oneself (Rizzolatti \& Craighero, 2004). Simulating a partner's action from a first-person perspective can then be used to make predictions about upcoming events (Wilson \& Knoblich, 2005). Additionally, the motor system is preferentially activated for predictions of others' actions within a joint action context (Kourtis, Sebanz, \& Knoblich, 2010). What is simulated and how perceptual information available can be transferred into a motor simulation is still a topic of vivid discussion (see for example Uithol et al., 2011).

The necessity of incorporating another agent's actions in a similar way to one's own actions when interacting with a joint partner suggests that the ability to represent other agents' actions in a similar way to one's own would be a developmental prerequisite for appropriately planning one's actions within a joint context. One piece of behavioral evidence that young children seem to represent others' actions in a similar way to their own actions is that infants' ability to produce particular actions is directly related to their perception, prediction, and motor activation when viewing others perform the same actions (e.g., Cannon et al., 2012; Gerson \& Woodward, in press, van Elk et al., 2008). Meyer and colleagues (2011) found neural evidence that this is especially so in joint action contexts. Greater activation in the motor system was found in three-year-old children watching a joint action partner than when these same children watched someone with whom they were not collaborating. Further, variation in performance on the joint game and in the amount of motor activation observed when the child watched the partner act were related, suggesting that the child's motor system activation was likely related to the integration of their partner's and their own actions.

In addition to a representation of others' actions, the incorporation of others' actions into one's own planning is critical to acting appropriately in joint contexts. In order to address how the presence of others affects planning, research must examine differences in planning one's own actions during individual and joint tasks. A recent study
with adults (Meyer, van der Wel, \& Hunnius, 2013) measured planning of actions that could be performed alone or with another person. It was found that participants learned to initiate actions based on predictions about the subsequent steps in a task after they gained experience acting in the task. This was true in both the individual and joint contexts, suggesting that participants were able to use their experience to predict their own or a partner's actions and plan their actions accordingly.

The research reviewed above indicates that motor activation during the observation and prediction of others' actions is heightened within joint action contexts and that the simulation of others' actions facilitates motor planning in joint contexts. Although motor planning is one important aspect of planning sequences of actions, sequence planning also requires higher-order processes such as future thinking and cognitive control. That is, when performing an initial action that propagates a series of embedded actions, one must plan not only the motor aspects (such as movement, timing, and spatial location) but also consider the consequence of these actions on the future steps in the sequence. Adults are proficient sequence planners, but planning skills are still undergoing development throughout early childhood (Carlson, Moses, \& Claxton, 2004; McCormack \& Atance, 2011). Difficulties in planning and other higher-order cognitive skills have been linked to the relatively prolonged development of the prefrontal cortex (see, for example, Welsh, Pennington, \& Groisser, 1991).

Previous research examining the development of sequence planning within joint action contexts has largely measured children's planning when engaged in a game with a parent or another adult. These studies have found that the development of planning with others is a prolonged process, in that older children (e.g., between 6 and 11 years) often outperformed younger children (e.g., between 3 and 5 years) on planning tasks (e.g., de la Ossa \& Gauvain, 2001; Gauvain, 1992; Gauvain \& Rogoff, 1989). This research, however, focused largely on the role parents played in guiding the joint actions through bids for joint attention, scaffolding of the child's actions, and teaching of strategies or rules. Because parents were involved and influencing children's actions during the joint planning games, measures of the child's planning skills were often measured after the joint task. The lack of planning measurements during joint actions does not take into account whether planning in a joint context adds more cognitive demands to a planning task. In the current study, we explore the planning skills of three-year-old children during a problem-solving task when playing alone or with a partner who acts in a predictable, uniform manner.

We created a game in which the child was required to plan ahead in order to accurately solve a matching game. If he or she did not plan ahead, the child had the chance to correct the error during a subsequent step of the game. All children played this game both alone and in alternating turns with a joint partner, "Kip." The joint partner was a hand puppet introduced during the joint action condition and kip
always acted predictably so that we could assess the influence of a social partner's presence without the social partner's actions directly influencing any of the child's actions. Kip was introduced as separate from the experimenter and the experimenter used a different voice when acting as Kip so that the child did not expect Kip to scaffold his or her actions. We then examined differences between children's accuracy in planning and problemsolving during the individual versus joint conditions. If simulating a person's actions in order to motorically plan one's own actions is the key difference between individual and joint planning, then children's performance during the joint condition should not be hindered. In fact, because children took turns playing with Kip, the joint condition required less motor planning than the individual condition; children only had to place two balls in the correct buckets during each trial instead of four. Therefore, if all planning was carried out through the motor system, children's planning should be better in the joint condition than the individual condition. If, however, other cognitive processes are necessary in order to integrate one's own plans with another person's actions, plans, and goals, then children should perform worse in the joint condition than in the individual condition. That is, if the presence of another actor increases the cognitive demands of higher-order functioning, such as cognitive control, future thinking, and sequence planning, children should perform better in the individual condition than the joint condition.

## Method

## Participants

Thirty-two 37 -month-olds (mean age $=3$ years, 38 days) were included in the final data set for this study ( 15 females, 17 males). All children were recruited from a database of families who volunteered to participate in child studies. An additional 10 children participated but were not included due to equipment malfunction ( $n=2$ ), experimenter error ( $n$ $=2$ ), not completing all trials $(\mathrm{n}=3)$, or lack of learning of the rules of the game or refusal to play with Kip ( $n=3$ ).

## Stimuli and Procedure

Each trial consisted of a set of four balls, four buckets, and a clear, plastic tube that held the balls. There were always two buckets of one color (e.g., green) and two buckets of another color (e.g., yellow). In all but the first training trial, there were two balls of one color (e.g., green), one ball of a second color (e.g., yellow), and one ball that was multicolored (e.g., half green and half yellow). The tube was created to dispense the balls one at a time in a particular order while still allowing participants to see the colors of the upcoming balls (see Figure 1). The multi-colored ball always came out of the tube in the second position, and the three solid-colored balls were pseudorandomly distributed in the first, third, and fourth positions. Except in the demonstration trial, different color combinations (consisting of red, light blue, dark blue, green, and yellow) were used
across trials so as to minimize learning specific rules about colors and to keep the children's attention. In joint play trials, the experimenter wore a hand puppet of a chicken (called "Kip"). The experimenter used a different voice so as to differentiate herself from the puppet.

Figure 1: Example of the game setup. Each trial involved three-solid colored balls, a multicolored ball, and two buckets in each of two colors.

Training Children were taught how the game worked via a set of training trials. First, the experimenter placed a set of four solid-colored balls (brown and black) into matching buckets. This short phase was to teach children that balls had to go into matching buckets. Next, one of the solid balls (the one in the second position) was replaced with a multicolored ball. When the experimenter extracted the multicolored ball, she showed the child that it could go in either the brown or the black bucket. After showing them this, she always left the ball in the inappropriate bucket in terms of meeting the end goal. That is, if there were two brown balls in the tube, the multi-colored ball would be placed in a brown bucket (and vice-versa if there were two black balls). This "mistake" was made in order to show participants the importance of considering the upcoming balls in the tube and to indicate how errors could be corrected. The experimenter then placed a black and brown arrow in front of the bucket to indicate which bucket held the multicolored ball. After the incorrect placement of the multicolored ball, the experimenter would show the child that one of the remaining solid-colored balls no longer had an appropriate bucket in which to be placed. She would talk to the child about how this could possibly be fixed and remind them about the meaning of the arrow and hint about a possible solution: "Do you remember what this arrow means? This means that the multi-colored ball is in this bucket. And where can the multi-colored ball go?" She would then extract the multi-colored ball and place it in the opposite colored bucket. She moved the arrow to the new bucket and then placed the solid-colored ball in the appropriate bucket. After having done this, she would remind the child of how the problem had been solved.

Two training trials followed this demonstration in which the experimenter scaffolded the child throughout the game. These two trials consisted of two different sets of colored balls, randomly assigned. During these trials, the experimenter handed the participant each of the balls and asked him or her to place them in the matching bucket. She
frequently reminded the child that all the balls had to "fit" in the buckets (and pointed to the balls in the tube). If the child struggled, the experiment gave a series of hints. If the child encountered a solid-colored ball that had no matching bucket, the experimenter first gave him or her time to try to solve the problem themselves. Then she gave the participant a series of hints, allowing time for the child to recognize the solution between each hint. As in the demonstration trial, hints increased in detail, ranging from asking what the arrow meant to reminding the child that the multi-colored ball could go in either bucket. If the child still did not respond to the hints, the experimenter moved the mixed ball and demonstrated the solution to the problem. In this way, at the end of the training trials, the experimenter always ensured that the balls were matched with an appropriate bucket at the end of the trial. After these two trials, the experimenter told the child he or she was ready to play without help. Individual or joint play trials then began (counterbalanced between participants).

Individual Play The individual condition consisted of six trials. In each of these trials, the child retrieved each ball from the tube, one at a time, and placed it into a bucket. The experimenter did not participate except to ensure that the child did not retrieve the following ball before placing the one in his or her hand into a bucket. If the child encountered a problem (i.e., a solid-colored ball without a matching bucket), the experimenter did not interfere unless the child looked to the experimenter for help. When the child expressed uncertainty and enquired for help, the experimenter would give the same hints as during the training trial, again giving the child time to solve the problem at each step. After all of the balls were placed in buckets, the experimenter asked the child if they were all correct (regardless of whether or not they were). If the child realized then that there was a problem, the experimenter again only helped (as above) if the child enquired.

Joint Play First, a small hand puppet was introduced to the child. The child was told the name of the puppet (Kip) and that Kip wanted to play with him or her and they could take turns (see Figure 2). The joint play session consisted of nine trials. In the first, fourth, and seventh trial, Kip let the child place the first (and third) ball and Kip placed the second/multi-colored (and fourth) ball. Kip always placed the multi-colored ball in the bucket that allowed all forthcoming balls to be placed correctly. In the other six trials, Kip placed the first and third balls and the child placed the second and fourth balls. This ensured that the number of trials for which the child had to plan (by placing the multi-colored ball correctly) was matched across the individual and joint conditions. If the child incorrectly placed the multi-colored ball and realized this error when later attempting to place a solid-colored ball, the experimenter followed the same procedure as in the individual play trials as far as waiting for the child to enquire in order to give any hints. If Kip had to place the
solid-colored ball that had no matching bucket, she would knock on the full buckets and say "uh oh-this ball can't go in this one" while looking at the empty bucket and would ask for the child's help. If the child did not immediately solve the problem, the experimenter followed the same pattern for giving hints as in other trials.

Figure 2: During the joint action condition, children alternated taking turns with Kip, the hand puppet.

Coding The focal question in this study concerned children's ability to plan where to place the multi-colored ball so that all following balls could fit in matching buckets. For each trial in which the child placed the multi-colored ball (six individual play and six joint play trials), a trained coder judged whether the child placed the multi-colored ball in the correct bucket (for the end goal achievement) before the following ball was retrieved from the tube. This factor will be referred to as planning. The proportion of trials within the individual and joint condition for which the child's planning was correct was calculated and used as a dependent variable. A second question was whether children would correct errors if their initial ball placement was incorrect. For this factor (called problem solving), coders judged whether the child removed the mixed ball and placed it in a correct bucket. If so, the coder noted whether the child carried out this action with or without needing the assistance of hints from the experimenter. The proportion of trials correct after problem solving without hints from the experimenter were calculated for each condition (note: this gave children credit both for initially correct and correctly solved trials without assistance). A second trained coder coded $25 \%$ of the videos and agreed on $99 \%$ of trials.

## Results

As described above, the variable of interest for planning was the proportion of trials for which children were initially correct in their placement of the multi-colored ball and the variable of interest for problem solving was the proportion of trials in which the child had correctly placed all balls (without hints) by the end of the trial. Initially, we conducted a repeated-measures analysis of variance (ANOVA) with Condition (i.e., individual or joint play) and Solution Stage (planning vs. problem-solving) as within subjects factors. The between-subjects counterbalancing factor of Order (i.e., whether the child participated in the
individual or joint condition first) was also included to account for possible learning effects across time. This analysis revealed a main effect of Solution Stage $(F(1,30)=$ 93.33, $p<.001, \mathrm{n}_{\mathrm{p}}^{2}=.76$ ), a Solution Stage X Condition interaction $\left(F(1,30)=5.15, p=.031, \eta_{\mathrm{p}}^{2}=.15\right)$. No other main effects or interactions were found ( $p s>.13, \eta_{p}{ }^{2} \mathrm{~s}<$ .08). The main effect of Solution Stage indicated that the proportion of trials that children successfully planned was significantly lower than their problem solving performance. The interaction suggests that the extent of this difference was affected by condition (individual vs. joint). The lack of main effect or interactions with Order suggests that children who engaged in the joint versus individual task first did not differ from one another in their performance.

In order to follow up on this interaction, we examined pairwise comparisons of estimated marginal means. The difference between individual and joint conditions was significant for planning ( $m d=.11, S E=.048, p=.031$; see Figure 3) in that children were significantly better at planning during the individual than the joint condition. This difference between conditions was not present for problemsolving ( $m d=.001, S E=.035, p=.98$ ). That is, children were equally able to solve the problem in both conditions. Additionally, children performed significantly better during problem-solving than planning within both individual and joint conditions ( $p \mathrm{~s}<.001$ ).

In order to examine planning and problem-solving performance relative to chance levels ( $50 \%$ of trials correct), we conducted one-sample t-tests. In the individual condition, children were better at planning than would be expected by chance ( $M=.61, S E=.028, t(31)=3.95, p<$ .001 , Cohen's $d=1.42$ ). Children were not above chance levels of planning in the joint condition ( $M=.50, S E=.037$, $t(31)=.034, p=.97$, Cohen's $d=.012$ ). When children had the opportunity to correct their errors (i.e., problem solve), they performed at above chance levels in both conditions ( $t \mathrm{~s}$ $>12.3, p \mathrm{~s}<.001$ ).

Figure 3: Children were significantly better at planning in the individual than joint condition ( ${ }^{*} p=.031$ ), but were above chance in problem solving in both conditions.

## Discussion

Children were significantly better at planning their actions appropriately when they played alone than when they took turns playing with a social partner. That is, when playing
alone, they were more likely to take into account the colors of the remaining balls when choosing where to place the mixed ball. When playing with a partner, children's initial placement of the mixed ball was seemingly random (i.e., the placement was correct about half the time [at chance level]). Importantly, this was true despite the fact that children had fewer actions to carry out during the joint condition. In the individual condition, children were responsible for placing all four balls correctly. In the joint condition, however, children only needed to place two of the four balls. The joint partner always played correctly on her trials, so the task of placing half the balls should have, in principle, been easier. The fact that children did not perform as well in this case suggests that something about sharing the task with a partner made it more difficult for the children to plan. That is, motor planning alone was not sufficient for carrying out the task; the demands of sequence planning were made more difficult by the presence of another actor.

In contrast to the difference found in planning, when children encountered a proceeding ball for which there was no matching bucket, they were equally competent at solving this problem regardless of whether they were playing alone or with a partner. The fact that children could and did solve the problem without hints from the experimenter (or Kip) in both conditions suggests that children understood the goal of the task and what actions were necessary in order to achieve this goal. Thus, it was not a lack of understanding of the task that prevented children from planning appropriately during the joint condition. This is impressive given the complexity of the task carried out by the children.

Further, children's planning and problem solving did not change as a function of the order in which they played the individual and joint conditions. This indicates that children did not learn the task over time, regardless of which condition they played first. Additionally, the fact that children who played the joint condition first did not plan more effectively during the individual condition than children who played the individual condition first suggesting that children were not learning how to plan from Kip's turns placing the mixed ball. Given that Kip always placed the mixed ball correctly (on the three trials in which she placed this ball), it was possible that children could have used their partner's correct actions to improve their own planning, but the lack of order effect suggests this was not the case in this study.

An important question to address in future studies is why children were better able to plan during the individual than the joint condition. Several possibilities remain to be examined, including aspects of attention, inhibition, and the social nature of the task.

One possibility is that attention to the future balls to be placed differed when children were playing alone or with Kip. If attention does differ, it suggests that the presence of a partner made it more difficult for children to concentrate on the task at hand and control their attention according to the task goal. Baron (1986) has suggested that the presence of others causes shifts in cognitive processing. This might
be particularly true during early development when attentional control is still developing.

Similarly, children may have struggled to maintain attentional control because of the timing differences between the two task conditions. That is, children could play continuously during the individual condition of the task but were required to pause their own play while their partner acted during the joint condition. It is possible that, it was not simply the presence of the other, but the fact that the child's play was interrupted that made planning more difficult. Whether the break in play led to disrupted attention control or directly to difficulty with planning is unclear, and may be driven by other mechanisms such as inhibitory control or working memory. Ongoing studies in our laboratory aim to address this possibility.

Finally, the mere presence of a social partner, rather than the pauses in play or attention, may have undermined children's planning. Sebanz, Knoblich, and Prinz (2003) suggest that the presence of others influences task performance, regardless of whether one is acting with the other person. They argue, "social facilitation effects are not moderated by the specific actions carried out by others" (p. 12). Instead, they suggest that the presence of another improves performance on simple tasks but impairs performance on more complex tasks. This possibility would be interesting to explore developmentally because of shifts in complexity of particular tasks as children gain both domain-general and domain-specific skills.

The current findings shed light on the difficulties encountered when first attempting to incorporate predictions of a partner's actions with one's own planning. It suggests that planning for two individuals, even when they share a common goal, is more difficult than planning for oneself. The relative complexity of the planning task in this study may have provided the ideal setting in which to examine planning differences across contexts at this age. It is possible that, given a less demanding task (or this task at an older age), children would have performed similarly in both conditions. On the other hand, a more difficult task may have created floor effects in which children would not have performed at above chance levels in either condition. The variability in planning in this study was likely due to an interplay between task difficulty and developmental period. Whether and how individual versus joint planning differs in different developmental periods and at different levels of task complexity should be explored further.

The joint action condition in this study was minimally "joint" in that it involved a turn-taking task in which the social partner always performed correctly. Turn-taking reduced timing and coordination demands common in other joint action tasks. Further, if children learned that the joint partner always acted correctly, he or she could have simply ignored the partner and continued to play without taking him or her into account. The fact that children did perform differently in individual and joint conditions suggests that they likely viewed these conditions differently (but see possibility of timing differences above). Future research
should consider the differential influences of more or less involved interactions with the social partner.

Findings from the current study suggest differences in three-year-old children's planning, but not problem-solving, when they play alone or jointly play with a partner. The mechanisms underlying this difference should be addressed in future research. Given that children of this age have the ability to view a partner as an intentional agent, predict another's actions, and plan their own actions, it seems that the integration of these skills is still undergoing development. How this differs when playing with parents, who may scaffold their actions, or with peers, who are less predictable in their actions, is an interesting avenue of future work. A better understanding of how planning within joint actions develops is important in order to further explore educational consequences, underlying neural mechanisms, and individuals who show a prolonged or atypical developmental pattern.

## Acknowledgments

We would like to extend our gratitude to Angela Khadar, Dirkje van der Aa, Marlene Meyer, Denise Janssen, Celeste Peereboom, Barbarien Bruens, and other members of the Nijmegen Baby Research Center for their help with data collection and thought-provoking discussions. We are especially grateful to the parents and children who participated in this study. This work was funded by a Brain-and-Cognition-Excellence-Grant from NWO (433-09-253).

# Back on track: Backtracking in counterfactual reasoning 

Tobias Gerstenberg (t.gerstenberg@ucl.ac.uk), Christos Bechlivanidis (c.bechlivanidis@ucl.ac.uk), David A. Lagnado (d.lagnado@ucl.ac.uk)<br>Cognitive, Perceptual and Brain Sciences, University College London, London WC1H 0AP

#### Abstract

Would Dan have died if Bob hadn't shot? In this paper, we show that people's answer depends on whether or not they are asked about what would have caused Bob not to shoot. Something needs to change in order to turn an actual world into a counterfactual world. Previous findings of how people reason about counterfactuals have been mixed: sometimes people appear to backtrack and reevaluate the causes of a counterfactual state (e.g. Rips, 2010). At other times, people appear to treat counterfactuals like interventions that leave the past unchanged (Sloman \& Lagnado, 2005). We experimentally manipulated the order in which participants were asked to consider the consequences of a counterfactual state. The results show that participants are more likely to backtrack when explicitly asked to consider a counterfactual's causes. However, when directly asked about the effects of a counterfactual state, most people don't backtrack.

Keywords: counterfactuals; causality; inference; backtracking.

## Introduction

Counterfactual thoughts play an important part in our everyday lives (see, e.g. Roese, 1997): if we had missed the submission deadline, you wouldn't be reading this paper. If we hadn't embarked on scientific careers, we would have become famous musicians. How do we evaluate the truth of such counterfactual statements? As life does not come with a rewind button, we can never know for sure. Hannes Kürmann, the protagonist in Max Frisch's play Biography: A Game, gets the unique chance to go back in time and play the game of life for a second time. However, despite full awareness of how his unhappy life will unfold and the firm belief that things could have turned out differently, Kürmann cannot bring himself to undo his past (and consequently, his present and future).

Max Frisch's play paints a rather fatalistic picture and suggests that counterfactual thoughts about how our life could have turned out differently are likely to be false. If everything happened as it actually did up until the point of the considered counterfactual, it has to turn out false. At some point, the counterfactual world has to diverge from the actual world in order to ensure the truth of the if-part (or antecedent) of a particular counterfactual statement. At least a change of mind would have been required to transform a scientist's life into that of a rock star.

Often there are a number of ways to realize the truth of a counterfactual's antecedent and the way in which we do so can sometimes have quite dramatic consequences. Consider the following situation: Anne is the commander of a firing squad and blows a whistle to signal to Bob and Chuck that it's time to shoot poor Dan (see Figure 1, cf. Pearl, 2000). Both Bob and Chuck shoot and Dan dies. Let us assume that

(a) What actually happened

Figure 1: If Bob had not shot, would Dan have survived?
the relevant causal relationships are deterministic: whenever Anne gives the signal, Bob and Chuck shoot and they never miss. Furthermore, each of Bob's and Chuck's shots are individually sufficient to bring about Dan's death. What do you think: would Dan have survived if Bob had not shot?

In this paper, we investigate how people evaluate counterfactual statements about simple devices that are structurally equivalent to the scenario just described. We first review theoretical frameworks that yield competing predictions about whether certain counterfactuals are true and then summarize previous empirical work on how people reason counterfactually. In a series of experiments, we test whether or not people spontaneously backtrack by manipulating the order in which participants are asked different counterfactual questions. We find that participants are more likely to backtrack when asked to explicitly consider the cause of the counterfactual's antecedent and suggest that the effect of question order can be explained in terms of a local processing strategy.

## Theories of counterfactual conditionals

Let us illustrate the differences between theories of counterfactuals via the example of the counterfactual conditional "If Bob had not shot then Dan would have survived".

According to Lewis's (1979) account, the counterfactual conditional is true if the counterfactual world in which Bob had not shot $(B=0)$ and Dan would not have died $(D=0)$ is more similar to the actual world than any counterfactual world in which Bob had not shot $(B=0)$ but Dan would have died anyhow ( $D=1$ ). To generate the relevant counterfactual world, we are supposed to imagine a small miracle that transforms $B$ from its original state to the considered counterfactual state and then let the counterfactual world unfold
according to the laws of nature. There are several problems with Lewis's account whereby most of which relate to the underspecified notion of similarity between different worlds (cf. Hiddleston, 2005). While Lewis aims to provide a non-causal account of counterfactuals and reduce causality to counterfactuals, others have argued that this puts the cart before the horse (Hiddleston, 2005; Pearl, 2000).

More recently, theories have been developed that take the notion of causality as primary and evaluate the truth of counterfactuals via reference to explicit causal assumptions that can be represented in causal Bayesian networks (CBN, Hiddleston, 2005; Pearl, 2000). In the spirit of Lewis's (1979) account, these theories evaluate the truth of counterfactuals by referring to similar worlds. However, they differ in how they conceptualize the causal similarity between different possible worlds.

According to Pearl's (2000) pruning theory ${ }^{1}$, the evaluation of a counterfactual involves three steps. First, we update the values of the variables in the causal network based on our observations in the actual world (i.e. $A=1, B=1, C=1$ and $D=1$ ). Second, we change the value of the antecedentvariable (i.e. B) by means of an intervention. Such an intervention results in a mutilated causal network in which all incoming links to the intervened-on variable are removed (see Figure 1b). Third, we evaluate the consequent-variable (i.e. $D)$ based on the variables' values in the mutilated network. Since the intervention in $B$ disconnects all influences of upstream variables, $A$ 's value in the mutilated network remains unchanged. Because Chuck shoots whenever Anne gives the signal (i.e. $C=A$ ) and Dan dies if either Bob or Chuck shot (i.e. $D=\max (B, C)$ ) the counterfactual is false. Dan would have died even if Bob had not shot.

Pearl's (2000) account of dealing with counterfactuals is similar to Lewis's (1979) in that the considered counterfactual world is identical to the actual world up until the point of the antecedent-variable. The antecedent-variable's counterfactual value is realized via an intervention that locally violates the causal relationships of the structure. The resulting counterfactual world is similar to the actual world in that the values of all variables that precede the antecedent-variable (or are causally independent from it) remain unchanged. However, it is dissimilar in that some of the causal relationships that were true about the actual world are not respected in the counterfactual world.

The opposite is true for Hiddleston's (2005) minimalnetwork theory. In this theory, the truth of a counterfactual conditional is evaluated by considering whether it holds in all worlds that are minimally different from the actual world but consistent with its causal laws. Given that the relationships between the actors in our scenario were described as deterministic, there are only two possible worlds that are causally consistent. The actual world (in which the values of all variables are 1) and a counterfactual world in which Anne did not give the signal, neither Bob nor Chuck shot and Dan survived

[^276](i.e. all values are 0). Hence, according to minimal-network theory, the considered counterfactual is true. If Bob had not shot, Dan would have survived (see Figure 1c).

The relevant counterfactual world is dissimilar from the actual world in that all events are different from how they actually were (including events that were temporally prior to the considered counterfactual). However, it is similar in that none of the actual causal relationships have been tampered with.

Note that evaluating the truth of counterfactuals according to minimal-network theory requires us to not only consider the consequences of the antecedent-variable. Bringing about the counterfactual state of the antecedent-variable in a way that is consistent with the causal laws requires us to backtrack and change the values of the antecedent-variable's causes as well. More generally, whereas pruning theory yields that backtracking counterfactuals (e.g. If Bob had not shot then Anne would not have given the signal) are always false, minimal-network theory holds that they can be true (at least in deterministic contexts).

## Psychological studies of counterfactual reasoning

The results of previous studies on how people reason about counterfactuals have been mixed. Sloman and Lagnado (2005) found that people's counterfactual judgments are closely in line with the predictions of pruning theory. In one of their experiments, participants received descriptions of a causal structure identical to the one in the above scenario. In the abstract version of the task, they were informed that $A$ causes $B$ and $C$, and that $B$ and $C$, in turn, each cause $D$. Knowing that $D$ definitely occurred, participants answered the following two counterfactual questions: (a) If $B$ had not occurred, would $D$ still have occurred? (b) If $B$ had not occurred, would $A$ have occurred?

Pruning theory predicts that participants should answer 'yes' to both questions whereas minimal-network theory predicts negative responses. $80 \%$ of the participants answered 'yes' to (a) and $79 \%$ to (b). Responses were similar for scenarios in which the variables and causal relationship were described more concretely (a: $78 \%$, b: $81 \%$; averaged).

However, there has also been empirical support for minimal-network theory (Dehghani, Iliev, \& Kaufmann, 2012; Rips, 2010; Rips \& Edwards, in press). Rips (2010) and Dehghani et al. (2012) focused on backtracking counterfactuals and found that participants' judgments were sensitive to information about the base rates of the antecedentvariable's causes, the way in which these interact (disjunctive vs. conjunctive) and whether the causal links are deterministic or probabilistic. Since pruning theory rules out all backtracking counterfactuals, it cannot account for any of these effects. Recently, Lucas and Kemp (2012) have extended pruning theory to handle backtracking counterfactuals by allowing that variables which are not affected by the counterfactual intervention may take non-actual values.

One might argue that what answers a theory gives to backtracking counterfactuals is not of utmost importance for psychological theorizing. In everyday life, we are normally in-
terested in the effects rather than the causes of counterfactuals. However, as the firing-squad scenario has shown, in some causal structures, whether or not a theory allows for backtracking also affects the truth of non-backtracking counterfactuals. Dan would have survived if Bob had not shot only if we backtrack and change Anne's action.

Rips and Edwards (in press) investigated participants' counterfactual reasoning using abstract devices that were structurally identical to the firing-squad scenario. They varied whether the causal links were described as deterministic or probabilistic (e.g. A's operating always/usually causes $B$ to operate) and whether $B$ and $C$ brought about $D$ in a disjunctive $(D=\max (B, C))$ or conjunctive manner $(D=\min (B, C))$. Furthermore, they manipulated the framing of the counterfactual question between participants. Participants were either asked to consider that a certain component had failed or not operated (e.g. If $B$ had not operated [failed] would $A / C / D$ have operated?). Generally, participants tended to show less backtracking in the failed condition which suggests a local failure in the device than in the not operated condition. Furthermore, there was less backtracking for probabilistic compared to deterministic devices.

We will focus on structures with deterministic causal links for which the predictions between pruning theory and minimal-network theory dissociate strongest. Remember that for the deterministic disjunctive device, Sloman and Lagnado (2005) found that most participants answered positively to the question of whether $A$ (or $D$ ) would have occurred if $B$ had not occurred, Rips and Edwards (in press) found that in their not operated condition, almost all participants answered negatively. In the following, we will explore whether the way in which people mentally process counterfactual questions might account for these divergent findings.

Note that pruning theory and minimal-network theory make different predictions about what states of the system people need to consider when asked whether $D$ would have operated if $B$ had not operated. According to minimalnetwork theory, we first have to backtrack and infer that if $B$ had not operated then $A$ would not have operated. From this it follows that $C$ and $D$ would not have operated. Pruning theory, in contrast, predicts that we can evaluate the truth of the counterfactual without considering the state of $A$ (see Figure 2). Since the counterfactual intervention on $B$ does not affect the state of $C, D$ is predicted to operate even if $B$ had

Figure 2: Hypothesized counterfactual reasoning process in the $D-C-A$ condition.
not operated (because of $C$ ).
This reasoning suggests that the order in which participants are asked to answer different counterfactual questions might influence how likely they show backtracking. In Sloman and Lagnado's (2005) experiment, participants were always asked about $D$ first and then about $A$. In Rips and Edwards's (in press) experiment, participants were asked about $A, C$, and $D$ and free to answer the questions in any order (cf. Figure 3a). Participants indicated their processing order on the response sheet and, generally, answered the questions from left to right (i.e. from $A$ to $B / C$ to $D$ ). In our experiments, we use a computerized task which allows us to manipulate the question order. Based on the discrepancy between Sloman and Lagnado's and Rips and Edwards's findings, we hypothesized that when asked to consider $A$ before $D$, participants will be more likely to show backtracking than when asked about $D$ before $A$. Note that neither pruning theory nor minimal-network theory predict any effects of question order.

## Experiment 1: Replication

We first attempted to replicate Rips and Edwards's (in press) findings in the not operated condition using a computerized interface. Participants ( $N=40$, recruited via Amazon Mechanical Turk) saw eight different devices in randomized order and were asked to answer whether each of the other three components would have operated if $A, B$ or $D$ had not operated (i.e. 8 devices $\times 3$ antecedent components $\times 3$ consequent components $=72$ questions). ${ }^{2}$ The devices differed in whether the causal links were described as deterministic or probabilistic and whether $B$ and $C$ combined disjunctively or conjunctively. The probabilistic devices differed in whether (i) all links were probabilistic, (ii) only the links from $A$ to $B$ and $C$ or (iii) from $B$ and $C$ to $D$ (see Rips \& Edwards, in press, for more details).

The order in which participants were asked about the different antecedent components was counterbalanced ( $A-B-D$ vs. $D-B-A)$. For each antecedent component, participants were free to answer the counterfactual questions for the different consequent components in any order (see Figure 3a). For example, if $B$ was the antecedent component (i.e. if $B$ had not operated) a participant could answer about $A$ (e.g. $A$ would not have operated), $C$ and $D$ in any order. For each counterfactual, participants' response options were to say that the component would have operated, would not have operated or might have operated.

## Results and Discussion

We followed Rips and Edwards's (in press) procedure and coded participants' responses as -1 (does not operate), 0 (might operate) and 1 (operates) in order to run standard statistical analyses. Figure 4 shows a selection of the results. Overall, we closely replicated Rips and Edward's findings with a correlation of $r=.92(R M S E=0.23)$ between the

[^277]

Figure 3: Screenshots of the interface in Experiments 1 and 2 ( $D-C-A$ order condition).
averaged responses to the 72 questions in both experiments. Participants again tended to answer the counterfactual questions from left to right. For example, the average order in which participants indicated to have answered the counterfactual questions when $B$ was the antecedent component was 1.23 for $A, 2.10$ for $C$ and 2.67 for $D$ (the corresponding values in Rips and Edwards's experiment were $A: 1.44, B: 2.21$ and $D: 2.23$ ).

Whereas both pruning theory and minimal-network theory predict the same pattern of responses when $A$ is the antecedent component, their predictions differ when the antecedent components are $B$ or $D$. Minimal-network predicts that the answers to all counterfactual questions are negative. Pruning theory, in contrast, predicts that when $D$ is the antecedent, the answers to all consequent components should be positive. When $B$ is the antecedent component, pruning theory predicts that the answers to both $A$ and $C$ should be positive. For the $D$, the answer is predicted to be negative for the conjunctive and positive for the disjunctive device.

In line with Rips and Edwards's findings and as predicted by minimal-network theory, a majority of participants answered the counterfactual questions negatively. For example, when asked whether $A, C$ and $D$ would have operated if $B$

Figure 4: (i) Mean judgments separated for the disjunctive and conjunctive deterministic device. The labels on the $x$-axis correspond to the consequent-components. Most frequently endorsed structures for the (ii) disjunctive and (iii) conjunctive devices. Note: R\&E = Rips and Edward's (in press) data.
had not operated for the conjunctive device, 24 participants showed backtracking whereas only 8 participants responded in line with pruning theory (see Figure 4b).

## Experiment 2: Order Manipulation

Having replicated Rips and Edwards's finding, Experiment 2 tests the hypothesis that the order in which participants are asked to answer different counterfactual questions influences the degree to which they backtrack. With $B$ as the counterfactual antecedent, we predicted that participants will show more backtracking when asked about $A$ before $D$ and less backtracking when asked about $D$ before $A$.

Between participants ( $N=320$, recruited via Amazon Mechanical Turk), we manipulated the question order ( $A-C-D$ vs. $D-C-A$ ), whether the device was disjunctive or conjunctive as well as whether, in actuality, all or none of the components were operating ( 40 participants per condition). When all components were operating participants were asked to consider the counterfactual that $B$ had not operated (see Figure 5a and b). When none of the components were operating, participants considered that $B$ had operated (see Figure 5c and d).

Our processing hypothesis predicts an interaction between the question order, the type of device and its actual state. The question order is predicted to influence participants' judgments about the counterfactual state of $D$ for (a) the disjunctive device in which everything is actually operating and (d) the conjunctive device in which nothing is operating (see Figure 5 a and d). In these cases, whether $D$ would have been different from actuality depends on whether or not participants backtrack. Accordingly, we predicted that participants in the $D-C-A$ condition are more likely than participants in the $A-$ $C-D$ condition to say that $D$ would have operated for (a) and less likely to say that $D$ would have operated for (d). In contrast, we do not predict an effect of question order for devices (b) and (c). The counterfactual state of $B$ is by itself sufficient to bring about a change in $D$ without the need to consider the states of the other components.

Figure 3 b shows a screenshot of the $D-C-A$ condition. Participants first only saw the text box for $D$. Having answered that question, the response was locked and the next text box

Figure 5: Mean judgments (ii) and frequency of endorsed networks (iii) for different causal devices (i). Note: For each device, the leftmost networks in (iii) are predicted by minimal-network theory and the rightmost networks by pruning theory. The networks in the middle are the most frequently endorsed networks predicted by neither of the two theories.
appeared. All participants just provided answers for a single device.

## Results and Discussion

For ease of interpretation, we analyze the results for devices in which everything is operating initially (Figures 5 a and b) and in which nothing is operating (Figures 5 c and d) separately and focus on participants' answers to component $D$.

For the operating devices $(\mathrm{a}, \mathrm{b})$, there was a significant main effect of structure, $F(1,156)=44.13, p<.001, \eta_{p}{ }^{2}=$ .459 and no main effect of question order ( $p=.097$ ). Participants were more likely to think that $D$ would have operated for the disjunctive ( $M=0.25, S D=0.88$ ) compared to the conjunctive device ( $M=-0.9, S D=0.41$ ).

More interestingly, there was a significant interaction between structure and question order $F(1,156)=9.59, p=$ $.002, \eta_{p}^{2}=.058$. For the disjunctive device, participants in the $D-C-A$ condition were more likely to say that $D$ would have operated ( $M=0.5, S D=0.82$ ) than participants in the $A-C-D$ condition $(M=0, S D=0.88), t(78)=-2.64, p=$ $.01, d=-0.6$. For the conjunctive device, there was no significant difference as a function of question order $(p=.101)$.

The results for the non-operating devices (c, d), closely mirrored the results of the operating devices. Again, there was a significant effect of structure, $F(1,156)=39, p<$ $.001, \eta_{p}{ }^{2}=.302$ and no main effect of question order ( $p=$ .079). Participants were more likely to think that $D$ would have operated for the disjunctive ( $M=0.70, S D=0.68$ ) compared to the conjunctive devices ( $M=-0.29, S D=0.87$ ).

The interaction between structure and question order was significant $F(1,156)=5.26, p=.003, \eta_{p}{ }^{2}=.055$. While there was no significant difference of question order for the
disjunctive device ( $p=.329$ ), in the case of the conjunctive device, participants in the $D-C-A$ condition were less likely to say that $D$ would have operated ( $M=-0.58, S D=0.78$ ) than participants in the $A-C-D$ condition ( $M=0, S D=0.88$ ), $t(78)=3.1, p=.003, d=0.70$.

These results demonstrate that the order in which participants were asked about the different components affected whether they believed that $D$ would have operated. In the $A-C-D$ condition, 36 participants (out of 160 ) answered as predicted by minimal-network theory and 42 as predicted by pruning theory (see Figure 5iii). These numbers shifted towards much less backtracking in the $D-C-A$ condition: only 15 participants answered consistently with minimal-network theory, whereas 68 answered in line with pruning theory.

The results also revealed another interesting pattern: the absolute value of participants' averaged answers about component $A(M=0.15)$ were generally less certain (i.e. closer to $0)$ than their answers about $C(M=0.33)$ and $D(M=0.53)$. The shift towards averaged 0 responses from component $C$ to $A$ in Figures 5a and d for the $D-C-A$ condition is neither predicted by pruning theory nor minimal-network theory. We consider this to be evidence that people process counterfactual questions in a more local fashion rather than simultaneously considering the states of all variables in the system.

For example, when asked whether $D$ would have operated if $B$ had not operated (cf. Figure 5a) most participants in the disjunctive $D-C-A$ condition answer 'yes' to $D$. Having answered positively to $D$ commits participants to saying that $C$ would have operated as well (cf. Figure 2). Otherwise, there is no explanation for why $D$ operates. However, when considering $A$, participants have reached a state of causal inconsistency. Having answered 'yes' to $C$ but knowing that $B$ did not

Figure 6: Hypothesized local counterfactual reasoning process in the $A-C-D$ condition.
operate, they can either resolve this inconsistency by answering 'yes' to $A$ and assuming a fault in $B$. Alternatively, they can answer 'no' to $A$ and assume that $C$ must have operated spontaneously. The same rationale also explains the pattern of results for device (d). For devices (b) and (c), participants’ response to $D$ does not commit them to a particular response for component $C$ - the counterfactual state of $B$ already accounts for the change in $D$.

Participants in the $A-C-D$ condition have to resolve the potential causal inconsistency right at the start (see Figure 6). As the results show, participants are split in how they do so: some backtrack and respond in line with minimal-network theory. Others don't and respond as predicted by pruning theory.

## General Discussion

The capability to think about possible states of the world and reason through what would or could have happened is one of the hallmarks of human cognition. Counterfactual thoughts are of central importance to attributions of responsibility (Lagnado, Gerstenberg, \& Zultan, accepted) and causality (Gerstenberg, Goodman, Lagnado, \& Tenenbaum, 2012). In this paper, the aim was to gain insight into people's counterfactual processing. Based on mixed findings in previous research (Dehghani et al., 2012; Meder, Hagmayer, \& Waldmann, 2009; Rips, 2010; Sloman \& Lagnado, 2005), we investigated whether the order in which participants are asked to reason about the consequences of certain counterfactual states could shed light on these inconsistencies. We first replicated Rips and Edwards's (in press) experiment and then manipulated the order of counterfactual questions in an identical experimental setup.

As hypothesized, participants' answers were more in line with the predictions of minimal-network theory (Hiddleston, 2005) when asked to consider a possible cause of the counterfactual state first. In contrast, when participants were asked to consider the effect of a counterfactual state first, participants showed less backtracking and followed the predictions of pruning theory (Pearl, 2000) more closely. However, the overall pattern of results was not predicted by either theory. We discussed that a more local processing strategy is consis-
tent with this data (cf. Fernbach \& Sloman, 2009, for a similar idea in causal learning). Accordingly, when asked to consider a certain counterfactual, people do not spontaneously think through the implications that this counterfactual state has for the whole system. Rather, participants' responses are indicative of a more local processing strategy that considers only parts of the system. The order in which participants are probed about the counterfactual world hence has a significant effect on what changes they make in order to account for the stipulated counterfactual state. Applied to our initial example, whether Dan is believed to have survived if Bob had not shot depends on whether we are asked to consider Anne first.

While the results of Experiment 1 have shown that participants' responses were closely in line with minimal-network theory, the results in Experiment 2 were more mixed. In future research, we aim to (i) generalize these findings using less abstract stimuli and (ii) investigate more closely what differences between the reported experiments account for participants' tendency to backtrack or not. We speculate that both the explicit contrast between deterministic and probabilistic systems as well as the fact that participants have to think through a great number of different devices, encourages them to endorse a more holistic strategy that favors responses that are causally consistent. However, when not asked explicitly to consider the causes of a counterfactual state, most participants stay on track and don't backtrack.

## Acknowledgments

We thank Lance Rips for providing the data and Brian Edwards for insightful comments. This work was supported by a doctoral grant from the AXA research fund (TG) and an ESRC grant RES-062-33-0004 (DL).

# Musical training and auditory global-local precedence 

Anne T. Gilman (anne.gilman@gmail.com)<br>Juniata College Psychology Department, Good Hall, 1700 Moore Street<br>Huntingdon, PA 16652 USA<br>Elizabeth Ebbets (lizaebbets@gmail.com)<br>Juniata College Psychology Department, Good Hall, 1700 Moore Street<br>Huntingdon, PA 16652 USA

#### Abstract

People demonstrate a consistent tendency to favor holistic or global processing over processing of local details in many perceptual domains; this tendency is called global-local precedence. Formal musical training is associated with qualitative changes in auditory processing, but the number of years required remains unclear, particularly for any perceptual differences between untrained and minimally trained participants. In this study, participants with zero to over ten years' music training identified the direction of pitch changes in three-sound sequences. Only participants with three or more years' training demonstrated a significant global-local precedence. Individuals without musical training consistently identified the local direction of pitch-change sequence elements better than global pitch changes across each sequence. Although musical training was associated both with greater task accuracy and with global-local precedence, improved accuracy did not explain the musically trained participants' preferential processing of global auditory characteristics.

Keywords: Global-local precedence; musical training; temporal processing; auditory perception.

## Perceptual learning and cognition

People's experiences can alter their perceptual processing, even as adults. Perceptual learning thus takes part in core cognitive mechanisms underlying storage of past experiences and their subsequent application to similar but non-identical situations later on. Distinctions between global (or holistic) processing and local (or detail) processing have only recently been examined while taking perceptual learning into account. This connection offers particular interest in the auditory domain, given long-established differences in how trained musicians and musically naïve listeners perceive sounds (Bever \& Chiarello, 1974).

## Global-local precedence

People who become so engrossed in the details of a complex scene or situation that they fail to notice compelling overall patterns are said to be "missing the forest for the trees". This colloquial expression has a parallel in human perception: decades of vision research has documented a bias or precedence towards overall or global characteristics of an image rather than its local details (Navon, 1977). For example, given an image made up of a dozen K's arranged in the shape of an H , viewers are more likely to describe what they see as an H than as a group of K's. When asked to identify either the big letter or the little component letter in a series of many such composite stimuli, viewers are likely to make fewer errors overall when identifying the big rather than the little letters, thus global-local precedence can be identified by greater
overall accuracy for global trials. Viewers in such studies also show a pattern in their errors for incongruent stimuli such as an H made of K's-one could also create a congruent stimulus by arranging K's in the shape of a larger K. Viewers more often mistakenly offer the big letter as an answer on local (little-letter trials) than they err by naming the little letter on global trials, showing an uneven influence-greater for global patterns-of these different processing levels on perception. This uneven influence can also be described as interference by global processing in the local decision. A growing body of evidence supports the overall global-local processing distinction in auditory and other non-visual modalities (Justus \& List, 2005; List \& Justus, 2007, 2010; List, Justus, Robertson, \& Bentin, 2007; Ouimet, Foster, \& Hyde, 2012; Sanders \& Poeppel, 2007).

Cognitive scientists have found ongoing and robust preferential processing of global over local patterns (Love, Rouder, \& Wisniewski, 1999; Ripoll \& Marty, 2005) even while some boundary conditions have been delineated (Navon, 2003). This precedence is considered an outcome of normal maturation rather than one of learning. A large body of evidence, summarized by Poirel and colleagues (2011), suggests that young children shift from a local to a global visual focus around the age of 6 ; Poirel et al. found that lowered greymatter volume corresponded to this shift, again characterizing global precedence as the healthy adult norm. Visual and auditory findings of differences in holistic versus detailed processing bear on issues ranging from autism (Rondan \& Deruelle, 2007) to the acquisition of reading skills (Foxton et al., 2003). For instance, exceptions to global-local precedence for auditory stimuli correspond to autism diagnoses, even though the detail-specific advantages shown by autistic participants were not explained by deficits in global processing as previously thought (Mottron, Peretz, \& Ménard, 2000). In all of the above investigations, global-local precedence is taken as an indicator of healthy and fully-developed perception, and only very recently has this tendency been evaluated with respect to prior musical training in a parallel auditory study (Ouimet et al., 2012).

## Expertise: Musical training

Auditory perception varies qualitatively-not just in accuracy-depending on learning or expertise. Comparing perception of tones presented to the right or left ear has revealed that hemispheric dominance for this task switches
following formal music training (Kellar \& Bever, 1980; Bever \& Chiarello, 1974). Subsequent studies have shown that musical training changes listeners' perception of auditory patterns, both for musical stimuli themselves (Fujioka, Trainor, Ross, Kakigi, \& Pantev, 2004; Foxton, Brown, Chambers, \& Griffiths, 2004) and for the pitch changes that characterize fluent speech (Moreno et al., 2009). Musical training also contributes to changes in numerous other cognitive processes, and better understanding of the precise impact of such training on auditory perception may clarify ongoing questions about music and its contribution to formal measures of intelligence and academic achievement (Schellenberg \& Peretz, 2007).

The one investigation (other than the present study) of the role of prior musical training in auditory global-local precedence found this precedence more strongly demonstrated among less-trained listeners (Ouimet et al., 2012). Accuracy results were contrasted between expert musicians-with at least seven years' formal training-and novices, where the lower-expertise group could have one or two years of prior training, or none at all. This division is consistent with other key precedents in music perception (Warrier \& Zatorre, 2002). However, findings in visual perception, where a mere ten hours' practice with a video game significantly and enduringly changed participants’ skills (Green \& Bavelier, 2003), suggest that the perceptual performance of participants with minimal amounts of musical training should be contrasted with the performance of those with no training at all.

## Evaluating global-local precedence and musical training

The present study reevaluates global auditory bias for possible influences of perceptual expertise, employing the same three-part sweep sequences tested in Sanders and Poeppel's (2007) ERP study to contrast performance of participants with varying levels of musical expertise, including no prior training whatsoever.

## Method

## Participants

Over multiple semesters, 104 undergraduates with normal or corrected-to-normal hearing participated in the experiment, receiving either course participation credit or snack food as compensation.

## Materials

The auditory stimuli selected for this study were created for an ERP study of global versus local auditory processing (Sanders \& Poeppel, 2007). Each stimulus consists of three frequency-modulated octave sweeps or chirps that can go up or down in frequency at the global or local level, as follows. Each chirp lasts only 40 ms , with 190 ms of silence separating the chirps; the three-chirp sequence takes 500 ms total. Each chirp travels smoothly up or down one octave-this direction constitutes the local direction, and all three chirps

Figure 1: Stimulus frequency distributions over time.
of a given sequence go in the same direction. The progression of each sequence is monotonic, with the central pitch of each sweep being higher than the previous one in global upward sequences and lower for downward sequences. The difference in central frequency between the first and the last octave sweeps is .2 octaves. In musical terms, if the central frequency of one chirp were a C note, the central frequency of the next chirp would be a bit over a half step higher or lower that that of the first chirp. See Figure 1 for sample spectrograms, obtained using Praat (Boersma, 2001).

Congruent stimuli (e.g. Figure 1(a)) have changes in frequency which go in the same direction (up or down) at the local and global levels. Incongruent stimuli (e.g. Figure 1(b)) require the participants to accurately distinguish between levels to answer correctly. The stimulus set includes eleven sequences per condition, namely local-up/global-down, local-up/global-up, local-down/global-down, and local-down/global-up, for a total of 44 stimuli. Frequencies used in these stimuli range between a minimum of 0 Hz and a maximum of 3500 Hz . The intensity of each stimulus file measures between 88 and 92 dB , but participants could control playback volume.

## Procedure

Participants were asked to discriminate between upward and downward sweeps (local) and sweep sequences (global) after training involving both passive familiarization and active practice, replicating Sanders \& Poeppel's (2007) behavioral protocol. During familiarization, participants first read a description of the type of sounds they were about to hear, e.g. sounds that go down as a whole, and then heard all of those stimuli (global-down ones in this example) in randomized order. During practice trials, the participants heard a sound stimulus while either "PART" (cueing a local judgement) or "WHOLE" (for a global judgement) was displayed at the center of the screen. They indicated by keypress whether the current stimulus was going up or down, and then they received on-screen feedback showing whether or not their answer was correct. After two rounds of practice, participants then enagaged in four blocks of testing trials, which were identical to the practice trials except that no feedback was provided.

After completing the sound discrimination task, participants indicated whether they had ever studied a musical instrument, including voice. They then had the opportunity to clarify if they had studied music for more than one, more than two, or more than five years.

## Apparatus

Sounds and instructions were presented on two Macintosh iBook G4s equipped Sennheiser HD 202 headphones and running code written by the first author in PEBL (Mueller, 2006). Participants were free to adjust the computer volume to a comfortable level; they pressed keyboard keys ("U" and "D" for "up" and "down") to record their answers.

## Results

An overall global-local precedence in auditory discrimination was demonstrated by our participants, who showed $61.8 \%$ accuracy on global trials versus $51.5 \%$ accuracy on local trials. A $2 \times 2 \times 2$ analysis of variance (ANOVA) comparing the impact of task focus (global or local), stimulus type (congruent or incongruent), and musical training (any or none) showed this difference to be highly significant, $F(1,18296)=$ $55.8, M S E=4262, p<.001$. All analyses were performed using R (R Development Core Team, 2005).

As expected, participants were more successful judging the direction of pitch change for congruent stimuli, demonstrating $66.7 \%$ accuracy on congruent trials and $51.5 \%$ on incongruent trials, $F(1,18296)=451.8, M S E=4262, p<.001$.

To evaluate whether our participants demonstrated any global-local precedence, each person's percent accuracy for global and judgements was compared using the simple difference of their average performance in each condition, $M_{\text {global }}-M_{\text {local }}$. A positive score indicated global-local precedence, while a negative score indicated the opposite. Our participant group as a whole demonstrated an average global-local precedence of .05. This average differed significantly from zero, $t(103)=3.07, p=.0027$. The significant interaction between task focus and sound type, $F(1,18296)=$

| Music Training | Local Advantage | Global Advantage |
| :---: | :---: | :---: |
| None | 15 | 5 |
| Some | 31 | 53 |

Table 1: Number of participants demonstrating each sort of bias according to presence or absence of past musical training
82.7, $M S E=4262, p<.001$, further supported our finding of global-local precedence. A Pearson's correlation between this precedence measure calculated over all trials and the same measure calculated over only incongruent trials showed that these incongruent trials were indeed driving the precedence results, $r=.89, t(102)=20.1, p<.001$. This correlation confirms the presence of the second sign of global-local precedence, where errors on local trials show what can be described as interference from global processing: participants made more errors on local trials, and they did so to a greater extent on incongruent ( $M=0.46$ ) than congruent ( $M=0.67$ ) local trials.

The remaining analyses consistently indicated that musical training is associated with differences in global-local precedence. Those participants who reported any musical training at all showed significantly higher task accuracy (60.2\%) than those with none $(54.7 \%), F(1,18296)=45.6, M S E=$ $4262, p<.001$. Reaction times were lower among musicallytrained participants. These times were not recorded for half of the participants, due to experimenter error; the available times did not show any interactions with other variables. Greater musical training was associated with significantly different global-local precedence, however, $t(31)=-2.5, p=.017$, with an opposite precedence pattern for those with some musical training ( $M=8 \%$ ) as compared to those with none ( $M=-6 \%$ ). This difference clarifies the significant threeway interaction found in the main ANOVA between task focus, sound type, and presence or absence of prior musical training, $F(1,18296)=21.9, M S E=4262, p<.001$.

To evaluate this difference without making assumptions about the distributional characteristics of either the training or the precedence score, we compared this indicator of global versus local advantage to reported prior musical training using a $\chi^{2}$ test (see Table 1). Those with no prior musical background were far more likely to demonstrate better accuracy on local than on global judgements ( 15 out of 20), while participants with some musical training were more likely ( 53 out of 84) to demonstrate global-local precedence. This difference was significant, $\chi^{2}=8.022, d f=1, p=.0046$.

To explore this difference further, participants were grouped according to their reported level of musical expertise. Twenty participants reported having no musical training, 16 reported up to one year of training, 17 up to two years, 2 up to five years, and 49 more than five. For these analyses, responses from the two lone participants with between two and five years of training were combined with the most experienced musicians.

As expected, participants with the most musical training in
our sample showed the greatest overall accuracy in identifying the direction of pitch change in these three-part auditory sequences: those with more than one year of training showed $61 \%$ accuracy; those with up to one year, $57 \%$; and those with none, $55 \%$. All groups performed at above chance levels, $p<.001$.

Figure 2: Participant accuracy in identifying direction of pitch changes. The difference between global and local accuracy shows the opposite pattern among non-trained participants compared to the rest both for congruent and incongruent stimuli. Other than incongruent trials for those with 12 years' training and local incongruent trials for those with none all accuracies differ significantly from chance perfomance (dotted line).

## Discussion

A parallel investigation of global-local precedence in the auditory domain found the opposite results to those presented here, in that their less-trained participants exhibited significant global-local precedence and to a greater extent than their more expert participants (Ouimet et al., 2012). In our study, on the other hand, more expert participants demonstrated global-local precedence, but that precedence only reached statistical significance for those with more than 3 years of training. Those reporting no training at all performed better on local than on global trials, on average. Our study differs from Ouimet et al.'s in multiple ways, however, particularly in the temporal characteristics of the stimuli used and in the grouping of less-expert participants.

## Stimulus differences

Ouimet and colleagues used sequences of tones that correspond to notes on a musical scale (Ouimet et al., 2012, p. 2539), based on hierarchical stimuli developed by Justus and List (Justus \& List, 2005). Although these tone sequences incorporate a hierarchical structure similar to the sequences of
octave sweeps used in our study, there are several important differences.

First, the majority of their sound stimuli lasted much longer. Their three-part sequences of steady tones ranged in duration from 150 ms to 600 ms , so total stimulus durations ranged from 450 ms (comparable to our 500 ms , but with no silence) to 1800 ms . They found only a "negligible" (Ouimet et al., 2012, p. 2539) relation between stimulus duration and accuracy, however, adding support to List and Justus' arguments for the relational invariance of their tone-sequence tasks (List \& Justus, 2010, p.16).

Second, the tone and sweep elements differ sharply in their rate of change of frequency as well as their absolute duration, and the detection of direction of changes in pitch recruits neural resources not required for tone discrimination (Johnsrude, Penhune, \& Zatorre, 2000), possibly adding further difficulty for the sweep task. These stimulus differences, however striking, are unlikely to fully explain our differing results, however, since our participants also showed lower accuracy than that found in prior work with these same octave-sweep sequences (Sanders \& Poeppel, 2007), while still performing at above-chance levels. Some of our error level may arise from having collected data from pool participants at very different points in the semester (Grimm, Markman, \& Maddox, in press). A Pearson's correlation between week of the semester (ranging from 6 to $17, M=11.3$ ) and participant accuracy showed a modest negative correlation, $r=-.25, t(102)=-2.6, p=.0096$. Time of semester showed no interaction with precedence ( $p>.5$ ) or with musical training ( $p>.9$ ); repeating the initial analysis of variance including time of semester did not alter the results obtained.

A third important difference between the two stimulus sets is that in our study, the magnitude of each local change in pitch (one octave) is much greater than each stepped change in the global progression of pitch (one tenth of an octave). In Ouimet et al.'s study (2012), though, global pitch steps are three times the magnitude of local pitch intervals (147 cents, or about $1 / 8$ th of an octave). These stimulus differences complicate our interpretation of which accuracy changes are due to global versus local processing and which are due to discrimination difficulty.

## Participant differences

The other barrier to explaining the opposite precedence findings between the two studies for less-trained participants lies in the mismatch in the two studies' categorizations of musical training levels, a topic of ongoing debate. While Sanders and Poeppel did not measure musical expertise in their ERP study (2007), other assessments of global-local precedence in the auditory domain did record this participant characteristic. In the study presenting the tone-sequence design discussed above, one experiment had more musically trained than untrained participants, while the second had only musically trained participants (Justus \& List, 2005). In one of List and Justus' more recent studies, all participants reported at least 6 years' musical training (List \& Justus, 2007), and
in another, all participants had at least 2 or 3 years, with each participant group reporting a median of 10 years' training (List \& Justus, 2010). Other studies of music perception vary, such as Levitin and colleagues performing fMRI studies on musically-naïve participants who could have up to two years of training (Sridharan, Levitin, \& Menon, 2008; Sridharan, Levitin, Chafe, Berger, \& Menon, 2007) and other studies where participants all had at least five years' training (Vines, Krumhansl, Wanderley, Dalca, \& Levitin, 2011; Vines, Krumhansl, Wanderley, \& Levitin, 2006). Ouimet and colleagues (2012) defined musicians as those reporting 7 or more years (versus non-musicians with less than 3 years) of musical training. If most of their non-musicians had 1-2 years' training, then their finding of global-local precedence in that group comes closer to paralleling our findings. If most of their non-musicians had no musical training at all, the contrast between their and our findings would argue all the more strongly for an examination of the stimulus and task differences. None of the precedents listed above assessed differences between those with little training and those with none. This omission may stem in part from widespread reliance on undergraduates as study participants: finding 20 untrained participants required recruiting over 100. However, since a mere ten hours of video game playing can resolve perceptual deficits previously considered to be genetically driven (Feng, Spence, \& Pratt, 2007), examining constrasts between untrained and minimally trained listeners is essential.

Refining our examination of perceptual acuity associated with small amounts of musical training increases a risk of possible person confounds in the interpretation of our results. Are individuals with better auditory discrimination more likely to have and/or to continue with music instruction? While this risk cannot be ruled out, our results go beyond what would be predicted from person differences alone. If greater accuracy on our task were purely a matter of better auditory acuity, which may indeed influence individuals’ choice to seek or persist in musical training, there would be differences in overall accuracy as found here, but not an interaction with task focus. Another concern, though, might be that novices' greater difficulty with the overall task might disguise a truly universal global-local precedence that can only be detected among those with greater perceptual acuity. This interpretation was not supported by our data, as shown by a follow-up analysis of each participant group. Under the disguise theory, task accuracy should correlate positively with global-local precedence. As shown in Figure 3, all participant groups showed a zero or, in one case, negative correlation between task accuracy and global-local precedence. In simpler terms, better accuracy with this task did not explain the greater global-local precedence found among more-expert listeners.

There are many ways in which our definition of musical training or expertise could and should be made sharper. Error rates in this data set provide some support for concerns about differing performance across the semester within a participant

Figure 3: Non-correlation between task accuracy and globallocal precedence, assessed separately for each participant group according to their prior musical training.
pool. Even with these concerns, though, our results demonstrate a consistent difference according to musical training in an attribute that is more typically presented as a universal trait in healthy populations. Ongoing scientific interest both in the global-local distinction and in cognitive changes associated with musical training suggests that these results may bear on a wide range of investigations and may specifically help future studies of auditory processing avoid a confound of participant expertise.

## Acknowledgments

The authors would like to express our gratitude to Lisa Sanders for sharing stimuli and helpful feedback, and to John Limber for improving an earlier draft of this submission.

# Visual Strategies in Analogical Reasoning Development: A New Method for Classifying Scanpaths 

Yannick Glady, Jean-Pierre Thibaut, Robert French<br>\{yannick.glady, jean-pierre.thibaut, robert.french\}@u-bourgogne.fr LEAD-CNRS, UMR 5022, University of Burgundy, Pôle AAFE - Esplanade Erasme<br>21065 DIJON. FRANCE

#### Abstract

Development of analogical reasoning is often explained by general maturation of executive functions. A consequence of the involvement of executive functions would be that children and adults differ in the visual strategies they apply when solving analogical problems. Since visual strategies can be studied by means of eye-tracking, we compared the visual scanpaths of children and adults in three different analogical reasoning tasks. This comparison was done by means of a novel technique that combined a recently developed algorithm for computing a "distance" between any pair of scanpaths (Jarodzka, Holmqvist, \& Nyström, 2010), multidimensional scaling (MDS), and a neural network classifier. This analysis clearly showed a difference between adults' and children's visual strategies in solving analogy problems. We focus both on the demonstration that adults and children employ different visual search strategies to solve analogy problems and on the novel technique used to do this. This general technique complements other approaches to eye-movement analysis that rely on local properties of scanpaths, in particular, itemfixation times.

Keywords: Analogical reasoning; development; eye-tracking; strategies.

## Introduction

Analogical reasoning is a ubiquitous process in thinking and reasoning (Gentner \& Smith, 2012; Holyoak, 2012). It can be defined as a comparison of two domains (the source and the target domains) on the basis of their respective relational structure (Gentner, 1983). Studies of analogy making have explored two main explanations for its development, increase of structured knowledge (Gentner \& Rattermann, 1991; Goswami, 1992) and maturation of executive functions (Halford, 1993; Richland, Morrison, \& Holyoak, 2006; Thibaut, French, \& Vezneva, 2010a, 2010b). One important prediction of the executive-function view is that children and adults use different strategies when solving analogy problems. The present study addressed this question by means of a combination of a recently developed algorithm (Jarodzka et al., 2010) for comparing visual scanpaths from an eye-tracker, multi-dimensional scaling (MDS), and a neural net classifier. This technique allowed us to give an affirmative answer to the central question of this paper - namely, whether or not children's analogy strategies are quantifiably different than those of adults.

## Background

Humans rely heavily on vision for virtually every task they do (e.g. categorization, spatial orientation, problem solving, etc.) and it remains a privileged way of acquiring information about the environment. In the case of problem solving, what information is sought and how this search is organized through time to come to a solution for the problem (i.e. visual strategies) may help researchers understand which solving strategies are used. Attention and gaze-fixation are highly correlated, especially for complex stimuli (Deubel \& Schneider, 1996; He \& Kowler, 1992) and the fixation time for a given object is correlated with its informativeness in a scene (Nodine, Carmody, \& Kundel, 1978). This argues in favor of studying eye-movements as indicators of the application of a specific strategy through control of attention.

Eye-tracking data, especially if they involve scanpaths i.e., the complete visual trajectory of a participant's eye movements during the task - are often complex and hard to analyze. For this reason scanpath information is often reduced to static information about the participant's gaze times at specified locations. This simplification, while certainly easier to analyze, generally fails to fully capture the temporal aspects of the data involved in visual strategies. Even when an attempt is made to take into account temporal aspects of the data, it is often difficult to compare two scanpaths because, in general, they differ in length and complexity. Jarodzka et al. (2010) have developed a method that is able to compare any two scanpaths. As the Jarodzka et al. algorithm plays a key role in the analysis that follows, we will describe our variant of this algorithm in some detail below. We combined this scanpath-comparison algorithm with multidimensional scaling and a neural-network classifier to demonstrate that children's analogy-making strategies, as reflected in their visual search patterns across three different problems, are measurably different from those of adults.

We are not the first to use eye-tracking technology to study analogy making, but this type of analysis is, nonetheless, still in its infancy. Eye-tracking techniques were first used by Bethell-Fox, Lohman, \& Snow (1984) to study strategies when reasoning by analogy. They found strategic differences in adults with high or low fluid
intelligence when solving geometric A:B::C:? problems. More recently, Gordon \& Moser (2007) investigated adults' strategies in scene analogy problems. Thibaut, French, Missault, Gérard, \& Glady (2011) also used an eye-tracker to examine infants' gaze locations and item-to-item transitions during an analogy task. However, all of these studies focused on what information was searched for by participants as they attempted to solve the analogy problem.

None of this research compared participants' global scanpaths. In other words, previous eye-tracking studies have focused on local aspects of participants' scanpaths as a means of revealing part of the dynamics of visual search in doing analogy problems. By contrast, in the present study we will use participants' global scanpaths in our attempt to respond to the question of whether children have different visual search strategies than adults when solving visual analogy problems. Woods et al. (2013) showed that the organization of search in visual-attention tasks becomes less variable over the course of development. Because the tasks we used rely on visual attention, we expected children to have more variable scanpaths than adults.

## Experiment

## Methods

## Participants

Subjects were 20 adults ( 14 females, 6 males; mean age $=20 ; 5$ years; $\mathrm{SD}=2.21$; range: 17 to 27), students at the University of Burgundy and naïve to analogical reasoning tasks and 266 -year-olds ( 16 females, 10 males; mean age= 79.5 months; $S D=3.6$; range: 73 to 84 ). For children participating in this experiment, parents' informed consent was required from their parents.

## Materials

Three tasks, each composed of three training trials and four experimental trials, constituted the experiment (see Figure 1). The first task was a scene analogy problem task, the second a standard $\mathrm{A}: \mathrm{B}:: \mathrm{C}:$ ? task and the third an $\mathrm{A}: \mathrm{B}:: \mathrm{C}:$ ? task with the items composing the problems put within a context. Each problem of each task was composed of 7 black and white line drawings.

In the scene analogy problems, the top scene was composed of two elements depicting a binary semantic relation (e.g. a cat chasing a mouse). One of these two elements had an arrow pointing to it. The bottom scene was composed of five drawings: the two elements depicting the same relation as in the top picture (e.g. a boy chasing a girl), a distractor item, and two elements that were consistent with the scene but that had no salient relation with the elements of the relation. These pictures (501x376 pxs) were based on Richland et al., (2006) except for the distractor that was chosen not to be perceptually, only semantically, related to one member of the relation in the bottom picture.

In the standard $\mathrm{A}: \mathrm{B}:: \mathrm{C}:$ ? trials, the $\mathrm{A}, \mathrm{B}, \mathrm{C}$ drawings were presented in the top row along with a black empty square symbolizing the location of the solution. The four remaining pictures (the Target, a Related-to-C Distractor, and two Unrelated Distractors) were presented in a row at the bottom of the screen. The size of each picture was 200 x 195 pxs. The A:B::C:? task within context was constituted of two scenes ( 501 x 376 pxs ). The top picture was composed of two black and white line drawings with a relation between them (e.g. a wolf and meat, with the wolf looking at the meat) with a contextual cue (e.g. a horizontal line for the horizon or the lines of the joining walls and floor for a room). The bottom picture was composed of the five remaining drawings: the C term, the Target, the Related-to-C Distractor and the two Unrelated Distractors. This task differed from the first task in that it was the C term that was

Figure 1. Presentation of the three tasks used for this experiment: a) scene analogy task, b) standard $\mathrm{A}: \mathrm{B}:: \mathrm{C}:$ ? task, c) sceneoriented A:B::C:? task
pointed at with an arrow, and not one of the elements constituting the source relation. It differed from the second task because of the different pictures constituting the problems being grouped in two scenes, but equivalent to the standard $\mathrm{A}: \mathrm{B}:: \mathrm{C}:$ ? task in other respects.

The materials of the last two tasks were based on materials previously used by Thibaut et al. (2011). The four trials of each task were two trials with weak association strengths between A and B, C and T, and C and Dis, and two with strong association strengths in order to equilibrate this factor.

The tasks were displayed on a Tobii T120 eye-tracker device with a $1024 \times 768$ screen resolution.

## Procedure

Appropriate controls were carried out to ensure that the participants knew what the items in each of the problems were and that they understood the instructions. In the first task, they were asked to point to the element in the bottom scene that played the same role as the one which had an arrow pointing to it in the top scene. The two others tasks were administered as in Thibaut et al. (2011). Eye-tracking data was gathered from moment of the initial presentation of the problem to the moment a choice of one of the answers was made. The participant's scanpath for a particular problem consisted of a record of his/her gaze-fixation points taken every 8 ms .

## Data Analysis

Figure 2. Simplification of a scanpath
The goal of this analysis is to compare the sets of children's and adults' scanpaths and to show that there are quantifiable differences in the two. To do this we use a combination of (a variant of) Jarodzka et al.'s (2010) scanpath-comparison algorithm, multidimensional scaling and a neural-net classifier. As the latter two techniques are well known, we will not discuss them at length. However, the Jarodzka et al. algorithm is relatively recent and requires explanation.

## Jarodzka et al. (2010) scanpath-comparison algorithm

The algorithm is designed to determine the similarity of any two scanpaths. It consists of two phases, a simplification
phase and a comparison phase. A scanpath is considered to be made up of a series of "saccade vectors," i.e., a connected series of vectors whose endpoints correspond to coordinates of successive gaze points (Figure 2a). First, the scanpath is simplified by combining into a single vector two consecutive saccade vectors if:
i) their combined length does not exceed 200 pixels in amplitude (i.e., each is very small) and
ii) they are nearly in straight line (i.e., the angle between them is between 2.62 and 3.67 rad ).
In other words if a saccade vector is very small or very linear with respect to its predecessor in the scanpath, the two vectors are combined (Figure 2b).

Once each of the two scanpaths has been simplified, they can be compared. We begin by giving an intuitive explanation of how this is done. Assume, for example, there are two simplified scanpaths, $S_{1}$ and $S_{2}$ made up of 3 and saccade vectors, respectively. In other words, $S_{1}=\left\{u_{1}, u_{2}\right.$, $\left.\mathrm{u}_{3}\right\}$ and $\mathrm{S}_{2}=\left\{\mathrm{v}_{1}, \mathrm{v}_{2}, \mathrm{v}_{3}, \mathrm{v}_{4}\right\}$. Note that these saccade

a) |  | $\boldsymbol{v}_{1}$ | $\boldsymbol{v}_{2}$ | $\boldsymbol{v}_{3}$ | $\boldsymbol{v}_{4}$ |
| :---: | :---: | :---: | :---: | :---: |
| $\boldsymbol{\mu}_{1}$ | $\Delta\left(\mathrm{u}_{1}, \mathrm{v}_{1}\right)$ | $\Delta\left(\mathrm{u}_{1}, \mathrm{v}_{2}\right)$ | $\Delta\left(\mathrm{u}_{1}, \mathrm{v}_{3}\right)$ | $\Delta\left(\mathrm{u}_{1}, \mathrm{v}_{4}\right)$ |
| $\boldsymbol{\mu}_{2}$ | $\Delta\left(\mathrm{u}_{2}, \mathrm{v}_{1}\right)$ | $\Delta\left(\mathrm{u}_{2}, \mathrm{v}_{2}\right)$ | $\Delta\left(\mathrm{u}_{2}, \mathrm{v}_{3}\right)$ | $\Delta\left(\mathrm{u}_{2}, \mathrm{v}_{4}\right)$ |
| $\boldsymbol{\mu}_{3}$ | $\Delta\left(\mathrm{u}_{3}, \mathrm{v}_{1}\right)$ | $\Delta\left(\mathrm{u}_{3}, \mathrm{v}_{2}\right)$ | $\Delta\left(\mathrm{u}_{3}, \mathrm{v}_{3}\right)$ | $\Delta\left(\mathrm{u}_{3}, \mathrm{v}_{4}\right)$ |

b)

Figure 3. Saccade-vector difference table (a): Each of the saccade vectors from each of the two scanpaths are compared based on the chosen metric. (b) The comparison of each pair of stretched scanpaths corresponds to a traverse of the table from the upper-left to the lower-right corner of the saccade-vector difference matrix (the only directions of movement permitted are down, right and diagonally down-and-right). We find the path that produces the lowest total difference value and this value is the similarity measure assigned to $\mathrm{S}_{1}$ and $\mathrm{S}_{2}$
vectors are ordered in time. For example, in $\mathrm{S}_{1}$, the saccade vector $u_{1}$ is followed by $u_{2}$, which is followed by $u_{3}$. To compare $S_{1}$ and $S_{2}$, we need two scanpaths of the same length. To achieve this, we will "stretch" each scanpath by adding immediate repetitions of saccade vectors, so that
they both have the same length. Our goal is to find the two stretched scanpaths, $\mathrm{SS}_{1}$ and $\mathrm{SS}_{2}$ that are as similar as possible with respect to the chosen metric (orientation, length, etc.). This similarity will be the measure of the distance between $S_{1}$ and $S_{2}$.

The easiest way to illustrate this stretching is by means of a saccade-vector difference table for the two scanpaths, $\mathrm{S}_{1}$ and $S_{2}$, defined above.

A saccade-vector difference matrix is first created (Figure 3a). Each of the saccade-vectors making up one of the scanpaths $S_{1}$ is compared to each of the saccade-vectors of the other scanpath $\mathrm{S}_{2}$, according to a metric, generally, vector magnitude or orientation (length in our study). Once this table is constructed, we consider all paths through the table that begin with the comparison of the first saccade vectors in both scanpaths (i.e., cell $(1,1)$ of the table, $\Delta\left(\mathrm{u}_{1}\right.$, $\left.\mathrm{v}_{1}\right)$ ) and end with a comparison of the final saccade vectors in each scanpath (i.e., cell $(3,4)$ of the table, $\left.\Delta\left(u_{3}, v_{4}\right)\right)$ and always move to the right, down, or diagonally down-andright. Three examples of paths through the matrix are illustrated in the right-hand panel of Figure 3. Each path through the table corresponds to the comparison of two specific stretched scanpaths. For example, the uppermost path shown corresponds to a comparison between $\mathrm{SS}_{1}=\left\{\mathrm{u}_{1}\right.$, $\left.\mathrm{u}_{1}, \mathrm{u}_{1}, \mathrm{u}_{2}, \mathrm{u}_{2}, \mathrm{u}_{3}\right\}$ and $\mathrm{SS}_{2}=\left\{\mathrm{v}_{1}, \mathrm{v}_{2}, \mathrm{v}_{3}, \mathrm{v}_{3}, \mathrm{v}_{4}, \mathrm{v}_{4}\right\}$. This path corresponds to the sum of the values in the cells $(1,1),(1,2)$, $(1,3),(2,3),(2,4),(3,4)$ of the saccade-vector difference matrix. When all of these paths through the matrix are considered, the path which has the smallest value (i.e. the smallest cumulative sum of comparisons) is selected. This path corresponds to the two stretched scanpaths that are the most similar. This value, normalized by the number of comparisons done, is the similarity measure assigned to the comparison of scanpaths $\mathrm{S}_{1}$ and $\mathrm{S}_{2}$.

Note that the algorithm as described here differs from Jarodzka et al. (2010) in that it does not rely on the more complex Dijkstra (1959) tree-search algorithm. Instead, we constructed a matrix, cell by cell, with the lowest cumulative sum of comparisons possible for each cell while taking into account the constraints put on the comparisons of the two scanpaths (navigate rightward, downward, or diagonally downward and to the right). In our example, the final distance value between $S_{1}$ and $S_{2}$ is the cumulative sum in $\mathrm{C}(3,4)$ normalized by the number of steps taken through the matrix. This algorithm was computationally less complex for identical results.

The Jarodzka et al. (2010)/MDS/MLP algorithm applied to scanpaths of analogy problems

We only compared the scanpaths from strictly identical problems, but not different trials from the same task. Thus, when we were comparing an adult scanpath and a child's scanpath, the disposition of the items in the problem they were solving was identical.

In this way, for a given set of isomorphic problems (i.e., where all of the items were in identical places on the screen), we computed the differences between all pairs of scanpaths. In other words, if there were $S_{1}$ to $S_{n}$ scanpaths from children and $A_{1}$ to $A_{m}$ scanpaths from adults on the same set of isomorphic problems, we computed the similarity of all pairwise comparisons of scanpaths $S_{i}$ versus $\mathrm{S}_{\mathrm{j}}, \mathrm{S}_{\mathrm{i}}$ versus $\mathrm{A}_{\mathrm{j}}$, and $\mathrm{A}_{\mathrm{i}}$ versus $\mathrm{A}_{\mathrm{j}}$ for all $i$ and $j$.

Once we had calculated the mean differences between scanpaths generated by each participant in each task, we used Multidimensional Scaling to obtain the coordinates on a 2D map that best preserved the distance between scanpaths. As can be seen in Figure 4, for each of the three tasks, the scanpaths clustered according to participant type (Adult or Children). We verified this clustering using a 3layered perceptron (MLP) with a bias node on the input and hidden layers ( 5 hidden units, learning rate $=0.05$, momentum $=0.9$ ) with the coordinates of each scanpath on the MDS map translated into bipolar values and concatenated on input. We used a Leave-One-Out crossvalidation technique to test the robustness of the classification. Leave-One-Out cross-validation is a standard technique in machine learning whereby the classifier (in this case a neural network) is trained on all items but one. Once training is complete, the classifier is tested on the item that had been left out to see whether or not it is classified correctly.

## Results

Using the method of analysis described above, we did a pairwise comparison of all scanpaths generated by adults and children on isomorphic analogy problems. We then conducted a multi-dimensional scaling analysis of this data, which produced the location-map clusters shown in Figure 4. These points are a 2D representation that best reflects the distances between the scanpaths. The crosses correspond to children's scanpaths; the circles correspond to adults' scanpaths.

## Classification of adults' versus children's scanpaths

The Jarodzka et al. (2010) method along with Multidimensional Scaling led to a 2D location map that best represented the relative distances between the set of scanpaths, as calculated by the Jarodzka et al. algorithm (Figure 4). A three-layered feedforward backpropagation network (MLP) with a Leave-One-Out cross-validation method, was used to test the robustness of a classification of the points representing the two groups (i.e. children and adults). For the scene analogy and $\mathrm{A}: \mathrm{B}:: \mathrm{C}:$ ? tasks (Figure 1a and 1b), the network classified $74 \%$ of the participants correctly based on their scanpath ( $70 \%$ of the 20 adults and $78 \%$ of the 23 children for both tasks). For the real-world A:B::C:? task, the network classified $72 \%$ of the subjects correctly ( $65 \%$ of the adults and $78 \%$ of the children). This
was significantly above chance (50\%) for each task (binomial test: $\mathrm{Z}=14.89 ; \mathrm{p}<.001$ for the first and second; $\mathrm{Z}=14.30$; $\mathrm{p}<.001$ for the third). Intuitively, this result can be

b)

c)

Figure 4. Location-map of an MDS analysis of the relative differences among participants for the scene analogy task (a), the standard $\mathrm{A}: \mathrm{B}:: \mathrm{C}:$ ? task (b), and the scene-oriented A:B::C:? task (c).
seen in Figure 3. The adult group tends to be more homogenous than the children as the crosses (children's scanpaths) are more scattered than the circles (adults' scanpaths), and this is reflected in the high degree of accurate classification of the MLP.

## General discussion

The present study addressed the following question in a novel manner: Do children and adults have different visual strategies in analogical reasoning tasks? To answer this, we used an eye-tracking methodology whose data were analyzed by a combination of the Jarodzka et al. (2010) scanpath-comparison algorithm, the transformation of this data into a 2D location map using multidimensional scaling, and, finally, a quantitative adult/child classification by means of a feedforward backpropagation network. The neural-net classification was done by training the network on the scanpath data for all but one participant. Once the network was trained, it was tested on the one scanpath that was left out of the training set. This was done for each participant's scanpath data and the result was scored according to whether the network classified the test scanpath correctly or not. The results obtained with this method agree with previous results from Thibaut et al. 2011 who also showed, by analyzing item gaze times and the number of transitions between items that adults and children differed in their search strategies in the standard $\mathrm{A}: \mathrm{B}:: \mathrm{C}:$ ? analogy task. The present work, using an approach based on individuals' entire scanpaths, also extends this previous work to scene analogy problems and scene-oriented A:B::C:? problems. This scanpath analysis showed, among other things, that children's scanpaths were more variable than those of adults in the three tasks. These differences support the hypothesis of the key role of executive functions in analogy making because the lower variability of adults' scanpaths is indicative of them applying, through control of attention, a previously adopted plan for solving analogy problems (Woods et al., 2013)

The scanpath analysis presented in this paper provides a means of studying various search strategies in analogy making. The technique presented in this paper overcomes thorny problem of comparison of scanpaths of different lengths and allows to take into account the dynamic features of search, which are largely missed in other, more static eye-tracking approaches based on item fixation times. It could also be used, for example, to confirm differences in analogy-making strategies observed in adults in Bethell-Fox et al. (1984) and to classify participants based on their scanpath data (i.e., "elimination strategies" for participants with low fluid intelligence and "constructive matching strategies" for participants with high fluid intelligence). This method is, of course, not limited to studies of analogymaking, and could be used with any other type of problems whose crucial information for its solution could be presented on a screen.

## Conclusion

The method of scanpath analysis presented in this paper provides a new tool to analyze the dynamic aspects of search strategies in a wide variety of experimental contexts. As shown by the results, this method is sensitive to global differences between scanpaths and is useful to discriminate clusters of strategies. In this paper it has been used to show that children's and adults' differ in their variability while solving analogical reasoning problems, suggesting the involvement of executive functions in such tasks. However, to fully understand the causes of these differences, it is inevitable to use local information. Thus, it should be used in combination of other existing methods, in particular, Area-of-Interest (AOI) methods that provide information on what information is sought and how long it is watched (informativeness of stimuli), since this information is not captured by the Jarodzka et al. method. On the other hand, AOI methods give limited information about the dynamic progression of search, something which is captured when full scanpath information is used. In short, the Jarodzka et al. (2010), combined with an MDS analysis and a classifier (backpropagation networks, Support Vector Machines, etc.), provides a potentially far-reaching tool for analyzing participants' dynamic strategies in various problem-solving contexts.

# A Critical View on Conceptual Blending Theory 

V.V. Glebkin (gleb1514@gmail.com)<br>Gymnasium 1514, 12 Krupskoi Street Moscow, 119311 Russia

#### Abstract

This study addresses conceptual blending theory, originated by J. Fauconnier and M. Turner. The author raises some criticism of the theory's underpinnings and methodology. Particularly, he points at the lack of cultural-historical analysis and the neglect of experimental data as the shortcomings of the theory as stated. It is shown in the paper that the view on blending as an important tool to adapt knowledge to the experience of average people is more correct than its interpretation as a basic instrument for the creation of new knowledge.

Keywords: conceptual blending; criticism; cultural-historical approach; popularization.

## Introduction

Conceptual blending (or conceptual integration) theory is, without a doubt, one of the central conceptual pillars of modern cognitive linguistics, and it has considerable influence on cognitive science in general. According to the authors, J. Fauconnier and M. Turner, conceptual blending is "a great mental capacity that, in its most advanced "doublescope" form, gave our ancestors superiority and, for better and for worse, made us what we are today. We investigate the principles of conceptual blending, its fascinating dynamics, and its crucial role in how we think and live" (Fauconnier, Turner 2002, V; for an extended commentary see: ibid., 389-396). In other words, conceptual blending here is claimed to be the key to the mystery of human evolution and cognition.

At first sight, such a groundbreaking point would be expected to lead to an intensive debate and to meet strong criticism from the less radical researchers. However, in fact, there are no heated debate around conceptual blending theory. We can find a number of papers raising some objections (Gibbs 2000; Harder 2003; Brandt 2005; Oakley, Hougaard 2008, 12; Ferguson, Sanford 2008, 610), but a comprehensive analysis of the theory's underpinnings, methodology, and heuristic potential is a matter of the future. This paper can be considered as a step in that direction.

## Theoretical underpinnings and structure of conceptual blending theory

Although this may be familiar information to some of readers, I will start with a coarse-grained description of the Fauconnier and Turner's attitudes. It allows more relevant understanding of my criticism in the second part of the paper. To be sure, some aspects of conceptual blending theory were touched earlier, but its first systematic description holds, presumably, in Fauconnier, Turner 1994.

Fauconnier, Turner 1996; Fauconnier, Turner 1998; Fauconnier, Turner 2000; Sweetzer 2000; Fauconnier, Turner 2002; Fauconnier, Turner 2008; Fauconnier 2009 should be mentioned as the salient milestones in the theory's development.

The gist of the theory can be formulated as follows: a) the unique feature of human beings is the capacity to create new meanings from existing ones; $b$ ) the main way to implement this capacity is to perform double-scope blending, that is, to build an integrated mental space on the base of a number of input spaces.

A star example illustrating that point is the Buddhist Monk riddle: "A Buddhist monk begins at dawn one day walking up a mountain, reaches the top at sunset, meditates at the top overnight until, at dawn, he begins to walk back to the foot of the mountain, which he reaches at sunset. Make no assumptions about his starting or stopping or about his pace during the trips. Riddle: is there a place on the path that the monk occupies at the same hour of the day on the two separate journeys?" (Fauconnier, Turner 2002, 39).

This riddle has an elegant solution if we imagine the monk strolling up and down on the same day, in other words, combine both walks. In such a blended space the monk is to meet himself and that place is the positive answer to the riddle question. The authors illustrate the solution with the following schema:

Fig. 1. The basic schema of the Buddhist Monk riddle (Fauconnier, Turner 2002, 45)

We can see here the two input spaces (the day of climbing on and that of climbing down), blended space and generic space, containing "what the inputs have in
common: a moving individual and his position, a path linking foot and summit of the mountain, a day of travel, and motion in an unspecified direction" (ibid., 41)).

Another striking example is "The Debate with Kant" ${ }^{1}$. Authors suggest to imagine a contemporary philosopher discussing the issue whether reason is innate capacity when leading a seminar. During that dispute he appeals to Kant as his opponent, namely, states his point, then poses hypothetical objections retrieved from Kant's treatises, then again come up with his own counterarguments, etc. For the audience it looks as face-to-face debate of two modern scholars. For the authors we have here the two input spaces connected with modern philosopher making claims in English and with Kant thinking and writing German. In the blend we find two philosophers speaking English to discuss ultimate philosophical problems. Thus, the blended space emergent structure in some aspects differs from that of input spaces radically reflecting the novel mental (but not ontological) reality.

The next example is so called Regatta. The backstory for it holds such facts: "The clipper ship Northern Light sailed in 1853 from San Francisco to Boston in 76 days, 8 hours. That time was still the fastest on record in 1993, when a mod-catamaran, Great American II, set out on the same course" (ibid., 63). According to authors, "a few days before the catamaran reached Boston, observers were able to say: At this point, Great American II is 4.5 days ahead of Northern Light" (ibid.). This sentence constructs blended space in close similarity with the Buddhist Monk riddle; like two monk trips above, two 140 -yeardistanced voyages are combined into a novel event, in this case, into the boat race. Such time scale compression paves the way for a pictorial perception of two voyages just as "The Debate with Kant" blend provides the audience's emotional engagement in the process of philosophical reasoning.

How wide the field covered by conceptual blending theory is, can be illustrated with two examples below. The first one is complex numbers, the second one is the computer desktop. As is well-known, complex numbers, expressed in the form $a+b i$, can be viewed as points or position vectors in a two-dimensional coordinate system called the complex plane where the real part of a number is represented with the horizontal projection, and the imaginary part with the vertical one. The authors suppose this representation to be the blend, where the first input space holds points in oriented plane with its vector transformations, whereas the second one contains real numbers with operations of addition and multiplication. The generic space in this case holds commutative ring operations on pairs of elements. In that perspective the blended space have a number of new features with regard to input ones (unlike real numbers there is not an order relation between two complex ones; unlike points and vectors complex numbers can be multiplied and divided by each other). So, for

[^278]authors, conceptual blending is an important tool used to create the new knowledge in mathematics (see also Alexander 2011).

A computer desktop, for authors, is the blend of our day-to-day experience space (where we open folders to place or extract documents, throw old folders into a trash can, etc.) and space of formal operations performed in a computer (an abstract language of computer commands which correspond to virtual motions in the blend). In this case, again, the structure of the blend has obvious novelty as compared with input spaces.

Conceptual blending, the authors state, is an important tool to create novel grammatical and lexical constructions in language. Thus, the construction Noun-Phrase Verb Noun-Phrase Prepositional-Phrase, found in a great number of languages to express caused motion, is a conceptual blend of two different actions (e.g., Jack threw the ball into the basket includes three steps: Jack acts on the ball; the ball moves; the ball is in the basket. The blend combines the beginning and the end of the action, omitting the middle part). In some languages, like English, it can be extend to some other classes of action, e.g., Anna sneezed the napkin off the table or The commander let the tank into the compound, etc. (Fauconnier, Turner 1996; cf. Mandelblit 2000).

Such figures of speech as metaphor and metonymy are also blends, according to the authors. They describe highly conventional source-target metaphors as singlescope networks, where the integrated space frame is supplied by only one input space; e.g., Murdoch knocked Iacossa out for companies Murdoch and Iacossa. The integrated space here is a blend of a boxing match and business competition, but the blend topology has no in common with business, it is completely defined by the boxing space frame (Fauconnier, Turner 2002, 126-129).

Meanwhile, only a narrow class of metaphors can be represented by single-scope networks. For instance, this representation is impossible for the expression digging one's own grave (e.g., They dug their own financial grave). In this case the blend inherits the structure from "digging the grave" and "unwitting failure" inputs. However, in the blend the input frames are not simply juxtaposed; the emergent structure is radically different from both of them in some aspects. Thus, in "digging the grave" space people dig the grave not for themselves, but for other people, who have already died. Furthermore, this action here is not a big blunder as opposed to the blend frame. In a similar vein, unwittingly failed (particularly, in the financial sphere) person is unlikely to operate with a real spade as his counterpart in the blend.

This type of integration frame entitled double-scope network characterizes, as mentioned, the unique human capacity distinguished human beings from other species. They date the emergence of this capacity to the epoch about 50,000 years ago and draw the birth of religion, art and language as a conclusion (ibid., 180-187). The gist of their argumentation can be formulated in the form of the following syllogism: a) the general process to provide the
human culture development is the emergence of novel conceptual structures on the base of existing ones; b) in doublescope networks the emergent blend structure has a novel quality with regard to the input spaces; hence, c) doublescope conceptual integration can provide the development of a wide range of cultural forms created by humans.

It is noteworthy that Fauconnier and Turner don't analyze concrete data to argue for this point, and their approach looks a bit like an "ivory tower" theory. At the same time such analysis can be found in the papers of other researchers working within Fauconnier and Turner's paradigm, particularly, in Sweetser 2000. In her work the author describes a hypothetical buffalo hunting ritual where primitive hunters perform a ritual dance in order to provide success in a real hunt in the future. In accord with Sweetser's views, such a ritual is a blend "between (Input 1) the ritual setting and participants and (Input 2) a hunting scene and its participants" (ibid., 319). The blended space holds the new elements which have no counterpart in the input spaces; a buffalo rock painting is transformed here into a real buffalo which is struck in the ritual dance, etc.

A researcher working with blending as a real cognitive process encounters the two general questions: which phases does this process have in on-line regime and what are the criteria to select the elements in the input spaces for the projection into the blend. Fauconnier and Turner try to tackle these issues, although it is hard to say if they are clear about that.

According to authors, "there are three operations involved in constructing the blend: composition, completion, and elaboration" (Fauconnier, Turner 1998, 144). The first stage is characterized by composing the blend from the elements of input spaces; then, the blend is completed with a great range of background conceptual structure; and on the last stage it is developed "through imaginative mental simulation according to principles and logic in the blend" (ibid.). The model described, however, did not rest on any experimental data and it is a problem to check whether it holds water.

With regard to the second issue the authors speak about constitutive and governing principles of conceptual integration. The first ones are connected with the general laws of logic and the rules of language, the second ones are more flexible and not so strictly defined. The authors mark out the overarching goal driving all of the governing principles: Achieve Human Scale, and several subgoals, namely, Compress what is diffuse; Obtain global insight; Strengthen vital relations; Come up with a story; Go from Many to One. Alongside with that, they suggest a number of more concrete principles, such as, Topology Principle ("Other things being equal, set up the blend and the inputs so that useful topology in the inputs and their outer-space relations is reflected by inner-space relations in the blend" (Fauconnier, Turner 2002, 327)) or Integration Principle ("Achieve an integrated blend" (ibid., 328)), etc. Again, the algorithm of applying these principles to particular cases is not transparent; e.g., it is not clear how to find out if topology is useful or not.

Given the overview of conceptual blending theory as completed here, let us move on to the next step.

## Some objections against conceptual blending theory

There are three aspects of conceptual blending theory as stated to be cast in doubt.
A) Contrary to Fauconnier and Turner's interpretation, almost all examples they suggest are connected with the form the conceptual operations are presented in, but not with their essence (the only exception is, perhaps, the quite specific Buddist Monk riddle). The main task of the blend in the examples given is to represent conceptual structure in a convenient, compact, familiar for an average person form; in other words, to provide its popular presentation ${ }^{2}$. The direct link between the popularization and conceptual blending is clear in the popular science literature, where extremely abstract ideas are represented in the form of visible images to be processed by the less educated audience. The S. Hawking's analogy between balloon in which cover tension holds air pressure within it and star where the gravitational interaction between atoms are balanced by the star gas pressure is a classic blend from conceptual blending theory perspective (the input space-1: a balloon, located near the earth's surface; a rubber cover; gas within the balloon; the input space-2: a star; helium and hydrogen atoms within the star; the blend: the star is a balloon with heated air inside, situated among other stars).

Another striking example of such "popular science blend" was suggested by A. Einstein to explain the space curvature in the general theory of relativity. It is the analogy between hypothetical "flat beings" existing in two dimensions and humans living in the three-dimensional space. The "flat beings" are able to perceive the line curvature, but not the space one; the humans can comprehend the curvature of the plane, but the curvature of the space is beyond their comprehension. The blend here holds human beings living inside the plane.

Let us now look from this perspective at Fauconnier and Turner's examples described above. Given "The Debate with Kant" story, the emergence of the blend has no impact on the essence of the problem discussed (in this case, as mentioned, the question whether reason is innate capacity). Such a debate could be held with another philosopher who shared Kant's ideas or, say, in inner dialog of the philosopher with himself. The format described by the authors gives the opportunity to adopt the disputed issue to the audience; it is a "pedagogical trick" transforming an abstract philosophical matter into a kind of

[^279]performance, in other words, coming up with a story.
The "Regatta" example has the same structure. The blend gives here a visible and attractive picture of the events, while touching no ground or even distorting their ground (thus, it is not clear, if the context of the regatta described is relevant to the clipper Northern Light, which goal it pursued during the voyage from San Francisco to Boston, etc.).

The computer desktop example is consistent with the ones examined above. The emergence of the blend helps an average user to work with a computer because it transforms an abstract machine language into the set of objects from his day-to-day experience. Here again we deal with the adaptation of the conceptual structure to the cognitive horizon of the lay observer.

The "complex numbers" case, which is, perhaps, the strongest argument for blending as creation of novel conceptual knowledge, rests on misunderstanding. Complex numbers, as mentioned, are an ordered pair of real numbers which can be represented as a point in oriented plane. However, real numbers can also be represented as a point in oriented line or as a vector which reference point coincides with the origin of coordinates. We can only wonder why the authors address such representation for complex numbers and don't apply it to real ones. A geometric representation of complex numbers is in demand much less than an algebraic or a trigonometric one. The gist of complex numbers has no connection with properties of points in oriented plane or plane vectors. The gist of complex numbers as expansion of real numbers is determined by introducing "imaginary unit" $\boldsymbol{i}(\boldsymbol{i}=\sqrt{ }-1)$ and by a lot of interesting properties connected with that. The analogy with points in plane provides visual image for complex numbers; hence, this case is situated in line with the ones examined above.

The construction Noun-Phrase Verb Noun-Phrase Prepositional-Phrase works, by and large, in the similar direction. Omitting middle links and pointing out only the beginning and the end of the process offer a more visible and dynamic process description which facilitates its perception.

To sum up my contention here, I would like to get to the general point: blending can not provide the emergence of new conceptual knowledge; its function is to adapt existing knowledge to the needs of average people. To consider blending as great mental capacity, which brought about the emergence of various forms of culture, means to put shoes on the wrong foot.
B) The lack of cultural-historical analysis is the next defect of the Fauconnier and Turner's approach. In order to illustrate that let us return to the metaphor digging one's own grave. This expression is likely to appear in different languages in the first decades of the $20^{\text {th }}$ century. According to The Oxford English Dictionary, its earliest example dates back to 1934. Similarly, in Russian language it arises as metaphor in the $1920^{\text {th }}$ alongside with its emergence in direct meaning (e.g., Chasto jertvy prinujdalis' ryt' sebe sami mogilu (Often victims were forced to dig their own grave,
1924)). If it is so, we can suppose that the metaphor digging one's own grave came into being as the comprehension of the new social experience of the first quarter of the $20^{\text {th }}$ century, reflected by literature and language. The picture of people digging their own graves at gun point turned out so vivid and emotionally affecting that it entailed its expansion in other regions. Given this assumption is correct the metaphor structure proves to radically differ from the authors' description. To be sure, we can find here double-scope blending (a man digging his own grave at gun point performs this action by necessity, whereas a man plunging into financial adventure operates by choice; so, it is not fairly correct to speak about direct mapping of the "digging" input space onto the blend), but the other thing is important. Importantly, this or that construction emerges in the here and now, but not in the transcendental reality; in that, its emergence is brought about by socio-cultural shifts, but not by abstract schemas like one suggested by Fauconnier and Turner.
E. Sweetser's interpretation of the buffalo hunting ritual is, perhaps, even a more representative example of distortions influenced by eliminating socio-cultural aspect from the analysis. In order to argue that we need to address the school of cultural-historical psychology and, particularly, the concept complex thinking originated by L. Vygotsky (Vygotsky 1986). The Russian psychologist defined complex as a structure where the bonds between its components are contextual and flexible rather than abstract and fixed. He illustrated his approach with the striking Darwin's example: «A child's use of 'quah' to designate first a duck swimming on the pond, then any liquid, including the milk in his bottle; when he happens to see a coin with an eagle on it, the coin is also called a 'quah', and then any round, coinlike object. This is typical of a chain complex ${ }^{3}$ - each new object included has some attribute in common with another element, but the attributes undergo endless changes» (ibid., 127). When thinking in complexes a child keeps in mind the same objects as an adult (which provides the right communication between them), but his way of operating these objects, and his mental schemas are radically different.

Given this concept as the ground, Vygotsky, among other things, explained the French cultural anthropologist L. Lévy-Bruhl's account of Bororo (the tribe of Northern Brazil) views which sounded counter to Aristotelian logic (Lévy-Bruhl 1978, Lévy-Bruhl 1979). For instance, the Bororo (the tribe in Northern Brazil) boasted that they were red araras (parakeets), which did not merely signify that they would become araras after their death, or that araras metamorphosed the Bororo, but they claimed that they were araras at the current time, which was their actual identity. Levi-Bruhl defined this operation as the law of participation and such way of reasoning as pre-logical thinking.

[^280]For Vygotsky, the Bororo and araras make up a single complex; they are not two discrete entity. A great number of such complexes can be found in primitive and ancient cultures. For instance, magical operations with the name of the enemy were used to damage him, and because of that people endeavored to keep their true name in secret.

The buffalo hunting ritual is the part of the phenomenon described above. A buffalo rock painting and a genuine buffalo are not the two separate objects; they are the elements of the same object, namely, a complex with the topology, rather unusual for the modern people. If it does, to find the blend in this ritual is an obvious mistake.

Reasons of this kind cover a lot of other expressions examined by Fauconnier and Turner (particularly, their analysis of the Grim Reaper metaphor). The lack of the cul-tural-historical component in the analysis leads (at least, in some cases) to failure to reveal the true causes of blend emergence and evolution and to account for the real conceptual structure of the phenomena investigated.
C) It is also to the point to address here a set of experimental researches providing us with some data to estimate the correctness of conceptual blending theory from the psycholinguistic perspective. We will focus on the investigation of counterfactual conditionals as a significant example of such researches (de Vega et al. 2007; de Vega 2008; Ferguson, Sanford 2008; de Vega, Uritta 2011). Fauconnier and Turner take great pains to examine counterfactuals. Such counterfactuals as If Clinton were the Titanic, the iceberg would sink alongside with the Buddhist Monk riddle or "The Debate with Kant" story would be considered as arch examples of conceptual blending. This sentence, for the authors, is the double-scope blend of Titanic and President Clinton mental spaces; in the blend Clinton collides with the iceberg and the iceberg is sinking. In this case blend is figured out as the novel mental space with the unique topology.

A part of experimental data in this field is completely consistent with the interpretation given. Thus, when participants read short stories like Marta switched on the radio and heard the winning lottery numbers. Since she won the lottery prize, the first thing she did was to buy a new Mercedes car and Marta switched on the radio and heard the winning lottery numbers. If she had won the lottery prize, the first thing she would have done was to buy a new Mercedes car and after reading were asked to verify a test probe belonged to the beginning of the story ("heard"), they verified it faster in the counterfactual than in the factual stories, which means, according to the authors, that in counterfactual story the situation model is not updated and the attention of the readers focuses on the initial information. This observation, in turn, argues for the view on counterfactual mental spaces as endowed with special qualities in comparison with factual ones (de Vega et al. 2007; de Vega 2008, 296-297).

The fact that correct comprehension of counterfactuals requires knowledge about both real and counterfactual worlds is also in line with the conjectures of conceptual blending theory (de Vega 2008, 298-299; Ferguson, Sanford 2008, 610; de Vega, Uritta 2011, 962-963).

However, the more precise analysis gives the strong evidence that Fauconnier and Turner's attitudes are too speculative to account for a real time cognitive process. The key question in this context is whether mental spaces are exclusively mental structures, which have no connection with human perception, or they are based on human sensorimotor experience. Although de jure the authors of conceptual blending theory stress the second opportunity, de facto they work with the first one.

In the meantime, the data of the experiments testifies the sensorimotor anchoring of meaning for counterfactual expressions, at least, for special groups of words. Thus, the results of de Vega, Uritta 2011 show that in the process of blend construction counterfactuals apply to the sensorimotor anchors similar to their factual counterparts. Similar point is formulated in Ferguson, Sanford 2008. The authors claim that the processing of a true utterance in the factual context and of a false utterance in the counterfactual one face similar obstacles at the first stage, and the principles of counterfactual space topology are comprehended by the reader only at the second stage of this process.

In other words, the schema of three phases in blend construction (composition, completion, and elaboration) doesn't work, at least, in two aspects. Firstly, the background conceptual structure doesn't complement the blend on the second step; it is kept in mind from the very beginning. Secondly, even after the blend constructed, its elements are perceived at the first phase as objects in the real space with all spectrum of sensorimotor reactions, and only afterwards they are replaced in the counterfactual space.

## Conclusion

I would like to sum up by saying that conceptual blending theory contains a lot of fascinating observations and provocative ideas extending the horizon of our knowledge. At the same time the authors seem to be prone to unreasonable generalizations, and they are not fairly correct in revealing the cognitive meaning of the operation they discovered. The view on blending as an important tool to adapt knowledge to the experience of average people seems to fit the gist of this procedure better than the intention to look at blending as a basic instrument for the creation of new knowledge.

The second weak point of conceptual blending theory is the lack of cultural-historical analysis as well as the absence of experimental data justifying it. It may therefore be interesting in this context to address the demarcation between formal as-if theories and heuristic theories, fitting the process in on-line regime (Gigerenzer, Todd 1999; Hertwig, Hoffrage 2012). Fauconnier and Turner present their theory as heuristic, but, to considerable extent, it looks like as-if theory. The elimination of this contradiction could provide a new impulse for the theory development and strengthen its heuristic potential.

#### Abstract

We provide evidence that primacy and / or recency effects play a crucial role in infant visual categorization. First, we demonstrate that a connectionist model of infant categorization based on a self-organizing map (Gliozzi, Mayor, Hu, \& Plunkett, 2009) predicts an increased influence of the first and the last stimuli during familiarization on the category boundaries. We then present data from 10-month-old infants which confirm these effects. Future research will allow to discriminate between a primacy or a recency effect.

Keywords:infant categorization, self-organizing maps, connectionist modelling

## Introduction

familiarization/novelty preference paradigms have been widely used in experiments on infant categorization. In these types of experiment, infants are first familiarized with a sequence of stimuli. After the familiarization phase, infants are tested by simultaneously showing them two test stimuli: a within-category test stimulus and an out-of-category test stimulus. After the test phase is completed, category formation is assessed by comparing looking time at the withincategory test stimulus and looking time at the out-of-category test stimulus. Novelty preference - longer looking time at the out-of-category test stimulus than at the within-category stimulus - is taken as an indication for categorization: if looking time is indexed as a measure of surprise, this indicates that the out-of-category test stimulus is less familiar than the withincategory one, and therefore that infants have formed one category over the familiarization stimuli.

The assumption underlying the novelty preference test is that infants form a category representation close to the central tendency of the stimuli. In other words, this representation is equidistant from all the stimuli and represents them equally well, in a process that is unaffected by the order of the stimuli presentation. In this paper, we question this assumption, and argue that the process of category formation is

[^281]more disordered than this, and depends on many familiarization contingencies. In particular, we argue that a primacy or recency effect will affect the category formation process: the number and type of categories formed is modulated by the identity of the first, or last, stimuli presented. Future research will aim at distinguishing the relative roles of primacy and recency effects.
We will first show how the hypothesis of a primacy/recency effect was derived from the analysis of the behavior of a computational model, closely related to the model presented by Gliozzi et al. (2009). The model's predictions have been subsequently tested and validated by testing 10 -month-old infants in Oxford. This manuscript results from of a strong interplay between computational simulations and experimental results.

## Literature and Previous Results

Although it is clear that infants can form categories from visual familiarization stimuli (Younger, 1985; Eimas \& Quinn, 1994; Mareschal \& Quinn, 2001), the way in which familiarization contingencies impact category formation remained elusive until recently (Kovack-Lesh \& Oakes, 2007; P.C.Quinn \& R.S.Bhatt, 2010; Bomba \& Siqueland, 1983; Mather \& Plunkett, 2011) and the nature of the categories formed is yet to be understood.

In a previous experiment, Mather and Plunkett (2011) showed that the order of presentation of the familiarization stimuli can affect categorization. In particular, Mather and Plunkett (2011) compared infant categorization under two familiarization conditions that differ in the order by which the same set of stimuli (those used by Younger (1985)) is presented to infants during familiarization. Examples of familiarization stimuli, as well as of within-category (average), and out-of-category (peripheral) test stimuli can be found in Figure 1. In the high distance condition, infants were familiarized with sequences that maximize the Euclidean distance in feature space between successive stimuli whereas in the low

Figure 1: Example of familiarization sequences in the high distance condition with mild start/end stimuli and of the test stimuli
distance condition the Euclidean distance between successive stimuli is minimized. Mather and Plunkett (2011) found that only infants in the high distance condition successfully exhibited novelty preference at test, indicating that they had formed a category over the familiarization stimuli. Despite seeing the same items, with the only difference being the order of successive stimuli, infants in the low distance condition failed to discriminate between the test stimuli. The authors gave some potential explanations for this finding, ranging from faster habituation in the low distance condition, to the fact that infants in the high distance condition explore a bigger feature space than infants in the low distance condition, hence achieving more robust representations, until the fact that it may be more difficult to discriminate between small changes in feature space in successive stimuli in the low condition than when incremental changes in feature space are larger, as it is the case in the high distance condition. In this paper we provide a further explanation, while trying to gain further insight into the mechanisms underlying category formation with different familiarization contingencies.

Mather and Plunkett (2011)'s results are the starting point of this work. We first reproduce Mather and Plunkett (2011)'s results with a slightly-modified version of the model introduced by Gliozzi et al. (2009). As we will see, the updated model not only captures Mather and Plunkett (2011)'s results but also suggests an interpretation of its behavior which is different from the set of potential explanations provided by Mather and Plunkett (2011). Similarly to Mather and Plunkett (2011), we argue that categorization is affected by the order of presentation of the stimuli. However, in contrast from Mather and Plunkett (2011), we suggest that the largest effect impacting categorization is the identity of the first or last stimulus of the sequence, rather the average Euclidean distance in feature space between successive stimuli. In other words, we argue for a primacy/recency effect. As we will see, the experiments with infants confirm this hypothesis.

## Computational Model

## The model

The model we consider here is an adaptation of the model presented by Gliozzi et al. (2009). The model is a self-organizing map (Kohonen, 1997), which is recognized as a psychologically plausible neural network model (Kohonen, 1993), implementing a biologically plausible approach to human information processing: although our implementation is at a
high level of abstraction, we can be confident that the map architecture and learning algorithms used in the paper can be implemented at a physiological level of information processing. Psychological plausibility is added to our model by the fact that the map can be trained by following the same schedule of infants: by presenting each familiarization stimulus only once (instead of hundreds of times as in standard networks). The model receives visual inputs which are vectors with four dimensions (e.g. $[1,1,5,5]$ ) that represent the stimuli by Younger (1985) used by Mather and Plunkett (2011) (see Figure 1). Each value in the vectors corresponds to one feature in the cartoons presented to infants: length of the neck, length of the legs, the ears' orientation and the size of the tail. The encoding of the stimuli is the same used by Gliozzi et al. (2009), following Mareschal and French (2000). The stimuli can be either "mild", containing feature values close to the overall average (items with feature values 2 and 4 in Figure 1, with mild length legs and neck, etc), or "extreme", containing features further away from the overall average (combinations of values 1 and 5 in Figure 1, with very long or very short legs, very long or very short neck, etc)).

The model, like any self-organizing map, consists of a set of units, spatially organized in regular grids. Each map unit $u$ is associated with a weight vector $W_{u}$ of the same dimension as the input vectors. All weight vectors taken together can be seen as the map's representation of the world. The weight vectors are initialized to small random values. During training, the input vectors are presented to the network. After each presentation of a vector, its best matching unit is identified. This is the unit whose weight vector is closest to the input vector itself (in Euclidean distance). Next, the best matching unit's weights are adjusted to decrease the difference between the associated weight vector and the current input vector, according to the equation

$$
W_{u}(t+1)=W_{u}(t)+a(t)\left(I(t)-W_{u}(t)\right)
$$

where $W_{u}(t+1)$ and $W_{u}(t)$ are the weight vectors associated to unit $u$ at time $t+1$ and $t$ respectively. $I(t)$ is the input vector presented to the network at time $t$. For the best matching unit $u$ and for input $I(t)$, the difference $I(t)-W_{u}(t)$ is called the quantization error (qerr) of the network with respect to $I(t)$. Adjusting the weights can be seen as corresponding to an adaptation of the map's internal representation to accommodate for the new incoming familiarization stimulus. With respect to standard self-organizing maps our model is simpli-
fied and does not have any neighborhood function, due to its limited size. Results extend to a larger version of the model in which there is a (non-shrinking) neighborhood function.

Finally, $a(t)$ is the learning rate at time $t$, defined as $\max \left(0, \min \left(1, \beta * \exp ^{\alpha * \sqrt{q} e r r}\right)\right)($ with $\alpha=4.5, \beta=0.05)$. Results are robust (hold in more than $50 \%$ of the cases) when $\alpha$ ranges from 1 to 10 , and $\beta$ ranges from 0.04 to 0.4 . We have also studied a decreasing variant of the learning rate $a(t)^{\prime}=\max \left(0, \min \left(1, \beta * \exp ^{\alpha * \sqrt{q} e r r}\right)\right) / t$ that allows to replicate results under some parameters' combinations. In the following we restrict our attention to the non-decreasing learning rate. The model's adaptive learning rate has two important properties. The first of these is that it is usually higher than in standard self-organizing maps. This allows the network to be trained in analogy to an infant familiarization procedure: rather than training the network over hundreds of epochs, effectively presenting each stimulus many times, here each stimulus is only presented to the map once. The second property of the learning rate is that it depends on the quantization error: roughly speaking, the more novel the incoming stimulus is, the higher the learning rate will be. The consequence of this is that the learning rate can be considered as a computational counterpart of attention in infants: the adaptive learning rate corresponds to the general finding that infants pay more attention to novel stimuli rather than to familiar ones.

## The model's predictions

In order to replicate Mather and Plunkett (2011)'s results, we have trained our model in the same way in which infants have been familiarized in Mather \& Plunkett's (2011) study: we produced 24 maps per condition (low distance condition versus high distance condition), and each of these was trained with the encoding corresponding to the sequence presented to an infant, with the same schedule used in infant familiarization, i.e. presenting each stimulus exactly once.

After each network was trained, we assessed whether a category had been formed by measuring the network looking time, defined as the quantization error (as in Mareschal and French (2000) and Westermann and Mareschal (2004)). In analogy to the infant experiments, network categorization was assessed during a test phase in which network looking time at the overall average test stimulus was compared to looking time at the peripheral test stimulus: a proportion lower than chance indicates that the stimuli presented during familiarization have been organized in a cluster whose centroid is closer to the overall average test stimulus than to the peripheral one.

For each condition, the average of the ratios for all networks was calculated, and compared to the corresponding ratio calculated by Mather and Plunkett (2011). The model reproduces Mather and Plunkett (2011)'s results with infants: networks familiarized in the high distance condition exhibit a stronger novelty preference for the peripheral test stimulus than those familiarized in the low distance condition.

Although the model successfully reproduces Mather and

Plunkett (2011)'s results, the organization of its internal representation during training suggests an explanation of the results which is different from that provided by Mather and Plunkett (2011). Indeed, the model predicts that the nature of the start and end stimuli impacts categorization more than the Euclidean distance, as suggested by Mather and Plunkett (2011). In particular, novelty preference on test is stronger for maps familiarized with sequences starting and ending with mild values than for those familiarized with sequences starting and ending with extreme values.

In order to understand how Euclidean distance, on the one side, and the nature of start-end stimuli, on the other side, influence the model's behavior, we have conducted simulations in a $2 * 2$ design considering four different conditions. The conditions are obtained by varying the average Euclidean distance between successive stimuli as well as the nature of the start and end stimuli (whether mild or extreme). We thus consider the four possible combinations: low distance \& mild start/end stimuli (Low/Mild); low distance \& extreme start/end stimuli (Low/Extreme); high distance \& mild start/end stimuli (High/Mild); high distance \& extreme start/end stimuli (High/Extreme). In all conditions start and end stimuli are either both mild or both extreme

The model predicts a main effect of start/end stimuli on categorization. For some choices of the learning rate's parameters ( $\alpha$ and $\beta$ ) one obtains an interaction between start/end stimuli and Euclidean distance.

In the following we give an intuitive idea of the model's mechanisms that lead to the prediction. Roughly speaking, the prediction derives from the way in which successive stimuli are organized throughout the training phase: an internal representation (or several internal representations) corresponding to the stimuli experienced is formed and updated run-time, after each stimulus presentation (in line with several other models, as Gliozzi et al. (2009); Gureckis and Love (2004); Westermann and Mareschal (2004)). Depending on the strength of the update of this internal representation after each stimulus presentation (i.e. depending on the value of the learning rate), at the end of the familiarization phase the internal representation is close to the first or last stimulus experienced during familiarization. For our sequences, where start and end type were bound, sequences starting and ending with mild stimuli lead to internal representations of the familiarization stimuli containing mild attributes' values, whereas sequences starting and ending with extreme stimuli lead to internal representations containing extreme attributes' values. For this reason, maps familiarized in the mild condition will find the average test stimulus (that also contains mild values) much more familiar than the peripheral test stimulus, whereas for maps familiarized in the extreme condition the difference will be much less dramatic.

Do infants tested with the same $2 * 2$ design exhibit the same behavior? Can we say that they process the familiarization stimuli in a way similar to the model?

We will see in the next section that infant data reflect the
model's predictions. The question naturally arises on how precisely the model's behavior and infant behavior parallel each other. We address this question by considering looking time throughout familiarization/training. As we will see in the next section, infant looking time decreases throughout the familiarization phase in the low-distance condition while remaining stable in the high distance condition. However, the original model does not exhibit this kind of behavior. In order to achieve this behavior in the model we have to add two elements to the learning mechanism : (i) a form of weight decay: the weights associated to the maps' units that are not involved in training (because they are not selected as the best matching unit) slowly decay towards the initial values, and (ii) a form of habituation: the learning rate decreases if the same unit is the best match over multiple trials. With these two new elements, the network looking time mimics infant looking time also in the familiarization phase.

## Experiments

## Methods

Participants In total, 104 infants (mean age: 310 days; 52 females) took part in this study. An additional 31 infants were excluded due to technical reasons $(\mathrm{N}=12)$ or a failure to reach the looking time criterion ( $\mathrm{N}=19$; criterion: a minimum of 6 trials with looking time data including trials 1 and 8 , total looking time greater than two standard deviations below the mean). Infants were recruited at the maternity ward of the local hospital.
Procedure Infants were seated on the caregiver's lap in front of a large television screen ( $110 \mathrm{~cm} \times 95 \mathrm{~cm}$ ) at a distance of approximately 90 cm . They were presented with eight familiarization trials, followed by four test trials (see Figure 1); all trials were 10 seconds in duration. During the eight familiarization trials, a single familiarization image (subtending ca. 14 degrees visual angle) was displayed either on the left or right hand side of the screen. During the test trials, two images were shown side by side. The first two test trials paired one of the peripheral stimuli with the overall average, with a location switch between the trials, and counterbalancing the position of the average stimulus on Test trial 1 across subjects. Test trials 3 and 4 involved one pairing of the novel stimulus with the average stimulus, and one pairing of the novel stimulus with the peripheral stimulus shown during tests 1 and 2 (order of trials and location of stimuli were counterbalanced). The infant's face was filmed by two cameras mounted above the screen to the left and right. Throughout the procedure, the experimenter monitored infants' gaze from a control room next to the testing booth. Trials were initiated manually by the experimenter after confirming that the infants gaze was directed at the screen, or re-directing the infant's gaze at the screen through verbal communication via microphone (e.g. "Look (baby’s name)! What s next?").

Figure 2: Looking time during familiarization.

Figure 3: Looking time during categorization test trials

## Results

The video streams from left and right cameras were manually scored for infants' gaze direction (left vs. right).

Looking time during familiarization A mixed ANOVA on the looking times for familiarization trials (see Figure 2) with within-subjects factor Block (Block 1: trials 1-4, Block 2: trials 5-8) and between-subjects factors Distance (low, high) and Start/End Stimulus (mild, extreme) revealed a main effect of Block $(\mathrm{F}(1,98)=8.253$, $\mathrm{p}=.005)$ and a Block x Distance interaction $(\mathrm{F}(1,98)=4.072, \mathrm{p}=.046)$. T-Tests confirmed that looking time decreased between Block 1 and 2 in the low-distance conditions, but remained the same in the highdistance conditions.

Categorization: Test trials 1 and 2 In order to assess categorization performance, looking preference scores were obtained for each test trial from each participant by dividing the time spent looking at the average stimulus by the time spent looking at either test stimulus, average or peripheral (see Figure 3 for results). The resulting preference scores from the first test trial were subjected to an ANOVA with factors distance (low vs. high) and start and end stimulus (extreme vs. mild). This revealed a main effect of start/end stimulus $(F(1,92)=6.242, p=.014)$. All other effects remained non-significant (all $F$ s $<.31, p \mathrm{~s}>.57$ ). Follow-up t-tests
showed that infants in the mild start/end stimulus conditions exhibited a preference for the peripheral stimulus on Test trial 1 (Looking proportion for average stimulus 3333: $\mathrm{M}=41.7 \%, \mathrm{SE}=2.9 \%$; $\mathrm{t}(50)=2.882, \mathrm{p}=.006$ ), whereas infants in the extreme start/end stimulus condition exhibited no preference (Looking proportion for stimulus 3333: $\mathrm{M}=51.4 \%$, $\mathrm{SE}=2.4 \%$; $t(44)=.564, p=.576)$. On Test trial 2, the observed pattern of behavior was different. An ANOVA with factors distance and start/end stimulus revealed a significant interaction between distance and start/end stimulus $(\mathrm{F}(1,93)=5.534$, $\mathrm{p}=.021$ ). No other effects were significant (all $F \mathrm{~s}<.75$, $p \mathrm{~s}$ $>$.39). Further analysis of the interaction showed that only infants in the high/extreme condition had a significant preference, again for the peripheral stimulus $(t(23)=2.198, p=.038)$. Preferential looking in all other conditions did not differ from chance ( 0.5 ; all $t \mathrm{~s}<1.2, p \mathrm{~s}>.24$ ).

Novelty preference: Test trials 3 and 4 In order to establish that looking on the first test trials was driven by novelty preference rather than familiarity preference, preference scores were obtained for test trials 3 and 4 by dividing the amount of looking at the novel stimulus by the total looking time for each trial. The preference scores were subjected to an ANOVA with factors Test type (novel vs. average, novel vs. peripheral), Trial order, (novel vs. average first, novel vs. average second), Distance, and Start- and End-stimulus. This revealed a main effect of Trial order $(\mathrm{F}(1,84)=4.895$, $\mathrm{p}=.03$ ). All other effects were non-significant. Follow-up t -tests showed that there was always a significant novelty preference on the first of the two trials (Novel vs. Peripheral: $M=.66, S E=.04, t(50)=4.6, p<.001$; Novel vs. Average: $M=.57, S E=.03 ; t(46)=2.03, p=.048$ ), but on the second test trial infants only exhibited a (marginally) significant novelty preference if they had previously seen the pairing of the novel stimulus and a peripheral stimulus, and were now looking at the average and the novel stimulus ( $M=.57, S E=.04$; $t(46)=2.0, \mathrm{p}=.051)$. Infants who saw the novel stimulus paired with the overall average first did not exhibit a preference on the second novelty preference test trial ( $M=.55$, $S E=.03 ; t(46)=1.6, p=.107)$. These results are consistent with Mather \& Plunkett's (2011) findings.

## Discussion of Experimental Findings

The main effect of start and end stimulus found for Test trial 1 suggests that a recency or primacy effect determines looking on Test trial 1. This is consistent with the model predictions described above. As expected, infants who saw a mild stimulus on familiarization trials 1 and 8 exhibited a preference for the peripheral stimulus on Test trial 1. For these groups, the average stimulus appears particularly familiar when they get to Test trial 1. Infants in the groups with extreme start and end stimuli on the other hand do not exhibit any preference on Test trial 1. This is, empirically, the more surprising result: Younger (1985) reported merely an overall preference for the peripheral stimulus on the equivalent test trial. A conservative interpretation of our data would assume that no category was
formed in the extreme conditions. However, the model's performance indicates that instead of no category being formed the category's central tendency is merely closer to the peripheral stimulus than in the mild condition. This suggests that the null preference we observe is merely due to the fact that with this shifted category representation the average and peripheral test stimuli are equally interesting to the infants.

Test trial 2 is harder to interpret, as the pattern of preferences is very different from Test trial 1. Such order effects are common in familiarization / novelty preference paradigms (for a discussion see Schöner and Thelen (2006)). A likely cause for this is that learning does not stop at the end of familiarization: infants may incorporate both test stimuli presented on Test trial 1 in their category, and this will influence looking preferences on Test trial 2. Further work is required in order to explain the exact patterns observed, but the fact that all four conditions differ on this test trial indicate that Euclidean distance has a secondary impact, i.e. Mather and Plunkett (2011) assumption still holds. Looking times during familiarization imply that Euclidean distance is an important factor for maintaining infants interest during learning. Infants in the high distance conditions maintained looking, whereas infants looking times in the low distance conditions decreased, indicating that they began to habituate. This behavior is consistent with Mather and Plunkett (2011) interpretation of the impact of Euclidean distance on infants' attention.

## General Discussion

Decades of research on early categorization have assumed that categorization patterns were not impacted by the order of presentation of the familiarization stimuli. familiarization sequences were randomised and results averaged over different realisations. Recently, Mather and Plunkett (2011) challenged this view and showed that the order of presentation of the familiarization stimuli had an impact on infant category formation. Reasons for this behavior are yet unclear, which is why we decided to implement a model so as to evaluate the role of the order of presentation of the stimuli on the pattern of categorization.

First, we created a variant of the neural network model introduced by Gliozzi et al. (2009). The model is built with a simple self-organizing map and successfully reproduces Mather and Plunkett (2011)'s results. However, the model proposes an explanation of these results which is different from that provided by Mather and Plunkett (2011). In particular, the model predicts a primacy/recency effect: category formation depends on the nature of the first or last stimuli used in the training sequence.

The model's predictions have been confirmed by data from infants. 104 10-month-old infants were familiarized with sequences in the same four conditions presented to the network. Novelty preference scores on test indicate that responses are mainly driven by primacy/recency effects, whereas the average Euclidean distance influenced looking time during familiarization. This implies that, at odds to common assump-
tions about familiarization, 10-month-old novelty preference responses can be heavily influenced by familiarization stimuli at the start or end of the familiarization sequence, a factor which is often ignored in infant familiarization studies.

Our results are consistent with both primacy and recency effects, and future research will determine whether category formation is more heavily influenced by either primacy or recency.

In conclusion, this paper questions the traditional view underlying the novelty preference procedure suggesting that familiarization stimuli are categorized in an abstract representation of all the stimuli. In this traditional view, the representation formed is independent from familiarization contingencies. On the contrary, our results show that infants are sensitive to the order of presentation of the stimuli and support models that advocate infant category learning as an incremental process by which, on a moment-by-moment basis, infant refine the boundaries of new categories (Gliozzi et al., 2009; Gureckis \& Love, 2004; Westermann \& Mareschal, 2004). In contrast, our results cannot be explained by models in which the infants only establish the category boundaries once they have sampled all familiarization items.

## Acknowledgments

This research was supported by Wellcome Grant 084386/Z/07/Z to Kim Plunkett and the Winkler Career Development Fellowship at St Hugh's College, University of Oxford, to Nadja Althaus. We wish to thank all parents and infants who participated in this study.

#### Abstract

Solving an open problem as proposed by inventing and productive failure approaches has been shown to prepare learners effectively for subsequent direct instruction even though invented solutions are often suboptimal for the given problems. Inventing can make the learners aware of knowledge gaps (cognitive) and more curious about and interested in the learning contents (motivational effects). However, working on the same problem with a given (optimal) solution helps avoid misconceptions and disorganized knowledge, while providing useful basic knowledge. Therefore, a given solution could be more effective. In an experiment $(N=42)$, we tested to what extent working on an open problem (inventing) versus a solution prepares student teachers for learning strategy evaluation. The inventing group invented criteria to evaluate learning strategies while the worked solution group studied the same problem in a solved, worked-out version. We found differential effects: inventing enhanced knowledge-gap experience, curiosity, and interest. However, studying the worked-out solution enhanced learning outcomes.

Keywords: instruction; invention activities; worked examples; teacher education; learning-strategy assessment.

## Introduction

In order to prepare learners for a new topic and to raise their attention as well as curiosity, teachers often address interesting problems in the beginning before they directly instruct learners about the topic. Similarly, there are experimentally tried-and-tested problem-oriented
approaches (Schmidt, De Volder, De Grave, Moust, \& Patel, 1989) such as inventing problem solutions (Schwartz, Chase, Oppezzo, \& Chin, 2011; Schwartz \& Martin, 2004) or productive failure at initial problems (Kapur, 2010). These approaches aim at preparing learners for subsequent direct instruction (preparation for future learning, Schwartz \& Martin, 2004). However, when preparing a lesson, should a teacher really put such initial problems up for "inventing" or "productive failure" before implementing direct instruction? Is it not more productive to immediately begin with tried-and-tested forms of direct instruction such as example-based learning in order to avoid wasting time when students search for problem solutions that are very hard to find (see Sweller, Kirschner, \& Clark, 2007)?

When starting immediately with methods of direct instruction, a problem might arise: learners often process directly presented information only superficially (Berthold \& Renkl, 2010), leading to little knowledge acquisition and transfer. Problem-oriented introductions such as invention activities can prepare learners to more deeply process directly presented information. For example, Schwartz and Martin (2004) had learners invent formulas describing four different distributions of pitches around a target. Later, the learners were taught the concept of mean deviation. Schwartz and Martin assumed that inventing creates preparedness for future learning by generating "early forms of knowledge" (p. 132). These early forms of knowledge can then be used to easily assimilate further knowledge.

Invention activities can appear problematic because learners might not generate canonical or even false solutions. According to the IKEA effect - the increased valuation of self-made products (Norton, Mochon \& Ariely, 2012) -, these own suboptimal solutions can be valued higher than expert ones. Similarly, research on the continued influence effect (Johnson \& Seifert, 1994) suggests that learners tend to stay with their own suboptimal solution instead of taking up the directly instructed canonical one. However, research on productive failure (e.g., Kapur, 2010, 2012) shows that initial problem-solving activities can be effective even though invented solutions to problems are often suboptimal or even false (see Schmidt et al., 1989, for similar findings). In addition, larger numbers of suboptimal solutions were followed by higher learning outcomes (Kapur, 2012). Difficulties as well as the production of suboptimal solutions can be seen as productive because they cause impasses making the learners realize that certain solutions do not work for all cases. Furthermore, research on impasse-driven learning has shown that instructional explanations are more effective when given in the context of such an impasse (Sánchez, García-Rodicio, \& Acuña, 2009; VanLehn, Siler, Murray, Yamauchi, \& Baggett, 2003). If prior knowledge is not sufficient to solve the inventing task and an impasse is reached, a perceived "vacuum" can help to see more clearly the "information needs" and "knowledge gaps to be filled", which can lead to a better focus on the most relevant contents in a subsequent learning phase.

Besides the more cognitive effects of creating a form of prior knowledge and an experience of knowledge gaps, problem-oriented instruction can influence motivation. Enhancing motivation can foster deep processing, understanding, and transfer (Belenky \& Nokes-Malach, 2012; Entwistle \& Ramsden, 1983; Pintrich, 2000; Pugh \& Bergin, 2006). Schmidt et al. (1989) discussed an epistemic curiosity (i.e., motivation to strive for knowledge) which could explain higher learning outcomes in the problembased condition of their experiment. Interest can be enhanced because "people like to produce things" (Schwartz \& Martin, 2004, p. 171; diSessa, Hammer, Sherin, \& Kolpakowski, 1991; Norman \& Schmidt, 1992). Enhancing learner motivation is argued to be a major advantage of problem-oriented learning in general, but there is little research bearing directly on motivational issues (HmeloSilver, 2004). Most studies do not assess learners' perceived knowledge gaps, either.

Some researchers criticize the postulated effects of such forms of problem-oriented learning (Mayer, 2004). Sweller et al. (2007) as well as Kirschner, Sweller, and Clark (2006) assume that the problem-oriented activities and especially failure within these activities are unproductive. "Not only is unguided instruction normally less effective; there is also evidence that it may have negative results when learners acquire misconceptions or incomplete or disorganized knowledge" (Kirschner et al., 2006, p. 84). They criticize that many studies favoring problem-oriented learning did
not employ an adequate control group. Such a control group would have to engage in the same topic as the experimental group for the same timespan (see Sweller et al., 2007).

Against the background of these different positions on the value of inventing, we designed an experiment with a control group that is adequate and "strong" in the sense of implementing "good" direct instructional procedures, but using the exact same problem as in an inventing group. However, the problem was presented in a worked-out version. Boths group engaged in their problem for the same amount of time. Specifically, we tested the following hypotheses and asked the following research questions:
(1) The inventing activity leads to more experience of knowledge-gaps, more epistemic curiosity, and more interest than working through the worked-out solution. (2) The more knowledge gaps participants perceive, the higher their focus on the most relevant contents in a subsequent learning phase. (3) Does the inventing activity lead to superior learning outcomes when compared to a "strong" control group? (4) Is failure in the inventing activity productive (Kapur, 2010, 2012), that is, (4a) how is the appropriateness of solutions to the invention problem related to learning outcomes? and (4b) how is the number of (different) suboptimal invented solutions related to learning outcomes?

## Method

## Participants and Design

As participants, forty-two German student teachers (sex: 12 female, 30 male; $M_{\text {age }}=22.74, S D=3.44$ ) were randomly assigned to two conditions: "inventing" $(n=21 ; 13$ female, $\left.M_{\text {age }}=22.05 ; S D=2.92\right)$ and "worked solution" $(n=21 ; 17$ female; $M_{\text {age }}=23.43, S D=3.83$ ). As learning domain we used the assessment of learning strategies in learning journals written by high school students. By writing learning journals, for example, as homework after biology or mathematics classes, high school students are encouraged to apply learning strategies. For example, they can develop their own thoughts based on the new learning contents (elaboration strategy). Ideally, they can do this in a detailed way and on their own, for example, "I realized that nothing can grow without mitosis, not even myself! Because (...)." Such an elaboration can be evaluated as high in quality (see Glogger, Schwonke, Holzäpfel, Nückles, \& Renkl, 2012).

The inventing group invented criteria to evaluate the quality of learning strategies applied in learning journals. First, all participants received a short introduction (134 words) about learning journals and the quality of learning strategies in general. The instruction to the subsequent activity (for both groups) read as follows: "On pages B and C, you will find four extracts from learning journals. Each extract shows a variation of the same elaboration strategy (developing own thoughts) in a way a student in a biology class (dealing with the topic mitosis) could have realized it." The extracts looked similar in length, but differed systematically in two quality criteria "detailed elaboration
vs. wordy, but shallow elaboration" and "self-made vs. copied from the lesson". Participants in the inventing group were prompted to contrast the four extracts, rate the quality of each one on a 3-point scale (low, medium, or high), make notes on discerning aspects, and generalize from these aspects to generic evaluation criteria for the learning strategy elaboration. The student teachers had to write down their criteria in a box labeled "my criteria." They were also instructed to check whether or not the final criteria really work to discern all extracts (cf. Roll, Holmes, Day, \& Bonn, 2012). In contrast, participants in the solution condition neither had to rate the extracts nor to invent the evaluation criteria. Instead, they were asked to carefully study the same problem that was worked out by a (fictitious) experienced teacher. That is, the canonical criteria were written in the "my criteria" box, the quality of the four extracts was rated, and short notes about discerning aspects were written down. In summary, the two groups had the exact same work sheets with four extracts. However, the inventing group had to generate a solution to the problem how to evaluate the quality of learning strategies whereas the worked-solution group was given the solution, namely the criteria. That is, the inventing group had to generate core learning principles by contrasting cases, whereas the solution group worked through the contrasted cases with the given principles. The two criteria (principles) were explained in the subsequent learning phase (inter alia), that is, the information on the criteria was redundant for the solution group. Both groups were given the same amount of time ( 15 minutes) for their preparation activity. Participants were compensated with 15 Euros for the average 85 minutes duration of the study.

## Materials

Pretest and Demographic Questionnaire. A web-based pretest assessed participants' topic-specific prior knowledge. Participants received up to five points for the four open questions ( $\alpha=.83$, e.g., "Which learning strategies can students apply by writing a learning journal?"). Two independent raters scored $25 \%$ of the pretests $(I C C=.87)$ and of all following data with open format including posttest. A demographic questionnaire assessed sex, age, number of semesters in teacher education, experience with learning journals, and computer skills.

Process Variables. Questionnaires assessed the participants' experience of knowledge gaps, epistemic curiosity, and interest by items with 6-point rating scales (6: absolutely true). Experience of knowledge gaps was assessed with nine items ( $\alpha=.89$; e.g., "My knowledge was insufficient to complete the task"). Epistemic curiosity was assessed with 10 items $(\alpha=.85)$, based on the "Melbourne Curiosity Inventory - State Form" (Naylor, 1981) and adapted to the present context (e.g., "I feel curious about how to evaluate learning strategies"). Topic-specific interest (Schiefele \& Krapp, 1996) was measured with six items ( $\alpha$ $=.72$; e.g., "Learning how to evaluate learning strategies is entertaining."). In addition, we rated the appropriateness
(quality) of the invented solutions (i.e., in the inventing group only) on a 6-point scale ranging from 1 (not at all appropriate) to 6 (absolutely appropriate, ICC $=.82$ ); and we counted solutions, operationalized by the number of (different) criteria invented by participants.

## Computer-Based Learning Environment and Learning

 Time. After the experimentally varied preparation activity and the questionnaires, participants worked individually in a computer-based learning environment (CBLE). The CBLE explained several sub-categories of elaboration strategies, how they improve comprehension, and how they can be identified in learning journals. A subsequent unit explained the quality criteria of elaboration strategies, using various (new) examples (i.e., not used in the preparation phase). Learners could navigate freely. The focus on the most relevant learning contents was operationalized as the time learners spent in the quality criteria unit. The duration spent in this unit and in the environment as a whole was logged by the software.Posttest. A posttest consisting of seven tasks measured learning outcomes as application of quality criteria on students’ learning strategies $(\alpha=.75)$. Each task consisted of a short extract from a learning journal, representing one sub-category of an elaboration strategy. This sub-strategy was labeled. All extracts were new so that the tasks required transfer (content transfer, Barnett \& Ceci, 2002). Participants were asked to rate the quality of the strategy (low, medium, or high) and to explain their rating by applying the previously learned criteria. Answers were rated on a 6-point scale ranging from 1 (no conceptual understanding) to 6 (very clear conceptual understanding; SOLO taxonomy by Biggs \& Collis, 1982; ICC = .93).

## Procedure

We required participants to work on the web-based pretest four days before the experiment in order to avoid knowledge activation effects. On the day of the experiment, participants first filled out the demographic questionnaire. Next, they worked individually on the task that prepared the following learning phase (inventing vs. worked-out solution) for 15 minutes. Subsequently, questionnaires assessed participants' experience of knowledge gaps, epistemic curiosity, and interest. The participants then worked on the CBLE without time limits ( 20 minutes on average) as we were interested in potential effects of the two conditions on the learning time spent in the environment. After the learning phase, interest was reassessed. Finally, participants worked on the posttest.

## Results

A significance level of .05 was used for all analyses. We used $d$ as an effect-size measure with values between .20 and .50 classified as small, values between .50 and .80 as medium, and values $>.80$ as large (Cohen, 1988). We did not find any significant differences between the groups in prior knowledge (inventing: $M=2.05$ [41 \% correct], $S D=$

Note. All 6-point scales: Knowledge-gap experience, epistemic curiosity, and interest: from 1 (not true at all) to 6 (absolutely true); Posttest: from 1 (no conceptual understanding) to 6 (very clear conceptual understanding). ${ }^{\text {a }}$ Knowledge-gap experience. ${ }^{\text {b }}$ Interest after the learning phase. ${ }^{\text {c }}$ Learning time (in minutes) in the most relevant unit of the CBLE on quality criteria. ${ }^{\text {d }}$ one-tailed. ${ }^{e}$ two-tailed.
1.44, solution: $M=2.37$ [47.4 $\%$ correct], $S D=1.29, t(40)=$ $.75, p=.459$ ) or in demographic variables (sex, age, number of semesters, experience with writing learning journals, and computer skills; all $p$ 's > .05).

Table 1 presents the means and standard deviations of knowledge-gap experience, epistemic curiosity, interest, learning time, and the posttest for the two experimental groups. Directly after the preparation task, the participants of the inventing condition stated higher knowledge-gap experience (large effect), and higher epistemic curiosity (medium effect), than participants of the solution condition, confirming hypothesis 1 . Even after the learning phase, they stated higher interest in learning about the assessment of learning strategies in learning journals (medium effect).

Table 2 shows correlation coefficients between all process variables and dependent variables. Regarding hypothesis 2 , perceived knowledge gaps did not significantly correlate with learning time (simple correlation, Table 2). However, when controlling for condition (and prior knowledge) we found a significant partial correlation, $r(36)_{\text {part }}=.34, p=$ .035, medium effect. Thus, the more knowledge gaps
participants perceived (independent from their condition and prior knowledge), the more time they spent in the most relevant learning unit about quality criteria indeed.

Surprisingly, even though the inventing group experienced more knowledge gaps (correlating with learning time), higher epistemic curiosity, and higher interest, this group did not achieve better learning outcomes (research question 3, see Table 1). Participants of the solution condition even outperformed the inventing condition (medium effect). Controlling for prior knowledge, the effect remained stable, $F(1,38)=4.95, p=.032, d=$ -0.72 . For exploratory purposes, we searched for variables explaining this effect. 'Learning time' is the only variable that correlated significantly with learning outcomes (Table 2 ), even if controlled for condition, $r(38)_{\text {part }}=.55, p<.001$, large effect. Against this background, we analyzed whether the effect of conditions on learning outcomes is mediated by learning time. We tested this mediation effect with a set of related multiple regression equations, following a products-of-coefficients strategy (MacKinnon, 2008). In this approach, there are essentially two assumptions to be met in order to speak of a mediated effect. First, an independent variable must significantly affect a mediating variable (path a). Second, the mediating variable must significantly affect a dependent variable (path b). The significance of the effect can be tested according to Sobel (1982).

The independent variable 'condition' did in fact significantly affect the mediating variable 'learning time' (path a): The worked solution group spent more time learning in the CBLE (quality criteria unit, $b=-1.09, S E=$ $0.41, b^{*}=-.39, p=.010$; controlled for prior knowledge). The learning time predicted learning outcomes significantly (path b: $b=.210, S E=0.0404, b^{*}=.625, p<.001$; controlled for prior knowledge). Learning time significantly mediated the effect of conditions on learning outcomes (Sobel test $=-2.37, p=.018$ [two-tailed], $L C L=-0.418404$, $H C L=-0.04032$ ).

Referring to research question 4 a , the appropriateness of participants' invented solutions $(M=2.8, S D=1.31)$ correlated substantially with learning outcomes, $r(16)_{\text {part }}=$ $.52, p=.028$, (large effect, controlled for prior knowledge. The more a participant failed to invent an appropriate solution to the inventing problem, the more this participant failed in the posttest as well.

Table 2: Intercorrelations of pretest, process variables, and posttest.

|  | Knowledgegap | Epistemic curiosity | Interest pre | Interest post | Learning time ${ }^{\text {a }}$ | Posttest |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Pretest | . 18 | .40* | . 19 | -. 01 | . $30^{+}$ | . 25 |
| Knowledge-gap experience | - | . 52 *** | .33* | . 24 | $.10{ }^{\text {b }}$ | -. 10 |
| Epistemic curiosity |  | - | .61*** | .48** | . 09 | -. 20 |
| Interest pre |  |  | - | . 53 *** | . 01 | -. 11 |
| Interest post |  |  |  | - | -. 13 | $-.29^{+}$ |
| Learning time ${ }^{\text {a }}$ |  |  |  |  | - | .66*** |

Note. $N=44 .{ }^{a}$ Learning time (in minutes) in the most relevant CBLE unit on quality criteria. ${ }^{b}$ Partial correlation differs and is given in the text with condition controlled. ${ }^{+} p<.10 .{ }^{*} p<.05 .{ }^{* *} p<.01 .{ }^{* * *} p<.001$.

Finally, hypothesis 4 b was rejected. The number of suboptimal invented solutions ( $M=4.1, S D=1.52$ ) did not correlate significantly with learning outcomes, $r(16)_{\text {part }}=$ $.28, p=.135$ (one-tailed, controlled for prior knowledge).

## Discussion

In line with the literature on problem-oriented learning (e.g., Hmelo-Silver, 2004), we found that an inventing activity had positive motivational effects (see also Belenky \& Nokes-Malach, 2012). Learners are more curious about and interested in the target learning domain. Learners also become aware of knowledge gaps to be filled. The more knowledge gaps learners perceived, the higher their focus on the most relevant learning contents. The motivational and knowledge-gap effects can be seen as a preparation for learning. However, they did not lead to higher learning outcomes in the inventing group. In contrast to the inventing and productive-failure literature, the worked solution group achieved better learning outcomes, mediated by learning time.

The results are in line with Sweller et al.'s (2007) and Kirschner et al.'s (2006) argument that positive results in problem-oriented learning studies could be an effect of "weak" control conditions or different time-on-task during the experimental variation. The worked-out solution condition resembles a worked-example condition. Possibly, a worked-example effect (Renkl, 2011; Sweller, 2006) had the worked solution group outperform the inventing group, even though self-explanations were not prompted, which is usually sensible in order to exploit the potential of examplebased learning (cf. Chi, Bassok, Lewis, Reimann, \& Glaser, 1989; Renkl, 2011). In the present case, the preparation activity of working through a worked-out solution of a problem obviously prepared learners to learn, possibly by enhancing basic knowledge about quality criteria. This wellorganized basic knowledge might have facilitated working intensively with the instructional explanations and explained strategy examples of different quality in the CBLE. That is, cognitive mechanisms such as deeper elaboration and spontaneous application of the learned concepts to presented examples during the learning phase could account for the results. Findings of a subsequent think-aloud study indicate such mechanisms. The cognitive mechanisms could have predominated motivational mechanisms in this study. Alternatively (or additionally), if the worked-solution functioned as a worked example (a model of a good solution), self-efficacy could have been enhanced. Selfefficacy can enhance effort and persistence (Schunk, 1990) which could explain the short learning time in the inventing group despite enhanced curiosity and interest.

One could interpret a speed-accuracy tradeoff: learning outcomes as well as learning time is higher in worked example. However, in the context of self-regulated learning in a CBLE, where diverse learning paths are provided and working through it can be more or less thorough, enhancing learning time can be advantageous. To put it differently, inventing might have constrained learning time, because
learners did not want to deal thoroughly with the learning contents (see also below). Also note that we did not find any differences between groups in efficacy (learning outcome per minute spent in the quality part, $p=.751$; in the CBLE, $p=.975$ ).
Another evidence for the claim that some "correct" basic knowledge of quality criteria facilitated future learning in the CBLE can be seen in the highly positive correlation between the level of appropriateness of the inventing solutions and the learning outcome. Failure was not productive in the present case. The number of suboptimal invented solutions was not significantly related to learning outcomes. These findings contradict Kapur's $(2010,2012)$ approach of productive failure. Additionally, findings about the continued influence effect (Johnson \& Seifert, 1994) and the IKEA effect (Norton et al., 2012) suggest that the inventing group could have clung to their initial suboptimal solution (quality criteria) even though the canonical criteria were explained and exemplified in the CBLE. Holding on to one's own solution ideas and partly neglecting canonical explanations could be another reason why the inventing group spent less time with learning in the CBLE. If they partly held on to their own solutions, the role of a transition phase, which is a usual part of a productive-failure procedure, could be of major importance: The teacher leads a discussion about students' own (suboptimal) solutions towards the canonical one.

Usually, productive failure and inventing include a collaborative learning setting. Students work on preparatory open problems either in groups (Kapur, 2012; Schmidt et al., 1989; Schwartz \& Martin, 2004) or in pairs (Schwartz et al., 2011; Westermann \& Rummel, 2012). The collaborative setting has not been explicitly discussed as an "active ingredient" of the preparatory activities. However, invention activities might only be effective in collaborative learning settings. This is a point to consider about the present study in which participants worked only individually.
Thus, further studies on problem-oriented learning settings such as inventing should investigate whether collaborative work during preparatory activities is a crucial ingredient of such instructional approaches. It can also be worthwhile to look at the learning processes that follow inventing and inventing-enhanced motivational states (e.g., applying basic knowledge from the preparatory activity, holding on to own solutions) in order to explain why inventing did not enhance learning outcomes when compared to working through a worked-out solution. More generally, it is important to use strong control groups in future research. In doing so, research should not simply investigate which instructional approach is better or worse. Instead, the results of the present study show that future research should achieve a differential analysis of cognitive and motivational effects of the various approaches.

#### Abstract

Prior research indicates a protracted developmental course in category-based reasoning. One possible explanation for the development of this ability is the gradual reorganization of semantic knowledge. To measure development of semantic knowledge we developed a new paradigm, the Semantic Space task, which uses distance in a two-dimensional space to infer semantic similarities between two objects. Using this paradigm we examined development of semantic knowledge in young children (preschoolers, kindergarteners, and first-grade children) and in adults. We also examined whether conceptual organization as measured by the Semantic Space task is predictive of children's scores on a category-based reasoning task. The findings point to the possibility that development of semantic knowledge plays an important role in the development of category-based reasoning.

Keywords: Semantic Space; Concepts; Cognitive Development

## Introduction

Category-based reasoning is a critical cognitive ability that enables an individual to generalize from the known to the unknown (Hayes, Heit, \& Swendsen, 2010; Proffitt, Coley, \& Medin, 2000). For example, upon learning that a chicken has 39 pairs of chromosomes, one may infer that a dove also has 39 pairs of chromosomes because chickens and doves are the same kind of animal (i.e., birds). Prior research indicates that children's category-based reasoning undergoes a protracted developmental course (e.g., Badger \& Shapiro, 2012; Fisher, Matlen, \& Godwin, 2011; Godwin, Matlen, \& Fisher, in press; Fisher, 2010; Fisher \& Sloutsky, 2005; Sloutsky, Kloos, \& Fisher, 2007), with marked improvements in category-based reasoning apparent between 4 and 6 years of age. However, it is not clear what factors underlie this improvement. One possible explanation for the development of category-based reasoning is representational change: the gradual accretion and reorganization of domain-specific knowledge (Goswami \& Brown, 1989, 1990; Rattermann \& Gentner, 1998).

Representational change has been identified as a factor that fosters cognitive development in a wide array of domains such as numerical development (e.g., Opfer \& Siegler, 2007), problem solving (e.g., Karmiloff-Smith, 1986), and analogical reasoning (e.g., Gentner, Rattermann, Markman, \& Kotovsky, 1995).

One of the few studies to examine the relationship between semantic development and category-based reasoning was conducted by Chi, Hutchinson, and Robin (1989). Chi et al. classified 6 -year-old children as either dinosaur experts or novices, based on their pre-test performance. Subsequently, the children completed an inference task about dinosaurs. The stimuli were digitally modified in order to create novel dinosaurs for both experts and novices. Chi et al. found that children who were classified as domain experts tended to make category-based inferences about the novel dinosaurs (e.g., "he is probably a good swimmer ... cause duckbills are good swimmers", p. 48). In contrast, children who were classified as dinosaur novices tended to make inferences based on a salient attribute (e.g., [the dinosaur] "could walk real fast cause he has giant legs", p. 49). These findings can be taken to suggest that category-based induction is a function of one's domain knowledge (also see Gobbo \& Chi, 1986).

There is also converging evidence suggesting that representational change may play a role in semantic development. First, multidimensional scaling studies have investigated people's ability to classify familiar objects. These studies provide evidence of advancement in classification from initially classifying objects according to more concrete characteristics to utilizing more abstract features when making groupings (e.g., Howard \& Howard, 1977; Saltz, Seller, \& Sigel, 1972). For example, preschoolage children are likely to classify familiar animals on the dimension of size, whereas school-age children are more likely to classify animals along the dimensions of domesticity and predativity.

Second, studies on the development of priming suggest that associative priming (e.g., faster responding to the word 'banana' after 'monkey' is presented) appears early in development whereas semantic priming (e.g., faster responding to the word 'banana' after 'cherry' is presented) develops during the school years (McCauley, Weil, \& Sperber, 1976; Arias-Trejo \& Plunkett, 2011).

Finally, work in cognitive modeling points to a gradual developmental progression in conceptual organization from relatively undifferentiated (e.g., groupings including a penguin, a trout, and an alligator) to more differentiated groupings (Kemp \& Tenenbaum 2008; Rogers \&

McClelland 2004). However, these predictions are yet to be confirmed by empirical studies.

The present study investigates how young children organize knowledge and whether the organizational structure changes over the course of development. In particular, we are interested in examining whether semantic similarity influences how knowledge is organized. In order to examine this issue, we developed a task in which participants are asked to represent the semantic similarity of animal dyads in two-dimensional space. The distance between animal pairs is taken as a measure of how closely the participants represented the concepts. The use of physical distance as an indicator of representational similarity has been successfully used in prior studies (e.g., Goldstone, 1994; Howard \& Howard, 1977).

Unlike multidimensional studies, in which children are free to arrange the items along any desired dimension, we explicitly asked children to put animals of similar kind close together on the game board. Therefore, this paradigm allowed us to examine whether knowledge of semantic similarity changes over the course of development in 4- to 7 -year-old children. We also assessed whether children's semantic organization scores are predictive of their tendency to engage in spontaneous category-based reasoning.

## Method

## Participants

Participants were preschool children ( $N=43$, Mage $=4.32$ years, $S D=0.28$ years), kindergarteners ( $N=22$, Mage $=5.41$ years, $S D=0.30$ years), and first-grade children ( $N=23$, Mage $=6.96$ years, $S D=0.32$ years) attending local preschools and elementary schools. The preschool children were also part of a longitudinal study examining the development of inductive reasoning (see Godwin, Matlen, Fisher, 2012). Adult participants were undergraduate students ( $N=20$, Mage $=20.38$ years $S D=1.22$ years) from a local university who received partial course credit for participation.

## Design \& Procedures

Children were tested individually in a quiet room adjacent to their classroom. Adult participants were tested in a laboratory located on campus. Tasks were administered by hypothesis-blind experimenters.

## Semantic Space Task

This task was designed to assess children's semantic organization. Visual stimuli entailed a game board consisting of a $9 \times 9$ grid (see Figure 1). Two 1" wooden blocks were used as game pieces. The wooden blocks were used as game pieces instead of pictures so that children would use their knowledge about kinds rather than rely on perceptual similarity. A similar approach has been successfully used in prior studies (e.g., Howard \& Howard, 1977).

Linguistic stimuli included 24 pairs of animal names. The stimuli could be classified into one of four categories: (1) semantically-similar dyads (e.g., lamb-sheep), (2) dyads that
share a common setting or habitat (e.g., lamb-horse), (3) unrelated dyads (lamb-swan), and (4) filler items. During the game, the target item was paired with three different test items (i.e., category-choice, setting/habitat match, and unrelated item). Linguistic stimuli is provided in Table 1.

Figure 1: Schematic depiction of the Semantic Space game board. Squares highlighted in red indicate the location of the critical trials. Squares highlighted in yellow mark the location of the filler trials. In the experiment proper, the location of the critical and filler trials was not marked and all squares on the board were white.

Table 1: Linguistic Stimuli for the Semantic Space Task

| Critical Trials |  |  |  |
| :---: | :---: | :---: | :---: |
| Target | Category <br> Choice | Setting/ <br> Habitat | Unrelated |
| Crocodile | Alligator | Fish | Grasshopper |
| Chick | Hen | Goat | Goldfish |
| Lamb | Sheep | Horse | Swan |
| Whale | Dolphin | Octopus | Elephant |
| Monkey | Gorilla | Parrot | Chipmunk |
| Mouse | Rat | Pig | Hippo |
| Filler Pairs |  |  |  |
| 1. Zebra/Turkey; 2. Bear/Snake; 3. Panther/ Turtle; |  |  |  |
| 4. Tiger/Butterfly; 5. Frog/Lion; 6. Giraffe/Seal |  |  |  |

In the Semantic Space task, participants were asked to help Zibbo the zookeeper organize his zoo by placing animals of the same kind close together. At the beginning of the task, the experimenter introduced the game and provided the participants with two examples (Example 1: a bunny and a rabbit were placed on adjacent squares on the game board and the experimenter explained that they should be placed close together because they are the same kind of thing; Example 2: a dog and a shark were placed far apart on the game board and the experimenter explained that they should be placed far apart because they are not the same kind of thing). On each test trial, the experimenter showed the participant where Zibbo put the target animal (e.g., the experimenter placed the first game piece on one of the squares marked in red in Figure 1 and said, "The zookeeper put the mouse here"). Then, the experimenter handed the participant the second game piece and asked him or her to identify where the test item should be placed (e.g., "Where
do you think the hippo should go?"). The participant's response was recorded in order to calculate the distance between the placement of the target and test item. After each trial was administered, the game board was cleared before the experimenter presented the next pair.

Placement of the 18 critical trials (i.e., semanticallysimilar dyads, common habitat/setting dyads, and unrelated items) was pseudo randomized to eight central squares (marked in red in Figure 1). The central squares were utilized for the critical trials in order to equalize the maximum possible distance from the square where the experimenter placed the target. Each of the eight squares was utilized at least twice and no more than three times. The six filler trials were randomly assigned to one of the remaining 24 squares in order to encourage participants to use the entire game board. The animal dyads were presented in one of two pseudo randomized orders. The following stipulations were used when creating the presentation orders: one filler trial was presented after every three critical trials, at least three trials were required in between target repeats, and at least two trials were presented in between semantically-similar dyads. The presentation order was counterbalanced across participants.

Participants' responses were scored in the following way: Raw scores were calculated for each trial by adding the number of squares occupied by the game pieces plus the number of squares between the target and test item (the distance was based on the shortest route between the two game pieces barring diagonal movement). A composite score for non semantically-similar dyads was created by averaging together participants' raw scores for common setting/habitat dyads and unrelated items. A Semantic Space Difference score was calculated by subtracting the average score for semantically-similar dyads from the non semantically-similar composite score. Positive difference scores indicate that participants put semantically-similar dyads closer together and non semantically-similar dyads farther apart. Difference scores approaching zero indicate that participants did not reliably discriminate between semantically-similar dyads and non semantically-similar dyads.

## Category-Based Reasoning Task

The Category-Based Reasoning task is a propertyinduction task in which children are presented with triads of objects and asked to generalize a novel property from the target to one of the test items. Each triad included a target, a category-choice, and a lure (e.g., lamb-sheep-frog). Nine label triads were administered: 3 triads referring to artifacts, 3 triads referring to inanimate natural kinds, and 3 triads referring to animate natural kinds (see Table 2 for the complete list of linguistic stimuli). The 3 animate natural kind triads were also included in the Semantic Space task.

Visual stimuli were presented on the computer and consisted of sets of three identical doors; see Figure 2. The objects remained hidden behind the doors in order to encourage children to rely on the category information
conveyed by the labels. This procedure has been utilized successfully in prior work (e.g., Fisher et al., 2011; Godwin et al., in press).
On each test trial children were told where each object was hiding. Children were told that the target item had a novel property and asked to generalize this property to either the category-choice or the unrelated lure. Concerns regarding the working memory demands of the task are mitigated based on Fisher et al.'s (2011) findings in which children recalled, with high accuracy, which objects were hiding behind each door at the end of each test trial.

All properties were two-syllable blank predicates. Two presentation orders were created: In order 1 all trials were randomized and the presentation order was reversed for order 2. Presentation order was counterbalanced across participants.

Table 2: Category-Based Reasoning Task Linguistic Stimuli

| Target | Category <br> Choice | Lure | Property |
| :---: | :---: | :---: | :---: |
| Artifacts |  |  |  |
| Rug | Carpet | Window | Koski |
| Sofa | Couch | Cup | Creighan |
| Shoe | Boot | Car | Troxel |
| Inanimate |  |  |  |
| Sea | Ocean | Apple | Manchin |
| Hill | Mountain | Flower | Erwin |
| Rock | Stone | Grass | Higa |
| Animate Natural Kinds |  |  |  |
| Alligator | Crocodile | Butterfly | Omat |
| Rat | Mouse | Fish | Lignin |
| Lamb | Sheep | Frog | Matlen |

Figure 2: Schematic depiction of the Category-Based Reasoning task. All instructions were given verbally by the experimenter.

## Picture Identification Task

The picture identification task served to assess children's familiarity with the labels utilized in the Category-Based Reasoning task. The picture identification task is a computer-based task akin to the Peabody Picture Vocabulary Test (Dunn \& Dunn, 1997). Stimuli included 27 labels and 108 pictures. On every trial, children were presented with 4 pictorial response options (the target object and 3 lures). Children were asked to point to the target object. The trials were presented in one of two orders. The presentation order was counterbalanced across participants. The task was administered immediately following the Category-Based Reasoning task.

The Category-Based Reasoning task and the picture identification task were not administered to adults; only preschoolers, kindergartners, and first-grade children completed this portion of the experiment. Additionally, because preschool children were also participating in a related longitudinal study, they participated in the CategoryBased Reasoning task twice, with approximately one week between the two testing sessions. Repeated testing was administered to obtain a more stable estimate of young children's performance. As children's scores on both testing sessions were within $3 \%$ (adjusted means $M$ time $=63 \%$, $M$ time2 $=66 \%$ ), we averaged the scores across the repeated administrations of the task. The analyses reported below are based on these average scores.

## Results

## Semantic Space Task Performance

Preschool children exhibited considerable variability in their performance on the Semantic Space task, with Difference scores ranging from -2.58 to 5.67 , and an average Difference score of 1.37 ( $S D=1.88$ ). Kindergarten children's performance was also highly variable, with Difference scores ranging from -0.92 to 7.00 and an average Difference score of 2.44 ( $S D=2.48$ ). The Difference scores of first-grade children ranged from -0.17 to 8.25 and their average difference score was $4.23(S D=2.08)$. The Difference scores of adult participants ranged from 2.50 to 6.50 and their average Difference score was 4.99 ( $S D=1.13$ ); See Table 3.

Participants' Difference scores were analyzed in a oneway ANOVA with age as the between-subject factor. This analysis revealed a significant effect of age, $F(3$, $104)=20.41, p<0.0001$. This effect was further explored through planned comparisons.

Performance on the Semantic Space task was found to improve with age. In general, preschoolers exhibited greater difficulties discriminating between semantically-similar and non semantically-similar dyads compared to the other age groups. Post-hoc Tukey tests revealed no significant difference between mean Difference scores of preschoolers ( $M=1.37$ ) and kindergartners $(M=2.44), p=0.163$. At the same time, both first graders $(M=4.23)$ and adults $(M=4.99)$ exhibited superior performance compared to preschoolers ( $M=1.37$ ), both $p s<0.0001$. A marked improvement in
performance on the Semantic Space task was observed between kindergarten $(M=2.44)$ and first-grade ( $M=4.23$ ), $p=0.014$. There was no significant difference between the Difference scores of first-graders and adults ( $p=0.583$ ), providing preliminary evidence that semantic differentiation for certain animal categories may begin to reach adult levels by 6 to 7 years of age. Taken together, the pattern of results suggests that the ability to reliably discriminate between semantically-similar and non semantically-similar dyads improves with age; see Figure 3.

Figure 3: Mean difference scores by age group. Semantic Space Difference scores were calculated by subtracting the average score for semantically-similar dyads from the non semantically-similar composite score. Error-bars represent the standard errors of the mean.

Table 3: Semantic Space mean scores by item type and age group.

| Age Group | Mean (SD) |
| :---: | :---: |
| Semantically-Similar Dyads |  |
| Preschool | $4.37(1.35)$ |
| Kindergarten | $4.09(1.63)$ |
| First-Grade | $2.91(0.87)$ |
| Adults | $2.32(0.42)$ |
| Non Semantically-Similar Dyads |  |
| Preschool |  |
| Kindergarten | $5.74(1.51)$ |
| First-Grade | $6.53(1.93)$ |
| Adults | $7.14(1.79)$ |
| Common Setting/Habitat Dyads |  |
| Preschool | $7.31(0.99)$ |
| Kindergarten | $6.83(1.60)$ |
| First-Grade | $6.66(1.87)$ |
| Adults | $6.13(1.14)$ |
| Unrelated Dyads |  |
| Preschool |  |
| Kindergarten | $5.64(1.76)$ |
| First-Grade | $6.61(1.95)$ |
| Adults | $7.62(2.08)$ |

## Picture Identification

The results from the picture identification task indicated that children were familiar with the labels used in the CategoryBased Reasoning task (Preschoolers: $M=.92, S D=.14$, Kindergarteners: $M=.99, S D=.01$, First-Graders: $M=.99$, $S D=.01$ ). As an additional precaution, for the preschool group the Category-Based Reasoning scores were adjusted for their vocabulary knowledge to ensure that children possessed the pre-requisite knowledge to perform categorybased induction. Thus, if a child missed an item on the picture identification task, this trial was removed from this child's Category-Based Reasoning score. This adjustment resulted in the increase of mean Category-Based Reasoning scores in preschoolers from $M=.62$ to $M=.64$. Because the picture identification scores of the other groups of participants were nearly at ceiling, no adjustments to the induction scores were made in the older age groups.

## Category-Based Reasoning Performance

Participants' reasoning scores were submitted to a oneway ANOVA with age as the between-subject factor. This analysis revealed a significant effect of age, $F(2,82)=16.49$, $p<0.0001$. This effect was further explored through planned comparisons.

Category-Based Reasoning performance improved as a function of age; see Figure 4. Posthoc Tukey tests revealed that both kindergarten and first-grade children exhibited superior performance on the Category-Based Reasoning task compared to the preschoolers; all $p s<.0001$. However, there was no significant difference in performance on the Category-Based Reasoning task between the kindergarten children and the first-grade children; $p=.90$.

Figure 4: Proportion of category-based responses by age group. Error-bars represent standard errors of the means. Line indicates chance performance.

The final analysis compared the mean Category-Based Reasoning scores to chance (.50) using single sample t-tests. Participants in all age groups exhibited Category-Based Reasoning performance that was significantly above chance; Preschoolers: $M=.64, S D=.22$; Kindergartners: $M=.87$,
$S D=.18$; First-graders: $M=.89, S D=.14$; all $t s>3.67$, all $p s<0.0001$. The rate of category-based responding in preschool-age children was somewhat higher than in our prior studies ( $M=.54$ across Fisher et al., 2011; Godwin et al., in press, Matlen, Fisher \& Godwin, under review). However, it should be noted that in the present study the sample of preschool children was recruited entirely from a laboratory campus school at a private university and our prior research utilized more diverse community-based samples.

## Is Category-based Reasoning Related to Children's Semantic Space Organization?

A correlational analysis was conducted to examine the potential relationship between children's Category-Based Reasoning performance and their performance on the Semantic Space task. This analysis revealed a significant positive correlation between the Semantic Space Difference scores and Category-Based Reasoning scores when scores were aggregated across preschoolers, kindergarteners, and first-graders, $r=.484, p<0.0001$ (see Figure 5). When separated by age group, there was a significant correlation in the preschool group ( $r=.473 ; p=0.002$ ), a marginally significant correlation in the kindergarten group ( $r=.34$, $p=0.12$ ), and no correlation among first-graders ( $r=.10$, $p=0.66$ ).

It is perhaps not surprising that the magnitude of the correlation between the Semantic Space Difference scores and Category-Based Reasoning scores decreased with age, as children's performance on both tasks improved and variability in performance decreased (e.g., many children achieved ceiling scores on the category-based reasoning task by first-grade). However, it is noteworthy that in preschoolage children, who exhibited a high degree of variability on both tasks, there was a fairly strong relationship between children's category-based reasoning and semantic organization.

Figure 5: A scatterplot of children's Category-Based Reasoning scores and their Difference scores on the Semantic Space task.

## Discussion

The results from the present study point to several novel findings. First, the new paradigm designed to measure development of semantic organization successfully captured increased differentiation among the animal concepts during the preschool and early school years. The gradual increase in the Semantic Space Difference scores in preschoolers, kindergarteners, and first-graders suggests that children increasingly become more sensitive to semantic similarity.

Second, the present findings provide preliminary evidence that individual differences in knowledge organization, as measured by the Semantic Space task, may be related to developmental differences in category-based reasoning.

In conclusion, these findings indicate that children's semantic knowledge undergoes gradual reorganization across development. Additionally, performance on this measure was found to predict preschoolers' inductive generalization performance. This latter finding suggests that the ability to make inductive inferences based on categories may be related to improvements in semantic organization.

## Acknowledgments

#### Abstract

Maintaining focused attention in the classroom is considered an important factor for successful learning. Loss of instructional time due to off-task behavior is recognized as a significant challenge by both researchers and practitioners. However, there has been little research into the factors contributing to off-task behavior. This paper reports results from the first large-scale study investigating how elementary school children allocate their attention in classroom environments and how patterns of attention allocation change as a function of gender, grade level, and instructional format. The findings indicate that instructional format is related to off-task behavior in elementary school students. These findings can begin to form a foundation for development of research-based guidelines for instructional design aimed to optimize focused attention in classroom settings.

Keywords: Off-Task Behavior; Attention

## Introduction

Loss of instructional time due to off-task behavior is a well-established problem in educational settings, recognized both by researchers (e.g., Baker, 2007; Karweit \& Slavin, 1981; Lee et al., 1999) and practitioners (e.g., Lemov, 2010) for over a hundred years (cf. Currie, 1884 as cited in Berliner, 1990). The link between the quality of attention and performance has been demonstrated in the cognitive psychology literature (e.g., Choudhury \& Gorman, 2000; Dixon \& Salley, 2007; DeMarie-Dreblow \& Miller, 1988). It has also been documented that off-task behavior has a negative impact on performance and learning outcomes in school settings (for reviews see Frederick \& Walberg, 1980; Goodman, 1990).

Despite considerable prior research on off-task behavior, designing effective, easy to implement, and scalable interventions to reduce off-task behavior has been challenging. Roberts (2001) suggests that many existing
interventions may be unsuccessful because they do not take into sufficient account the conditions that lead to off-task behavior. The goal of the present study was to expand upon prior research on off-task behavior in elementary school students to begin to elucidate the factors involved in off-task behavior, particularly the factors which are related to classroom activities and thus are malleable.

## Off-task Behavior

There is a variety of reasons why loss of instructional time occurs in schools; these reasons include but are not limited to: weather (e.g., snow days), sudden onset interruptions (e.g., announcements over the loudspeakers), and special events. However, it has been shown that student inattentiveness (i.e., engagement in off-task behavior during instructional time) is the biggest factor that accounts for loss of instructional time (Karweit \& Slavin, 1981). Prior research examining the frequency of off-task behavior has estimated that children spend between $10 \%$ and $50 \%$ of their time off-task in regular education classrooms (Lee et al., 1999; Karweit \& Slavin, 1981). Classrooms employing cognitive tutors report similar results with estimates of offtask behavior constituting $15 \%$ to $25 \%$ of instructional time (e.g., Baker, Corbett, \& Koedinger, 2004; Baker, 2007).

However, there has been limited research examining the factors associated with off-task behavior. Recently researchers have begun to explore the role of classroom design on children's off-task behavior. Godwin and Fisher (2011) found that classroom environments that contained relatively large amounts of visual displays (e.g., charts, posters, manipulatives) elicited more off-task behavior in kindergarten children compared to visual environments that were more streamlined. These design choices were found to hinder children's ability to attend to the content of the lesson and reduced learning outcomes. Related findings were obtained by Barrett et al. (2012). Barrett and
colleagues took a more holistic approach to design and incorporated building factors (e.g., physical space, navigation, furniture scale, etc.), environmental elements (e.g., light, sound, temperature, air quality, etc.), as well as classroom decor (e.g., color, organization, etc.). Barrett et al. found that these design choices (in combination with pupil factors) were related to students' later academic achievement.

Instructional format (e.g., whole-class instruction, small group instruction, etc.) is another important aspect of instructional design. Yet, little is known about the relationship between instructional format and overall rates and types of off-task behavior. The goal of the present study was to examine whether type of instruction is related to incidence of off-task behavior in elementary school students.

## The Present Study

This study examines whether specific instructional strategies are associated with incidence of off-task behavior in elementary school children, both in terms of the overall amount of off-task behavior, and the form which off-task behavior takes. Towards this goal we recorded patterns of attention allocation in elementary school students during a variety of instructional activities (e.g., whole-group instruction, small-group work, etc.).

## Method

## Participants

Twenty-two classrooms participated in the present study. Participating classrooms were selected from 5 local charter schools. Five grade-levels were recruited: Kindergarten through fourth-grade. The distribution across the five gradelevels was as follows: 5 kindergarten classrooms, 4 firstgrade classrooms, 5 second-grade classrooms, 2 third-grade classrooms, and 6 fourth-grade classrooms. The average class size was 21 students ( 10 males, 11 females). However, due to absences the average number of children observed in a single observation session was 18.9 children. The number of children observed per session ranged from 15 to 22 .

## Design and Procedure

Each classroom was observed four times during the second-half of the school year, resulting in a total of 84 observation sessions. Due to time constraints in four of the 22 classrooms only three observation sessions were conducted. The observation sessions were staggered across two time periods (Time 1: February-April 2012, Time 2: May-June 2012) with two observation sessions occurring during each time period. The average delay between observation sessions within a single time period was 3.7 days (the delay ranged from 1 to 14 days). The average delay across time periods was 73.2 days. Each observation session lasted approximately one-hour.

## Operationalization of on- and off-task behavior

For the present study, focused attention was defined as a "state in which attention is directed more or less exclusively
to one target or task" (Ruff \& Rothbart, 1996, p.110). Focused attention was operationalized through visual engagement. If children were directing their eye gaze at the teacher (or classroom assistant), the instructional activity, or toward appropriate instructional materials, the child was classified as on-task. If the child was looking elsewhere, they were classified as off-task. Eye gaze is a common measure of visual attention (for reviews see Henderson \& Ferreira, 2004; Just \& Carpenter, 1976), and it is arguably a reasonable (albeit imperfect) measure of focused attention.

## Coding

All coders were trained in the Baker-Rodrigo Observation Method Protocol (BROMP) for coding behavioral data in field settings (Ocumpaugh, Baker, \& Rodrigo, 2012) using software developed for the android handheld computer. All coders received extensive training consisting of coding videotapes and live observation sessions. Inter-rater reliability was established prior to the study proper. Kappa values ranged from 0.79 to 0.84 . This level of reliability is in line with past classroom research coding off-task behavior, and exceeded the 0.75 threshold to which Fleiss (1981) refers as "excellent" in field settings.

Children were observed using a round-robin coding strategy, in order to reduce the tendency of observers to attend to more salient instances of off-task behavior. The order in which children were observed was determined at the beginning of each session. Each time a child was observed the observation lasted for up to 20 seconds. The first unambiguous behavior observed during the 20 -second period was recorded. Quick glances were considered ambiguous behaviors, and coders were instructed to wait for a clear behavior to occur. If a behavior was noted before 20 seconds elapsed, the coder proceeded to the next child, and a new 20 -second observation period began. Coders observed the children using peripheral vision or side-glances. Peripheral vision was utilized in order to avoid looking directly at the student being observed. This technique makes it less apparent to the child that $\mathrm{s}(\mathrm{he})$ is being observed. This procedure has successfully and reliably captured students' behavior in prior work which assessed student behavior and affect (cf. Baker et al., 2006; Baker et al., 2010; Ocumpaugh et al., 2012).

Coders classified children's behavior as on- or off-task. If the child was looking at the teacher (or classroom assistant), the instructional activity, and/or the relevant instructional materials, they were categorized as on-task. If the child was looking elsewhere, they were categorized as off-task. Contextual clues (i.e., teacher instructions) were also taken into consideration when distinguishing between on- and offtask behavior. For example, if a child was instructed to discuss an idea with a partner, coders would classify conversing with another peer as on-task unless the coders could clearly discern that the conversation was unrelated to the instructional task.

If the child was classified as off-task, the type of off-task behavior was recorded. Six mutually exclusive categories of
off-task behavior were logged: (1) Self-distraction, (2) Peer distraction, (3) Environmental distraction, (4) Supplies, (5) Walking, or (6) Other. Self-distraction entailed engagement with something on the child's own body, such as an article of clothing or an appendage, as well as episodes in which the child would close their eyes. Peer distraction was defined as interacting with or looking at another student(s) when not directed to do so. Environmental distractions include interacting with or looking at any object in the classroom that was not related to the task at hand, while Supplies consists of inappropriately using any object that was part of the assigned task (e.g., playing with a writing utensil). Walking was operationalized as a student physically walking around the classroom when it was not considered appropriate for the task. Other distractions included student behavior that was off-task but did not clearly align with the five aforementioned categories. A seventh category Unknown was also included to capture rare instances in which it was unknown whether the child was on- or off-task, and it was impossible or inappropriate for the observer to relocate in order to obtain a better view of the child. Unknown was also used when students left the classroom for various reasons (e.g., to use the restroom).

Children in each session were treated as a different set of students since it was not possible to link observations across the four sessions. Thus, a total of 1,587 student-session pairs were observed. A student-session pair refers to a specific student observed by a coder within a specific session. The average number of observations per session was 330.13 and the average number of observations per child within a session was 17.58.

## Data Analysis: Variables

Using these data, we attempted to predict within an observation session each student's total on- or off-task behavior as well as the type of behavior the student tended to engage in while off-task. Two categories of predictor variables were considered for incorporation into the models: student characteristics and instructional design. Gender and grade were included as student characteristics. Predictor variables pertaining to instructional design included the proportion of each classroom instructional format and the variable Transitions/Duration of Instructional Format.

Instructional format was included as a predictor variable in order to examine whether certain instructional formats elicit differential amounts of off-task behavior. Six different instructional formats were coded: (1) individual work, (2) small-group or partner work, (3) whole-group instruction at desks, (4) whole-group instruction while sitting on the carpet, (5) dancing, and (6) testing. The proportion of time students spent in each of the aforementioned formats was calculated. The average duration for each instructional format is provided in Table 1.

Transitions were noted every time the teacher paused instruction to change from one activity to another (e.g., transitioning from working on a math problem to listening to a short story). In many cases, transitions coincided with a
change in instructional format (e.g., switching from wholegroup instruction to small-group instruction); however this was not always the case as transitions could occur without a change in instructional format (e.g., with children rotating from one small group activity to another). Transitions were frequently marked by the teacher asking the children to get out new instructional materials (e.g., "Please get out your math binders") or requesting students to change locations (e.g., "Please put your notebooks away and come to the carpet").

Table 1. Time spent in each instructional format

| Average Time Spent (sec) Per Instructional Format |  |
| :---: | :---: |
| Individual Work | 1,424 |
| Small Group | 1,587 |
| Whole-group Instruction at Desks | 1,805 |
| Whole-group Instruction on Carpet | 1,263 |
| Dancing | 141 |
| Testing | 2,530 |

The primary dependent variable was the proportion of ontask behavior of a specific student within a specific session. Additional models were also constructed in order to predict peer off-task behavior and environment-based off-task behavior, as these two types of off-task behavior were common sources of distraction for elementary school children (See Table 2). Environment-based off-task behavior was of particular interest as it is a malleable factor that could theoretically be targeted when designing interventions aimed to mitigate off-task behavior.

## Data Analysis: Approach

We predicted student on-task behavior using a regression tree algorithm (cf. Witten \& Frank, 2005), which sets up a decision tree to predict a numerical value. Binary decisions are made based on specific variables. After several decisions are made, a numerical prediction is given. To determine these specific variables, regression trees find breakpoints within data, where relationships change (mostly) at a certain value of a variable. Regression trees can find more complicated interactions and relationships between variables than is typically possible with linear regression methods, while still remaining more constrained than neural networks or support vector machines-as such, they occupy a moderate position in the trade-off between goodness of fit and flexibility of fit/parsimony. The specific implementation of regression tree used in this paper is REPTree in RapidMiner 5.2 (Mierswa et al., 2006). This relatively rapid algorithm builds a tree using reduced error pruning; an approach designed to produce relatively conservative models (Witten \& Frank, 2005).

Resultant models were evaluated using six-fold student level cross-validation. In this process, students are split randomly into six groups. For each possible combination, a feature is developed using data from five groups of students
before being tested on the sixth "held out" group of students. By cross validating at this level, we increase confidence that features will be accurate for new students.

Within this paper, cross-validation (Efron \& Gong, 1983) is used instead of statistical significance testing for multiple reasons. First, cross-validation assesses how accurate a model is likely to be for new data, rather than assessing the likelihood that a specific data set's results are due to chance. In assessing generalizability, cross-validation has the same goal as the use of information criteria. In fact, the k-fold cross-validation approach used here is thought to be asymptotically equivalent to the Bayesian Information Criterion (BiC) (Shao, 1993). Second, there is not an appropriate statistical significance test for the data used here for two reasons: (1) there is not a well-known statistical significance test for regression trees, and (2) student IDs are not connected across sessions. Testing statistical significance without a student term would result in a bias strongly in the direction of statistical significance; conversely, using a student-session term would result in having an order of magnitude more parameters, biasing strongly against statistical significance.

## Results

Consistent with prior research, children were largely on task: $71 \%$ of children's observed behaviors were on-task. As seen in Table 2, three of the most common types of off-task behavior observed were Peer distractions (45\%), SelfDistractions (18\%), and Environmental distractions (16\%).

Table 2. Descriptive statistics for students' on- and off- task behavior

| Proportion of Observed Behaviors |  |
| :---: | :---: |
| On-task Behavior | $71 \%$ |
| Off-task Behavior | $29 \%$ |
| Proportion of Off-task Behaviors |  |
| Self-Distraction | $18 \%$ |
| Peer Distraction | $45 \%$ |
| Environmental Distractions | $16 \%$ |
| Supply Distractions | $11 \%$ |
| Walking | $3 \%$ |
| Other Distractions | $8 \%$ |
| Descriptive Statistics | Mean (SD) |
| Observations per session | $330.13(63.6)$ |
| Observations per session per child | $17.58(3.7)$ |
| Student/Session pairs observed | 1,587 |

Models predicting on-task behavior were fit based both on instructional design and on limited student demographics (e.g., grade-level and gender). The best overall model predicting on-task behavior was found for the regression tree when student demographics were not included. This model obtained a cross-validated correlation coefficient of $r=0.352$. The cross-validated correlation coefficients for the
"instructional design plus demographic" models were as follows: A regression tree which added gender achieved a cross-validated correlation of 0.322 to the frequency of student on-task behavior and a regression tree model which added grade-level achieved a cross-validated correlation of 0.329. As these "instructional design plus demographics" models achieved lower cross-validated correlation than the simpler model which only considers instructional design, we can infer that including this demographic information does not improve model fit in a generalizable fashion (as mentioned above, this is akin to achieving a better BiC : the additional fit does not compensate for the added model complexity/flexibility of fit). As such, for determining offtask behavior it does not appear to be important whether an elementary school student is a boy or a girl, once instructional design is taken into account. Similarly, gradelevel does not seem to be an important factor, once the influence of grade on instructional design is taken into account.

In this data set, regression trees achieved generally better performance than linear regression. A linear regression model based on instructional design achieved a crossvalidated correlation of 0.221 to the frequency of student on-task behavior. No linear regression model (regardless of the feature set used) performed better than the corresponding regression tree model.

Within instructional design, both the format and the variable Transitions/Duration of Instructional Format were associated with a better model. Removing either of these variable types from the model resulted in worse crossvalidated correlation.

The final regression tree model was rather complex, with 63 leaf nodes (final decision values) and 62 decision nodes. It can be easier to understand some of the key data relationships by considering the cross-validated and regular correlations for single-feature linear regression models. In Table 3, both cross-validated correlations and regular correlations are given. It is worth noting that cross-validated correlations should always be positive (a negative crossvalidated correlation does not imply a negative relationship, but that the relationship reverses direction when applied to different parts of the data; e.g., a negative cross-validated correlation implies that the model is worse than chance). Directionality of the relationship should be inferred from the regular correlation.

As seen in Table 3, the relationship between instructional format and on-task behavior varies as a function of the type of instructional format. Individual work and whole-group instruction at desks were negatively associated with on-task behavior, while small group-work, whole-group instruction while sitting on the carpet, dancing, and testing were positively associated with on-task behavior. It is worth noting that the individual variables may have weak associations, even as reasonable prediction is achieved from a combination of variables. Note, however, that this is not simply a case of an overly-complex model predicting noise; the cross-validated correlation of the overall model is an
indication that the model works on entirely unseen data. The variable Transitions/Duration of Instructional Format was also found to be positively correlated with on-task behavior.

We also generated models to predict peer off-task behavior and environmental off-task behavior, using the same features and modeling methods. The cross-validated correlation of the REPtree model based solely on instructional design was 0.244 for peer off-task behavior and 0.161 for environmental off-task behavior. These correlations did not increase substantially if gender or grade-level were included. With these results, the peer model appears to perform somewhat better than the weak correlation achieved in the environment model, but neither model was as effective as the model predicting the overall amount of on-task behavior.

Table 3. Goodness of single-feature linear regression models at predicting on-task behavior (note that cross-validated correlations are always positive, unless the model performs worse than chance on new data).

| Feature | Direction <br> of <br> relationship | Cross- <br> validated <br> correlations | Correlations |
| :---: | :---: | :---: | :---: |
| Individual <br> work | Negative | .000 | -.018 |
| Small-group <br> work | Positive | .000 | .032 |
| Whole-group <br> instruction at <br> desks | Negative | .114 | -.113 |
| Whole-group <br> instruction <br> carpet | Positive | .110 | .110 |
| Dancing | Positive | .017 | .043 |
| Testing | Positive | .025 | .051 |
| Transitions/ <br> Duration of <br> Inst. Format | Positive | .075 | .075 |
| Gender | Positive | .108 | .109 |
| Grade | Positive | .005 | .039 |

The strongest individual feature correlation (using linear regression and non-cross-validated correlations) for peer off-task behavior is the amount of time spent in wholegroup instruction while sitting on the carpet ( $r=-0.136$ ), followed by the amount of time spent in small-group work ( $r=0.119$ ). Similarly, the strongest individual feature correlation for environmental off-task behavior is smallgroup work ( $r=-0.115$ ). These findings suggest that instructional format does matter for determining specific off-task behaviors. However, the magnitude of correlation for the full model indicates that instructional format determines to a greater degree whether a student will go off-
task, than exactly how they will go off-task. Clearly, the type of instructional format may influence students' choices of how they will go off-task (e.g., a student may be more likely to engage in peer off-task behavior during smallgroup work when another child is in close proximity); however, the exact manifestation of off-task behavior may be influenced by momentary factors (i.e., the most interesting item/person in the classroom at a specific moment).

## Discussion

The present work is the first large-scale study of off-task behavior in elementary school students to investigate the relationship between features of instructional design and incidence of off-task behavior. Specifically, we examined whether type of instructional format (e.g., individual work, small-group work, whole-group work, etc.) and the variable Transitions/Duration of Instructional Format are related to the overall rate of off-task behavior. Our findings indicate that both variables are related to children's engagement in instructional activities. At the same time, children's gender and grade-level (K-4) made only a marginal contribution to off-task behavior once features of the instructional design (e.g., instruction format and variable Transitions/Duration of Instructional Format) were taken into account.

The reported results also indicate that certain types of instructional format are associated with more on-task behavior than others, although further research is required to explicate this finding. There are several possible hypotheses that could be explored. One potential underlying factor is variations in teacher supervision. It is feasible that classroom management is easier for certain instructional formats (e.g., small-group work) than others (e.g., wholegroup instruction at desks). Consequently, instructional formats that are easier for teachers to supervise may result in a reduction in opportunities for students to go off-task.

Secondly, student engagement in the instructional task may also vary across instructional formats. For instance, instructional activities that take place individually or at the students' desks (i.e., whole-group instruction at desks) may be less engaging or motivating than small-group activities which tend to be more socially oriented and include more hands-on learning components. Instructional activities that are more motivational may in turn increase students' on-task behavior. Additionally, instructional duration varies across these formats. Thus, children may be better able to maintain a state of focused attention when instruction consists of small blocks of instructional activities verses instructional activities that occur over a longer duration (cf. Ruff \& Lawson, 1990; Sarid \& Breznitz, 1997). Currently these hypotheses are speculative, and they require additional investigation to determine their viability.

As stated previously, off-task behavior is a significant problem in educational settings because it is thought to impede learning. Optimizing instructional design to promote on-task behavior is a desirable goal; however, there is a paucity of research linking instructional design choices to
attention allocation in classroom settings. The present findings are a first-step in providing empirical evidence to inform instructional design.

## Acknowledgments

We thank Laura Pacilio for her help collecting data. We also thank the children, parents, and teachers who made this project possible. The work reported here was supported by a Graduate Training Grant awarded to Carnegie Mellon University by the Department of Education (R305B090023) and by the Institute of Education Sciences, U.S. Department of Education (R305A110444). # How pitch accents and focus particles affect the recognition of contextual alternatives 

Nicole Gotzner (nicole.gotzner@hu-berlin.de)<br>Katharina Spalek (katharina.spalek@staff.hu-berlin.de)<br>Department of German Language and Linguistics, Humboldt-Universität zu Berlin, Dorotheenstr. 24, 10117 Berlin, Germany

#### Abstract

Listeners are sensitive to contrastive alternatives in online language comprehension (e.g., Braun \& Tagliapietra, 2010). Such alternatives play a crucial a role in the definition of particles like only which have been found (i) to facilitate recall of contextual alternatives (Spalek, et al., in revision) and (ii) to hamper the rejection of unmentioned alternatives (Gotzner et al., in preparation). The present study investigated the impact of combining a contrastive accent with a particle on memory for contextual alternatives. The results revealed that $\mathrm{L}+\mathrm{H}^{*}$ accents (contrastive) facilitate recognition of a contextual alternative to the accented item compared with $\mathrm{H}^{*}$ accents (non-contrastive). Adding either the particle only or also to the $\mathrm{L}+\mathrm{H}^{*}$ accent slows probe recognition relative to a condition with bare $\mathrm{L}+\mathrm{H}^{*}$ accent. Hence, while contrastive accenting directly increases the salience of alternatives in a listener's mental model, focus particles lead to an initial processing cost.

Keywords: contrastive alternatives, $\mathrm{L}+\mathrm{H}^{*}$ pitch accent, focus particles, recognition memory.

## Introduction

Certain pitch accents convey the information that a statement is contrastive (cf. Pierrehumbert \& Hirschberg, 1990). For example, when uttering the sentence Mary passed the exam with a specific intonation contour on the noun Mary ( $\mathrm{L}+\mathrm{H}^{*}$ according to the ToBI system), a speaker expresses that Mary passed the exam in contrast to other persons in the discourse.
There is evidence that contrastive intonation contours lead to the activation of alternative expressions to the contrastively-stressed elements. For example, Braun and Tagliapietra (2010) found that a sentence produced with an $\mathrm{L}+\mathrm{H}^{*}$ accent on the critical word initiated priming of contrastively-related targets to the critical words in a lexical decision task (e.g., ANTENNA facilitated satellite).

There is also evidence that prosody influences longterm memory for contextual alternatives. Fraundorf, Watson and Benjamin (2010) compared contrastive $\left(\mathrm{L}+\mathrm{H}^{*}\right)$ and non-contrastive ( $\mathrm{H}^{*}$ ) pitch accents in discourses that contained a contrast set with two elements. After exposure to all stimuli, participants had to perform a recognition memory task. The results revealed that the $\mathrm{L}+\mathrm{H}^{*}$ accent increased both the number of hits to correct statements, and the number of correct rejections of the
contrast item, suggesting that contrastive pitch accents enhance memory for the accented element itself as well as for its alternatives. The rejection of unmentioned items (lures), however, was not affected by the pitch accent manipulation.

According to the contrast representation account advocated by Fraundorf et al. (2010) listeners use contrastive accents to encode additional information about items in the contrast set. So, on this account, processing our example sentence Mary passed the exam with an $\mathrm{L}+\mathrm{H}^{*}$ accent would encourage the inference that other students did not pass the exam.

## Focus Particles

Another means of expressing such a contrast is provided by certain lexical items. Placing the focus particle only in front of the utterance (Only) Mary passed the exam results in a similar effect, since the particle expresses that the focused element Mary but not the alternatives lead to a true assertion (cf. König, 1991).

In a previous delayed recall study (Spalek, Gotzner \& Wartenburger, in revision), we explored the impact of focus particles on memory for contextual alternatives. We exposed participants to dialogs that introduced a set of three elements and either contained the particle only, even or no particle (control condition) in the critical sentences. The pitch accent type on the element mentioned in the critical sentences, the focused element, was constant across conditions ( $\mathrm{H}^{*}$ on the accented syllable). The results showed that memory for the alternatives to the focused element improved in the presence of the particles only and even relative to the control condition.

In a subsequent study (Gotzner, Spalek \& Wartenburger, submitted), we tested the effects of focus particles on the recognition of contextual alternatives and rejection of unmentioned alternatives after exposure to an item. We found that participants were slower in rejecting unmentioned alternatives to a focused expression in case the utterances contained the particles only, even or also. This inhibitory effect was present when we enumerated a set of alternatives in the context and when the stimuli only mentioned a semantic category. We concluded that focus particles encourage richer encoding of the alternative set
which leads to better recall of the mentioned alternatives particle when tested at a longer delay (cf. Spalek et al., in revision).

Apart from the fact that focus particles and pitch accents belong to a different formal linguistic level, the two have a different impact on the status of inferences about the alternatives, according to linguistic theory (see for example Krifka, 2007 for an overview). The exhaustivity inference (that the statement does not hold for the alternatives) drawn from a contrastive accent is an implicature which arises through pragmatic reasoning. By definition, implicatures are cancellable inferences and it follows that an utterance with an $\mathrm{L}+\mathrm{H}^{*}$ accent has a reading that does not exclude the alternatives. On the contrary, the exclusion of alternatives is part of the conventional meaning of only, i.e. lexically encoded (cf. Rooth, 1992). In accordance with these theoretical distinctions, experimental work has shown that German participants draw fewer exhaustive inferences from sentences that bear intonational focus than from sentences with only (cf. Onea \& Beaver, 2011). ${ }^{1}$

In contrast to exclusive particles, additive particles like also and even presuppose that a statement holds for at least one of the alternatives and express that the proposition holds for the focused element as well (cf. König, 1991). Yet this linguistic difference did not affect the retrieval of alternatives in the experiments we carried out so far. Therefore, we concluded that the observed effects were driven by the fact that focus particles must refer to a set of alternatives by their semantic definition.

To sum up, there is evidence that focus particles facilitate recall of contextual alternatives (Spalek et al., in revision) and hamper the rejection of unmentioned alternatives when the focused element carries an unmarked accent (Gotzner et al., in preparation). Contrastive pitch accents lead to the activation of contextual alternatives (cf. Braun \& Tagliapietra, 2010) and have been found to facilitate long-term memory for focused elements and contextual alternatives, but not for unmentioned items (cf. Fraundorf et al., 2010).

## The Current Experiment

The aim of the current study was to investigate whether focus particles and contrastive pitch accents rely on the same cognitive mechanism and whether combining the two induces additive effects. That is, if the presence of alternatives is indicated by a contrastive pitch accent in addition to a focus particle, does the accessibility of contextual alternatives increase even further?

In non-tonal languages like English and German focus can be marked prosodically and by specific lexical and syntactic structures (cf. Krifka, 2008) while the different types of focus marking are not mutually exclusive. Following the proposal in Calhoun (2009), we assume

[^282]that by choosing a particular structure, the speaker wishes to make the alternatives particularly salient for the hearer. Hence, it might be that highlighting the alternatives from multiple sources leads to additive effects.

Participants in our experiment were presented with short discourses that mentioned two referents and one of them was mentioned again in the second critical sentence, either pronounced with (a) an unmarked accent $\left(\mathrm{H}^{*}\right)$ or (b) a contrastive one $\left(\mathrm{L}+\mathrm{H}^{*}\right)$. In addition to the $\mathrm{L}+\mathrm{H}^{*}$ accent, condition (c) contained the exclusive particle only and (d) the inclusive particle also. After exposure to the stimuli, participants were asked to recognize the alternative to the noun mentioned in the critical sentences (not the mentioned noun itself).

Additionally, we introduced a delay manipulation that was based on a study by Glenberg, Meyer and Lindem (1987). In their experiment, they found that manipulating the associatedness of a referent and an object affected the mental model listeners constructed from a discourse only after a delay of one filler sentence but not if no filler sentence was presented before test. Since we were not interested in priming effects (cf. Braun \& Tagliapietra, 2010), but in the participants' mental model representation of the contrast set, we administered a similar probe recognition task with a delay manipulation like Glenberg et al. (1987). Accordingly, we hypothesized that the effects only unfold if probe recognition is tested at a delay of one filler sentence.

We predicted that the $\mathrm{L}+\mathrm{H}^{*}$ accent will facilitate recognition of contextual alternatives compared to the $\mathrm{H}^{*}$ accent. Concerning the comparison between the $\mathrm{L}+\mathrm{H}^{*}$ condition and the particle conditions there are three alternative predictions: If accenting and particles rely on the same cognitive mechanism, we should obtain the same magnitude and time-course of the effects. If, however, contrastive accenting and particles are additive, we expect that participants are fastest at recognizing the focus alternative in the two conditions with particles (i.e., (c) and (d)) since they contain a particle in addition to the contrastive accent. Alternatively, it might be that pitch accents are used immediately to encode information about the alternatives (see for example Watson et al., 2008) while such effects take more time to unfold in the case of focus particles. According to this hypothesis, we expect the $\mathrm{L}+\mathrm{H}^{*}$ accent to facilitate the recognition of alternatives after one intervening filler sentence whereas the particles should not cause any positive effects at this point of time.

## Methods

## Participants

A total of 24 native speakers of German ( 15 female and 9 male, mean age 26.1 years, age range $22-30$ ) were recruited from a participant pool at the Institute of Psychology of Humboldt University and were paid 7

Euros in compensation. None of them reported any vision or hearing difficulties.

## Materials

We created 80 discourses that followed the structure of the example presented in (1). The first sentence introduced two referent nouns. The second critical sentence mentioned one of the referents again and described an action. As described above, we introduced a delay variable: On 50 percent of the trials, an additional filler sentence (in brackets in the example) was presented. The filler sentence always consisted of five words and contained a pronoun keeping the referent foregrounded (cf. Glenberg et al., 1987). Across stimuli, the order of mention of the two referents was counterbalanced.
(1) Der Richter und der Zeuge verfolgten die Beweisführung. (Nur/Auch) der RICHTER/der Richter glaubte dem Angeklagten. (Er verkündete das Urteil.)

## Approximate translation:

The judge and the witness followed the argument. (Only/also ${ }^{2}$ ) the JUDGE/the judge believed the defendant. (He announced the verdict.)

The critical sentences were recorded in four versions in each of the conditions $\left(\mathrm{H}^{*}, \mathrm{~L}+\mathrm{H}^{*}\right.$, only and also) by a female research assistant who was trained on focus accentuation and had a middle German accent close to the standard variety of German. After recording, the utterance with the $\mathrm{L}+\mathrm{H}^{*}$ accent (b) was cross-spliced into the two utterances with only (c) and also (d). Thereby, conditions (b), (c) and (d) all contained the $\mathrm{L}+\mathrm{H}^{*}$ accent and all prosodic characteristics of the sentences were held constant. In total, there were 8 experimental conditions: 4 focus conditions crossed with the delay of either 0 or 1 filler sentence.

Acoustic analyses were performed to compare the accented syllable of the $\mathrm{H}^{*}$ (a) and $\mathrm{L}+\mathrm{H}^{*}$ (b) conditions. Figure 1 shows the pitch contour of the accented syllable averaged over all items. Additionally, acoustic analyses were performed to compare the duration, maximum pitch, pitch difference and intensity across accent type condition. Table 1 summarizes the means, standard deviations and results of repeated measures ANOVAs (within item) comparing these acoustic parameters. The analyses revealed that the syllable with $\mathrm{L}+\mathrm{H}^{*}$ accent had a higher pitch excursion, a greater pitch difference, intensity and duration.

The critical trials always probed recognition of the alternative to the noun in subject position, hence requiring

[^283]a yes response ${ }^{3}$. A set of 50 filler items was constructed and 60 items from another experiment were added to counterbalance yes- and no-responses and to prevent subjects from concentrating on the nouns in subject position. Half of the filler items consisted of 2 sentences and half of them consisted of 3 sentences.

Figure 1: Mean pitch contour of the accented syllable across $\mathrm{H}^{*}$ and $\mathrm{L}+\mathrm{H}^{*}$ conditions.

Table 1: Summary of acoustic analyses. Table shows mean values (SE) by accent type and results of F-tests.

| Parameter | H | $\mathrm{L}+\mathrm{H}^{*}$ | $F_{(1,79)}$ | $p$ - <br> value |
| :--- | :--- | :--- | :--- | :--- |
| Duration (s) | 0.17 | 0.23 | 129.1 | 0.001 |
|  | $(0.01)$ | $(0.01)$ |  |  |
| Maximum Pitch | 195.1 | 226.9 | 19.7 | 0.001 |
| (Hz) | $(4.5)$ | $(6.2)$ |  |  |
| Pitch difference | 33.6 | 56.3 | 8.5 | 0.005 |
| (Hz) | $(4.5)$ | $(6.2)$ |  |  |
| Intensity (dB) | 69.1 | 73.3 | 208.0 | 0.001 |
|  | $(1.9)$ | $(2.2)$ |  |  |

Eight experimental lists were created by rotating through the focus ( $\mathrm{H}^{*}, \mathrm{~L}+\mathrm{H}^{*}$, only and also) and delay conditions ( 0 vs. 1 filler sentence) according to a Latin square design. Hence, there were 10 items per condition within a given list. Each list further contained the 110 filler items resulting in a total of 190 items. The lists were pseudo-randomized for each participant so that no more than three filler or test trials were presented in a row and a given focus condition appeared only twice in a row.

[^284]
## Procedure

The experiment started with an instruction displayed on the computer screen. The instructions told the participants that they will be presented with auditory stimuli and that their task is to decide whether a subsequently presented word had appeared in the story or not. They were also asked to respond as accurately and as quickly as possible and to listen to the exact wording. After the instructions were displayed, participants performed four practice trials and were allowed to adjust the sound volume.

Each trial began with the onset of a central fixation cross displayed for 700 ms followed by a discourse that was presented over headphones. Each of the sound files included 2000 ms of silence after the last sentence. On 50 percent of the trials, the audio files contained an additional filler sentence. Probes appeared after the entire audio files, that is, either after the critical sentence (50\%, delay 0 ) or after the filler sentence ( $50 \%$, delay 1 ).

Each probe was administered visually with an offset of 50 ms and the participants indicated whether it had appeared in the discourse by button press. The probe word stayed on the screen until a response was made. If subjects did not respond within a time frame of 4000 ms , the trial counted as a miss. With an offset of 500 ms the next trial was initiated. Every 33 trials, subjects had a short break. In total, there were 6 experimental blocks. The entire experiment lasted about 50 minutes.

## Results

Trials in which subjects responded incorrectly (5.9 \%) or that were more than 2 standard deviations from a participants' mean reaction time ( $4.9 \%$ ) were excluded from the analysis. Accuracy was similar across conditions. The log-RTs were analyzed with a series of mixed models following the procedure described in Baayen (2008). Since we had different predictions for the two delay conditions, we fit two separate models for the two data sets.

Figure 2 shows the mean RTs and standard errors across focus conditions at 0 delay. The final statistical model contained the log-RTs, focus condition and trial as fixed factors, subjects, items as random factors and random slopes for trial. We chose the condition with the $\mathrm{L}+\mathrm{H}^{*}$ accent as reference level, since the two conditions with particles contained an $\mathrm{L}+\mathrm{H}^{*}$ accent as well and since we were interested in whether the particles caused effects in addition to the contrastive accent. The final model had a log likelihood of 222.6 with 828 observations (27 further observations were excluded based on the distribution of residuals and fitted values). Regarding the focus conditions, the model did not reveal any reliable differences across conditions ( $p>.2$; see Table 2 for model details). This is in line with Glenberg et al. (1987) who argued that effects of foregrounding in a mental model should only be observable after a delay of 1 filler sentence.

Figure 2: Mean RT across conditions (delay 0). Error bars indicate standard errors.

Figure 3 displays the mean RTs broken by focus condition at delay 1 . The final mixed effects model for this data set contained the same factors and it had a log likelihood of 206.1 (803 observations, 27 excluded). The analysis revealed that the alternatives were recognized slower in the condition with $\mathrm{H}^{*}$ accent in comparison with the $\mathrm{L}^{+} \mathrm{H}^{*}$ accent ( $t=2.8, S E=.03, p<.01$ ). Hence, the $\mathrm{L}+\mathrm{H}^{*}$ accent facilitated recognition of the alternatives. Compared to the condition with $\mathrm{L}+\mathrm{H}^{*}$ accent, the two particles only and also led to an inhibitory effect ( $\mathrm{L}+\mathrm{H}^{*}$ vs. only: $t=2.0, S E=.03, p<.05 ; \mathrm{L}+\mathrm{H}^{*}$ vs. also: $t=2.5$, $S E=.03, p<.05)$. Thus, adding a focus particle to the contrastive pitch accent led to slower probe recognition times. Table 3 summarizes estimates, confidence intervals and $p$-values extracted by Markov chain Monte Carlo sampling (10000 runs).

## Discussion

The study reported here extends earlier findings on the role of pitch accents in the retrieval of contextual alternatives in two ways. First, it indicates that the $\mathrm{L}+\mathrm{H}^{*}$ accent not only induces priming or activation of contrastive alternatives (cf. Braun \& Tagliapietra, 2010) but it also benefits recognition memory for contextual alternatives. Second, it shows that such effects already unfold after one intervening filler sentence (in comparison with the long delay introduced by Fraundorf et al., 2010).

The task we used required participants to construct a mental model from the auditory discourses they were presented with and they had to recognize a referent that was an alternative to the element mentioned in the critical sentences. In accordance with Glenberg et al. (1987), the effects we observed only evolved after the inclusion of one filler sentence. This finding also provides evidence that there were no general processing differences across conditions. For example, it might be argued that the conditions with particles contained one more word compared to the other conditions leading to increased processing times. However, we would expect to see the same differences across conditions at 0 delay if this were the right explanation of the effects.

Looking at the recognition times in the $\mathrm{H}^{*}$ and $\mathrm{L}+\mathrm{H}^{*}$ conditions across delays, it becomes obvious that recognition performance was equal at 0 delay. By comparison, the $\mathrm{H}^{*}$ slowed and the $\mathrm{L}+\mathrm{H}^{*}$ facilitated recognition times at delay 1. This pattern of results is in line with a recent study by Husband \& Ferreira (2012). They found that contrastively-stressed as well as neutral prime words primed contrastive targets at an immediate SOA. At a longer SOA, the contrastive associates only
maintained facilitation in the condition with $\mathrm{L}+\mathrm{H}^{*}$ accent. Hence, it seems that initially the activation of contrastive alternatives does not differ across $\mathrm{H}^{*}$ and $\mathrm{L}+\mathrm{H}^{*}$ conditions. At a delay of one filler sentence in our experiment, activation of the alternatives decays in the $\mathrm{H}^{*}$ case (as was also argued by Husband \& Ferreira, 2012) and augments in the $\mathrm{L}+\mathrm{H}^{*}$ case.

This pattern of results confirms the assumption by Watson et al. (2008) that the interpretational domains of the two accent types overlap to some extent in that $\mathrm{H}^{*}$ are compatible with contrastive and non-contrastive referents but that $\mathrm{L}+\mathrm{H}^{*}$ favor contrastive referents. The data are hence in line with the claim that $\mathrm{H}^{*}$ and $\mathrm{L}+\mathrm{H}^{*}$ accent do not necessarily form two discrete categories but that the latter is the more contrastive variant of the former.

The $\mathrm{L}+\mathrm{H}^{*}$ pitch accent made the contrastive alternative more accessible at a delay of one filler sentence. In contrast, adding either an exclusive or inclusive particle led to a processing cost. It is conceivable that the observed pattern is due to a facilitatory effect by the contrastive accent combined with an inhibitory effect of the particles since the conditions with particles contained exactly the same (cross-spliced) recorded utterance.

Such inhibitory effects are consistent with the results of our probe recognition experiments where we found that participants were slower in rejecting unmentioned alternatives to a focused expression in case the utterances contained the particles only, even or also (vs. no particle). This inhibitory effect even showed when we explicitly introduced a set of three elements. Hence, we concluded that the particles led to the activation of further unmentioned alternatives in a listener's mental model slowing the participant's ability to indicate that these elements had not appeared in the story.
Interestingly, Fraundorf et al. (2010) did not find any effects of contrastive pitch accents on the rejection of unmentioned items (so-called lures). Despite the differences between the experiments, it might be that contrastive accents only affect the representation of items in the explicit contrast set while focus particles lead to the retrieval of further alternatives accounting for the inhibitory effects observed here (as well as in Gotzner et al., in preparation).

In conclusion, it seems that focus particles lead to an initial processing cost. The positive effect on the retrieval of contextual alternatives that we have observed in our delayed recall experiments (Spalek et al., in revision) seems to need time to develop. By contrast, pitch accents are used immediately by a listener to encode information about the alternatives (see also Watson et al., 2008 for a similar argument). Yet further research is needed to establish whether focus particles and contrastive pitch accents cause additive effects at longer delays or whether the effects level out. It should also be noted that the different experimental paradigms, probe recognition and delayed recall, impose quite different task demands.

Concerning the theoretical account of the observed effects, the comparison between the different types of focus particles leads to an interesting conclusion. Following the original formulation of the contrast representation account, we should expect the particle only to pattern along with contrastive accents but not the particle also since Fraundorf et al. (2010) speculate that contrastive accents create a representation of what did not happen. However, across all our experiments we found that both exclusive (associated with an exhaustive meaning) and additive particles affected memory for information-structural alternatives to a similar extent. Additive particles like also do not have an exhaustive meaning but they presuppose that a statement holds for at least one alternative. Yet what exclusive and additive particles have in common is that both require a salient set of alternatives.

In light of the findings, we propose a modification of the contrast representation account: We assume that focus-sensitive particles (and contrastive accents) make reference to an alternative set and highlight its relevance for interpretation (see also Krifka, 2007 for a recent definition of focus). This creates a salient representation of the alternatives and makes them more easily retrievable on the long run. In immediate recognition (after one intervening filler sentence), adding a particle to a contrastive accent hampers the participants' ability to match a probe with the alternatives encoded in the mental model, as observed in the present experiment.

The fact that the facilitatory effects of contrastive accenting already unfolded after one intervening sentence whereas the particles led to a processing cost at this point of time could either indicate that the underlying cognitive mechanisms are different in the two domains or simply that prosody is integrated at an earlier point of time. However, further research is required to determine the exact cognitive mechanisms that underlie the observed effects. Taken together with the results of Gotzner et al. (submitted), the inhibitory effects of the particles might indicate that listeners activate further unmentioned items interfering with the recognition of the explicitlyintroduced alternatives. Such effects might be absent in the case of contrastive accents considering the results of Fraundorf et al. (2010).

## Conclusion

We showed that contrastive pitch accents enhance the recognition of contextual alternatives after auditory exposure to an item. The combination of a contrastive pitch accent and a focus particle, in turn, led to an inhibitory effect. We therefore suggest that the facilitatory effects of focus particles on the retrieval of contextual alternatives (cf. Spalek et al., 2013) take time to develop.

#### Abstract

Two experiments investigated the production and comprehension of referring expressions that contain a negative property ("the marker without a cap"). Experiment 1 showed that participants do use negative properties in their object descriptions, but that they were almost always accompanied by other properties, leading to referential overspecification. In experiment 2, participants identified objects based on descriptions that contained negative properties. While participants were faster in identifying objects that were described with preferred properties such as color, response times for objects described with a negative property ("the marker without a cap") and a positive property ("the marker with a cap") did not differ. The results provide behavioral grounds for extending referring expression generation algorithms to include negative properties.

Keywords: Referring expressions, speech production and comprehension, negative properties

## (A sort of) Introduction

Image you are reading an interesting cognitive science manuscript and want to highlight an important passage. On the desk of your colleague (see figure 1) are two markers and since you prefer yellow markers, that is the one you would like her to pass on to you. You could phrase your request like this "Could you pass me the yellow marker, please?". In that case you have produced a referring expression with the property color as a means to distinguish between the two markers. However, a viable alternative to this question is "Could you pass me the marker without the cap, please?". In that case, you have used an negative property to refer to the marker of your choice. This paper investigates to what extent speakers produce referential expressions that contain negative properties and how listeners process these expressions. In doing so, we aim to inform computational models of referring expression generation.

Producing a suitable referring expression can be seen as a problem of choice (Krahmer \& van Deemter, 2012). Which properties does a speaker include in the description when asking for the marker? In addition to color and the absence of a cap, the location ("the marker on the left") and size ("the slightly smaller marker") come to mind as possible distinguishing properties for your marker. How to choose between these properties, when they are all suitable candidates for inclusion in the referring expression? Many current compu-

Figure 1: The two markers on the desk of your colleague.
tational approaches, such as Dale and Reiter's (1995) Incremental Algorithm use a fixed ordering of properties that are serially added to the description until all distractors have been ruled out. Since color is a property that is usually highly preferred (Pechmann, 1989), this is the first property that the Incremental Algorithm would add. Since the inclusion of color in the description uniquely identifies the item of your choice, the algorithm stops and produces "The yellow marker" and because the preference order is a fixed order, negative properties like "without a cap", would never be included in a referring expression.

Standard REG (Referring Expression Generation) algorithms such as the Incremental Algorithm do not consider boolean operations such as negation in the generation process (Krahmer \& van Deemter, 2012). Recently however, several attempts have been made to incorporate negation (and other boolean operators) in REG algorithms, either by extending the incremental algorithm (with a specific focus on referring to sets of objects) with boolean expressions (van Deemter, 2002; van Deemter \& Krahmer, 2006), or by reinterpreting the problem of referring expression generation in terms of description logic or conceptual graphs (Areces et al., 2008; Croitoru \& van Deemter, 2007). All of these approaches are computational in nature and until now the question of if, when, and how human speakers produce referring expressions with negative attributes has not been addressed. The behavioral data presented here can help inform computational approaches to referring expressions by, for example,
making the generated expressions more natural (Viethen \& Dale, 2006; Dale \& Viethen, 2010) or by providing inspiration for the further development of the algorithms. For example, the boolean extensions to the Incremental Algorithm proposed by van Deemter (2002) assumes that negative properties are less preferred than their positive counterparts. Here, we explicitly test this assumption with stimuli that do afford a description with negative properties, but can also be uniquely identified with other, more preferred properties.

While referring expression research is primarily concerned with the production of referring expressions, there is an increasing need to assess how listeners process the descriptions that are generated by REG algorithms (Krahmer \& van Deemter, 2012). The most important criterion for a successful algorithm is whether the expressions generated mimic those of humans. However, humans might not always be good at taking the needs of their listeners into account (Horton \& Keysar, 1996) and the references produced by human speakers might not be the most optimal ones. Thus, if our production experiment shows that speakers do use negative properties in their descriptions, this does not necessary mean that listeners will easily deal with such expressions. By combining a production experiment with a comprehension task, these issues will be addressed.

Two separate experiments will investigate the production and comprehension of referring expressions that contain an negative property. In the production experiment, three research questions are addressed. The first is whether speakers will produce referring expressions with negative properties at all in situations that afford (but not necessitate) the use of a negative property in a description. The second question is whether the number of positive properties necessary for a uniquely identifying description matters. It might be the case that speakers are more likely to use a negative property when the alternative means using a more complex description with, for example, two positive properties. This finding would contrast with the expressions generated by the Incremental Algorithm, which has no backtracking ability to take the length of the resulting referring expressions into account (Dale \& Reiter, 1995; van Deemter, 2002). Finally, the phenomenon of overspecification is addressed. Speakers often produce referential expressions that contain more information than strictly necessary (for example, by referring to the marker with "the yellow marker without a cap"). Speakers have been shown to be more likely to produce overspecified references when they use dispreferred properties such as orientation (Goudbeek \& Krahmer, 2012) and when they refer to target in more complex stimulus arrangements (Koolen et al., in press). Referring expressions with negative properties are arguably more complex and less preferred, leading speakers to overspecify descriptions that contain a negative property.

The comprehension experiment focuses on the processing of negative properties and addresses the question whether identifying objects that are described with negative properties takes more time than identifying objects that are described
with positive properties.

## Experiment 1: Producing referring expressions with negative expressions

In Experiment 1 participants produced descriptions of everyday objects. They could either refer to these objects with one or two positive properties ("the large marker" or "the large yellow marker") or with a negative property ("the marker without a cap" ${ }^{1}$. Additionally, this experiment investigated whether the number of properties necessary in the alternative description influenced the referential choices of the speakers.

## Method

## Participants

Twenty undergraduate students (eleven females) from the participant pool of Tilburg University took part in exchange for partial course credit. They were all native speakers of Dutch and were between 18 and 25 years old.

## Materials

In the production experiment, the stimuli consisted of 96 sets of three objects. The target object was always presented in the middle and was marked with a black rectangle. Of the 96 stimuli, 64 were target objects that needed one of more properties for unique identification and and 32 were typeidentifiable objects. Crucially, of the target objects, 32 could be described with a negative property such as "the marker without a cap" and 32 could be described with a positive property such as "the marker with a cap". The objects that had either positive or negative properties were a marker (with or without a cap), a cup (with or without a handle), a basket (with or without a lid) and a bottle (with or without a cap). See figure 2 for an example of two stimuli.

In addition to these properties, the target objects could alternatively be described with properties such as color or size. These are considered to be preferred properties in REG research (Dale \& Reiter, 1995; Pechmann, 1989) and should thus serve as viable alternatives. To investigate whether the number of preferred properties necessary for identification plays a role in determining whether speakers will use a negative property, there was a condition where one positive property would suffice (e.g., "the orange marker", see figure 2a) and a condition where two positive properties were necessary (e.g., "the large orange marker, see figure 2b). In both conditions, one negative property ("the marker without a cap") would always suffice (see figure 2 ).

In addition, the experiment contained 32 type-identifiable stimuli that could be described by using type only (e.g., "the rabbit", "the strawberry"), leading tot a total of 96 stimuli.

## Procedure

Participants were seated in a sound-attenuated room and were instructed to describe the object in such a way that a naive lis-

[^285]
(a) A target that can be referred to with one positive property ("the orange marker") or a negative property ("the marker without a cap").

(b) A target that can only be referred to with two positive properties ("the large yellow marker") or a negative property ("the marker without a cap").

Figure 2: The target stimuli used in the production experiment
tener would be able to identity the target object from the other two. The target object was always presented in the middle, and marked by a black square (see figure 2). Each stimulus was presented for five seconds, during which the participant's description was recorded. After the presentation and recording, a new set of objects immediately appears on the screen. Stimulus presentation and response recording took place on a PC and was controlled through the open-source package Opensesame (Mathôt et al., 2012). The experiment lasted about ten minutes, after which participants were debriefed and thanked for their cooperation.

## Results

The descriptions of the participants were annotated with respect to which property they used in their description (size, color, pattern, and whether their descriptions contained a negative property or not. We also annotated whether a description contained any redundant properties, to see whether the use of negative properties might cause speakers to overspecify. First, we investigated whether participants used the negative property in their referring expressions at all in the condition that afforded to do so (see the left side of figure 3).

While our prediction is that speakers would use the negative property in their descriptions, the algorithm proposed in van Deemter (2002) would never include negative properties

Figure 3: Proportion of descriptions with a negative property in conditions that afforded the use of negative properties (left) and proportion of descriptions with the corresponding positive property in conditions that afforded their use (right).
in the expressions it generates for these stimuli (since a preferred alternative is available). The results show that in almost half of the cases where the stimulus affords using a negative property, our participants did so $(M=.47, S D=0.31,95 \%$ $\mathrm{CI}=0.33-0.62$ ). A one sample t -test showed that this value did indeed differ significantly from zero $(t)(20)=6.76, p<$ .001 , Cohen's $d=1.52$ ). To investigate the effect of the target type (affording negative properties or not), we compared the proportion of descriptions with negative properties for stimuli that afforded the use of negative properties $(M=.47, S D=$ $0.31,95 \% \mathrm{CI}=0.33-0.62$ ) with descriptions with the corresponding positive properties for stimuli that afforded the use of positive properties $(M=.52, S D=0.30,95 \% \mathrm{CI}=0.38$ 0.66 ). The boxplot in figure 3 shows a large amount of overlap, indicating little difference between using a negative or a positive version of a property. A logistic regression with target type (positive versus negative) as outcome variable and proportion of properties used as predictor confirmed the lack of an effect of target type ( $\beta=0.53, \mathrm{SE}=1.06$, Wald $=0.25$, $\left.p=.62, R_{\text {Nagelkerke }}^{2}=0.01\right)$.

Next, we tested the hypothesis that speakers would be more inclined to use negative properties when the alternative description required two positive properties. Figure 4 shows that speakers indeed produced more descriptions containing negative properties when the alternative contains two positive properties $(M=.57, S D=0.34,95 \% \mathrm{CI}=0.41-0.72$ ) compared to when the alternative contains one positive property ( $M=.38, S D=0.33,95 \% \mathrm{CI}=0.23-0.53$ ). However, a logistic regression analysis with number (one versus two) as predictor and the proportion of descriptions with a negative property as outcome variable only yielded a marginally significant effect ( $\beta=1.72, \mathrm{SE}=1.00$, Wald $=2.98, p<.08$, $\left.R_{\text {Nagelkerke }}^{2}=0.10\right)$.

Finally, we investigated whether referring with a negative

Figure 4: Proportion of referring expressions with a negative property in conditions with alternatives that required one or two positive properties for a uniquely identifying description.

Figure 5: Proportion of overspecification in referring expressions that contained a negative property versus referring expressions that did not contain a negative property.
property causes speakers to overspecify (with a positive property) more than referring with positive properties only. For the subset of stimuli that afforded the use of negative properties, we calculated the proportions of overspecified references (defined as any reference that contains an additional property that would have been sufficent to uniquely identify it) for descriptions with negative and positive properties. Figure 5 clearly shows that when speakers use negative properties, they are more likely to use additional properties ( $M=.78, S D$ $=0.32,95 \% \mathrm{CI}=0.63-0.93)$ than when they do not use negative properties $(M=.123, S D=0.16,95 \% \mathrm{CI}=0.05$ 0.20 ). A logistic regression analysis with referring expression (negative versus positive) as predictor and the proportion of overspecified descriptions as outcome variable showed a significant effect ( $\beta=2.62, \mathrm{SE}=1.75$, Wald $=13.35, p<.001$, $\left.R_{\text {Nagelkerke }}^{2}=0.73\right)$.

## Discussion

The results of this experiment show that speakers certainly do not shy away from using negative properties in their referring expressions. In almost half of the cases participants included a negative property in their description when the stimulus afforded to do so. Importantly, our participants were never forced to use the negative property to identify the target referent: all objects could be uniquely identified by (a combination of) color, size or pattern, or by their type alone. This provides a psycholinguistic motivation for developing ways to generate referring expressions that contain negative attributes. Importantly, the boolean extensions of the Incremental Algorithm described in Areces et al. (2008), van Deemter \& Krahmer (2006), and van Deemter (2002) do not fully do justice to the patterns observed here. For instance, while van Deemter (2002) assumes that negative properties are dispreferred, our speakers produced them just as much as their positive counterparts, even when properties that are considered to be more preferred (such as color and size) were at their disposal.

The comparison between alternatives that contained either one or two positive properties showed, albeit marginally significant, that the more complex the alternative expression becomes, the more likely speakers are to use a negative property in their description. This is difficult to explain for REG algorithms that depend on entering properties from a fixed preference order and that do not take into account the length or the complexity of the resulting referring expression. Interestingly, even though speakers often produce descriptions with negative properties, our analysis also showed that the resulting referring expressions hardly ever contain only these negative properties, but were often overspecified. This is in line with findings from previous studies such as Goudbeek \& Krahmer (2012) and Koolen et al. (in press) that show that speakers are more likely to overspecify when their references include less preferred properties or when visual scenes get more complex. A possible explanation is that speakers could take the processing limits of their listeners into account (Arnold, 2008) and adjust the complexity of their utterances to suit.

## Experiment 2: Understanding referring expressions with negative properties

Experiment 2 investigated the comprehension of referential expressions with negative properties.

## Method

## Participants

Twenty-eight undergraduate students (nineteen females) from the participant pool of Tilburg University took part in exchange for partial course credit. They were all native speakers of Dutch and were between 18 and 25 years old. None of the participants took part in Experiment 1.

## Materials

For Experiment 2, the visual materials used in Experiment 1 were stripped from the black rectangle and were presented in the upper left, middle and upper right corner of the screen (see figure 6). They were complemented with a start box at the bottom of the screen. In addition, we recorded instructions to indicate the target object that contained five different ways to refer to the target. These referential expressions either used a positive property ("click on the marker with a cap"), a negative property ("click on the marker without a cap"), color or size ("click on the yellow marker"), color and size ("click on the large yellow marker"), and type-identifiable stimuli ("click on the strawberry"). All these descriptions were minimally specifying in that they provided sufficient, but not more, information to identify the target object. The instructions were spoken with a neutral intonation by a female speaker of Dutch that was unaware of the goal of the experiment. The position of the target was always either in the left or right upper corner and was counterbalanced across items. Since larger targets are easier to move towards and click on (Fitts, 1954), the size of the objects was counterbalanced as well (e.g., sometimes the instruction was "click on the small marker").

## Procedure

Participants were seated in a sound-attenuated room and were given headphones to listen to the prerecorded instructions. They encountered the setup displayed in Figure 6 and could start the spoken description by moving their mouse pointer over the box labeled "START", after which response recording started. The participants' task was to click as quickly as possible on the object that was being described by the prerecorded referring expression. We used the software package MouseTracker (Freeman \& Ambady, 2010) to present the images and speech stimuli and record the mouse movements and clicks. The experiment lasted about 20 minutes. After the experiment, the participants were debriefed and thanked for their cooperation.

## Results

Table 1 shows the response times of the participants for the five different referring expressions. It should come as no surprise that the participants responded fastest to the typeidentifiable items ("the strawberry"). Furthermore, the descriptions that used one were faster than those that used two two preferred properties. These in turn have faster response times than the conditions with either positive or negative properties, that do not seem to differ much.

These effects were evaluated statistically with a one-way within-subjects analysis of variance with type as a within factor with five levels (positive, negative, one, two, typeidentifiable) and response time as dependent variable. This analysis showed a significant effect of type $(F[4,108]=$ 187.01, $p<0.001, \eta^{2}=0.87$ ). Planned contrast showed that response times to type-identifiable objects $(M=1.6, S D=$

Figure 6: The stimulus presentation in the comprehension experiment. The target in the left upper corner can be described with "the marker without a cap" or "the large yellow marker".

Table 1: Response times, standard deviations and confidence intervals for the five different referring expressions in the comprehension experiment

| Type | RT (s) | SD (s) | 95\% CI |
| :--- | :--- | :--- | :--- |
| Positive property | 2.39 | 0.26 | $2.26-2.46$ |
| Negative property | 2.31 | 0.28 | $2.18-2.40$ |
| Two properties | 1.91 | 0.26 | $1.81-2.01$ |
| One property | 1.72 | 0.24 | $1.63-1.82$ |
| Type identifiable | 1.60 | 0.18 | $1.51-1.66$ |

$0.18)$ were faster than responses to descriptions with one preferred property $(M=1.72, S D=0.26): F[1,27]=38.46, p$ $<0.001, r=.76$, which in turn were faster than responses to descriptions with two preferred properties $(M=1.72, S D$ $=0.26) ; F[1,27]=117.81, p<0.001, r=.90$. These were faster than responses to descriptions with negative ( $M=2.31$ $S D=0.28$ ) or positive properties $(M=2.39, S D=0.26)$ ); $F$ $[1,27]=634.2, p<0.001, r=.98)$, which did not significantly differ from each other $(F[1,27]=2.25, p=0.15, r=$ .27).

## Discussion

In Experiment 2 participants identified objects based on to five types of referring expressions; these either contained a negative property ("the marker without a cap"), its positive counterpart ("the marker with a cap"), one preferred property ("the yellow marker"), two preferred properties ("the large yellow marker") or no properties at all (type-identifiable stimuli such as "the strawberry"). The results showed that listeners' response times closely follow the preferences of speakers. Our participants responded fastest to descriptions where using the targets type was sufficient for unique identification. They took (slightly) longer to respond to descriptions that contained preferred properties such as color or size, and it
took them significantly longer to identify targets that needed two properties to be uniquely identified instead of one. Not surprisingly, the response times were longest for the positive and negative properties that were not as preferred as size or color (having or lacking a cap, a lid, or a handle). Crucially, selecting the appropriate target that was described with a referring expression that contained negative properties did not take longer than selecting a target that was described with a positive property. This is in line with the observation from the production experiment, where speakers used the negative description ("the marker without a cap") as much as the the positive description ("the marker with a cap").

While we carefully controlled for the placement and size of the targets and their properties, the length and complexity of the descriptions was not the same for all descriptions. Descriptions that needed two properties contained more words than descriptions that needed only one property. However, the crucial comparison between descriptions with a positive or negative property differed in only one syllable ("with" versus "without" ${ }^{2}$ ). In addition, we measured response times from the start of the utterance, so our listeners could have already identified the target before the end of the referring expression, but see Arts (2004) for a discussion of measurements onsets in processing referential expressions. Although these issues might be difficult to control (referential expressions containing a negative property are inherently more complex than those with only one property), we do plan to take the length of the utterance into account in future work.

## Conclusion

Taken together, the production and comprehension experiment provide experiential evidence for the use of negative properties in referring expressions. Speakers easily produce expressions such as "the marker without a cap" and listeners are not particularly troubled by them. These findings contribute to our understanding of speech production and perception processes in general, and provide important data for extending the scope of REG algorithms to descriptions containing negative attributes.

## Acknowledgments

Many thanks to Carla van Gruijthuijsen for lending her voice to the stimulus material and to Sandra Augustin for her assistance in conducting the experiments. We gracefully acknowledge the financial support we received from The Netherlands Organization for Scientific Research (NWO, Vici grant 277-70-007 awarded to Emiel Krahmer).

# Lay biology in health: How adults conceptualize the benefits of exercise 

Sarah Gripshover<br>sarahjg@stanford.edu<br>Department of Psychology<br>Stanford University

Ellen M. Markman<br>markman@stanford.edu<br>Department of Psychology<br>Stanford University

#### Abstract

We present an approach to health interventions based on the insight that throughout life, individuals construct intuitive theories to predict, explain, and determine how to act on the world. We propose that an intuitive theory-based approach may be useful for teaching adults about the body's biochemical response to exercise. The first step in using this approach is to document the theories that a target population brings to bear on a health domain. We therefore present what is to our knowledge the first investigation of adults' reasoning about exercise. Specifically, we explore how adults explain why exercise confers various benefits, how plausible adults find the physical, emotional, and cognitive benefits of exercise, and how contingent on weight loss adults believe such benefits to be. These findings lay the groundwork for constructing an intervention to motivate adults to exercise more.

Keywords: health, intuitive theories, folkbiology

## Introduction

Throughout life, individuals construct and use coherent belief systems, or intuitive theories, to predict, explain, and determine how to act upon the world (Carey, 1987, 2009; Murphy \& Medin, 1985; Gopnik \& Wellman, 1994; Au, Romo, \& DeWitt, 1999; R. Gelman, Brenneman, Macdonald, \& Roman, 2009; S. Gelman, 2003). This insight has so far remained largely untapped, however, as a resource for health interventions.

We present an approach to health interventions that leverages participants' intuitive theories, builds on them when appropriate, and corrects misconceptions that would interfere with understanding the health message when necessary. This approach goes beyond most knowledge-based interventions that provide facts, "do's and don'ts',' and admonitions without a coherent explanatory framework (see Au, Romo, \& DeWitt, 1999). The intuitive theory based approach takes stock of participants' existing theories in the relevant domain, considers the specific nature of the health message, and determines what conceptual prerequisites need to be in place for participants to understand the message thoroughly, apply it flexibly, and believe it with conviction. The present work takes stock of participants' existing theories regarding exercise.

Gripshover and Markman (in press) used this intuitive theory based approach to teach young children that foods have different nutritional profiles-no one food provides all the nutrients the body needs-and therefore we need a variety of healthy foods. This explanation relies on several concepts, some readily understandable and others opaque. Preschoolers may find invisible, discrete, heterogeneous nutrients inside homogeneous-looking food puzzling because they expect
substances to be continuous (Au, 1994). Because preschoolers understand solutions (Au, Sidle, \& Rollins, 1993; Rosen \& Rozin, 1993), nutrients were explained by analogy to sugar dissolving in water. Nutrient extraction during digestion was explained in mechanical (not biochemical) terms: food enters the body, the stomach breaks it into smaller pieces, extracts the nutrients, and blood carries them throughout the body. This built on children's emerging mechanical understanding of digestion in which food enters and eventually exits the body, but little is known about the intermediate processes of digestion (Teixeira, 2000; Rowlands, 2004). Labels were used to unite perceptually distinct foods into foodgroup categories and convince children that they share important internal properties (S. Gelman \& Markman, 1986). Finally, while children believe that food enables biological processes (Inagaki \& Hatano, 1996), it was additionally explained that different processes require different nutrients. Children learned and generalized this new theory: over half described the role of blood in transporting food when answering open-ended questions about digestion, almost all claimed there were invisible nutrients inside of food, and nearly half justified their hypothetical snack choices in terms of nutrients or variety. Moreover, children even increased their vegetable consumption during snack time even though eating more vegetables was not explicitly mentioned in the intervention.

In the present research, we lay the groundwork for using such an intuitive theory based approach for motivating adults to exercise by taking stock of adults' theories regarding exercise. New findings in exercise research show profound and broad-ranging benefits of exercise, from increasing insulin sensitivity (Borghouts \& Keizer, 2000), to regulating the immune system and reducing inflammation (Woods, Vieira, \& Keylock, 2009), to warding off depression (Dunn, Trivedi, Kampert, Clark, \& Chambliss, 2005; Salmon, 2001) and even decreasing the risk for dementia among the elderly (Kramer, Erickson, \& Colcombe, 2006; Hillman, Weiss, Hagberg, \& Hatfield, 2002; K. Erickson \& Kramer, 2008). Though research is just beginning to delineate the specific mechanisms behind these benefits, the general explanation seems to be that the body sets in motion a cascade of biochemical processes that are specially adapted to sustain and repair body and brain cells and prepare them for the next physical challenge. This repair process explains why exercise improves such a wide range of health indicators, and even causes the creation of new brain cells. Exercise is more than just physical movement: it is in many ways like taking medicine.

We begin by asking what theories adults draw upon to reason about exercise. Very little research exists to guide us
in characterizing these theories. However, we expect nonexpert adults to explain the benefits of exercise by appealing to causal mechanisms that are more or less mechanical in nature; e.g., the heart works harder and thus propels more blood throughout the body; muscles physically grow larger as they become stronger; calories are used up and thus the amount of fat on the body is reduced. Under this view, health benefits would appear to result from biomechanical factors such as weight loss and increased strength of the muscles and heart.

If adults indeed do hold a predominantly biomechanical theory of exercise, we suspect that this theory will be inadequate to explain many of these recently-discovered benefits of exercise satisfactorily. Mental benefits, such as the reduced risk for dementia and improvements in cognitive ability should be especially problematic, because they cross a well-worn ontological boundary between the biological and psychological domains (see, e.g., Carey, 1987; Wellman \& Gelman, 1992, 1998; Inagaki \& Hatano, 1993; Erickson, Keil, \& Lockhart, 2010; Lynch \& Medin, 2006). For example, a normal-weight, or even thin, elderly person who is concerned about memory loss might be more likely to seek out crossword puzzles than physical exercise. An overweight person who embarks on an exercise program and fails to lose a significant amount of weight despite hard work may despair of receiving any health benefits. The present research seeks to document the theories that adults bring to bear on explaining the benefits of exercise as a first step towards creating an intuitive theory based intervention designed to communicate the newfound benefits of exercise to adults.

## Experiment 1

Experiment 1 explores 3 questions: (1) To what extent do adults evoke biomechanical, biochemical, and other causal mechanisms to explain the effects of exercise on the body? (2) How plausible do adults find physical and mental effects of exercise? (3) Do adults view physical benefits of exercise as contingent on weight loss?

## Methods

Participants Participants were 50 adults ( 27 women) from the United States recruited through Amazon's Mechanical Turk (AMT). Ages ranged from 18-25 years $(N=9)$ to $60-$ 69 years $(N=2)$.

Survey A survey was designed using Qualtrics. Question blocks were presented in a fixed order (i.e., plausibility ratings, explanation of benefits, importance of weight loss, and explanation of benefits without weight loss), but items were always randomized within blocks.
Plausibility Ratings Participants were given a list of claims about the effects of exercise and asked to rate their agreement on a scale of $0-100$ with their mouse using a slider. The endpoints of the scale were labeled "totally disagree" and "totally agree," and the midpoint was labeled "neither agree nor disagree." Items included 2 physical effects (improved blood pressure, increased heart rate), 2 emotional
effects (reduced depression risk, improved mood), and 2 cognitive effects (reduced risk for memory loss, improved problem-solving ability). Finally, half of the effects were framed as short-term (immediately after exercise, people experience increased heart rate, improved mood, and improved problem-solving ability) and half as longer-term (regular exercise helps improve blood pressure, reduce depression risk, and reduce risk for memory decline).

Explanation of benefits Participants were shown claims about the benefits of exercise and asked questions framed as, "Research shows that getting regular physical exercise can [claim about benefit]. If you had to guess, why would you say getting plenty of exercise [claim about benefit]?" Participants were asked to assume the claims were true and provide the best explanations they could. Items included 2 physical (reduced blood pressure / blood sugar), 2 emotional (reduced depression risk, reduced stress), and 3 cognitive benefits (improved memory, improved problem-solving ability, and reduced risk for dementia).

Importance of weight loss Seven questions asked whether participants saw value in exercise apart from weight loss. Participants rated how much they agree or disagree with 7 statements such as, "If someone exercises regularly for a long time and never loses any weight, they are probably wasting their time" on a scale of 1-100 using a sliding scale.

## Results and Discussion

Results did not differ by age and gender, so results are collapsed across these categories.

Plausibility Ratings Figure 1 presents mean agreement ratings for each effect of exercise. All ratings were significantly greater than the "neither agree nor disagree" midpoint (all $t$ 's > 3.2), demonstrating that all effects were more plausible than not. Ratings were arcsine transformed to ensure homogeneity of variance and compared to one another using a repeated-measures ANOVA with within-subjects factors of item type (physical, emotional, and cognitive) and time scale (long vs. short-term). Results revealed a main effect of item type $(F[2,48]=50.53, \mathrm{p}<.0001$ and a significant item type by time scale interaction $(F[2,48]=11.28, \mathrm{p}<.0001)$. Posthoc paired $t$-tests showed that emotional effects were less plausible than physical effects (physical $M=90.8 \%$ agreement rating, emotional $M=80.9 \%$ agreement rating, $t(49)=$ $6.09, \mathrm{p}<.0001$ ), and cognitive effects ( $M=66.5 \%$ agreement rating) were less plausible than emotional $(t[49]=6.14$, $p<.0001)$ and physical $(t(49)=9.75, p<.0001)$ effects. No differences were observed between long - and short-term items within physical and emotional effects ( $t$ 's $<1.8$ ), but improving immediate problem-solving ability ( $M=60.1 \%$ agreement rating) was less plausible than reducing risk for dementia ( $M=72.8 \%$ agreement rating).

Explanations of benefits Tables 1-3 present summaries of participants' open-ended explanations. Responses were

Figure 1: Mean plausibility ratings by items. Error bars represent standard error of the mean.
coded into one or more categories.

Physical benefits Explanations for physical benefits included biomechanical mechanisms such as circulation (improved/increased blood flow), "burning off" sugar/calories, clearing debris from blood vessels, strengthening the heart and/or blood vessels, and reducing weight; non-biological explanations (e.g., exercising helps people develop better health-related habits, self-discipline, confidence, etc.); biochemical explanations; and ambiguous biological explanations such as increasing metabolic rate. Table 1 presents the proportion of participants whose explanations featured each category. Biomechanical explanations were by far the most common.

| Items (2) | blood <br> pressure | blood <br> sugar |
| ---: | :--- | :--- |
| burns sugar / calories | 0.00 | 0.52 |
| weight | 0.24 | 0.26 |
| circulation | 0.36 | 0.08 |
| stronger heart | 0.34 | 0.00 |
| clears blood vessels | 0.12 | 0.00 |
| biochemical | 0.00 | 0.12 |
| metabolism | 0.00 | 0.12 |
| non-biological | 0.02 | 0.08 |
| other | 0.34 | 0.30 |
| dk | 0.00 | 0.02 |

Table 1: Proportion of participants appealing to each explanation type for 2 physical benefits of exercise: reducing blood pressure and blood sugar

Emotional benefits Table 2 presents a summary of explanations for the effect of exercise on stress and depression. A handful of biomechanical explanations were observed, such as improved circulation ( $4 \%$ and $2 \%$ for depression and stress) and the release of stress, tension, or negative energy ( $38 \%$ for stress only). However, explanations for stress and depression most commonly appealed to biochemical explanations ( $52 \%$ and $30 \%$ for depression and stress) and non-biological explanations ( $52 \%$ and $30 \%$ for depression and stress).

| Items (2) | depression | stress |
| ---: | ---: | ---: |
| non-biological | 0.52 | 0.32 |
| biochemical all | 0.50 | 0.30 |
| release | 0.00 | 0.38 |
| relax tire out | 0.00 | 0.12 |
| circulation | 0.04 | 0.02 |
| other | 0.12 | 0.12 |
| dk | 0.00 | 0.00 |

Table 2: Proportion of participants appealing to each explanation type for 2 emotional benefits of exercise: preventing depression and reducing stress

Cognitive benefits Table 3 presents a summary of explanations for cognitive benefits of exercise. As with physical benefits, participants appealed predominantly to to biomechanical mechanisms such as circulation (improved blood or oxygen flow to brain and other tissues) and the brain itself getting a "workout" during physical exercise. Participants also claimed that exercise increases feelings of awakeness and improves overall health, and also offered non-biological explanations (e.g., exercise increases social activity, mental discipline, willpower, etc.), and a few biochemical explanations.

| Items (3) | dementia | memory | problem solving |
| ---: | ---: | ---: | ---: |
| circulation | 0.52 | 0.62 | 0.40 |
| nonbio | 0.18 | 0.16 | 0.20 |
| alert clear head | 0.00 | 0.14 | 0.22 |
| physical health | 0.18 | 0.10 | 0.08 |
| exercises brain | 0.14 | 0.12 | 0.06 |
| other | 0.10 | 0.10 | 0.08 |
| biochemical | 0.10 | 0.10 | 0.04 |
| dk | 0.06 | 0.00 | 0.02 |

Table 3: Proportion of participants appealing to each explanation type for 3 cognitive benefits of exercise: preventing dementia, improving memory, and improving problem-solving ability

Biochemical explanations Table 4 presents a summary of biochemical explanations across items. While participants mentioned a wide variety of biochemicals, the most commonly-mentioned was endorphins.

Summary of explanations of benefits Participants evoked primarily biomechanical explanations for physical and cognitive benefits of exercise, and primarily biochemical and nonbiological explanations for emotional benefits. This suggests that although many participants are aware of some biochemical processes related to exercise, they do not view the physical, cognitive, and emotional benefits of exercise as consequences of a single cascade of adaptive biochemical responses. Interestingly, biochemical explanations were overwhelmingly offered for emotional benefits, rather than phys-
$\left.\begin{array}{llllll}\hline \begin{array}{l}\text { Benefit } \\ \text { type }\end{array} & \begin{array}{l}\text { Explanation } \\ \text { type }\end{array} & \text { Item } & \begin{array}{l}\text { conditional } \\ \text { \% of participants }\end{array} \\ \hline \text { physical } & \text { insulin } & \text { blood sugar } & 1.00 & \text { (6 of 6 } \\ \text { emotional } & \text { endorphins } & \begin{array}{l}\text { depression } \\ \text { stress }\end{array} & 0.54 & (14 \text { of 26) }\end{array}\right]$

Table 4: Breakdown of biochemical explanations by benefit type (cognitive, emotional, and physical) and item (preventing depression, reducing stress, etc.). Presented as a conditional proportion of total biochemical explanations given for each item.
ical or cognitive ones, and the vast majority cited endorphins as the causal mechanism. We therefore suspect many of these biochemical explanations may reflect awareness of the wellpublicized "runners' high."

Importance of weight loss Reliability among the 7 questions about the importance of weight loss was high (Cronbach's alpha $=.93$ ) and so a composite importance-of-weight score was created, $M=23.2$ out of $100, s d=14.2$. This score was significantly lower than the "neither agree nor disagree" midpoint of the scale, $t(49)=13.34, p<.0001$, indicating that participants do not view exercise as beneficial solely in the presence of weight loss.

## Biochemical explanations in relation to other measures

To see whether participants who appealed to biochemical causal mechanisms viewed weight loss as less important, we divided participants into two groups: one who never offered biochemical explanations ( $N=18$ ), and one who did ( $N=$ 30). Participants who offered a biochemical explanation had lower importance-of-weight scores $(M=19.1)$ than participants who $\operatorname{did} \operatorname{not}(M=29.5, t[46]=2.56, p=.02)$. We also asked whether participants who offered at least one biochemical explanation rated cognitive and emotional benefits
of exercise as more plausible than participants who offered none, and found that they did not, $t$ 's $<1.3$.

## Discussion

Experiment 1 provided preliminary evidence that adults find the cognitive effects of exercise are less plausible than emotional effects, and emotional effects less plausible than physical effects. Furthermore, we provided preliminary evidence that adults appeal predominantly to biomechanical explanations for explaining the physical and cognitive benefits of exercise, but not the emotional benefits. Instead, adults frequently gave biochemical and non-biological, rather than biomechanical, explanations for the emotional benefits of exercise. However, we suspect these biochemical explanations represent isolated facts, rather than a coherent biochemical theory of the body's response to exercise. Nevertheless, awareness of at least some biochemical effects of exercise in the could be used as leverage for teaching a more coherent biochemical theory.

Finally, although participants were reluctant to endorse statements that blatantly identify weight loss as the primary source of exercise-related health benefits, participants who gave at least one biochemical explanation viewed weight loss as less of a critical factor than participants who identified none. However, it is possible that although adults concede that exercise can offer benefits aside from weight loss, they may still view achieving a healthy weight as important gauge of success if given more subtle questions. Experiment 2 tests this possibility.

## Experiment 2

Experiment 2 explores more closely the importance adults place on maintaining a healthy weight when gauging exercise-related health benefits.

## Methods

Participants Participants were 47 adults ( 23 women) from the United States recruited via AMT. Ages ranged from 18-29 ( $N=23$ ) to 50-59 $(N=4)$.

Survey A survey was designed using Qualtrics. Blocks were presented in a fixed order (i.e., open-ended health behaviors, thinness vs. fitness, weight loss vs. no weight loss), but items within blocks were randomized.

Open-ended health behaviors Participants were asked to list what they believe are the best ways to stay healthy. We were interested in whether participants would be more likely to list maintaining a healthy weight than exercise on its own.

Thinness vs. fitness Participants indicated which of two hypothetical people would be healthier: someone with a healthy weight who rarely exercises and has low physical fitness, or someone who is overweight, exercises frequently, and has high physical fitness.

Exercise vignettes: weight loss vs. no weight loss Participants viewed two vignettes about characters who are overweight and begin fitness programs. Both work out 4-5 times per week for $30-40$ minutes each time for a year. However, one character achieves a weight near the healthy range, and the other character only loses a few pounds and remains overweight. Participants estimated the percent likelihood that each character received a set of physical, cognitive, and emotional benefits. Order was randomized across participants.

## Results and Discussion

Results did not differ by age and gender, so results are collapsed across these categories.

Open-ended health behaviors Table 4 presents behaviors participants identified as important for health. Nearly all participants identified exercise and diet. No participants identified maintaining a healthy weight.

|  | \% of participants |
| ---: | ---: |
| healthy diet | 1.00 |
| exercise | 0.96 |
| weight loss | 0.00 |

Thinness vs. fitness $15 \%$ of participants said that a person who is lean and not physically fit is healthier than someone who is fit and overweight. $23 \%$ of participants said both are equally healthy, and $61 \%$ said that an overweight, fit person is healthier, $\chi^{2}(2)=16.2, p=.0003$.

Exercise vignettes: weight loss vs. no weight loss Reliability across likelihood ratings for physical, cognitive, and emotional benefits was high (alpha $=.93$ for no-weight-loss vignettes and .92 for weight-loss vignettes) mean composite score for each vignette was computed for each participant across items. Participants rated benefits as significantly more likely in the presence of weight loss (no-weight-loss vignettes $M=56 \%$ likely, weight-loss vignettes $M=72 \%$ likely, $t[46]$ $=6.8, p<.0001$ ).

Because the vignettes were identical except for weight loss, it was possible that participants used weight explicitly to differentiate their ratings. We therefore performed a betweensubjects comparison using only each participant's first vignette. Figure 2 presents these ratings. Again, participants rated benefits as more likely when they occurred in the presence of weight loss ( $M=76 \%$ likely) than in the absence of weight loss ( $M=65 \%$ likely), $t(45)=2.4, p=.02$.

This suggests that adults do at least to some extent view weight loss as an indication of progress in an exercise program. This was true for nearly every benefit we presented, including physical and emotional benefits.

## Discussion

Participants identified diet and exercise as the best ways to improve health nearly $100 \%$ of the time, and they recognized

Figure 2: Ratings of percent likelihood that the character in each vignette experienced each benefit. Considering only each participant's first vignette
that a fit, overweight person is likely to be healthier than a normal-weight, unfit person. On the other hand, participants rated nearly all of the benefits of exercise that we presented as less likely to occur for a character who loses very little weight. It is possible that participants found it implausible that a character could truly comply with an exercise program for a year and not lose weight. Exercise physiology research has shown, however, that some individuals do comply rigorously with an exercise program but lose very little weight, and yet still reap health benefits similar to those who lose more weight (King, Hopkins, Caudwell, Stubbs, \& Blundell, 2009). The vignettes furthermore gave identical descriptions of both exercise regimens. Participants still may have assumed the non-weight-loss character was not working out as intensely, however. Further research is needed to determine whether adults view weight loss as a mechanism behind certain health benefits, or as diagnostic of adequate effort.

## General Discussion

These studies to our knowledge provide the first systematic exploration of how adults bring their biological theories to bear on the topic of exercise. Although many participants were aware of some biochemical effects of exercise, we did not find evidence of participants holding coherent theory of exercise triggering a cascade of beneficial chemical responses in the body.

Although adults do not view weight loss as more important than exercise, we found that they do view many benefits as less likely to occur without weight loss. A biochemical theory of exercise may therefore be useful to de-emphasize weight loss as a gauge or mechanism for health benefits.

We also identified one area in which biochemical effects of exercise are already well-known: the emotional benefits of exercise. Widespread knowledge of the "runner's high" can therefore be leveraged to teach a more general biochemical theory of exercise.

Finally, we identified one way in which a biochemical theory of exercise may fail to support a coherent understanding of the wide-ranging benefits of exercise. Adults view cog-
nitive benefits of exercise as less plausible than physical and even emotional benefits. They also explain cognitive benefits primarily by appeal to biomechanical explanations-few participants offered biochemical accounts. This raises the interesting possibility that a lay biochemical theory of exercise does not support a coherent, compelling explanation for the cognitive benefits of physical exercise. This may have implications for motivating older adults to exercise. Maintaining cognitive acuity may be much more important to older adults than more well-known aims of exercise such as building strength and improving physical appearance. At the same time, these cognitive benefits may be the most difficult to understand in light of adults' lay theories. An intervention that explains the cognitive benefits of exercise may therefore be especially useful if targeted towards older adults.

Future research will test whether teaching adults a biochemical theory of exercise increases their conviction about the cognitive benefits of exercise, diminishes focus on weight as an indicator of success, and actually motivate adults to exercise more. The present research documents adults' lay theories of exercise and establishes the potential utility of an intuitive theory based approach to motivating adults to exercise.

# Bayesian Adaptive Estimation of Psychometric Slope and Threshold with Differential Evolution 

Hairong Gu, Jay I. Myung, Mark A. Pitt, and Zhong-Lin Lu<br>\{Gu.124, Myung.1, Pitt.2, Lu.535\}@Osu.Edu<br>Department of Psychology, Ohio State University<br>1835 Neil Avenue, Columbus, OH 43210 USA

#### Abstract

The adaptive experimentation methodology has been adopted in visual psychophysical modeling in the pursuit of efficiency in experimental time and cost. The standard scheme only optimizes one design in each experimental stage, although simultaneous optimization of multiple designs per stage can be beneficial, but difficult to implement because of a surge in computation. In this study, we incorporated the adaptive experimentation methodology under a Bayesian framework with differential evolution (DE), an algorithm specialized in multi-dimensional optimization problems to explore the multiple-designs-per-stage approach. By taking advantage of parallel computing, DE is computationally fast. The results showed that the multiple-designs-per-stage scheme resulted in a more stable estimation in the early stages of the parameter estimation.

Keywords: Visual psychophysics, Bayesian inference, adaptive estimation, evolutionary computing

## Not All Designs are Equally Informative

Experimental design is a critical step in carrying out effective experiments. Traditionally, the practice of experimental design is guided by heuristic norms, using a one-shot design, chosen at the outset, throughout the course of the experiment. Although this approach may be adequate in some scientific quests, its shortcomings are obvious. First, not all experimental designs are equally informative. The traditional approach does not guarantee that the design, including the number of treatments, the values of treatments, and the number of participants in each treatment, is an optimal choice. A non-optimal design may contribute little to the goal of the experiment. Further, the most informative designs may change as the experiment progresses with more responses being observed. Thus, a one-shot design ignores utilizing what can be learned during the course of an experiment.

Second, the traditional experimental design method typically relies on increasing the number of participants or the number of measurements to increase the power of statistical inference. Obviously, this increases the experimental cost, which would matter for experiments that use expensive technology such as fMRI, or research whose target population is difficult to recruit (children, senior citizens, mentally disordered).

Third, the traditional methods of experimental design center on randomization, reduction of variation, blocking etc., with the purpose of revealing the group or treatment
effects while ignoring the individual variation. However, more and more recognition has been given to the importance of individual differences. For example, in drug development, it is important to know how different people react differently to the same drug to guide the prescription. Thus, experimental designs should not be identical for every participant.

To illustrate how experimental designs can be unequally informative, suppose that a researcher is interested in studying how the rate of detection changes with the brightness of a stimulus. A psychometric function is used to describe the probability $p$ of detecting a stimulus of certain brightness $x$. A simplified example assumes a sigmoid function $p=1 /(1+\exp (-x+t))$, where $x$ is the design variable representing the brightness and $t$ is the parameter, threshold, a characteristic associated with a particular individual, reflected in the shift of the model in the design dimension. Suppose that there are only 5 possible values of $t$. The corresponding predictions are depicted as the five lines in Figure 1. The red line represents a particular subject's true $t$ value and the other four blue lines are from the wrong $t$ values. The researcher conducts an experiment to estimate the threshold value of that subject by presenting two designs with intensity D1 and D2. Visualization of the model suggests that D1 is a good design because the predictions from the five $t$ values are very differentiable so that the observation can be informative of the true $t$ value. On the other hand, D2 would be a bad design because the prediction differences are so small that little information about the exact shift of the true model is given.

Figure 1: A sample psychometric function with 5 possible parameter values (see text) with the true value indicated by the red line and the wrong values by the blue lines. A good design D1 offers the most discriminability, whereas D2 is a bad design for a lack of differentiability in prediction.

## Adaptive Experimentation

In practice, we do not possess full knowledge of the approximate values of good designs because the model can be quite complex and the range of parameters can be much larger. In addition, an experiment usually contains multiple trials, so the best designs at the beginning of an experiment may be different from those at the later trials of the experiment. Therefore, an efficient experimentation should adaptively identify the best design for the current trial based on the responses already collected from the participant. Facing these challenges for a better experimental design regime, a statistical methodology, dubbed adaptive design optimization (ADO, Cavagnaro et al., 2010; Myung et al., 2012) under a Bayesian framework has been developed to meet these needs.

The general framework of ADO is illustrated in Figure 2. The traditional experimentation starts from a particular experimental design, with which data are collected, and it stops at cognitive modeling where data are fit to a proposed model to make statistical inferences. In contrast, in ADO, the inference from cognitive modeling continues to influence the choice the designs for the next experimental stage. To put it in another way, the whole experiment is divided into multiple stages, and in each stage, the design is based on what is learned from the data collected in the previous stages. By doing that, every selected design is the most imminently useful one for the immediate trial. As such, ADO is efficient in a way that it reduces the time, cost of experiments and the number of participants without sacrificing the quality of the statistical inferences.

Figure 2: Schematic illustration of ADO paradigm.
There are other desirable features of ADO that make it more attractive to the traditional experimental methods. It is found that bad designs not only increase the cost of experiments, but also deteriorate the quality of data so as to hurt the final inference. ADO adopts an information theoretic computational algorithm to ensure the quality of the selected designs so that the risk of having bad designs is minimized. Additionally, ADO is able to reveal individual differences in response strategy or characteristics because the designs are tailored based on the subject's responses in each experiment. Classification of participants can also be done after individuals' properties are estimated.

Because of its efficiency and versatility, ADO has found its usage in various disciplines. It has been used for designing electrophysiology experiments in neuroscience (Lewi et al., 2008), drug dosage assignment in clinical drug development (Miller, et al. 2007), etc. In psychology, it has
been implemented in the discrimination of retention models in simulations (Cavagnaro et al., 2010) and human experiments (Cavagnaro et al., 2011).
A promising application of ADO is in psychophysical experiments with potential clinical applications that put high stake on the reliability of the results and usually have tight time restraint on the experiments. In this area, the previous studies have only optimized one design in each experimental stage. The difficulty of exploring a different scheme, multiple designs per stage, lies in a lack of a smarter algorithm and the increase in computation.
In this paper, we explore ways to improve upon the current efficiency of ADO by implementing the multiple-designs-per-stage scheme that is solved with an evolutionary computation algorithm known as differential evolution (DE). In what follows, we begin with a brief introduction of the ADO methodology. We will then review past studies in adaptive experimentation of visual psychophysics, followed by a discussion of the motivation and application of the multiple-designs-per-stage scheme and DE. Finally, we present and discuss results from ADO simulations.

## How ADO Works

In this section, we provide some technical details of ADO. Readers who prefer to skip technicalities may bypass this section. Figure 3 is a schematic illustration of the steps involved in ADO. First, the application of ADO requires that the model should be formulated as a statistical model defined as a parametric family of probability distributions, $p(y \mid \theta, d)$ 's, which specifies the probability of observing an experimental outcome $y$ given a parameter value $\theta$ and a design $d$. As mentioned before, ADO is a circulating process going through design optimization (DO), experiments and cognitive modeling. In each round, the process starts with the assumed or learnt probability distribution of the parameters, the prior distribution $p(\theta)$. Next, in the step of DO, the optimal design $d^{*}$ is selected from a design set $D$ by the principle of maximum utility.
In DO, a utility function $U(d)$ is pre-defined to quantify the usefulness of a design $d \in D$ for the purpose of the experiment. For parameter estimation, the utility $U(d)$ of each design $d$ is the expectation of the local utility $u(d, \theta, y)$ taken over the parameter space and the outcome's sample space, formally written as

$$
\begin{align*}
d^{*} & =\underset{d \in D}{\operatorname{argmax}}(U(d)) \\
& =\underset{d \in D}{\operatorname{argmax}} \iint_{y, \theta} u(d, \theta, y) p(y \mid \theta, d) p(\theta) d y d \theta, \tag{1}
\end{align*}
$$

where $u(d, \theta, y)$ is defined on a set of particular design $d$, parameter value $\theta$ and observation $y$. The goal of parameter estimation is to obtain accurate estimation of the true parameter values with the smallest number of experimental trials. Functionally, an appropriate utility quantifies the usefulness of designs in reducing the variation of the parameter estimates. Or in the language of information theory, a utility amounts to the information gain or the
uncertainty reduction of the unknown parameters after observations are collected. One formulation of utility that directly quantifies the information gain of the parameter $\Theta$ with the observation $Y$ is Mutual Information $I\left(Y_{d} ; \Theta\right)$. According to the property of mutual information, the utility $U(d)$ can be written as

$$
\begin{aligned}
U(d) & =I\left(\mathrm{Y}_{d} ; \Theta\right) \\
& =\iint\left(\log \frac{P\left(\mathrm{y}_{d} \mid \theta\right)}{P\left(y_{d}\right)}\right) p\left(y_{d} \mid \theta\right) p(\theta) d \theta d y_{d}
\end{aligned}
$$

In which $\log \frac{P\left(y_{d} \mid \theta\right)}{P\left(y_{d}\right)}$ corresponds to the local utility $u(d, \theta, y)$ in Equation (1).

Two general methods have been used in ADO to solve the multiple integral problem of Equation (1), grid search and sequential Monte Carlo (SMC). In grid search, the design space is discretized and grids are the fixed designs on the space. To calculate $U(d)$, one way is to discretize the parameter space also and just replace the integral with summation. Or we can draw a large sample of $(\theta, y)$ from the model's prior and sampling distribution, and then calculate Equation (1) by Monte Carlo approximation. On the other hand, in SMC, solving ADO is recasted as a probability density simulation problem. The utility function is extended to a joint distribution with parameters, observations and designs. By adopting Metropolis-Hasting algorithm and simulated annealing procedure, the marginal distribution of $d$ can be obtained. In this paper, we will present a third method, differential evolution (DE) (Storn \& Price, 1997) as an alternative that is specialized in multidimensional optimization problems.

After DO, the optimal design $d_{s}$ for the current stage will be presented to the participant. The responses until the current stage will be used to update the knowledge of the parameters. Mathematically, we calculate the posterior probability distribution of the parameters by Bayes' rule, $P_{g+1}(\theta \mid y, d)=\frac{p(y \mid d, \theta) p_{g}(\theta)}{p(y \mid d)}$. Then the posterior distribution of the parameters of stage $g$ is treated as the prior distribution of the next stage $g+1$. And the ADO process continues.

## Adaptive Estimation of Psychometric Function

In visual psychophysics, a major interest is to study the relationship between the intensity of visual stimuli and their perception. This relationship is usually modeled by a psychometric function with two parameters, threshold and slope. Accurate estimation of the parameter values on individual level not only provides knowledge of the underlying psychophysical process, but also assists in the diagnosis and classification (Lesmes et al., 2010). A major, practical challenge is that a large number of experimental trials is often needed to accurately estimate the parameters with the finding that different design schemes of fixed patterns produce varying accuracy, precision of parameter estimation and model fit (Wichmann \& Hill, 2001).
Addressing this issue, a variety of adaptive experimental methods have been proposed for efficient parameter estimation while the design dimension was restricted to be one. ADO, as a more general optimization algorithm, is able to handle large scale, non-linear models with multiple design variables. Next, within the framework of ADO, the $\Psi$ method (Kontsevish \& Tyler, 1999) was developed that can easily be generalized to incorporate more than one stimulus. It has been applied to such research as diagnosis of visual deficit (Lesmes et al., 2010).

## Multiple-designs-per-stage Scheme

All the methods mentioned above assume that there is just one design to be optimized and one response to be collected in each adaptive estimation stage. It is worthwhile to explore if there is any benefit when more than one design is optimized simultaneously and executed in each stage, by which $d$ in Equation (1) becomes a vector. Intuitively, a multiple-designs-per-stage approach can be beneficial because multiple responses are collected jointly in one stage, and according to the information theory, the joint entropy or information from a set of random variables is more than or equal to the sum of entropy from individual variables. Therefore, we hypothesize that if multiple responses are collected in one stage, the relationship or synergy of the responses can benefit the modeling process more than the case when the responses are collected one by one.

Figure 3: Schematic illustration of the steps involved in adaptive design optimization (ADO).

One computational challenge in the application and implementation of multiple-designs-per-stage scheme is the curse of dimensionality. Most published studies on parameter estimation with psychometric functions used brute-force grid search, which is to fix a certain number of design points on the design space. Because the dimension of the design space increases with the number of designs per stage, the quantity of grids need to enlarge exponentially to keep a certain resolution, which causes a waste of computing resource because most of the grids are far from the best design and not worth being computed in each stage. As such, it begs for a different algorithm that suits multi-dimensional optimization problems in an accurate and efficient way.

## Differential Evolution Search

DE is an evolutionary computation algorithm to optimize nonlinear and non-differentiable continuous functions by keeping track of, iteratively evolving and updating multiple particles. A brief explanation of the algorithm is as follows. To search the global maximum of a $D$ dimensional space, it keeps track of $N P$ D-dimensional vectors $x_{i, G}(i=1,2, \ldots, N P)$, where $N P$ is the number of particles and $G$ the generation index. At the beginning, the vectors can be randomly selected. Then for each target vector $x_{i}$, a mutant vector $v_{i, G+1}$ for the next stage is generated by $v_{i, G+1}=x_{r 1, G}+F \times\left(x_{r 2, G}-x_{r 3, G}\right)$ where $r 1, r 2$ and $r 3$ are randomly chosen integers from 1 to NP except $i$, and $F$ is a constant factor controlling the contribution of the difference of the two randomly chosen vectors. The next step, crossover, creates a trial vector for each target vector with each element either from the mutant vector $v_{i}$ or the target vector $x_{i}$. Then the cost function values of both the target vector $x_{i}$ and the mutant vector $v_{i}$ are computed. If the mutant vector $v_{i}$ yields a smaller cost, the target vector is set to $v_{i}$. Otherwise, the target vector is retained from the last generation. DE is illustrated in Figure 4 with a simple toy example in which DE was used to search the global maximum of a bimodal distribution.

Figure 4: Illustration of DE algorithm searching for the global maximum of a 2-dimensional bimodal distribution. Initially (left), the particles are randomly selected. At $30^{\text {th }}$ generation (right), they converged to the larger mode.
DE is a natural approach to our problem of optimizing multiple designs per stage simultaneously. Because different particles can be processed independently in one stage, DE can benefit from parallel computing.

## GPU-based Parallel Computing

Although ADO retains the quality of the data with fewer trials, the heavy computation of ADO is still an issue to reckon with, especially in real-time experiments. One solution to speed up the computation lies in parallel computing. Traditionally, computer instructions are stored and processed by a central processing unit (CPU), and executed in a serial manner. On the other hand, parallel computing employs multiple cores on a single chip to perform many independent numerical operations simultaneously. Graphic processing units (GPUs) were originally dedicated to processing graphics. However, in recent years, GPUs are being increasingly popular as a general-purpose parallel computing tool in image processing, data mining, and machine learning.

In our previous work, we have implemented GPU computing to accelerate ADO computing. Compared with CPU-based ADO, GPU-based ADO is around 100 times faster, which substantiates the feasibility of using GPU computing to accelerate the computational speed of ADO computing ( $\mathrm{Gu}, 2012$ ). Given that the DE algorithm is intrinsically parallelizable, GPU computing can be beneficial for accelerating the computation.

In the present work, we implemented DE on graphic processing units (GPUs) to speed up the ADO computation.

## Simulations

ADO-based parameter estimation of the psychophysical model in Kontsevich and Tyler (1999) was simulated with artificial data under the assumption that the data are from a stationary process with no variation of lapses or learning. The data-generating model was defined in the following equations

$$
\begin{aligned}
& Y \sim \operatorname{Binomial}(1, \Psi(x)) \\
& \Psi(x)=\Phi(r(x) / \sqrt{2} ; \mu=0, \sigma=1) \\
& r(x)=10^{\wedge}\left(10^{s}(x-t)\right)
\end{aligned}
$$

in which $\quad \Phi(m ; \mu, \sigma)=\frac{1}{\sqrt{2 \pi}} \int_{-\infty}^{m} \exp \left(-\frac{(c-\mu)^{2}}{2 \sigma^{2}}\right) d c ; \quad Y$ represents the experimental observation; $x, t$ and $s$ are the design variable and the parameters, threshold and slope, transformed in log decimal scale. The range of $x, t$ and $s$ are set to be $(0,3),(0,3)$ and $\left(\log _{10} 0.7, \log _{10} 7\right)$, respectively. The prior distributions of $t$ and $s$ are both uniform. In the simulation, the true values for $t$ and $s$ are set to be 1.5 and $\log _{10} 3.5$ or approximately 0.544 .

Multiple designs are optimized at the same time in one stage by DE algorithm. Computationally, DE is used to search for the global maximum of the defined utility function. For a two-alternative forced choice (2AFC) problem, the response $y$ is either 0 or 1 . So the utility function of an $n$-dimensional space can be written as

$$
U(\tilde{d})=\sum_{\theta} \sum_{y_{i}=0,1} u\left(d_{1} \ldots d_{n}, y_{1} \ldots y_{n}, \theta\right) P\left(y_{1} \ldots y_{n} \mid \theta\right) P(\theta)
$$

in which the parameter space $\theta$ is also discretized so that the integral in Equation (1) becomes a summation. The
local utility $u\left(d_{1} \ldots d_{n}, y_{1} \ldots y_{n}, \theta\right)$ is in the form of mutual information $\log \frac{P\left(y_{1} \ldots \mathrm{y}_{n} \mid \theta\right)}{P\left(y_{1} \ldots y_{n}\right)}$.

First the two-designs-per-stage scheme was implemented. Five two-dimensional particles were generated and shown to be enough for the convergence, which was evaluated by the closeness of the particles at the last generation. Until the $50^{\text {th }}$ generation, the 5 particles are identical up to the second decimal number, indicating that 50 generations are enough for DE to locate the maximum of the utility space. The algorithm was coded in parallel computing with a single GPU card, Tesla C2050 by Nvidia, which contains 448 CUDA cores. A third party library in C++, Arrayfire, is called to access the GPU computing function.

One experiment contains a total of 150 stages or 300 trials. To visualize the effect of parameter estimation, the model predictions based on the prior distribution and the posterior distribution at the last stage is shown in Figure 5. On the left, the model prediction is based on the initial uniform distribution of the two parameters. On the right, the prediction is based on the posterior distribution of the $150^{\text {th }}$ stage of the two parameters. Compared to the initial stage, the range of the likely outcome of the model is much narrowed and concentrated, indicating the convergence of the estimation.

Figure 5: The model predictions based on the prior distribution (left) and the posterior distribution at the $150^{\text {th }}$ stage (right). Darker colors indicate high probabilities.

The joint and marginal posterior distributions of threshold and slope at the end of the experiment are shown in Figure 6. Both the posterior distributions tend to converge to the true values of the parameters. Conforming to the previous studies, the estimation of the threshold is more accurate and has less variation in its posterior distribution while the estimation of slope is less stable.

In each stage, one point estimate is computed for each parameter by calculating the mean of the distribution. 100 experiments of 150 stages were run. Let $\theta_{i}$ be the point estimate in each stage, and $\theta_{\text {true }}$ be the true parameter value, each in log decimal scale. Then we can compute the average bias and standard deviation of the estimation in each stage across the 100 experiments by

$$
S D(\theta)=\sqrt{\frac{\sum_{i=1}^{i=I}\left(\theta_{i}-\theta_{\text {true }}\right)^{2}}{I-1}} \cdot 20 d B
$$

Posterior PDF of threshold $t$

Figure 6: The joint and marginal posterior distributions of threshold and slope at the $300^{\text {th }}$ trial.

To compare the two-designs-per-stage scheme with the traditional one-design-per-stage scheme, we ran 100 experiments of 300 stages with one design in each stage and computed the bias and standard deviation of the estimates in each stage. Figure 7(a) shows the comparison between the two different schemes. In the later trials, the two different schemes do not seem to have significant differences. There is no significant bias at the $300^{\text {th }}$ trial for both threshold and slope. The standard deviation of threshold is about 0.2 dB and that of slope is about 1.1 dB . Although the two-designs-per-stage scheme has less fluctuation in the early stages in the bias of threshold, the difference may result from the random effect.
Next, the five-designs-per-stage scheme was implemented. Because the dimension increases, 200 generations are needed for DE to converge. One hundred experiments of 60 stages ( 300 trials in total still) were run and the point estimates were computed for each stage. Figure 7(b) shows the comparison between the five-designs-per-stage and the one-designs-per-stage schemes. We can see that there is much less fluctuation in the bias of threshold for five-designs-per-stage than that of one-design-per-stage at the early trials, which is consistent with the improvement in the two-designs-per-stage scheme. Other than that, there is no obvious difference between the two schemes.

As expected, simply increasing the number of designs in one stage while still keeping the total number of trials constant resulted in improvement in the accuracy of parameter estimation, at least at the early stages. As we hypothesized, the relationship or synergy provided by multiple responses is greater or at least different than the sum of the information from single responses. We expect that such improvement can be more obvious when it is applied to more complex models because in those cases, more trials are needed for simply exploring the model in
the early stages of an experiment. However, we should not expect that the performance continues to improve as the number of designs per stage increases. By the principle of ADO, a good design should be based on solid information conveyed by the participants' responses. A large number of designs per stage may probe into unfruitful regions of the design space. A balance must be sought in deciding how many designs per stage are good for different models.

Figure 7: The comparison of one design per stage with two designs per stage (a) and five designs per stage (b) in the bias and standard deviation of the estimates of threshold and slope.

## Conclusion

In psychophysical studies, many endeavors have been made to bring further efficiency to the process in parameter estimation. One clear direction is in global optimization or multiple steps ahead to improve the current greedy method that only evaluates the design utilities at the next stage. If global optimization provides the ultimate solution, the approach we studied in this paper, multiple designs per stage, is an initial step in this direction. Thus, in this paper, we sought one eclectic choice between the traditional one-shot experimental design at the very beginning of an experiment and the advanced adaptive experimentation with only one design per stage. The results showed that multiple designs per stage can benefit the estimation in the early stages of an experiment. The reason for the benefit is reminiscent of
holistics in Gestalt psychology and the principle in information theory, with the multiple responses offering extra information than the sum of the individual responses.
To realize the optimization of multiple designs in one stage, we integrated the adaptive design optimization framework with an evolutionary computation algorithm, differential evolution, which is specialized in searching a multi-dimensional space for the purpose of optimization. DE can also be naturally applied to models that contain multiple design variables, for which brute-force grid search is usually applied. DE is less computationally demanding than grid search when the design space is large. Other than that, DE can also benefit from parallel computing to accelerate the computation within each experimental stage.
As such, DE-based adaptive design optimization has large potential of applications in the future experiments for parameter estimation.

# Spatial meanings for function words? The link between conjunctions and spatial representations

#### Abstract

While formal theories of language consider function words to have little semantic content, more recent theoretical work has argued that even function words have meaning. Yet, there is little experimental work on the representations underlying the meaning of function words such as conjunctions. In two offline experiments, we examined whether conjunctions (and, or, but, either...or) are associated in systematic but distinctive ways with spatial information. In Experiment 1, participants drew schematic representations to depict how two abstract conjuncts might be connected by each of the four conjunctions. These drawing were evaluated on three spatial dimensions (distance, containment and size). In Experiment 2, participants evaluated how well schematic sketches (that differed in distance, containment, and size) represented different conjunctions. In both experiments, spatial information was systematically and distinctively associated with conjunctions. Either... or and or conjunctions were reliably associated with the use of large distance and separation via containment of the conjuncts. And, by contrast, was associated with shorter distance between, and no containment of, the conjuncts. Finally, but was associated with differences in size. We discuss implications of these results for the spatial foundation of linguistic meaning, and the link between lexical semantics and logic.

Keywords: Conjunctions, spatial representation, drawing, rating, simulation, embodiment.

## Introduction

Natural language conjunctions such as and and or are used in ways that differ markedly from their logical or "truthtabular" senses. For instance, and often expresses the temporal order of two conjoined events (Bloom et al, 1980). Thus, (1) and (2) mean quite different things:
(1) He ran through the door and slipped on a banana peel.
(2) He slipped on a banana peel and ran through the door.

While (1) and (2) differ only in the order of the conjuncts, this results in a different temporal ordering of the events. Conjunctions can also express causality, counterfactuals, or subordination (see Culicover \& Jackendoff, 1997). This departure from formal logic has long been recognized by linguists of all stripes (e.g., Hoeksema, 1987; Klinedinst \& Rothschild, 2012). But what about those cases where and
and or are used in a sparse discursive context and actually appear to express a simple logical relation? What are the lexical semantics of and and or in their most austere uses?

On a classic formal account, the semantics of these function words is impoverished, contributing to the meaning of an utterance only in virtue of the meaning of the conjoined content words (e.g., Keenan \& Faltz, 1985; cf. Boole, 1854). More recent work, however, has prompted a reconsideration of the semantics of function words, and of the semantic content of grammar more generally. Langacker (2008) has argued that grammar is inseparable from meaning, since it shapes conceptualization in subtle but reliable ways. According to Langacker (1987), conjunctions like and and or prompt the "juxtaposition" of two or more objects or events in a dynamic conceptualization. Moreover, he and others (e.g. Landau \& Jackendoff, 2003; Talmy, 2000) have argued that schematic spatial information may lie at the core of linguistic meaning. Could the "juxtaposition" prompted by conjunctions rely on implicit spatial representations?

This possibility aligns with recent evidence that language comprehension involves the dynamic construction of an embodied mental simulation. In contrast with approaches that posit abstract, symbolic representations (e.g. Landauer \& Dumais, 1997; Markman \& Dietrich, 2000), embodied approaches argue that linguistic meaning is fundamentally tied to perceptual, motor and affective representations (Barsalou, 1999). Understanding "He threw the apple into the air," might involve activating cortical circuits implicated in perceiving the color red (Connell, 2007), perceiving motion (Saygin et al, 2012), or performing the action of throwing (Masson, Bub, \& Warren 2008). To account for how less concrete language is grounded in perception and action, proponents of some embodied approaches to language comprehension have appealed to "metaphorical" representations that map concrete experience to abstract linguistic content (Gibbs, 2006; Gallese \& Lakoff, 2005). For instance, respect can be conceptualized in terms of vertical height-"I look $u p$ to my superiors"-while similarity can be conceptualized in terms of closeness"Our ideas are quite close" (Lakoff \& Johnson, 1999). And, in fact, comprehending language about respect, similarity,
and other abstract concepts appears to involve schematic spatial representations (Guerra \& Knoeferle, 2012; Richardson et al., 2003; but see Bergen et al., 2007). Thus, the meaning of content words-both concrete and abstract-may include schematic spatial information.

But what about function words, such as conjunctions? Could their meaning also involve schematic spatial information, co-opting space to juxtapose conjuncts? There is evidence that grammatical tense, for instance, activates spatial representations. Santiago and colleagues (2007) found that participants were faster to categorize words as referring in the past tense when words were presented on the left (vs. right) side of the screen, but faster for words in the future tense when presented on the right (vs. left)—as if grammatical tense activated a left-to-right mental timeline (see also Torralbo, Santiago \& Lupiáñez, 2006). The "juxtaposition" prompted by conjunctions may also rely on schematic spatial representations, such as containment (see Glenberg, 2010). Comprehension of and, for instance, could involve a spatial grouping of the conjuncts, while or could mark alternatives by separating them spatially via containment. However, there is no clear experimental evidence showing that function words such as conjunctions are indeed related to spatial representations.

In the present two studies, we used two offline tasks to probe spatial representations underlying the meaning of conjunctions. In the first drawing study, participants created schematic sketches of conjunctions; in the second rating study, they rated schematic spatial diagrams on how well they represented different conjunctions. Both drawing and rating tasks have been used to study spatial representations activated by language, but only for concrete and abstract content words (Richardson et al, 2001). If conjunctions also co-opt spatial schemas to keep track of conceptual relations between conjuncts, then we should see a reliable, systematic use of spatial properties like distance, size, or containment to represent different conjunctions.

## Experiment 1: Drawing study

Experiment 1 used a drawing paradigm to examine whether representations of space are used to understand and visually depict the relationships expressed by four conjunctions (and, or, but, and either... or). If spatial representations are co-opted, then participants should systematically use spatial information to differentially represent the relations expressed by conjunctions. Alternatively, if conjunctions relate the meaning of the conjuncts in an abstract or logical fashion, no reliable differences in the use of spatial information should emerge.

## Method

Participants 108 native speakers of German completed the drawing task. They all gave informed consent and received monetary compensation for their participation.

Materials Three German conjunctions (und 'and'; aber, 'but'; and oder 'or') and a German correlative conjunction
(entweder... oder, 'either... or') were presented on a single sheet of paper (Fig. 1). Each conjunction appeared as "Object X conjunction Object Y " at the top of a blank square. Participants could select objects and frames for their drawings (Fig. 2).

Figure 1: Example of the drawings from a single participant.

Figure 2: Objects and frames of different shapes and sizes to be used in the drawings.

Design and procedure In a within-subjects design, with conjunction as a factor ('and', 'but', 'or', 'either... or'), each participant was instructed to make one drawing for each conjunction (see Fig. 1) using the objects in Figure 2. Participants saw two examples for the prepositions with and without. They were told that there were no correct or incorrect answers. The order of the conjunctions (Fig. 1) was counterbalanced.

Analysis We examined the drawings' spatial dimensions of distance, containment and size. Distance was defined as millimeters (mm) between objects' centers; containment codes whether objects were (or weren't) separated by one or more frames; size codes whether the objects had the same or a different size. Normalized distance scores ( $z$-scores) were analyzed with linear mixed effect regression (LMER, lme4 package for R statistical software). Mixed-effects models are suitable for analyzing unbalanced data and capture participants' variation around multiple fixed effects similar to ANOVAs (Quené \& van den Bergh, 2008). Our LMER modeled distance with conjunction as fixed effect, participant as random intercept, and the fixed effect as random slope.

For the analyses with containment and size, we calculated the percentage of representations that used these dimensions (e.g., containment was scored as present when an object was drawn with a frame around it, and size when differentlysized objects were used). A binomial test evaluated whether these percentages differed significantly from chance.

## Results

Distance Figure 3 shows the normalized mean distances between objects by conjunction. A positive deviation from zero (the intercept and grand mean) indicates objects were drawn farther apart than the grand mean object distance; a negative deviation indicates they were closer together. Figure 3 illustrates that while objects were drawn farther apart than average for 'either... or' and 'or', they were drawn closer together for 'and'. Object distance for 'but' did not differ from average. The LMER ${ }^{1}$ model confirmed a main effect of conjunction for distance ( $p<.001$ ).

Figure 3: Normalized mean distances between objects for each conjunction. Error bars represent standard errors.

Post-hoc comparisons (Bonferroni corrected) confirmed shorter between-object distance for 'and' than any of the other conjunctions ( $p \mathbf{s}<.001$ ); objects for 'either...or' were significantly farther apart than those for 'but' ( $p=.01$ ). The difference in distance between 'or' and 'but' did not reach significance ( $p=.24$; uncorrected $p=.037$ ), and 'either...or' and 'or' did not differ ( $p=1$ ).

Figure 4: Participant percentage using containment (upper graph) and size (lower graph) for each of the conjunctions.

Containment \& Size Figure 4 illustrates, for each conjunction, the percentage of participants who used frames around objects and different object sizes in their drawings.

[^287]For 'but', the use of containment did not differ from chance ( $47 \%, p=.6$ ). Instead, differently-sized objects distinguished the conjuncts ( $62 \%, p=.017$ ). For 'either... or', containment ( $61 \%, p=.026$ ), but not size ( $36 \%, p=.008$ ) was used above chance. For 'or', the use of containment did not differ from chance ( $47 \%, p=.6$ ), but differences in size were systematically avoided ( $37 \%, p=.012$ ). Finally, drawings for 'and' avoided the use of containment $(28 \%, p<.001)$ and used size at the level of chance ( $46 \%, p=.4$ ).

## Discussion

As predicted, different conjunctions were reliably associated with particular spatial dimensions. When two objects were conjoined by 'and', they were drawn close together and not separated by frames. By contrast, for 'or' and 'either...or' objects were drawn farther apart and separated by frames. Finally, depictions of 'but' relied on size to contrast the objects, but made no use of containment or distance. These conjunctions, therefore, elicited reliable spatial depictions in the absence of content words or linguistic context.

But do these results reflect spontaneous associations between conjunctions and space, or task-induced strategic reflection? To rule out that participants interpreted all four conjunctions and planned their sketches, perhaps to contrast them, we conducted a self-paced rating study based on the results of Experiment 1. In the rating study, participants only saw one conjunction-schema pair at a time. If sketches served to contrast the conjunctions, then use of space should disappear, or at least be greatly diminished in the rating task when only one pair is rated at a given time.

## Experiment 2: Rating study

Each conjunction ('and', 'or', 'but', ‘either...or') was paired with each of eight spatial schemas, designed to contrast three spatial dimensions: distance, containment, and size (Figure 5). These conjunction-schema pairs were randomly presented, so that participants could not predict the ensuing schema-conjunction pair. If the use of spatial information was not strategic, then ratings of how well a given depiction illustrates the meaning of a conjunction should replicate findings from Experiment 1. Specifically, we predict higher ratings for 'either... or', and 'or' when paired with schemas representing far (vs. close) distance and separated containers (vs. objects-contained). By contrast, ratings for 'and' should be higher with schemas representing close (vs. far) distance and objects-contained (vs. separated containers). Finally, we predict no differences for 'but' on distance- or containment-related schema ratings, but higher than average ratings for size-related schemas.

## Method

Participants A further twenty-four native German speakers completed Experiment 2. They all gave informed consent and received monetary compensation for their participation.

Materials Figure 5 shows the schematic depictions. Seven visual schemas covered the three dimensions analyzed in

Experiment 1 (i.e., distance, containment, size, Fig. 5, A-G); an eighth schema served as a baseline (Fig. 5 H). Each schema was presented on the computer screen with each one of the four conjunctions from Experiment 1.

Figure 5: Depictions for the spatial schemas: far (A); close (B); big (C), small (D), one-container (E); two-containers (F); objects-contained (G); and baseline (H).

Design and procedure A within-subjects design, had schema (eight schemas; Fig. 5) and conjunction ('and', 'or', 'but', 'either...or') as factors. Participants rated each possible pairing on how well a schema depicted a conjunction using a 7 -point scale (1=very bad to 7=very good). Items were presented one at a time on a computer monitor, and participants responded self paced. Experiment Builder v10.6 software (SR Research) recorded responses and randomized trial order.

Analysis For each conjunction, we normalized participants' raw ratings relative to their rating of the baseline schema H by subtracting their baseline rating from their other ratings ${ }^{2}$. Thus, within a conjunction, schemas that were judged more acceptable than baseline received a positive score, but a negative score if they were less acceptable than baseline.

Schema ratings were split into three subsets, based on the three spatial dimensions analyzed in Experiment 1. The distance subset included ratings for far and close schemas; the containment subset included ratings for one-container, two-containers and objects-contained schemas; and the size subset included ratings for big and small schemas. Each set of normalized ratings was then analyzed separately using an LMER model, with schema and conjunction as fixed effects, participant as random intercept, and the main effects and interaction of the fixed effects as random slopes. Planned dependent $t$-tests (Bonferroni corrected) compared ratings for each schema within conjunctions.

## Results

Distance The LMER showed neither main effects of schema nor conjunction ( $p s>.29$ ). However, as predicted, schema and conjunction interacted ( $p=.011$ ), with higher ratings for the far schema for 'and', but the close schema for 'either...or' and 'or' (Fig. 6).

Planned pairwise comparisons assessed the effect for each conjunction. For 'but', ratings did not differ for the far and close schemas ( $p=.92$ ). For both 'either... or' and 'or', by contrast, the far schema received higher ratings ( $p<.001$ and

[^288]$p=.018$, respectively). The pattern reversed for 'and', for which the close schema was reliably preferred ( $p<.001$ ).

Figure 6: Normalized-to-baseline mean rate for far and close schemas for all conjunctions. Error bars represent standard errors.

Containment LMER analyses showed a reliable main effect of conjunction ( $p=.002$ ) but not of schema ( $p=.3$ ); schema and conjunction interacted, as predicted ( $p<.001$, Fig. 7).

Planned pairwise comparisons examined containment preferences for each conjunction. For 'either... or', the twocontainers schema-which maximally separates the two objects-was rated higher than both the objects-contained and the one-container schemas (both $p<.001$ ). Similarly, for 'or', the two-container schema was significantly preferred over the one-container schema ( $p=.002$ ), and was marginally preferred over the objects-contained schema ( $p=.08$; uncorrected $p=.027$ ). By contrast, for 'and', the objects-contained schema-which groups both objects together-received the highest ratings among the containment-related schemas. The one-container schema was significantly disliked, compared to both the objectscontained and the two-container schemas (both $p<.001$, ps for the other comparisons, n.s.).

Figure 7: Normalized-to-baseline mean rate for onecontainer, two-container and objects-contained schemas. Error bars represent standard errors.

Size The LMER showed a main effect of conjunction ( $p=.002$ ). Schemas that highlighted differences in size were rated highly for 'but', nevertheless, dispreferred for all other conjunctions (Fig. 8, other ps n.s.).

Figure 8: Normalized-to-baseline mean rate for big and small schemas for all conjunctions. Error bars represent standard errors.

## Discussion

Experiment 2 confirmed that participants exhibit systematic preferences for spatial representations of conjunctions. Both 'either...or' and 'or' were rated higher with larger distances between objects, while 'and' was rater higher for shorter object distances. These conjunctions were also contrasted by the ratings for containment: the two-container schema was preferred for both 'either...or' and 'or', while the top-rated schema for 'and' contained both objects in a single frame. Finally, schemas that depicted size differences were reliably preferred for 'but', and rejected for all other conjunctions.

## General Discussion

Although previously suggested in the literature (e.g., Glenberg, 2010; Langacker, 2008), until now there was no experimental evidence that space might play a role in the representation of function words such as conjunctions. In two experiments, conjunctions were systematically associated with schematic spatial information, both when participants produced and when they rated spatial representations in the context of conjunctions.

We have framed these results in terms of semantics, and we believe they can shed light on the comprehension of conjunctions in natural language. But they may also tell us something about norms of visual representations or the communicative use of space. Logic and mathematics are rife with spatial diagrams used to represent and reason about logical relations, including and and or diagrams that are strikingly similar to the spatial representations in the current studies (Fig. 9; Guaquinto, 2007). Similarly, Langacker's Cognitive Grammar (2008) relies on spatial diagrams to represent relations between grammar and conceptualization. Sketches and diagrams, after all, are powerful tools for representing abstract concepts (Tversky, 2011).

Figure 9: Venn diagrams use spatial containment to depict logical relations: and (left) and or (right). And is depicted by a compact area, while or involves two separated areas.

If conjunctions are associated with spatial representations, then this may even account for some of the varied senses of and and or that have been discussed in the literature (e.g. Culicover \& Jackendoff, 1997). For instance, since time is also associated with spatial representations (e.g. Santiago et al., 2007), an implicit schematic spatial representation of the conjuncts could perhaps also induce a temporal ordering.

Where does this leave the relation between lexical semantics and logic? Perhaps closer than ever. In their book on the conceptualization of mathematics, Lakoff and Núñez (2000) suggest that "much of what is often called logical inference is in fact spatial inference mapped onto an abstract logic domain" (p.43). If so, then reasoning about logical relations, such as and and or, may rely on "metaphoric" representations of containment and distance (see, e.g., Boot \& Pecher, 2011; Guerra \& Knoeferle, 2012). If both the semantics of conjunctions and formal logic turn out to rely on space, then natural language semantics may be closer to formal logic than recently supposed-if we're willing to accept an appropriately naturalized version of formal logic, and an appropriately embodied version of lexical semantics.

Indeed, a question that remains unaddressed is whether schematic spatial information plays a spontaneous role in the real-time comprehension of conjunctions, when space is not an explicit part of the task. Suggestively, this is the case for content words. Richardson and colleagues (2001) used two offline norming studies to elicit schematic spatial representations associated with both concrete and abstract verbs (e.g. give, respect). They later found that these spatial schemas systematically influenced real-time comprehension of the associated verbs (Richardson et al, 2003), suggesting that the schemas elicited by the offline tasks were active during online language processing. We hypothesize that similar spatial processing may occur during the processing of conjunctions-that is, that the online comprehension of conjunctions may also involve schematic spatial representations of the kind examined here. Such online measures are necessary before we can draw definite conclusions about the semantics of conjunctions.

We do know, however, that conjunctions such as either...or modulate online sentence comprehension (e.g. Frazier, Munn \& Clifton, 2000 for and-coordinations). In a reading study, Staub \& Clifton (2006) examined the effect of the presence or absence of the word either on reading times for the second conjunct of or-coordinated structures (both for noun phrases and independent clauses). They found that the presence of either facilitated the reading of the content that followed the word or. These findings showed that conjunctions (and, either... or) can influence online sentence interpretation. Future studies should investigate whether these online effects extend to influences on spatial processing.

## Conclusion

We have shown that different conjunctions are distinctively associated with spatial dimensions of distance, containment, and size. In both a drawing and a rating task, people
associated 'and' with closeness and containment; 'or' and 'either...or' with distance and separation; and 'but' with contrasting size. Future work will investigate whether these schematic spatial properties are activated during online comprehension, and determine their functional contribution. Nevertheless, the present experiments highlight the use of space to distinguish abstract grammatical relations, suggesting the meaning of different function words can be expressed through distinct visual spatial representations.

#### Abstract

Apprehending the development of complex emotions is crucial to understand the development of decision-making. Regret and relief are complex counterfactual emotions, which can arise in private or in social contexts. The aims of the present study were (i) to uncover the development of regret and relief and (ii) to explore the development of a social form of regret and relief in a context of competition. The first experiment provides evidence that the ability to experience regret and relief continues to develop until adolescence, consistent with the implication of the orbitofrontal cortex in their experience. In a context of competition, we observed that adolescents were less able to experience social regret compared to children and adults, whereas their feeling of social relief was reinforced. Besides, adolescents failed to question the appropriateness of their initial decision. This result could provide an explanation for adolescents' enhanced propensity to engage in risky behaviours.

Keywords: Regret; Relief: Counterfactual thinking, Social context; Decision making; Development.

## Introduction

Psychology and neuroscience studies have provided converging evidence that emotions play a crucial role in adaptive decision-making (Loewenstein, Rick \& Cohen, 2008). Thus apprehending the development of basic and complex emotions is crucial to fully understand the development of decision-making. Among these emotions, counterfactually mediated emotions - like regret and relief are related to counterfactual thinking and rely on comparison processes. In a private context, these processes
rely on a comparison between what has happened and what could have happened if the subject had made another choice (Ritov, 1996). The counterfactual comparison has an informative function, as it enables to determine a reference point according to which the obtained outcome will be evaluated. This process can also be motivated by the social context. It will then rely on a comparison between what has happened to the subject and what has happened to another person, like a competitor, who made a different choice (Bault, Coricelli \& Rustichini, 2008).

To date, developmental psychology has mainly focused on the development of counterfactually mediated emotions in young children (Weisberg \& Beck, 2010) showing that the experience of regret develops around 5 years of age, whereas the experience of relief develops around 7 years of age. Recently, the development of regret and relief in adolescence has been investigated in a probabilistic gambling task (Burnett, Bault, Coricelli \& Blakemore, 2010). Participants' emotional ratings revealed that relief, but not regret, develops during adolescence. The lack of development of regret in adolescence is surprising given that increasing feelings of regret and relief are positively correlated with enhanced activity in the orbitofrontal cortex (OFC) that continues to mature until late adolescence (Camille et al., 2004; Gogtay et al., 2004).
A possible explanation of the lack of evidence for the development of regret in adolescence might relate to the nature of the variables used to study this emotion. Previous studies have focused primarily on emotional ratings. Knowing that counterfactually mediated emotions are related to participants' decision and in order to fully
apprehend these emotions, it was necessary to consider the degree to which participants are willing to reconsider their initial choice after experiencing regret (Chua, Gonzalez, Taylor, Welsh, \& Liberzon, 2009).

## Experiment 1 - Private context

Aims and Hypotheses. Thus, the aim of the first experiment was to uncover the development of regret and relief in late childhood, adolescence and adulthood.
In order to do so, participants performed a child friendly gambling task adapted from Camille et al. (2004). We asked participants to choose between two wheels of fortune that differed in the amount of gain and loss expected and the probability of winning. We manipulated the outcome of the wheel of fortune that was not selected by the participants to induce either regret or relief. For each trial, participants rated how they felt about the outcome and their willingness to modify their choice, on a classical likert-type scale.
As the OFC has a fundamental role in the experience of regret, and given the late maturation of this brain area, we expect to observe a progressive development of the emotional experience of counterfactually mediated emotions from childhood to adulthood, in the private context. Besides, the choice rating could be a more sensitive measure in order to study the developmental trajectories and understand the complexity of regret and relief.

## Method

Participants. In this private context, we recruited 53 volunteers: 19 children (mean age $=11.2$ years, $\mathrm{SD}=0.66$ ), 17 adolescents (mean age $=14.5$ years, $\mathrm{SD}=0.40$ ) and 17 university psychology students (mean age $=20.2$ years, SD $=1.48$ ).

Written parental consent was obtained for children and adolescents prior to the assessment session. Participants were tested in accordance with international norms governing the use of human research participants.

Experimental Procedure. Participants performed 36 trials of a child friendly gambling task (cf. fig. 1). For each trial, participants chose between two wheels of fortune, an advantageous wheel (with a positive expected value) and an attractive but disadvantageous wheel (with a negative expected value). Then, two feedbacks, partial and complete feedbacks, were successively provided to participants.

For the partial feedback, the outcome obtained on the selected wheel was displayed on the screen for 4 s (fig. 1.c.). Thus, the partial feedback induced either disappointment (in the case of losses) or elation (in the case of gains). For the complete feedback, participants were informed of the outcome of the alternative wheel for 4 s (fig. 1.f). They could thus compare the obtained outcome to the counterfactual outcome. The complete feedback was designed to induce either regret (when the comparison
between the outcomes was unfavourable to the participant) or relief (in the opposite case).

Figure 1: Experimental design of a trial inducing regret. Two 'wheels of fortune' were displayed on the computer screen (1.a.). After the participant's choice (1.b.), participants were informed of obtained outcome (partial
feedback-1.c.). Then the participant must rate an 'emotional' scale (1.d.) and a 'choice' scale (1.e.). Finally, participants were informed of the complete feedback (1.f.) and had to rate again an 'emotional' scale (1.g.) and a 'choice' scale (1.h.).

After each feedback, participants rated a 7-point 'emotional' scale (fig. 1.d. and 1.g.), ranging from 1 (I am unhappy) to 7 (I am happy). Participants then rated a 7 -point 'choice' scale (fig. 1.e. and 1.f.), ranging from 1 (I wish to modify my choice) to 7 (I do not wish to modify my choice), on which they indicated how much they wished to reconsider their choice.

## Results

Participants' ratings were analysed in four outcome conditions: (a) low loss vs. high loss condition, which should induce minimal relief; (b) low win vs. high win condition, inducing minimal regret; (c) low win vs. high loss condition, inducing maximal relief; and (d) low loss vs. high win condition, inducing maximal regret.
For the 'emotional' and 'choice' ratings analyses, we computed difference scores (see Weisberg \& Beck, 2010). Ratings on the partial feedback were subtracted from ratings on the complete feedback. Thus, the emotional and choice scores ranged between -6 and +6 . We carried out onesample t-tests to determine whether both scores differed from zero. A negative emotional score would suggest that participants experienced regret whereas a positive emotional score would suggest that participants experienced relief. A
negative choice score would suggest that participants wanted to modify their initial choice whereas positive choice score would suggest that participants want to maintain their initial choice.
A 3 (age: children vs. adolescents vs. adults) x 4 (outcomes: maximal regret, minimal regret, maximal relief, minimal relief) mixed-design ANOVA on the 'emotional' scores revealed that these scores differed between the three groups of participants, $\mathrm{F}(2,50)=3.24, \mathrm{p}<.05, \eta_{\mathrm{p}}^{2}=.12$, and between the type of outcomes, $\mathrm{F}(3,50)=57.95, \mathrm{p}<.001, \eta_{\mathrm{p}}{ }^{2}$ $=.54$. The age of the participants affected the emotional scores differently in the four types of outcomes, $\mathrm{F}(6,150)=$ 2.73, $\mathrm{p}<.05, \eta_{\mathrm{p}}^{2}=.10$. In the minimal regret condition, children and adolescents' average emotional scores were lower than adult scores, $t(34)=-1.60, p=.056, d=.72$ for children and $\mathrm{t}(32)=-1.59, \mathrm{p}=.052, \mathrm{~d}=.72$ for adolescents. Similarly, in the maximal regret condition, children and adolescents' emotional scores were lower than adult scores, $\mathrm{t}(34)=-2.41, \mathrm{p}<.01, \mathrm{~d}=.70$ for children and $\mathrm{t}(32)=-3.47$, $\mathrm{p}<.001$, $\mathrm{d}=1.75$ for adolescents (cf. fig. 2). No other differences were significant.
To sum up, all participants experienced regret in the conditions designed to induce this emotion, but children and adolescents' subjective experience of regret was reduced compared to adults. Besides, although all groups reported relief in the condition designed to induce maximal relief, children and adolescents did not experience relief when they lost a small amount of money but avoided losing a higher amount, $\mathrm{t}(18)<1$ and $\mathrm{t}(16)=2,39, \mathrm{p}=.09$ respectively.

Figure 2: 'Emotional' ratings for the private context mean scores (partial feedback ratings subtracted from complete feedback ratings) for regret and relief trials.
Ratings were analysed according to four types of outcome (minimal relief, minimal regret, maximal relief and maximal regret). We compared regret and relief scores to zero (onesample $t$-tests with zero as the test value, Bonferronicorrected, *p < .05, ** p < .005, ***p < .001).

The 3 (age) x 4 (type of outcome) mixed-design ANOVA on the 'choice' scores revealed a main effect of the type of outcome, $\mathrm{F}(3,150)=36.7, \mathrm{p}<.001, \eta_{\mathrm{p}}^{2}=.42$, but no main effect of age, $F(2,50)=2.87, p=.07$. Interestingly, the interaction between age and outcome was significant, F $(6,150)=2.54, \mathrm{p}<.05, \eta_{\mathrm{p}}^{2}=.09$. Planned comparisons of the 'choice scores' revealed that children were less willing to modify their initial choice than were adolescents, $\mathrm{t}(34)=$
$-2.41, \mathrm{p}<.01, \mathrm{~d}=.66$, and adults, $\mathrm{t}(34)=-3.00, \mathrm{p}<.005, \mathrm{~d}$ $=1.23$, in the minimal regret (win-win) condition. Similarly, in the maximal regret (loss-win) condition, children were less willing to modify their initial choice than were adults, $\mathrm{t}(34)=-1.70, \mathrm{p}<.05, \mathrm{~d}=.61$. No other differences were significant.
As expected, adults wished to modify their initial choice in the conditions inducing regret, $\mathrm{t}(16)=-5.43, \mathrm{p}<.001$ in the minimal regret condition and, $\mathrm{t}(16)=-4.55, \mathrm{p}<.001$ in the maximal regret condition. On the contrary, they wished to maintain their initial choice in the conditions inducing relief, $\mathrm{t}(16)=4.23, \mathrm{p}<.005$ in the minimal relief condition and, $\mathrm{t}(16)=4.74 \mathrm{p}<.001$ in the maximal relief condition. As opposed to adults, children did not wish to modify their choice in the minimal regret condition, $\mathrm{t}(18)=1.03, \mathrm{p}>.1$, even if they experienced a significant feeling of regret.

## Discussion

Analyses of the 'emotional' scores revealed developmental differences for both types of counterfactually mediated emotions (regret and relief). All participants experienced regret in the two outcome conditions designed to induce this emotion, but children and adolescents' subjective experience of regret was reduced compared to adults.
Our results are consistent with the ones reported in a recent study (Rafetseder \& Perner, 2012) showing that regret develops progressively from childhood to adulthood and reaches its maximum level in the adult group.
The fact that children experienced relief after a small gain (maximal relief condition) but not after a small loss (minimal relief condition) might suggest that this group has difficulties distinguishing between two outcomes that both lead to a loss and thus might focus more on the loss they obtained rather than on the high loss they avoided (see Weisberg \& Beck, 2012 for similar results).
Moreover, analyses of the 'choice' scores demonstrate that regret affects the participant's willingness to reconsider their initial choice in adults, whereas it does not systematically lead to a reconsideration of the initial choice in children.
Adults wished to modify their initial choice in the conditions inducing regret but wished to maintain their initial choice in the conditions inducing relief. As opposed to adults, children and adolescents expressed no preference about modifying their choice in the condition inducing minimised relief.
Finally, we identified a dissociation in children between the experience of regret and the willingness to reconsider an initial choice, in the minimal regret condition (low win vs. high win condition) specifically. In this condition, the salience of the counterfactual alternative might be reduced as participants have already won on the selected wheel. When the obtained outcome is already good for them, it seems difficult for children to think counterfactually, to take in account the alternative win and then expressing their wish to modify their choice.

## Experiment 2 - Social context

Our first experiment provided evidence that the ability to experience regret and relief continues to develop during late childhood and adolescence.
As little is known about adolescents' sensibility to complex negative emotions, we were particularly interested in the emotional experience of regret in adolescents. It has actually been demonstrated that the anticipation of complex negative emotions - such as regret - can significantly contribute to decrease risky behaviours in adolescents (Conner, Sandberg, McMillan, \& Higgins, 2006; Richard, Van Der Pligt, \& De Vries, 1996). Indeed, studies focusing on the role of anticipated regret in risky decision making have revealed that inciting adolescents to anticipate the regret they could experience after a risky behaviour can significantly decrease the intentions to engage in this behaviour.
In order to apprehend risky decision making in adolescence, neurobiological models have postulated the existence of two distinct brain systems involved in decision making: a cognitive control system - supporting goaldirected decisions through the ability to inhibit impulsive behaviour - and a socio-emotional system - based on the valuation and prediction of potential rewards, that can bias decision (Chein, Albert, O’Brien, Uckert, \& Steinberg, 2011; Sommerville, Jones \& Casey, 2010). These models posit an imbalance between the maturity of adolescents' socio-emotional system and the relative immaturity of the cognitive control system (Sommerville, et al., 2010). Due to this imbalance, adolescents are hypersensitive to rewards, particularly in salient socio-emotional contexts (Chein et al., 2011; Ernst et al., 2005). This kind of context selectively increases adolescents' sensitivity to potential rewards, which could explain why adolescence corresponds to a period of greater risk seeking in everyday life (Chein et al., 2011).

However, to our knowledge, no study has examined the impact of a salient socio-emotional context on adolescents' experience of regret and relief. Yet, in everyday life, adolescents not only experience these emotions alone but also in social contexts - e.g., in school, when they compare their achievements with those of their schoolmates.

Aims and Hypotheses. Thus, the aim of this second experiment was to explore the development of a social form of regret and relief in adolescents, compared to children and adults. Social regret was defined as the negative emotion that one feels when he has missed an opportunity while another person has seized it and social relief as the opposite feeling.
In the socio-emotional context condition, participants were additionally informed that they would be playing against a schoolmate and that their results would be compared to those of the other player throughout the game.
We hypothesized that adolescents should be more influenced by the social context of competition than children and adults (Chein et al., 2011). If adolescents are
hypersensitive to the emotional context, compared to adults and children, they should demonstrate a heightened sensitivity to the gains they obtain and their evaluation of social relief should be biased. Therefore, adolescents should experience an enhanced feeling of social relief. In addition, if the social context also influences negative complex emotions, they should experience a decreased feeling of social regret compared to children and adults. Thus, their willingness to reconsider an initial choice should be attenuated compared to the other groups.

## Method

Participants. In the social context, we recruited 54 volunteers: 18 children (mean age $=11.8$ years, $\mathrm{SD}=0.43$ ), 18 adolescents (mean age $=14.5$ years, $\mathrm{SD}=0.40$ ) and 18 university students (mean age $=20.2$ years, $\mathrm{SD}=1.48$ ).
Written parental consent was obtained for children and adolescents prior to the assessment session. Participants were tested in accordance with international norms governing the use of human research participants.

Experimental Procedure. Participants performed 36 trials of the computerized child friendly gambling task used in experiment 1. The procedure and the stimuli of the gambling task were the same as in experiment 1.
However, in order to induce social regret and social relief, children and adolescents were informed that that they would be playing against a schoolmate and adults were told that they will be playing against another student of the same age and the same institute. We additionally informed participants that all of their choices would be compared to those of their competitor. Thus, the complete feedback informed the participants about the outcome obtained by their competitor, so that they could compare it to their own outcome.

## Results

Participants' ratings were again analysed according to four outcome conditions: (a) low loss vs. high loss condition, which should induce minimal relief; (b) low win vs. high win condition, inducing minimal regret; (c) low win vs. high loss condition, inducing maximal relief; and (d) low loss vs. high win condition, inducing maximal regret. Besides, we computed difference scores for the 'emotional' and 'choice' ratings analyses (cf. experiment 1).
A 3 (age) x 4 (outcome conditions) mixed-design ANOVA conducted on 'emotional' scores revealed a main effect of age, $\mathrm{F}(2,51)=12.64, \mathrm{p}<.001, \eta_{\mathrm{p}}^{2}=.33$, a main effect of outcome condition, $\mathrm{F}(3,153)=51.01, \mathrm{p}<.001, \eta_{\mathrm{p}}{ }^{2}$ $=.50$, and a significant interaction between age and outcome condition, $\mathrm{F}(6,153)=2.36, \mathrm{p}<.05, \eta_{\mathrm{p}}{ }^{2}=.08$. Planned comparisons revealed that in the minimal social relief condition, adolescents' social relief was higher than that expressed by children, $\mathrm{F}(1,51)=12.98$, p $<.001$, $\mathrm{d}=$ 1.19 (cf. fig. 3). No other differences were significant.

Figure 3: 'Emotional' ratings for the social context mean scores on regret and relief conditions. Ratings were analysed according to four types of outcome (minimal relief, minimal regret, maximal relief and maximal regret). We compared regret and relief scores to zero (one-sample ttests with zero as the test value, Bonferroni-corrected, * p < $.05,{ }^{* *} \mathrm{p}<.005,{ }^{* * *} \mathrm{p}<.001$ ).

Notably, adolescents expressed lower social relief in the maximal relief condition compared to the minimal social relief condition, $\mathrm{F}(1,51)=6.18, \mathrm{p}<.05, \mathrm{~d}=0.71$. In the maximal social regret condition, adolescents expressed less regret than children, $\mathrm{t}(51)=2.60, \mathrm{p}<.05, \mathrm{~d}=0.82$, and adults, $\mathrm{t}(51)=3.51, \mathrm{p}<.001, \mathrm{~d}=1.34$. Beside, planned comparisons in this condition also revealed a significant quadratic trend between age and the expression of regret, revealing a U-shaped developmental pattern, $\mathrm{F}(1,51)=$ 12.46, $\mathrm{p}<.001$, and no significant linear trend, $\mathrm{F}<1$. These results suggest that adolescents experience less social regret than children and adults in the maximal social regret condition.
A 3 (age) x 4 (outcomes) mixed-design ANOVA conducted on 'choice' scores revealed that these scores differed between the type of outcome, $F(3,153)=22.21, p<$ $.001, \eta_{\mathrm{p}}^{2}=.30$, but not between the three age groups, $F(2,51)=1.13, p=.33$. Interestingly, the age of the participants affected the choice scores differently in the four outcome conditions, $\mathrm{F}(6,153)=2.67, \mathrm{p}<.05, \eta_{\mathrm{p}}^{2}=.09$.
The willingness to maintain the initial choice was lower in the maximal social relief condition compared to the minimal social relief condition for adolescents and adults, $t(51)=$ $2.12, \mathrm{p}<.05, \mathrm{~d}=0.63$ and $\mathrm{t}(51)=3.51, \mathrm{p}<.005, \mathrm{~d}=0.83$, respectively. Adolescents were less willing to modify their choice in the maximal social regret condition than in the minimal social regret condition, $\mathrm{F}(1,51)=9.52, \mathrm{p}<.01$, $\mathrm{d}=$ 0.67 , and than adults, $\mathrm{F}(1,51)=5.33, \mathrm{p}<.05, \mathrm{~d}=0.83$.

## Discussion

The results of this experiment evidenced that a salient socioemotional context of competition impacts the feeling of regret and relief, specifically in adolescents. Critically, when adolescents obtained an initial negative outcome, their feeling of social relief was reinforced, compared to children and adults. Adolescents were actually far more relieved after obtaining an initial loss (minimal social relief) than after obtaining an initial win (maximal social relief). Given that the only difference between the minimal and maximal social
relief conditions was the presence of an initial loss in the minimal social relief condition, this result may suggest that a salient context of social competition has a direct impact on adolescents' sensitivity to losses, increasing the feeling of relief when the competitor obtained a greater loss.
On the other hand, adolescents' feeling of social regret was considerably attenuated compared to children and adults. Theoretically, the condition of maximal social regret should have the greatest effect on participants' self-esteem. However, even if adolescents are able to experience regret (cf. experiment 1 and Burnett et al., 2010), they did not express a significant feeling of regret in the maximal regret condition. Thus, we argue that this specific lack of social regret in adolescents may be a consequence of a heightened sensitivity to negative outcomes in a social context. Interestingly, this weaker tolerance to losses leads adolescents to down-regulate their feeling of social regret and their willingness to reconsider their choice. As such, when adolescents obtain a negative outcome, they fail to question the appropriateness of their initial decision. This result is in line with studies that revealed a relative deficit in adolescents' ability to tolerate and to learn from negative outcomes compared to adults (Aïte, et al., 2012; Cassotti, Houdé \& Moutier, 2011).
Our findings indicate that adolescents are not only hypersensitive to rewards but also to losses in salient socioemotional contexts by demonstrating that the socioemotional context of competition significantly impacts their feeling of social regret and of social relief after an initial loss. These results are in line with the proposition of an imbalance between the socio-emotional system and the cognitive control system in adolescence (Chein et al., 2011; Sommerville et al., 2010).

## General Discussion

The aims of this paper were to (i) to examine the development of regret and relief from childhood to adulthood and (ii) to explore the development of the ability to experience social regret and social relief in adolescents compared to children and adults in a context of social competition.
The results of the first experiment provide evidence that the ability to experience counterfactually mediated emotions - regret and relief - is attenuated in children and adolescents compared to adults. This result is consistent with the implication of the OFC in the experience of regret and relief (Camille et al., 2004).
Moreover, we observed that regret affects the participant's willingness to reconsider their initial choice in adults, whereas it does not systematically lead to the same reconsideration in children. We actually identified that the experience of regret and the willingness to reconsider an initial choice can be dissociated in children. This result may indicate a developmental dissociation between feeling and doing that has previously been observed among participants of the same age range (Cassotti et al., 2011).

The results from the choice scale reveal the importance of using both 'emotional' and 'choice' ratings to study the precise development of counterfactually mediated emotions such as regret and relief.
The results of the second experiment is the first to evidence that a salient socio-emotional context of competition impacts the feeling of counterfactually mediated emotions - regret and relief - specifically in adolescents. Critically, when adolescents obtained an initial negative outcome, their feeling of social regret was considerably attenuated compared to children and adults, whereas their feeling of social relief was reinforced. The present results suggest that in a social comparison context, adolescents are less able to experience social regret and fail to question the appropriateness of their initial decision, particularly when another person (a competitor) has obtained a higher outcome by choosing differently.

## Conclusion

In conclusion, the present paper evidenced that the ability to experience regret and relief continues to develop in late childhood and adolescence.
This paper is also the first to evidence that a salient socioemotional context of competition can impact the feeling of regret and relief, specifically in adolescents.

Finally, the present results suggest that in a social comparison context, adolescents are less able to experience social regret and fail to question the appropriateness of their initial decision. Thus, this result could provide an explanation for adolescents' enhanced propensity to engage in risky behaviours in everyday life.

# Unifying Theories of Consciousness, Attention, and Conscious Attention 

Harry Haroutioun Haladjian (h.haladjian@uws.edu.au)<br>School of Social Sciences and Psychology, University of Western Sydney<br>Bankstown Campus, Penrith, NSW 2751 Australia<br>Carlos Montemayor (cmontema@sfsu.edu)<br>Department of Philosophy, San Francisco State University<br>San Francisco, CA 94132 USA

#### Abstract

One of the more challenging research areas in cognitive science is the attempt to understand how the brain supports consciousness. This historically philosophical endeavor is now actively studied in the sciences, with research on visual attention being an especially promising area that can further our understanding of consciousness. A major problem with this cross-disciplinary pursuit, however, is that for philosophers and scientists, the terms consciousness, attention, and conscious attention are ambiguous and used differently even by those within the same academic discipline. The goal of this paper is to begin laying the groundwork for a unified study of consciousness by delineating common terminology for attention and consciousness and by identifying the relationship between the two within the study of conscious attention. This includes categorizing current theories according to a spectrum of theoretical complexity.

Keywords: attention; consciousness; conscious attention; philosophy of mind; perception.

## Introduction

Although the relationship between consciousness and attention has been at the center of recent discussions in cognitive science, the proposals for this relationship are based on assumptions that are problematic. For instance, it is often assumed that the terms "attention" and "consciousness" unambiguously describe specific types of mental phenomena that can be identified experimentally. There is empirical evidence, however, that there are different types of attention, with different neural correlates that cannot be reduced to one another (Parasuraman, 2000), which complicates the attempt to establish a clear relationship between attention and consciousness. Furthermore, while many authors think that it is plausible to define "attention" in terms of several basic types of attention, other theorists think that defining "attention" is hopeless (see Allport, 1993; Johnston \& Dark, 1986).

Similarly, some theorists think that there are at least two types of consciousness (e.g., Block, 1995), and that only one of them is strictly related to the subjective experience of conscious awareness. Other theorists think that the "hard problem" of consciousness (i.e., the study of phenomenal or subjective experience) makes the empirical study of consciousness, unlike the study of perceptual attention, intractable (e.g., Chalmers, 1996; Nagel, 1974). Finally, there are theorists who think that the hard problem of consciousness is just a pseudo-problem, and that
consciousness can and must be studied empirically (e.g., Churchland, 1996; Dennett, 2005). These contrasting opinions and approaches have complicated the study of consciousness in relation to attention, often resulting in a gridlock of concepts between opposing theories. It is possible, however, that many of the current theories on consciousness are not necessarily in opposition, since there may be semantic ambiguities producing these disputes.

Because of the polysemy of the terms "attention" and "consciousness", one should avoid stipulating definitions without first delineating empirical and theoretical constraints that such definitions must satisfy. It is crucial to determine whether the different theoretical perspectives refer to the same types of attention and the same types of consciousness. Based on empirical findings and a theoretical classification of the possible views on this topic, we propose definitions for forms of consciousness, forms of attention, and forms of conscious attention in order to provide a foundation to compare and move forward different theories.

Another goal of this paper is to offer a brief account of recent theories on consciousness, with a focused consideration of how empirical research on attention can provide the grounding for an empirically-driven account of consciousness. One way to do this is by analyzing recent theories on consciousness and attention by categorizing them according to a spectrum of theoretical complexity, starting with the theories that impose the strictest requirements on the interpretation of empirical findings to those that allow the widest range of possible interpretations. For instance, Jesse Prinz (2012) has defended the view that consciousness is just attention. This "strict" view entails that there cannot be any finding about attention that is not a finding about consciousness and vice versa.

Although an identity approach is parsimonious, since it reduces that kinds of cognitive processes associated with consciousness and attention to a single type, it creates the problem of reducing significantly the room for interpretation. For example, the desideratum of empirical adequacy seems to demand more theoretical leniency for the interpretation of research findings that indicate disassociations between attentional processing and conscious awareness. Should it not be possible that some form of attention exists without consciousness, even if consciousness cannot occur without attention? Michael Cohen and colleagues (2012) argue in favor of this possibility. At the extreme opposite of the spectrum, one
finds the view that consciousness and attention can be fully dissociated (i.e., there can be forms of consciousness without attention and vice versa) advocated by Koch and Tsuchiya (2007) and Lamme (2003), among others. This range of possible theoretical complexities provides insight to the approach one can take in studying conscious attention. Due to the diverging views, a meta-analysis is crucial for advancing this field, and future work should focus on such an in-depth analysis. We present a brief overview of the development of the views described above and outline the start of a such meta-analysis.

## Problems of Consciousness

Thomas Nagel (1974) said that the problem of conscious experience is what makes the mind-body problem both interesting and intractable. The problem of how the mind connects with the world would lose its allure, and even become trivial or irrelevant, if one had no idea how solutions to this problem would explain consciousness. Once the theoretical and empirical options to account for consciousness are carefully assessed, however, it becomes clear that they are all problematic. The best way of formulating the intractability of this problem is in terms of what David Chalmers called the "hard problem" of consciousness, that is, why would anything physical have conscious experiences and what is the relationship between physical brain processes and the subjective experience of consciousness? Much has been written about this problem, and there is now widespread consensus that it is not only a difficult philosophical problem, but also one of science's more difficult unsolved puzzles.

## Access vs. Phenomenal Consciousness

Although the problem of consciousness is remarkably intricate, a great deal of progress has been made on the theoretical front. A significant amount of conceptual clarity has been achieved with respect to the question of why functions for cognitive processing may explain some forms of conscious integration required for working memory (what Ned Block, 1995, calls access consciousness), but may not suffice to account for the qualitative aspects of conscious experiences (what Block calls phenomenal consciousness). Access consciousness provides a "workspace" for concepts and multi-sensory information to be accessed for the purposes of reasoning and performing complex actions. These do not necessarily need to reach awareness (i.e., reach a cognitive state where one can report experiencing it). Another theory, by David Rosenthal (2002), proposes that a higher-order thought (HOT) is required for one to be conscious of mental states. These are thoughts about mental states (resulting from sensations or memory retrieval) that allow us to be conscious of them. The relationship between access and phenomenal consciousness (between thoughts and higher-order thoughts in awareness) is one area where attention research may help, for example, by clarifying how thoughts move from access to phenomenal consciousness.

## Self Consciousness

Another source of problems concerning treatments of conscious perception is the role of the self in phenomenal experience. A number of intricate questions originate from this topic. Can one be conscious of something (an emotion, a perceptual representation, etc.) without also being conscious that one is conscious of it? Is the "self" constitutive of every possible experience without itself being experienced? How should we understand consciousness, self-awareness, and the conscious self? One problem with an emphasis on the "self" view is that it seems to demand too much to account for all conscious creatures and because of this reason, it seems to be empirically implausible. Christof Koch (2012), for instance, argues that the self is not necessary to have conscious experiences. He criticizes the mirror test, which infants and most animals fail, as a test for consciousness (although it seems to be a good test for self-awareness). The reasoning is that infants and many animals must have some kind of consciousness (of the phenomenal kind) because they experience pain, feel emotions, etc. They may not have self-consciousness but, the claim is, they do have phenomenal consciousness.

Plausible as this criticism is, however, the relationship between consciousness and self is much more intricate than first appearances suggest. In a passage where Koch is defining the scientific problem of consciousness, he uses two incompatible interpretations of the word "self" when criticizing the conclusion that failure to pass the mirror test indicates the lack of consciousness. One notion of the "self" is the higher-order self that recognizes a particular thought as hers (the recognitional self). Koch seems justified in claiming that the recognitional capacities associated with this kind of self may not be necessary for consciousness. But how to interpret the more primitive "self" that Koch associates with experiences of "flow" (the phenomenal self)? This is a central question that needs to be answered in order to understand the relationship between higher forms of self-awareness and phenomenal consciousness.

## Unconscious Processes

The progress on the experimental front in consciousness research has been dramatic. The situation changed from being one in which the problem was completely ignored (perhaps because it seemed an intractable problem) to one in which substantial resources are spent in research laboratories, producing valuable empirical evidence about the nature of conscious awareness. What paved the way towards this progress was the experimental research on unconscious perception and unconscious cognitive processing. Bernard Baars (1988), for instance, used wellknown unconscious processes (with established research methodologies) to probe the contours of conscious processing. The comparison between the neural correlates of conscious and unconscious processing has already produced crucial insights into the nature of conscious awareness. For example, the thesis that consciousness is the result of a highly integrative process that occurs in a "global
workspace" (Baars, 2002) has been confirmed with neuroscientific evidence (e.g., Dehaene \& Naccache, 2001; Di Lollo, Enns, \& Rensink, 2000).

Another area of advancement is the range of related topics that are studied experimentally with the goal of better understanding consciousness. Experiments on conscious and unconscious perception, binocular rivalry, and mental imagery have expanded our knowledge of perceptual awareness. Additionally, research on the distinction between conscious inclinations for action and the unconscious processes that guide motor control has shown that the processes that reach awareness are indeed just the tip of the cognitive processing iceberg (Rosenbaum, 2002).

## Contents of Consciousness

An important philosophical development that has taken place in the last few years is the incorporation of insights made by psychologists and phenomenologists concerning the content of conscious experience. Susanna Siegel (2006), for example, uses the notion of phenomenal contrasts (a change in how one experiences something) in order to account for the content of conscious vision. This topic in the philosophy of perception concerns our understanding of the difference between conscious perception, illusions, dreams, and hallucinations.

In the history of cognitive psychology, ambiguous images have been considered a paradigmatic case of such contrasts. In the Necker cube (a geometrically ambiguous image that appears to point upward or downward) or the "duck-rabbit" drawing (a semantically ambiguous image that can look like a duck or a rabbit), the stimulus-or perceptual content-does not change but the subject experiences it in one of two alternative ways at a time, and never both at the same time. It is an established finding in vision science that these images alternate at a constant rate, regardless of the intentions of the subject. At first, one interpretation is salient, then it recedes and the other incompatible interpretation becomes the salient one. The subject can also direct her attention, however, and "flip" the interpretations, for example, by focusing on one of the inner corners of the Necker cube (e.g., focusing on the lower inner corner where three edges meet will encourage the ambiguous drawing to be perceived as an upward pointing cube). These attentional contrasts with phenomenological implications show that voluntary and involuntary forms of attention interact with consciously experienced contents in analogous ways.

Other phenomenal changes seem to depend fundamentally on attention, rather than represented content. In discussing the implications of findings on visual attention by Marisa Carrasco and colleagues (e.g., Carrasco, Ling, \& Read, 2004; Carrasco \& Yeshurun, 2009), Block argues that the phenomenal changes in experience, based on changes in attention, are not dependent on either external changes or changes in conceptual aspects of the stimuli (such as semantic ambiguity or expertise). He notes that the quality of these experiences (which he calls "mental paint") feels
"unreal", similar to visual experiences concerning afterimages. Block contends that these findings cannot be explained as illusions because the percept relies on how attention is allocated rather than being a true misrepresentation of the stimuli. The "subjective unreality" of these changes, Block (2010) claims, has not received any empirical investigation. They also remain unaccounted for in a broader theoretical treatment of consciousness. Here is where the study of attention can provide important insights.

## What Is Attention?

Attention research in cognitive psychology is quite active and covers a range of processes-from low-level perceptual systems to high-level cognitive systems. These processes act as "selection" mechanisms to determine what information reaches higher-level cognition, including conscious awareness. In this discussion, we are mainly referring to visual attention, which has the most active research. It is accepted in the scientific community that there are several types of attention comprised of distinct cognitive systems, which have been identified and supported through studies in neuroscience. For example, Posner and Petersen (1990) argued that there are at least three systems that are individually responsible for alerting, orienting, and target detection or executive function (e.g., the top-down processes of visual search). These classifications have held up over years of research, although there is recent evidence for additional attention networks for self-regulation and selfcontrol (Petersen \& Posner, 2012). It is crucial to identify the implications of the various forms of attention on cognition, especially to understand how attention and consciousness are related.

## Bottom-up vs. Top-down Attention

Attention can be stimulus-driven and automatically guided toward important external events that involuntarily catch the focus of attention, or it can be voluntarily guided through willful selection. This distinction is commonly conceived as bottom-up versus top-down processing (see Theeuwes, 2010). That is, attention can be thought of as a process that is exogenous, data-driven, and beyond our control in a cognitively impenetrable manner (bottom-up). This includes pre-attentive mechanisms that are reflexive in nature, such that salient features bias the neural activity for selection into higher processes and can affect behavior without reaching conscious awareness. Alternatively, attention can be described as being endogenous and more deliberate, which biases the competing neural activity in lower-level cognition based on the goals of the current task (top-down). This dichotomy has been challenged recently because there are other forms of attention that do not neatly fall into these categories, such as when learned rewards or habits influence attention (Awh, Belopolsky, \& Theeuwes, 2012). Nevertheless, there are many attentional processes that fall under one of these two descriptions.

## Effortless vs. Effortful Attention

Effortless attention, like bottom-up attention, is thought of as an involuntary, sensory form of attention and does not always reach conscious awareness. These "effortless" processes serve to obtain information from the environment for higher-level representations (which often require more effort to maintain). On the other end of this spectrum is effortful attention, which, like top-down attention, can be described as focused, deliberate, voluntary, or goal-driven and produces the subjective feeling of expending effort. Some complex attentional processes, however, can be so engrossing that they produce the subjective feeling of being involved in a task effortlessly such that one loses a sense of time (Bruya, 2010). It is this latter version of effortless attention that is particularly insightful, which may be related to expertise and is suggestive of how memory systems can interact with attention to influence the perception of effort and time (it is not a straightforward process).

## Varieties of Attention

Beyond the distinctions described above, attention has been characterized under several "varieties". Attention can be feature-based (see Maunsell \& Treue, 2006) and drawn to types of features, generally organized according to specialized regions in the brain that process certain types of sensory information (such as color, motion, or segment orientation). It can also be object-based (Scholl, 2001) and drawn to things in the world that display object-like properties (e.g., cohesion, symmetry). Feature Integration Theory and Object File Theory describe how object-based attention can operate via "object file" representations (Kahneman, Treisman, \& Gibbs, 1992; Treisman \& Gelade, 1980). This is a two stage process that requires the individuation of objects (a bottom-up process) and the identification of the object after a selective attention binds and maintains the features in an object file. This exemplifies the interaction between low-level and high-level forms of attention that makes the study of attention so complex.

Another influential model for attention is the "spotlight model" (Posner, Snyder, \& Davidson, 1980), where attention can be focused on a specific region, or it can be distributed and more diffuse to cover more area (with less detail). This spatial attention operates on empty space or objects in space, and also can quickly determine the "gist" of the information present. Covert attention is a particularly insightful form of attention and refers to the voluntary shift of attention outside the center of one's gaze (Wright \& Ward, 2008). This has been shown through various tasks where a subject views a center of a stimulus display but shifts the focus of attention to the periphery without moving their eyes (or making other physical movements). This type of attention may correspond to the ability to attend to certain thoughts from memory or other mental states that are not immediately linked to sensory information.

Additionally, research on attention has identified peculiar phenomena such as blindsight, inattentional blindness, and the attentional blink. All these describe occasions when
attention fails to perform as expected, particularly because focused attention overlooks targets (e.g., during a search task). The failures may be due to the relevant information not being detected by low-level sensory receptors or could be higher up where it fails to reach awareness. This exemplifies the complexity of the systems that make up the broad term of "attention", which all have the common goal of selecting perceptual information for cognitive processes.

## Conscious Attention

A problem in the empirical study of consciousness is how to identify and explain all the nuances of the theoretical understanding of consciousness at the neural level. For example, even if the experimental evidence confirms that consciousness correlates with a specific pattern of neural activation, what would that finding signify? Could we be able to distinguish access consciousness from phenomenal consciousness? Could it be that the pattern of activation is literally just correlated with consciousness and it neither explains nor identifies what is truly unique about it (i.e., it corresponds to the integration of information but not to the integration mechanism)? Much has been said about this issue, and we will not provide a metaphysical thesis here about the relevance (or lack thereof) of attempts to identify the neural correlates of consciousness. Despite the difficulties underlying the metaphysics of consciousness, we believe that the progress on the experimental front has been substantive. By focusing on the largely unexplored issue of conscious attention, we can outline the general features of an adequate theory of consciousness that would successfully guide future empirical research.

One way of clarifying the relationship between consciousness and attention is by examining the relationship responsible for successful reductions. The spectrum of views that are possible, from most to least restrictive, include: 1) Identity between consciousness and attention, with specific definitions of the kinds of consciousness and attention at stake; 2) Dissociative views of consciousness and attention, where there are several forms of attention without consciousness, but only one form of conscious attention, and attention is a necessary condition for consciousness; 3) Dissociative views that indicate all forms of consciousness are of the same type but that attention is not a necessary condition for consciousness; 4) Dissociative views that indicate there are forms of attention without consciousness but no possible form of consciousness without attention, although there may be many forms of conscious attention; and 5) Full dissociation between consciousness and attention.

The identity thesis for consciousness and attention is the most restrictive of these views and is akin to the reduction of questions about "life" to questions about DNA. According to this view, consciousness just is attention (e.g., Prinz, 2012). There are advantages of this view, but there are also major problems, both theoretical (Koch \& Tsuchiya, 2007) and empirical (Kentridge, 2011). Many of these problems are best understood as possible responses to
two different questions. 1) Are all forms of attention forms of conscious attention? The intuitive response is yes, but the empirical evidence is not clear-cut. 2) The inverse question: are all forms of consciousness forms of conscious attention? Here, things are much trickier and no obvious response seems without problems. The leading intuitions have epistemic or metaphysical flavors, but no leading intuition clearly commands the inquiry. Furthermore, this concerns only theoretical issues-when one looks at the empirical evidence, things are equally tricky. Despite its intuitive strength, the identity thesis is too simplistic to account for such intricate issues as identifying the various systems supporting consciousness and attention-but full dissociation seems to be too strong and so a landscape of options emerges. There seems to be attention without consciousness, for example, as in the case of blindsight. How prevalent are these forms of unconscious attention (i.e., to what extent do they guide cognitive processing)? There may be consciousness without attention and the same consideration about scope is pertinent. Depending on the degree of dissociation, one can envision several possibilities with critical theoretical implications.

What are the possible outcomes? Suppose the degree of dissociation is insignificant. In this case, one could distinguish a few forms of consciousness without attention (or vice versa), but they would be rare cases of little consequence such that one could almost identify consciousness with attention. Yet, even in this case several questions remain. Why would these forms of consciousness without attention (or vice versa) exist? All issues of scope are relevant here. Suppose that all forms of attention are forms of conscious attention but that there are a few cases of consciousness without attention (or attention without consciousness). This possibility would suggest that these forms of consciousness could not be easily integrated with attentional processes, where some forms of consciousness are more resilient to cognitive integration with other processes than others. Or perhaps it is strictly due to there being two fundamental kinds of consciousness.

Suppose, on the contrary, that the degree of dissociation is severe (we focus only on these polar opposites in this paper). Some cases of conscious attention could be associated with what Block calls mental paint, and be highly if not fully dependent upon subjectively unreal attentional contrasts. Other cases of conscious attention could be highly representational and depend on specific mental contents (as attention is generally understood). Finally, other cases of attention could be directed to the conscious self. Of course, there will be many cases in which attention is not accompanied by consciousness (at least phenomenal consciousness) and there will also be cases in which consciousness is not accompanied by attention. The main result would be that consciousness and attention are integrated in some cases, but operate independently from one another. Based on current empirical evidence, however, there is only weak support for consciousness without attention, because there are several types of attention that
must be examined when testing for the presence of consciousness without attention, and studies that claim this dissociation have failed to do so (see Cohen, et al., 2012). Also, this dissociation is unlikely if one accepts the premise that the purpose of attention is to determine what information reaches conscious awareness.

Examining the findings in neuroscience should help clarify the relationship between attention and consciousness. It is accepted that different areas of the brain support different forms of attention. For example, it seems that the cerebellum and other more "primitive" areas of the brain are not necessary for consciousness (Koch, 2012), and yet the cerebellum is crucial for navigation and thus has several areas devoted to attending to features of the environment. Areas associated with emotion, perception, and motivation, which were thought to be deeply related to phenomenal consciousness, are also unnecessary for conscious awareness. So based on the neuroscientific findings, one can make a very plausible case for dissociation. This conclusion has to be evaluated in conjunction with the considerations that led theorists to propose the identity thesis. Furthermore, innovative theories on how consciousness emerges, for example, from recurrent processes in the brain (Lamme, 2006), must be considered in this work.

To advance the understanding of conscious attention, one must provide an integrated account of consciousness and attention based on the latest psychological and neurological findings. By doing so, we can elucidate theoretical distinctions fundamental for an adequate understanding of the conscious mind, such as the distinction between higher forms of self-awareness (e.g., the recognitional self) and more minimal ones (e.g., the phenomenal self). Also, higher forms of attention and consciousness may be associated with the emergence of social interactions within species. That is, as social interactions become more complex (e.g., monogamous mating, social hierarchies, ability to follow gaze), a more sophisticated cognitive system is necessary and this may be correlated to consciousness. Research considering such a social account is also warranted.

## Conclusion

In order to advance the empirical study of consciousness and attention, a concerted effort must be made to unify the two areas in terms of language and goals. Attention research is a promising area for understanding consciousness, especially by clarifying the relationship between consciousness and attention via conscious attention. A main insight from the research findings on attention, which should guide future inquiry, is that attention is mainly concerned with connecting cognitive processing with objects in the external world by processing selective information-it is more analytic and selective in nature than consciousness, which is highly integrative. The past attention research in cognitive psychology, however, presents a challenge for integrated accounts with consciousness, such as the one we pursue here. Most psychologists working on attention had, because of the
intractability of the problem of consciousness mentioned above, either no interest in consciousness or no way to connect their findings with such considerations. Findings on focused attention, divided attention, failures of attention, and other aspects of attention shaped the field without making it explicit how they were compatible with theories of consciousness. Making these connections explicit is another crucial goal for future work that will inform our understanding of conscious attention, and can only emerge from a unified theoretical and conceptual understanding.

# Discovering Quantification and Number in a Role-Filler Model 

Aaron J. Hamer (ahamer@hawaii.edu)<br>University of Hawaii at Manoa, Linguistics<br>1890 East-West Road, Honolulu, HI 96822 USA

Leonidas A. A. Doumas (leonidas@hawaii.edu)<br>University of Hawaii at Manoa, Psychology<br>2530 Dole Street, Honolulu, HI 96822 USA

#### Abstract

Quantification plays a central role in human reasoning and models thereof, but the discovery and development of quantification remains an open question. We present a theory of how such concepts are learned from experience in the DORA model, a neurally-plausible computational model of relational learning and reasoning (Doumas et al., 2008). The same theory accounts for how concepts of number are acquired in this class of model. We are unaware of any prior model that accounts for the development of both quantification and number from unstructured (e.g., perceptual) input.

Keywords: number; quantification; relational discovery; computational modeling.

## Introduction

Quantification and number are key representational constructs in human cognition. These concepts are foundational in science, mathematics, music, and many other domains of human achievement. Many models of cognition rely on these representational primitives (e.g., any symbolic model that relies on first-order predicate calculus, many Bayesian models such as Piantadosi, Tenenbaum, \& Goodman's (2013) model of quantifier discovery, etc.), but as Carey (2009, p. 456) notes, "There is no proposal I know for a learning mechanism available to non-linguistic creatures that can create representations of objects, number, agency, or causality from perceptual primitives."

These concepts share significant semantic overlap ranging from their function as predicates over sets of objects (Barwise \& Cooper, 1981) to innate, scalar ordering (e.g., one, two, three \& some, many, most; Horn, 1972). Both sets of concepts can be derived from a small set of axioms via set theory (i.e., set membership, identity; Van Heijenoort, 1977). It does not seem unreasonable to consider the problem of their acquisition jointly. While there have been attempts to explain their acquisition in terms of a developmental trajectory from number to quantifiers or vice versa (e.g., Gelman \& Gallistel, 1978; Carey, 2004), we are unaware of any existing model that accounts for the development of representations of both quantification and number from unstructured (i.e., perceptual) input.

## Behavioral Data

## Quantification Facts

Behavioral evidence suggests that there are three broad areas of difficulty with the acquisition of quantification: quantifier spreading, mapping issues, and superlative quantifiers.

Quantifier Spreading Philip and his colleagues (1991a, 1991b) popularized the term quantifier spreading to describe a phenomenon first reported by Inhelder \& Piaget (1964). Children aged six to seven were unable to restrict universal quantifiers to a subset of items present in an array based on a shared feature. When presented with three purple triangles and a purple circle and asked "Are all the triangles purple?" the children would respond in the negative. When asked for an explanation, a typical response was "The circle is purple, too."

Mapping Issues Brooks \& Braine (1996) demonstrated that children have more rigid mappings for the quantifiers all and each than adults. Children preferred a grouped interpretation of all in scenarios such as "All of the roses are in a vase" and a distributed, one-to-one interpretation of each in scenarios such as "Each of the roses is in a vase". They interpreted scenes where roses were distributed over more than one vase as false for the all quantifier and scenes where there was not a one-to-one mapping of roses-to-vases (e.g., more roses than vases, more vases than roses) as false for the each quantifier. Children achieve adult-like performance reasoning about all at around age five but do not reach adult-like performance reasoning about each until age nine.

Superlative Quantifiers Scalar quantifiers can be divided into two types: superlative quantifiers that include their endpoints (e.g., at most three, three or more) and comparative quantifiers that exclude their endpoints (e.g., less than four, more than two). Musolino (2004) showed that five-year-old children performed worse on tasks relying on superlative quantifiers versus comparative quantifiers. Geurts et al. (2010) investigated this phenomenon further and showed that the difficulty of acquiring superlative quantifiers extended to 11 -year-old children. Geurts et al. also showed that superlative quantifiers were more difficult for adults to process (as shown by higher RTs). Hurewitz et al. (2006) found that three-year-olds interpret some as
inclusive of all. This result suggests that some undergoes a transition from a superlative quantifier to a comparative quantifier at some point in development.

## Number Facts

Our discussion of the behavioral data on the acquisition of number will focus on three areas: numerosity and counting, the linear shift, and operational momentum.

Numerosity and Counting Children as young as two-yearsold can subitize, or determine the numerosity of small sets without counting (Gelman \& Gallistel, 1978). However, three-year-olds struggle with the foundations of counting (Grinstead et al., 1997), and have difficulty with cardinality (Wynn 1990, 1992). By three-and-a-half, most children demonstrate exact judgments of numbers up to four and the ability to count to similar magnitudes (Gelman \& Gallistel, 1978; Hurewitz et al., 2006).

The Linear Shift Children initially estimate numerical quantities based on a logarithmic scale before undergoing a shift to using a linear scale at approximately 12 years of age (Siegler \& Opfer, 2003). Logarithmic estimations of quantity are consistent with a perceptual system that obeys the Weber-Fechner law (Fechner, 1860).

Operational Momentum McCrink et al. (2007) showed that adults overestimate sums and underestimate differences, a phenomenon referred to as operational momentum. The pattern of errors fits a Gaussian distribution if magnitudes are represented logarithmically rather than linearly.

## Summary of Behavioral Data

Children struggle with the acquisition of concepts of quantification and number. Some abilities are present early (e.g., subitization at two years) and others develop quickly (e.g., developing counting between ages three and three-and-a-half). Other abilities develop more gradually (e.g., restriction of quantifiers) and some developmental trajectories extend into adolescence (e.g., the linear shift). In some cases earlier points on the developmental trajectory are more compatible with formal logic than the adult norm (e.g., some as a superlative quantifier).

## Developmental Accounts

## Theories of Quantification

Existing accounts of the development of quantification can be grouped into three broad categories: connectionist models, symbolic models, and Bayesian models (e.g., Clark, 1996; Carey, 2004; and Piantadosi, Tenenbaum, \& Goodman, 2013, respectively). Existing connectionist models model the association of externally supplied
symbols such as words with first-order quantifiers. We have not found an account that does not assume pre-existing symbolic representations such as number ${ }^{1}$ (Carey, 2004) or the set theoretic equivalents of number, the existential quantifier, the universal quantifier, or formally equivalent items (i.e., cardinality, non-exhaustion, exhaustion, and membership \& identity, respectively; Piantadosi et al., 2013; Van Heijenoort, 1977).

## Theories of Number

We will examine four classes of models of the acquisition of number: connectionist models, spiking-neuron models, symbolic models, and Bayesian models.

Connectionist Models of Number Existing connectionist models provide an excellent account for the development of subitization via associative learning or summation encoding (e.g., Ahmad, Casey, \& Bale, 2002; Dehaene \& Changeux, 1993; and Verguts \& Fias, 2004). Various models have provided an account for innate ordering via unsupervised competitive recurrent back-propagation networks (e.g., Ahmad et al., 2002) and the association of external symbols with existing representations of number via co-occurrence (Verguts \& Fias, 2004). These models do not address phenomena that occur later in development, nor do they provide an account for the emergence of symbolic representations.

Spiking-Neuron Models of Number These models focus on tying specific abilities or developmental processes to what is known about neuronal behavior. Examples include modeling number as a consequence of gamma oscillations ${ }^{2}$ that predicts subitization behavior that obeys the WeberFechner law (Miller \& Kenyon, 2007) and a tuning function based on neuronal spike trains that accounts for both operational momentum and the linear shift (Prather, 2012).

Symbolic Models of Number Existing symbolic accounts either require "explicit external symbols" (e.g., Carey, 2009) or assume an existing set of quantifier representations (e.g., Gelman \& Gallistel, 1978). While these models account for many developmental phenomena, they openly assume a preexisting cache of symbolic currency to build upon.

Bayesian Models of Number Extant Bayesian models of the acquisition of number share the flaws of Bayesian models of quantification - they assume set theoretic equivalents of number, the existential quantifier, the universal quantifier, or formally equivalent items (i.e., cardinality, non-exhaustion, exhaustion, and membership \& identity, respectively; Piantadosi, Tenenbaum, \& Goodman, 2012; Van Heijenoort, 1977).

[^289]
## Summary of Developmental Accounts

Existing accounts of the development of quantification and number can be grouped into connectionist, symbolic, and Bayesian models. While each class of model has strengths, all existing models fail to account for the development of the symbolic currency such as predicates or set operations that they either map to or build upon. Furthermore, no existing model has accounted for both domains of concepts or all of the key developmental trajectories within a single domain.

## The DORA Model

## Overview

The DORA model is a symbolic connectionist architecture: a computational model using a neural network to store and manipulate structured representations. DORA represents objects and roles in a distributed fashion - that is, as patterns of simultaneous activation over units (analogous to groups of neurons) that represent the semantic features of the item being encoded.

DORA learns structured representations of properties shared between objects by comparing them. Features shared between objects receive input from multiple sources and are isolated via simple Hebbian learning. The resulting representations are comprised of these shared features, are independent of any specific objects, and can be bound to novel objects encountered in the future. ${ }^{3}$ When DORA compares instances of objects searching for another (e.g., a cat searching for a mouse and a sister searching for her brother) it learns representations of searcher (comparing the cat and sister) and sought (comparing the mouse and the brother). When observing a new instance of searching the existing representation of sought can apply (i.e., be bound) to the sought object.

The representations DORA learns are functionally equivalent to single-place predicates that take novel arguments. Although the initial representations that DORA learns contain extraneous features (e.g., the shared features of the cat and sister irrelevant to searcher), comparisons between different instances produce representations that are progressively more refined (i.e., comparing representations searcher learned from different instances causes contextspecific features to wash out).

The DORA model represents multi-place relations by combining sets of these single-place predicates - e.g., after learning representations of searcher and sought they can be combined to form a representation of the multi-place relation searching. If there is anything invariant about a concept (and there must be for us to recognize it), DORA
can learn a structured representation of it.

## Discovery of Quantification and Number

The DORA model learns new representations through a process of iterated comparison of items in the object and role layer, where featural overlaps ${ }^{4}$ are learned as new representations. This process allows for refinement of existing representations by comparing them to other existing representations or new input.

All quantifiers are learned by comparing instances of countable items and extracting numerosity features. There are many accounts of how a connectionist model can acquire basic numerosity features (e.g., Ahmad et al., 2002; Dehaene \& Changeux, 1993; and Verguts \& Fias, 2004); DORA implements a version of the Metric Array Module (Hummel \& Holyoak, 2001) which extracts magnitude features for any metric dimension, such as numerosity or length.

Figure 1: An example of comparing instances of countable items. Note that the featural representation of 3ness is active for higher cardinality sets, at least in quantities where subitization is an effective strategy to extract numerosity features.

Initial comparisons, especially when the arity of compared sets differ, will result in representations of quantifiers such as the all node in Figure 1. Note that the initial representation in this example contains the 3ness node as well. This process allows for the extraction of quantifiers such as all, and through additional experience, quantifiers such as some. The nodes 3ness and all referenced here are purely expository and stand in for the perceptual features that map to these concepts just as the

[^290][^291]nodes for catness and dogness are collapsed representations of the featural invariants present in cats and dogs.

Figure 2: Extraction of the quantity 3.
The same process accounts for the extraction of number representations. As a consequence of this process, concepts that are encountered more frequently (all, one, some) will be learned before concepts that are encountered less frequently (fifteen, at least), and previously learned concepts can be used to bootstrap the learning of future concepts. Eventually, pure conceptual representations of frequently encountered quantifiers and numbers are extracted through repeated comparison.

Figure 3: The resulting representations for frequently encountered quantities.

## Representational Consequences

The representations shown in Figure 3 are pure set representations, suitable for set operations. They can be bound to other relations to create bound sets (solving the quantifier spreading problem, assuming that the cognitive system has developed both these representations and scopelimiting representations and has enough WM to bind them together). There are some other significant consequences of this manner of representation.

Cardinality of the Universal Quantifier All quantifiers are learned through experience; there is never a time when a quantifier is perceived without being predicated over some set. Consequently, the universal quantifier is cardinal. While the cardinality of the universal (and other quantifiers) will change based on the specific context it is experienced or represented in, it will always possess cardinality. This underscores the results from set theory that suggest that numbers and quantifiers are formally equivalent (Van Heijenoort, 1977).

Place-Value Notation Numeral Systems Commonly encountered quantities will be explicitly represented in such a system. It is likely that specific quantifiers for the numbers one through ten exist in such a system. However, it is extremely unlikely that such a system learns a specific representation for quantities such as 347 . However, such representations can be built form the representational currency of lower-order numbers such as three, four, and seven, and a representation for place that takes on features of the base of the numeral system (e.g., 10 for Arabic numerals) and magnitude of the base (e.g., two for the hundreds place), and so on.

## The Way Forward - Count on DORA to Quantify Development

Our theory of quantification and number development handles three major issues not addressed in current models. First, we account for both domains within a single model using a small set of principles (e.g., comparison-based learning, building complex representations from singleplace predicates) and processes. Furthermore, we provide an account for how these symbolic representations are developed and structured as a consequence without drawing from an existing cache of symbolic currency. Finally, our model accounts for a wide variety of developmental trajectories within each domain using the same set of basic parameters and processes, as well as a wide variety of other developmental trajectories.

## Unifying Quantification and Number

One of the core goals of framing the acquisition of quantification and number within the DORA framework is to provide a unified account of their development. Unifying both domains as opposite endpoints of a developmental trajectory has been attempted (e.g., Gelman \& Gallistel, 1978; Carey, 2004) but such attempts fail to account for the intertwined developmental trajectories as they are built on assumptions of mastery within a domain as a foundation on which to build mastery of the other. The most successful Bayesian modeling attempts to account for the development of quantification and number are currently instantiated as separate Bayesian models built on the same set of priors (Piantadosi et al., 2012, 2013). While unifying Bayesian models built on the same set of priors is relatively simple, it remains to be done.

Our account of the development of quantification and number captures key developmental trajectories in both domains as a consequence of comparison-based learning
iterating over previously learned concepts and new experience. The interactions between the developmental trajectories of quantification and number are captured because they arise as a natural consequence of learning both domains at the same time. These interaction effects forced us to deal with both domains simultaneously as modeling either quantification or number learning in isolation failed to account the developmental facts for either domain. DORA cannot model either quantification or number in isolation as successfully as it can account for both together.

## Symbolic Structure Developed, Not Borrowed

Most accounts of cognition fail to explain where the structured symbolic representations they use to solve problems come from. Such structures range from predicates, set operators, and even quantifiers and cardinality. The core function of the DORA model is to extract invariance from unstructured (e.g., perceptual) input via comparison. Using a comparison-based learning mechanism not only explains how such structure arises, but also what this structure looks like. This mechanism creates the representations that many models rely upon.

Bayesian models of development rely on an external source of structured symbols to build a foundation upon. While Bayesian models provide an excellent way to model competency, when modeling development they run into more fundamental issues than failing to account for where the structures they rely on come from. The most successful Bayesian models of the development of quantification and number competency in people (i.e., Piantadosi et al., 2012, 2013) rely on priors that are a superset of the concepts they claim to develop. Put simply, they start with the assumption that people can already count to three and use the quantifiers for existence, some, all, and none. We find it difficult to characterize a model as developmental when it assumes its outputs as priors.

## Modeling Developmental Trajectories

We have provided a brief overview of how DORA learns cardinality and number from experience, but we have not yet laid out how our model handles the developmental trajectories at play.

DORA begins subitizing using the Metric Array Module, a simple, neurally plausible mechanism that could easily be available to two-year-old children. This mechanism outputs magnitude judgments that obey the Weber-Fechner law. Logarithmic judgments of magnitude explain why children treat numbers and analogous quantifiers such as some as superlative quantifiers initially because a point on a logarithmic scale corresponds to a range on a linear scale. As DORA is exposed to many instances of small sets (as children are) it quickly learns to represent small cardinal numbers explicitly. These explicit representations do not rely on logarithmic magnitude features; consequently, children no longer treat these numbers as superlative quantifiers.

Children gain working memory as the prefrontal cortex matures. Quantifier spreading disappears as children are able to marshall the working memory needed to build the complex representations required to simultaneously bind a
quantifier to a scope-limiting representation and match that representation to a particular situation. The representations for cardinal numbers continue to develop throughout childhood as larger and larger numbers become explicitly represented, accounting for the linear shift in early puberty.

We account for all of these developmental facts with a single set of parameters and simple processes. DORA also accounts for over 35 findings surrounding the development of relational thinking (Doumas \& Hummel, 2010; Doumas et al., 2006; Doumas et al., 2008; Sandhofer \& Doumas, 2008), including the relational shift (Rattermann \& Gentner, 1991), the development of relational representations (Smith, 1984), and the development of shape bias (Abecassis et al., 2001).

## Conclusion

Our proposal is a promising account of how concepts of quantifiers and number can be learned from perceptual input. The DORA model's working memory constraints allow a developmental trajectory to be modeled, and make specific predictions about how specific types of quantified reasoning will fail based on working memory demands, such as differing magnitudes of $n$-back tasks. We are exploring these predictions with human participants. Crucially, our model accomplishes these goals using the same parameters and processes that have allowed us to successfully account for more than 35 developmental phenomena in other domains.

# Disambiguating NN combinations with left/right stress 

James A. Hampton (hampton@city.ac.uk), Daniel Heussen (daniel@heussen.be), Zarah Argel (zarah_jayne@live.co.uk), Hasina Kanbi (hasina_k91@hotmail.com)<br>Department of Psychology, City University London, Northampton Square, London EC1V OHB, UK

#### Abstract

An interesting subclass of Noun-noun combinations in English can take two meanings depending on whether the first or second word is stressed in speech. A BRICK factory is one that makes bricks, whereas a brick FACTORY is one made of brick. An explanation is offered in terms of a bias for nouns from particular ontological categories to trigger particular semantic interpretations for a combination, together with the proposal that the unstressed noun provides the relation to be used. The explanation is tested in three empirical studies.

Keywords: NN combination, concepts, compounds, meaning, ambiguity, stress

## Introduction

Noun-noun compounds are found in many languages. They are the result of placing two nouns together in order to create a compound noun phrase with a new meaning (Gleitman \& Gleitman, 1970; Levi, 1978). The first nounthe modifier-serves to specialise the meaning of the second noun-the head. To take the example of cheese knife, the head noun knife determines the kind of thing involved-a cheese knife is a knife-while the modifier cheese specifies that it is designed for use with cheese. ${ }^{1}$

Looking at noun-noun compounds in English it is possible to differentiate those that are constructed on the fly to meet the communicative needs of a given moment from those that long ago entered the lexicon. A good example of the former is Downing's (1977) famous apple-juice seat to indicate the seat at a table at which the person drinking apple-juice should sit, whereas examples of the latter are toothpaste or lunch box. As they enter the lexicon, compounds in English may be lexicalized as single orthographic words (e.g., snowman), or optionally hyphenated (e.g., pigeon-hole), while others have two-word spellings (e.g., taxi driver). Lexicalization involves a number of changes in the status of a phrase. In particular, lexicalized compounds are also more likely to lack semantic transparency, and hence to appear in dictionaries. The meaning of such non-transparent phrases must be acquired through hearing them in context, rather

[^292]than being computable from the individual meanings alone. Examples like beer garden, water glass, or wine lake cannot be easily understood without appeal to knowledge external to the meaning of the two individual words.

In addition to the many lexicalized compounds in English, it is also possible to create new forms which can be readily understood. People have little trouble understanding new expressions like camel field, or student gardener, even though they may not have come across these combinations before. An explanation for this productivity was suggested by Gagné and Shoben (1997) in their CARIN model of Noun-Noun (NN) combinations. Earlier, Levi (1978) had proposed that the majority of compounds employ one of about 12 semantic relations, such as USE, LOCATION, MATERIAL COMPOSITION or CAUSE. Gagné and Shoben suggested that each noun in a person's vocabulary may be associated in memory with the relations that it most commonly enters into, as either a modifier or a head. Thus for example mountain as a modifier would normally indicate a location as in mountain goat, or mountain village. On the other hand magazine as a head would normally use an informational "about" relation as in train magazine or psychology magazine. When the two are put together to form mountain magazine, a search is instigated to find a plausible meaning. Since a magazine about mountains strikes most people as more plausible than a magazine in the mountains, in this case the head noun ends up dictating the preferred meaning of the phrase.
In the search for a plausible meaning, two equally plausible meanings can sometimes arise, each based on one of the two nouns and their preferred semantic relations, so that the compound is ambiguous. Kamp and Partee (1995) cite the example of a brick factory, which can either mean a factory that makes bricks or a factory that is made of brick. They also point out that the stress pattern employed when speaking the phrase can disambiguate its meaning. Thus one can compare (1) and (2):
(1) a BRICK factory $=$ a factory that makes bricks
(2) a brick FACTORY = a factory made of brick.

The account offered by Kamp and Partee is that the ambiguity relates to the use of two distinct syntactic forms. They suggest, following Bloomfield, (1933: 228) and Chomsky and Halle's (1968: 15-18) Compound Rule, that left stress is a general signal in English that the phrase is a compound, meaning that its semantics will depend on local
context and the argument structure of the head noun. Note how BEER garden, WATER glass, and WINE lake all take left stress patterns, indicating this compound structure. On the other hand, right stress typically indicates a simpler modifier+head noun phrase. For example a black BIRD is a bird that is black, in contrast to the left-stressed, lexicalized, compound BLACKbird, which in British English refers to the common species of garden bird, Turdus merula.
The meaning of the compound phrase BRICK factory requires an understanding that the concept of factory takes an argument of the kind of thing made in it, with the modifier noun placed into this slot, as in (3).
(3) FACTORY (makes X)

X $=$ \{jam, brick, car, clothing,.. $\}$
On the other hand brick FACTORY is interpreted by treating the noun "brick" as a modifier meaning "made of brick". This account is not entirely satisfactory, since the question of when a NN combination is a "true" compound is hard to make on purely semantic grounds. For example why should the meaning of "factory" not also have an argument equivalent to [made of] in which the noun "brick" could be placed? The occurrence of left stress in compounds is also not as clear or reliable as one might hope (see Bell \& Plag, 2010). While most single orthographic compounds do take left stress (e.g. SUNflower, TOOTHpaste, ICEcream) other highly familiar forms written as two-word phrases take right stress (plum JAM, pumpkin PIE). Nor is it that a given semantic relation such as MADE OF seen in these last two examples is consistently right stressed. Thus in British Received Pronunciation cake (unlike pie) is typically left stressed (GINGER cake, CHOCOLATE cake). It is unclear why the ingredients of jams and pies should be syntactically adjectival while the ingredients of cake should require an argument structure (a point noted by Lees, 1962: 120). Given these difficulties, in this paper we will refer to all NN combinations simply as compounds.

A large corpus-based analysis by Plag (2006) using a variety of models found the assignment of stress in spoken English to be largely unpredictable. The best means of prediction was by using analogy with other similar compounds (e.g. OIL painting, FINGER painting, ACTION painting), suggesting a role for similarity-based generalisation in the assignment of stress (Plag, 2010). Further work by Plag and colleagues has identified evidence for a semantic basis, and for families of semantically similar compounds taking the same stress (Plag et al. 2008). Bell \& Plag (2010) also reported that relative informativeness can direct stress on to the more informative of the two nouns.

The placement of stress in speech generally is clearly a very complex phenomenon (for a review see Cutler et al. 1997). There has been relatively little research on prosody in the psychological literature in relation to the interpretation of compounds. A study by Lynott and Connell (2010) manipulated spoken stress for an arbitrary set of novel NN compounds, and found that dual emphasis differentially speeded the generation of property interpretations (e.g. a zebra mussel as a striped mussel).

However they reported no effects of stress on the frequency with which different interpretations were generated, even though many of the compounds had more than one interpretation.

In this paper we focus on one particular use of stress in the context of the interpretation of compounds. Specifically, we ask how ambiguous compounds such as brick factory are disambiguated with the help of stress. Why should left versus right stress direct interpretation in two different directions? Our proposal is that stress indicates which of the two nouns provides the semantic relation for interpretation of the phrase. In particular we propose that it is the unstressed noun that determines the relation.

Recall the example of brick factory. The claim is that brick as a modifier will typically invoke a [MADE OF] interpretation, as in brick house, brick building, brick wall. On the other hand factory will invoke a [MAKES] relation, as in car factory, hat factory or furniture factory. Placing the stress on the modifier brick thus gives the relation preferred by the head (a factory that makes bricks), whereas stressing the head noun factory gives the relation derived from the modifier (a factory made of brick).

To make the principle operational and testable we needed some means to be able to generate ambiguous compounds where the ambiguity depended on two competing relations, one derived from the modifier and one from the head. Both interpretations needed to be plausible meanings for the written phrase (that is, as read in the absence of auditory stress information). Rather than depend on a frequency analysis of individual words occurring in either position, as Gagné and Shoben (1997) proposed, we adopted a suggestion from Maguire, Wisniewski \& Storms (2010) who proposed, on the basis of a corpus study of semantic patterns in compounding, that preferred semantic relations follow from the general ontological category into which a noun falls, rather than being individual to each noun. Thus brick is a member of the category of compositional materials, along with jam, water, cork, plastic etc. All of these will have a preference as modifiers for a MADE OF relation. Similarly factory belongs to a category of sources or origins of objects, from which the relation MAKES will naturally follow. The idea of interpreting NN compounds by recourse to a superordinate semantic categorization of nouns has had much support, particularly in the domain of automatic processing of natural language (Rosario \& Hearst, 2001), although no agreed semantic taxonomy has yet been developed.

Our strategy in creating a set of ambiguous compounds for testing was therefore first to find individual examples, and then to generate further examples using the same superordinate categories. The results of this process can be seen in Table 1 which shows the analysis of the compounds into general categories, together with examples of the materials used. The classification is necessarily fairly broad and provisional, but it serves to illustrate the analogies between, say, an airplane magazine and a church painting, both of which take either a LOCATION or an ABOUT
relation, and it provides some systematicity to our search for suitable examples. We predicted that with left stress, the compounds will have an interpretation of magazine (or painting) ABOUT an airplane or a church, while with right stress, the location relation will be dominant, yielding a magazine or painting LOCATED IN an airplane or church.

To assess the validity of our analysis, we put our predictions to the test. Experiment 1 and 2 provided participants with the ambiguous compounds spoken with either left or right stress, and asked them to write down their interpretation of the meaning. Experiment 3 provided participants with the spoken phrases, and then asked them to judge the plausibility of a given interpretation which could either match or mismatch the interpretation predicted for the stress pattern. We predicted that stressing the modifier or head would influence both the interpretations generated in Experiment 1 and 2 and the speed and accuracy of judgments in Experiment 3.

## Experiment 1

The purpose of Experiment 1 was to test our proposal that the unstressed word in an ambiguous compound should be the one from which the semantic relation will be derived. Hence a chimpanzee DRAWING should be a drawing done by a chimpanzee (taking the agency from the animate modifier noun), while a CHIMPANZEE drawing will be a drawing of a chimpanzee (taking the "information source about" relation from the head noun).

## Method

Participants Twenty-four students at City University London participated. All were native speakers of English.
Materials Forty ambiguous compounds were recorded spoken by a female voice in Received Pronunciation British English. The compounds were selected from a larger sample through pretesting. Participants in the pre-test read each compound (i.e., no stress information was given) and wrote down an interpretation. Items were then selected where just two alternatives were generated, each by at least $25 \%$ of the participants. For the final selection, on average the more frequent meaning was generated $57 \%$ of the time, and the less frequent meaning $35 \%$ of the time. Each compound was
recorded once with stress on the first word, and once with stress on the second word. To reduce the likelihood that the ambiguity of phrases would be noticed, 12 unambiguous fillers were included, two at the start, and ten more distributed every three to five trials through the rest of the experiment. They were familiar phrases like book bag and oak table.
Procedure Participants were seated in front of a PC, and wore sound insulating headphones, through which the speech samples were played. Instructions were displayed on the screen as follows:

In the present study we are investigating the meaning of so-called noun-noun phrases, phrases consisting of two nouns, such as "park bench". We are interested in your intuitive understanding of these phrases. For each noun-noun phrase, we would like you to write down its meaning in the textbox provided. A short description of the meaning that first comes to mind is sufficient. For example, when you hear "park bench", the first thing that might come to mind might be: A bench in a park.
Once the instructions were understood the trials began. Each trial began with the playing of the recording of a phrase. A button on the screen allowed the participant to repeat the playback if they wished to hear it again. If the replay button was clicked three times, a window appeared displaying the phrase (very occasionally people had trouble hearing the words spoken). Being written, no cue was given as to the stress pattern. A text box was provided on screen into which the participant typed their interpretation of the phrase. A "NEXT" button took them after a short pause to the next screen and a new recorded phrase.

Design Participants were divided into four groups of 6. Two groups had 20 compounds with left stress and 20 with right, while the other two groups had the alternative. In addition two different random orders were used.

## Results

One item was omitted owing to an error in the programming. The results were based on the remaining 39 items. The interpretations entered by participants to each

|  |  | Modifier-based <br> Relation | Head-based <br> Relation | Examples |
| :--- | :--- | :--- | :--- | :--- |
| AGENT/ PATIENT | AGENT | H who is M | H for M | athlete lawyer, celebrity doctor |
| AGENT/ PATIENT | ACTION/EVENT | H by/from M | H for/to M | company award, dolphin strategy |
| AGENT/ PATIENT | INFORMATION SOURCE | H produced by M | H about M | politician novel, chimpanzee drawing |
| LOCATION | AGENT | H comes from M | H done of M | Iceland painter |
| LOCATION | INFORMATION SOURCE | H found in M | H about M | airplane magazine, church painting |
| MATERIAL | INSTRUMENT | H made of M | H for making M | ceramic oven |
| MATERIAL | CONTAINER | H made of M | H contains M | clay bucket, wax pot |
| MATERIAL | INFORMATION SOURCE | H made of M | H about M | chocolate book, paper catalogue |
| MATERIAL | MATERIAL | H made of M | H for M | juice dye, plant poison |
| INSTRUMENT | ACTION/EVENT | H done using M | H done to M | dollar purchase, skateboard damage |

[^293]phrase were collated into a single table, without any information about the original stress pattern that they had heard. The first two authors worked through the table independently to code the interpretations as either (a) the meaning derived from the modifier, (b) the meaning derived from the head, or (c) other or unclassifiable. Initial agreement between the judges was $90 \%$. Disagreements were resolved by each judge reconsidering the disputed interpretations in the knowledge of the other judge's rating. Any remaining disagreements were treated as "other". (There were $13 \%$ of responses that could not be classified.) The predicted effect of stress was borne out in the data across 39 items, with more modifier meanings resulting from right stress (19.8) than from left stress (14.2), and more head meanings resulting from left stress (18.6) than from right stress (15.1). Overall, $57 \%$ of responses were as predicted by stress. The effect was highly reliable across participants, with 21 of 24 following the prediction on average, and none against it ( $\mathrm{p}<.001$, sign test). Across items the effect was less strong statistically, with 25 of 39 compounds following the prediction and 12 against ( $\mathrm{p}=.01$, sign test).

## Experiment 2

The effect in Experiment 1 was relatively small, with stress inducing a bias in interpretation of $57 \%$ versus $43 \%$. Experiment 2 was a replication in which we tested whether a new selection of materials and an improved quality of the sound recordings might show a stronger effect.

## Method

Participants Twenty-four students participated for course credit.

Materials Ambiguous compounds were constructed as in Experiment 1, with 40 compounds, 25 of which were new to this study. (The effect size in Experiment 1 for the 15 items used in both studies was identical to the overall mean effect size for that study, so these were not retained just on the basis of their being "good" items in terms of results.) New recordings were made, under improved recording conditions using a sound-proof studio and high quality microphone and recorder. The speaker had a London accent, more familiar to the student participant pool than was the RP used in Experiment 1. In addition when creating the recordings, to help the speaker produce meaningful stress patterns we used contrastive stress to generate the left versus right stress patterns. The speaker first read out a sentence such as "It's not a CLAY pot it's a ... WAX pot", while pausing before the last two words. In a second recording, the speaker read out the sentence "It's not a wax CANDLE, it's a ... wax POT". All speech except for the final two words of each sentence was then edited out to leave just the final two word phrase for use in the experiment. Hence participants in the experiment proper had no access to the contrastive meaning used in generating the spoken phrases, but just heard each
phrase either with left or with right stress.
Design and Procedure The design and procedure was identical to Experiment 1.

## Results and Discussion

Responses were classified as before. The effect size was considerably increased. For left stress, across the 40 items there were on average 27.8 head meanings and only 11.3 modifier meanings, while with right stress the means were reversed with 14.3 head meanings and 24.0 modifier meanings. The proportion of all responses in line with prediction increased from 57\% in Experiment 1 to $67 \%$ in Experiment 2. Across items, 34 out of 40 (85\%) showed the predicted effect, and only 6 went against the hypothesis. Across participants, 20 (83\%) showed the predicted effect, and only 3 went against. (Both, $\mathrm{p}<.001$ on a sign test).
Experiment 2 strengthened the evidence for our hypothesis. With a new selection of items and improved recording of the stress patterns, the effect size was greatly increased. The relatively weak consistency across items in Experiment 1 can probably be attributed to problems in the original recorded materials. For the set of 15 items used in both experiments effect size correlated across experiments at $.56(\mathrm{p}<.05)$. In the first experiment these items had the same effect size as the remaining items. In Experiment 2 their effect size increased in line with the other new materials ( 8.6 for the 15 retained items, and 7.3 for the 25 new items), supporting the effect of the improved audio recordings.

## Experiment 3

If stress assignment directs interpretation in the way we propose, then it should be easier to judge that a particular given interpretation is plausible for a spoken compound if the interpretation being judged is consistent with the stress pattern used. In Experiment 3, participants heard the same phrases as in Experiment 1 with either left or right stress. They were then immediately given a written interpretation, which was either one of the two plausible meanings, or a new implausible one. When the interpretation was plausible, it could either match that predicted from the assigned stress, or mismatch it (i.e. match the alternative interpretation). We predicted that trials on which a match occurred should lead to faster and more accurate responding.
(Because Experiment 3 was conducted before Experiment 2, the materials and recordings were the same as in Experiment 1).

## Method

Participants Initially 60 students at City University London participated in the study, of which 11 were replaced as they made more than $50 \%$ errors on all trials taken together.

Materials The same 40 spoken word phrases were used as in Experiment 1. Since the programming error for one item
was not detected in time, only 39 of the phrases could be used for the analysis. Fillers were included at the start (the first 5 trials), and throughout the sequence so that not all the phrases were ambiguous. In addition a set of 40 implausible meanings for familiar compound nouns was constructed (e.g., box office "an office about a box", bus seat "a seat that is a bus".)

Procedure Participants heard the spoken phrase over headphones, and then after a delay of 2 seconds saw an interpretation of the phrase on the screen. They had to decide as quickly as possible whether it was a plausible meaning or not. The following instructions appeared on the screen at the start of the experiment:
"In the present study we are investigating the meaning of so-called noun-noun phrases, phrases consisting of two nouns, such as "park bench". We are interested in how long it takes to understand different phrases. You will be presented with a spoken phrase, and shortly after you will see a possible meaning on the screen. If you think the meaning makes sense, then press the ALT GR key (on the right of the space bar). If it doesn't make sense as a meaning for the phrase, then press the ALT key on the left of the space bar. The first five trials are for practice, so feel free to ask if you don't understand what you are supposed to be doing. After that we would like you to proceed, making your responses as fast as you can while not making any errors. The experiment will take 10 to 15 minutes."

Design There were two random orders or presentation and two assignments of stress to each spoken compound. In addition the interpretation offered for judgment could be either the modifier-based or the head-based interpretation.

## Results and Discussion

Mean correct reaction times and error rates were calculated for Matching and Mismatching plausible trials for each participant and each item. Three RTs of over 10 seconds were removed from the analysis entirely, and another 18 reaction times of over 3 standard deviations above the mean for individual participants were truncated. Table 2 shows the results for RT and Error rates. When the interpretation to be judged as meaningful was consistent with the stress assignment, responses were on average 100ms faster and about $10 \%$ more accurate. Two 2-way ANOVA were run for RT and Errors with stress assignment and interpretation as factors, and with participants and items as random effects. (The error distribution for error rates was normal, skew $=-0.1$, matching the assumptions of ANOVA.)

Although RT showed the predicted interaction ( 2338 ms for matching and 2438 ms for mismatching meanings), it failed to reach significance ( $\mathrm{p}=.15$ ). However Errors showed the predicted interaction as significant ( $26 \%$ for matching and $31 \%$ for mismatching trials), with $\mathrm{F}(1,59)=$ $6.0, p=.018$ by subjects, $F(1,38)=4.3, p=.044$ by items.

No main effects were significant. (For filler implausible trials, mean RT was 2300 ms , sd $=771$, and the error rate was $17 \%$.)
While supportive of our hypothesis, the procedure in Experiment 3 is clearly less sensitive to the effects of spoken stress, requiring as it does a "sensicality" judgment. The weak effects may (as in Experiment 1) have reflected some difficulty that some participants may have had in clearly perceiving the spoken phrases. The high error rate may also be owing to this factor. It is also possible that some participants may have focussed on identifying the nonsensical meanings, which would allow them to ignore the spoken stress all together.

|  | MEANING |  |  |  |
| :--- | :--- | :--- | :--- | :--- |
|  | Resp. Time (ms) |  | Error (\%) |  |
| STRESS | Modifier | Head | Modifier | Head |
| Left | 2453 | 2324 | 30.5 | 25.3 |
|  | $(952)$ | $(833)$ | $(18.1)$ | $(17.0)$ |
| Right | 2353 | 2424 | 27.7 | 30.9 |
|  | $(943)$ | $(869)$ | $(16.2)$ | $(17.7)$ |

Table 2. Mean (SD) for response times and errors for Experiment 3

## General Discussion

In these studies we have sought to find evidence for our explanation of how stress assignment can disambiguate the interpretation of NN compounds. We showed in Experiments 1 and 2 that spontaneously generated meanings were influenced in the predicted direction by stress, and this result was supported in Experiment 3 with evidence that online processing of a potential meaning of a phrase was similarly affected by hearing a spoken phrase with the stress on the left or right word, at least in terms of error rates.
The results were typical of psycholinguistic data, in that the main effect of interest was (to various degrees) obscured by other factors and noise in the data. Using a speaker with a London accent, and a procedure for generating the spoken phrases that used contrastive stress ("It's not a CLAY pot it's a WAX pot) produced a marked increase in the size of the predicted effect in the second experiment. It is also very possible that different speakers are differentially responsive to the influence of stress. Both Experiments 1 and 2 found a bimodal distribution across participants. For example in Experiment 2, 16 participants had effects ranging from 43\% to $65 \%$, but the other 8 participants were in the range $87 \%$ to $100 \%$.
The principle explanation that we offer is that the unstressed word in an ambiguous NN compound determines the semantic relation. In light of the role of stress in directing attention, this principle may at first appear paradoxical. One might suppose that attention should be directed towards the noun that is "doing the work". However stress in spoken language is also often used to direct attention to the focus or new information in an utterance (Bell \& Plag, 2010; Bock \& Mazzella, 1983;

Clark \& Haviland, 1977). The difference between "I phoned my mother on FRIDAY" and "I phoned my MOTHER on Friday" is a matter of whether the focus of the utterance is the date of the call or the person called. In the case of our proposed principle, a similar analysis can be made. In an ambiguous compound, one of the nouns provides the background schema from which the general meaning will be derived, and the other provides the highlighted information placed into that schema. Take an example like chimpanzee drawing. Is the issue a matter of what kinds of things chimpanzees get up to, or is it about the kinds of things that get drawn? If the former, then chimpanzee goes unstressed as the new information is that they do drawings. If the latter, then drawing is the unstressed background schema, and the new information is that it is a chimpanzee that is the subject of the drawing. The two interpretations can be (loosely) represented thus;

## (4) A chimpanzee DRAWING

CHIMPANZEE .. [type of creature \{mammal, primate..\}]
.. [activities \{swinging from trees, hooting, DRAWING...\}]
(5) A CHIMPANZEE drawing

DRAWING.. [implements needed \{pencil, paper ...\}] .. [subject \{scene, still life, CHIMPANZEE...\}]
There may therefore be close parallels between the different roles that stress can play within discourse processes and in compound interpretation.

Our result is also consistent with Plag et al.'s (2008) finding that stress assignment is often constant across families of similar compounds, based on the similarity of either head or modifier nouns (see also Plag, 2010). Semantically similar concepts tend to have similar preferred relations, and so enter into similar patterns of stress assignment. For example location modifiers and material modifiers typically take right stress in unambiguous compounds, and there are other cases where given semantic relations are associated with particular stress direction. However, there must be other factors (such as historical accident) at work, as the example given in the introduction of the different stress assignment for pies versus cakes clearly demonstrates. More recently Bell and Plag (2010) have reported that stress can also be predicted from the relative informativeness of the two nouns in a compound, with the more informative being stressed. Our principle fits well with this idea. The unstressed noun sets up a background schema into which the stressed noun is placed as the new information.

The principle that we have described helps to shed some light on at least one aspect of the use of stress patterns in English. It remains to be seen how broadly the principle can now be applied outside of the realm of ambiguous NN compounds.

#### Abstract

There is substantial evidence from many domains that visual representations aid various forms of cognition. We aimed to determine whether learning to construct visual representations of argument structure enhanced the acquisition and development of argumentative writing skills within the context of first-year college writing course. We found a significant effect of the use of argument diagrams, and this effect was stable even when multiple plausible correlates were controlled for. These results suggest that natural-and relatively minor-modifications to standard first-year composition courses could provide substantial increases in student writing ability.

Keywords: argument diagramming; argument mapping; writing; critical thinking; graphic organizers.

## Introduction

The purpose of the First-Year Writing (FW) Program at Carnegie Mellon University is to develop the academic reading and writing skills each student needs to be successful in his or her college career. Each student at CMU must take the course Interpretation and Argument, which is the core of this writing program.

Thus, though not titled 'Critical Thinking,' the FW course taken during the first year is generally one of the student's first introductions to thinking critically at a college level. Among other goals, the specific learning objectives for the FW Program is for students to be able to: (a) analyze a written argument by identifying the conclusion and the premises (both implicit and explicit) and describe how the premises support the conclusion, (b) evaluate a written argument by determining whether the premises do in fact support the conclusion, and whether the premises are reasonable, and (c) write an essay that both analyzes and evaluates one or more arguments.

The over-arching goal for the FW course is to provide foundational reading and writing skills that will enable students to develop advanced literacy in their own disciplines.

Most educators agree that one aspect of "critical thinking" involves the ability to reconstruct, understand and evaluate an argument-cognitive tasks we may describe as 'argument analysis' (see, e.g., Ennis, 1987; Fisher \& Scriven, 1997; Kuhn, 1991). In college, the most common medium through which arguments are analyzed is writing. Interpretation and Argument is a research-based course that
understands that reading and writing are inseparable practices for college-level course work. In the course, students are exposed to a variety of different texts (mostly academic essays) so they can explore a single issue from multiple perspectives and eventually contribute an argument of their own to the discussion. Both the exploration and the contribution rely heavily on argument analysis at various stages.

The first step in this analysis is reading a text for the argument, as opposed to, for example, reading for the plot (as in a novel) or for the facts (as in a textbook). Mandler (1984) provides an overview of research supporting the claim that adults and children as young as 3 -years-old possess "story schemata" that guide understanding when reading or listening to a story. Thus, learning the skill of reading for the argument requires students to develop a new schema, or set of schemata, with which they can interpret the text appropriately.

Schema theory, first introduced by Bartlett $(1932,1958)$ and further developed by Evans (1967), Mandler (1984) and Rumelhart and Ortony (1977), explains cognition as information processing mediated by schemata. A schema is a packet of knowledge containing both data and information about the interconnections among the data. Rumelhart (1980) refers to schemata as the representations of concepts stored in memory, and Sweller (1994) describes schemata as representations of either concepts or problem-solution procedures.

To facilitate the acquisition of new schemas, Sweller (1994) recommends reducing the extraneous cognitive load during the learning process. One common way of reducing extraneous cognitive load is by using graphic organizers (GOs), such as diagrams, to supplement regular reading and instruction. Previous research has shown that students' use of GOs is generally efficacious in producing improvements on a wide range of cognitive tasks - including those generally labelled CT tasks - that are significantly higher than improvements gained by students engaged in reading and regular instruction alone (Horton, et al., 1993; Moore \& Readance, 1984). Thus, we are particularly interested in the efficacy of alternative teaching methods that incorporate GOs to increase argumentative writing performance.

In what might these alternative methods consist? Both Larkin and Simon (1987) and Winn (1991) argue that diagrammatic representations of information can make recognition of important features and drawing inferences
easier than a sentential representation of the same information. Indeed, research on student learning has consistently shown the efficacy of using diagrams to aid text comprehension (Armbruster \& Anderson, 1984; Dansereau, et al.; Novak \& Gowin, 1984; Schwartz \& Rafael, 1985), as well as vocabulary development, postreading activities and writing preparation (Johnson, et al., 1986).

One candidate alternative teaching method, then, is instruction in the use of argument diagrams as an aid to argument comprehension and evaluation (see Figure 1).

Figure 1: Example of a diagram for a simple argument.
If we think of an argument the way that philosophers and logicians do-as a series of statements in which one is the conclusion, and the others are premises supporting this conclusion-then an argument diagram is a visual representation of these statements and the inferential connections between them.

How does argument diagramming develop new schema? The argument diagramming curriculum consists in an online course introducing argument diagramming, followed by inclass and weekly homework assignments on representing the arguments in the course materials in diagrams. The students received oral and written feedback on their diagramming. The students are taught to discriminate between statements (or claims) and other kinds of sentences, as well as the difference between arguments and explanations. The students are also taught to look for words that indicate conclusions (e.g., 'thus' and 'therefore'), premises (e.g., 'because' and 'since'), linked arguments (e.g., 'but' and 'since') and convergent arguments (e.g., lists). All of these types of exercises help students develop an 'argument schema' for reading arguments in a variety of genres.

Recent research on the efficacy of an argument diagramming curriculum on the development of critical thinking skills includes studies on both philosophy students in introductory classes and a mix of undergraduates in critical thinking and informal logic classes. The former studies have shown that instruction that includes the use of argument diagrams to analyze, evaluate and create arguments significantly improves students' critical thinking skills over the course of a semester (Harrell, 2008, 2011, 2012).

The latter studies specifically on computer-supported argument visualization have shown that the use of software specifically designed to help students construct argument diagrams significantly improves critical thinking abilities over the course of a semester (Kirschner, Shum, and Carr 2003; Twardy 2004; van Gelder, Bissett, \& Cumming,
2004). Additionally, research in this area has shown that student's critical thinking about specific topics is improved if students collaborate on argument diagram instruction instead of working alone (Scheuer, McLaren, Harrell, \& Weinberger, 2011). This previous research, however, has all focused on performance on critical thinking skills testsespecially multiple choice tests like the California Critical Think Skills Test-and not on writing tasks.

Even so, we conjectured, that incorporating argument diagramming into our standard curriculum in Interpretation and Argument would help students develop their argumentative writing skills.

Hypothesis: Students who are able to construct argument diagrams and use them during argument analysis tasks will improve in performance on argumentative writing tasks over the course of a semester long composition class significantly more than students in the same class who do not have this ability.
Our first-year writing course was a natural place to study the skills acquisition of our students. We typically teach 2830 sections of this course each semester, with a different instructor for each section. While the general curriculum of the course is set, including the sequence of assignments, each instructor is free to choose the readings for his or her section. The students who take this course are a mix of all majors from each of the seven colleges across the University. This study tests this hypothesis by comparing the pretest and posttest scores of students in Interpretation and Argument who were taught argument diagramming to the scores of those students who were not during the Fall of 2009, and the Spring and Fall of 2010.

## Method

## Participants

Eighty-one students (39 women, 42 men) across 7 sections of Interpretation and Argument were studied. In each semester, each section of the course had a different instructor and the students chose their section. Over the three semesters there were 7 different instructors. The students taught by Instructors 2, 6 and 7 were taught the use of argument diagrams to analyze the arguments in the course readings, while the students in the other sections were taught more traditional methods of analyzing arguments.

## Materials and Procedure

We developed a pretest to be taken at the beginning of the semester, and a companion posttest to be taken at the end. For the next three semesters, students in both the treatment and control groups completed the pretests during the first week of the semester, and the posttest during the last week of the semester. Each test consisted in reading some text and completing two tasks. In Task 1, the student was asked to write an essay analyzing the argument presented by the author in the text. This analysis was to consist in identifying both the content and the structure of the argument. In Task

2, the student was asked to write an essay evaluating the argument presented by the author in the same text. The evaluation was to consist in a claim about the quality of the argument, and reasons to support that claim.

## Results

## Salient Features of Students' Writing

We recognize that text features alone do not constitute "good writing" and that there is no "right way" to read or write a text. We also recognize that privileging some text features over others might ignore other significant features. The features that we chose will help us locate change in demonstrable critical thinking between the pretest and posttest. We analyzed the texts for markers of text development and text coherence. We were interested in seeing to what extent there would be any kind of change in how many different ideas students could generate-about someone else's argument and about their own arguments. Within this category of "development," we identified the following for both Tasks 1 and 2 of the pre- and posttests: the number of different reasons or premises offered for the argument conclusion, and the number of counterarguments considered within the text.

For Task 1, we wanted to determine how much the students were understanding the argument in the text and what statements they would prioritize in their representations of it. For Task 2 only, we also considered whether students provided evidence or elaboration of their reasons. We wanted to distinguish between reasons that were supported with evidence and those that were not. Our concern was instances when students produced a lot of different ideas but failed to support them; we did not want to report "growth" in development without attempting to represent to what extent students were actually supporting their claims.

Because the number of ideas alone does not necessarily equate with good writing, and, in fact, one could argue that too many different ideas within an argument will result in chaos for a reader, we also looked for features that signaled an overall coherence in a written text. Vande Kopple has defined coherence as "prose in which nearly all the sentences have meaningful connections to sentences that appear both before and after them" $(1989,2)$. We also draw upon Enkvist's definition of coherence, "the quality that makes a text conform to a consistent world picture and is therefore summarizable and interpretable" (1990, 49). So, by coherence, we mean those features that enable a reader to make particular kinds of connections within the text. In coding Task 1, we considered the following as coherence markers: logical connections between premises and the argument conclusion, and logical connections between different premises

In coding Task 2, we looked at the following as markers of coherence: logical connections between premises and the argument conclusion, logical connections between different premises, and metacommentary (or "metadiscourse").

Metacommentary is language that writers use, according to Hyland (2003), to compose a text that is clear to a reader.

By providing linguistic "signposts" to readers, writers can create the effect that a text is coherent and holds together in an intentional way. Because these bits of language give clues for making sense of the text, their presence in a text can indicate that a writer is aware of a reader's needs for navigating the text successfully. These bits of language can also show that a writer understands his or her own text in particular ways and can point to a writer's strategic view of his or her writing. We were only interested in the effect that metacommentary has upon the readers-we were not interested in counting the different types. Therefore, coders scored Task 2 holistically for effective use of metacommentary.

## Test Coding

Pretests and posttests were paired by student, and singletest students were excluded from the sample, resulting in 81 pairs of tests. The tests were coded during one extended session, using one set of coders for Task 1, and a different set for Task 2 . Each coder independently coded all pairs of tests in his or her group ( 162 total tests). Each pre-/post-test pair was assigned a unique ID, and the original tests were blinded. To ensure reliability and validity, prior to each coding session, we had an initial coding-calibration session in which we and the coders coded several of the unpaired tests, discussed the codes, and came to a consensus about each code. After this, each coder was given the tests to be coded in a unique random order.

The categories to be coded for Task 1 were: Argument Conclusion, Counter-arguments, Premises, Connections and Errors. "Argument Conclusion" received a code of 1 if the student identified the conclusion of the argument, and a code of 0 if not. "Counter-arguments" received a code that indicated how many counter-arguments the student identified in the text. "Premises" received a code that indicated how many premises the student identified in the text. "Connections" received a code that indicated how many connections between premises or between a premise and the conclusion the student identified in the text. Finally, "Errors" received a code that indicated how many errors the student made; errors identified by the coders were (a) misunderstands counter-argument, (b) missing a major concept, (c) misreading (e.g. overstatement with no qualifiers), (d) misapplied quotation that shows disconnected reading, and (e) other.

The categories to be coded for Task 2 were: Conclusion, Premise, Evidence, Mismatch, Connections, Counterarguments, and Metacommentary. "Conclusion" received a code of 1 if the student stated a thesis, and a code of 0 if not. "Premises" received a code that indicated how many premises the student used in support of the thesis. "Evidence" received a code that indicated how many premises were supported by evidence. "Mismatch" received a code that indicated whether, for each premise, the evidence offered actually supported that premise.
"Connections" received a code that indicated how many connections between premises or between a premise and the conclusion the student identified in the text. "Counterarguments" received a code indicating how many counterarguments the student considered. Finally, "Metacommentary" received a code of 0 if there was no metacommentary, 1 if the metacommentary was present but weak, and 2 if the metacommentary was strong. Then, for each task, the codes from the two coders on these categories were averaged, allowing for a more nuanced scoring of each category than either coder alone could give.

For each task, the primary variables of interest were the individual averages for each category on the pretest and the posttest. In addition, however, the following data was recorded for each student: the student's math, writing and verbal scores on the SAT, the section in which the student was enrolled, the student's final grade in the course, the student's home college, the student's sex, and whether the student had been taught using the AD curriculum.

## Student Characteristics

To determine whether the students in the study differed in any statistically significant characteristic other than being taught AD, we tested how well we could predict students' gains from pre-test to post-test based on the variables we had collected. We performed a regression for Gain using Pretest, Instructor, Gender, Final Grade, College, Math, Verbal, and Writing as regressors. The results indicate that none of the variables besides Pretest and Instructor was a factor in a student's gain. Thus, we are confident that the students in the treatment group were not different in any important aspect from the students in the control group.

## Comparison of Students by AD Instruction

Our hypothesis was that the students in the first-year writing course who received training in Argument Diagramming would gain significantly more in each category on the two tasks than students who did not receive the training. Since the use of argument diagrams was explicitly taught only by Instructors 2, $6 \& 7$, this hypothesis was tested by determining whether the average gain of the students taught by Lecturers $2,6 \& 7$ was significantly different from the average gain of the students taught by Lecturers $1,3,4 \& 5$. The students taught by Lecturers $2,6 \& 7$ are represented in all the tables below by (AD), and the students taught by Lecturers 1, 3, $4 \& 5$ are represented by (No AD). The mean gain for the subpopulations of students in each treatment group is represented given in Figure 2 for Task 1, and in Figure 3 for Task 2.

To determine the predictive value of AD treatment on a student's gain from pretest to posttest, an ANCOVA was conducted for the gains in each category for Task 1 with AD as a factor and the corresponding pretest score as a covariate. So, for example, we conducted an ANCOVA on the Argument Conclusion Gain with AD as a factor and the

Argument Conclusion Pretest as a covariate. The results for Task 1 are given in Table 1.

Figure 2: Comparisons of gains in each category of Task 1 from pretest to posttest for students who were and were not taught argument diagramming.

Figure 3: Comparisons of gains in each category of Task 2 from pretest to posttest for students who were and were not taught argument diagramming.

Table 1: ANCOVA test results for the variable AD for each category on Task 1.

| Category | $F(1,80)$ | $p$ |
| :--- | :---: | :---: |
| Argument Conclusion | 2.47 | 0.120 |
| Counter-arguments | 0.94 | 0.335 |
| Premises | 4.54 | 0.036 |
| Connections | 7.35 | 0.008 |
| Errors | 6.91 | 0.010 |

The effect of AD was statistically significant in each category except Argument Conclusion and Counterarguments for Task 1.

An ANCOVA was also conducted for the gains in each category for Task 2 with AD as a factor and the corresponding pretest score as a covariate. The results for Task 2 are given in Table 2.

Table 2: ANCOVA test results for the variable AD for each category on Task 2.

| Category | $F(1,80)$ | $p$ |
| :--- | :---: | :---: |
| Argument Conclusion | 1.80 | 0.184 |
| Premises | 5.63 | 0.020 |
| Evidence | 6.70 | 0.012 |
| Mismatches | 12.36 | 0.001 |
| Connections | 12.35 | 0.001 |
| Counter-arguments | 5.73 | 0.019 |
| Metacommentary | 10.60 | 0.002 |

The effect of AD was statistically significant in each category except Argument Conclusion for Task 2.

## Discussion

## Findings

The results from Task 1 show that, when reading an argument, students who were taught argument diagramming were significantly more likely than those who were not to identify more of the relevant premises offered that support the author's conclusion, and explain more explicitly how the premises are supposed to work together to support the conclusion. In addition, these students were much less likely to make any errors in their analysis.

The results from Task 2 show that, when evaluating the argument in a text, students who were taught argument diagramming improved significantly more than those who were not in their ability to (a) provide more premises to support their own thesis, (b) offer more evidence in support of each premise (c) have fewer mismatches between premises and evidence, (d) explain more explicitly how the premises are supposed to work together to support the conclusion, (e) offer possible counter-arguments, and (f) provide metacommentary on their response.

Thus, it seems that students who were taught argument diagramming are developing new schema for reading arguments, and learning how to effectively translate this into their own writing. This is reflected most noticeably in the improvement of the metacommentary from pretest to
posttest. We conclude that incorporating argument diagramming into the curriculum of Interpretation and Argument is positively beneficial to realizing several of our course objectives.

## Educational Importance

The primary educational importance of this study is twofold. First, the results indicate that it is possible to significantly improve students' argumentative writing skills over the course of just one semester, even when the course is not only a critical thinking course. Second, these results indicate that a relatively small addition to the curriculum of a first-year writing course can have dramatic benefits for students. The initial instruction in understanding arguments and creating argument diagrams can be given in one or two class-periods (or an online tutorial) and regular, weekly homework assignments can be added to reading, summary and/or reflection assignments. Supplementing one's teaching with argument diagramming does not require a radical reworking of the syllabus, course readings or assignments. This is a great benefit to instructors who may be reluctant to change a curriculum that has been successful.

## Future Work

This study raises as many questions as it answers. While it is clear that the introduction of argument diagramming to the First-Year Writing Program curriculum significantly improves a student's ability to reach several stated course objectives, it would be interesting to explore further the cognitive basis for the effect of argument diagramming. In particular we would like to know what aspects of constructing diagrams help the most in developing new schema.

It would also be interesting to explore whether, once a student learns how to construct argument diagrams, the actual construction of a diagram is important for a particular analysis task. That is, for example, it could be that the new schema is in place, and so the diagrams are no longer needed, or it could be that the construction of a diagram while reading activates the new schema.

We would also like to consider whether there are other skills that we did not measure this time that this addition may help to improve. For example, because our work here did not distinguish between first and second language learners, we cannot speak to whether argument diagramming has more or less of an effect upon second language learners. Additionally, we have anecdotal evidence from several teachers that using argument diagramming during the peer review process was helpful. It would be extremely useful to know whether using argument diagramming in peer review of papers in general makes subsequent drafts better.

Lastly, unlike the relatively solitary activities in which students engage in our FW Courses-like doing homework and writing essays-there are many venues in and out of the classroom in which students may engage in the analysis and evaluation of arguments in a group setting. These may
include anything from classroom discussion of a particular author or topic, to group deliberations about for whom to vote or what public policy to implement. In any of these situations it seems as though it would be advantageous for all members of the group to be able to visually represent the structure of the arguments being considered. We would like to know whether knowing how to construct argument diagrams would aid groups in these situations.

## Acknowledgments

I would like to thank three anonymous reviews for their helpful comments. This study was funded by a joint grant from the Spencer Foundation and the Teagle Foundation, under the title "Systematic Improvement of Undergraduate Education in Research Universities."

# Why verbalization of facial features increases false positive responses on visuallysimilar distractors: A computational exploration of verbal overshadowing 

Aya Hatano (hatano.aya@c.mbox.nagoya-u.ac.jp), Taiji Ueno (taijiueno7@gmail.com), Shinji Kitagami (kitagami@cc.nagoya-u.ac.jp), and Jun Kawaguchi (kawaguchijun@nagoya-u.jp)<br>Department of Psychology, Graduate School of Environmental Studies, Nagoya University, Furo-cho, Chikusa-ku, Nagoya City, Aichi 4648601, JAPAN

#### Abstract

Verbal overshadowing refers to a phenomenon whereby verbalization of a non-verbal stimulus (e.g., he had slant eyes) impairs subsequent non-verbal recognition accuracy. In order to understand the mechanism by which this phenomenon occurs, we constructed a computational model that was trained to generate an individual-face-specific representation upon input of a noise-filtered retinotopic face (i.e., face recognition). When the model verbalized the facial features before receiving the retinotopic input, the model incorrectly recognized a new face input as one of the different, yet visually-similar, trained items (that is, a false-alarm occurred). In contrast, this recognition error did not occur without prior verbalization. Close inspection of the model revealed that verbalization changed the internal representation such that it lacked the fine-grained information necessary to discriminate visually-similar faces. This supports the view that verbalization causes unavailability/degradation of finegrained non-verbal representations, thus impairing recognition accuracy.

Keywords: verbal overshadowing; face recognition; computational modeling; verbalization

## Introduction

Language is the principal medium for carrying out daily communications. This is still true when communicating our non-verbal experiences, such as recounting a crime scene we have witnessed, or describing the physical appearance of a criminal. Particularly, if we do not have a record of the event such as a picture or video, then conveying an eyewitness memory relies on language. A crucial question in cognitive science, therefore, is the influence of verbalization on non-verbal memory. Many studies have revealed that language has extra-communicative functions, in that it affects such cognitive functions as perception, learning, and memory. For example, in a seminal study by Schooler and Engstler-Schooler (1990), participants watched a video of a bank robbery for 30 seconds and following which half of the participants described the appearance of the bank robber. Subsequently, all of the participants were shown a line-up that consisted of the bank robber's photo and seven distractors. Results revealed that participants who had verbalized the bank robber's appearance were worse at recognizing the target individual than those who had not, a phenomenon known as verbal overshadowing. The procedure of these experiments can be experienced beyond an experimental setting. For example, during criminal investigations, an eyewitness may provide a statement describing the appearance of a criminal and
subsequently identify them from a line-up. In such situations, it is crucial to prevent a false accusation and to examine the credibility of the eyewitness's testimony. Therefore, it is both theoretically and practically important to clarify the mechanism by which verbal overshadowing occurs. For this purpose, we constructed a paralleldistributed processing (PDP) model to simulate the effect of verbalization on subsequent visual recognition.

A closer review of the literature allows us to gain further insight into this phenomenon and therefore to establish a more specific aim for our model. First, although not all of the past studies have split the recognition scores into positive and negative trials, false alarm is sometimes more susceptible to verbalization before recognition than hit rates; that is, participants often inaccurately identify distractors as a target rather than miss a correct target (Meissner, Brigham, \& Kelley, 2001). Furthermore, recognition accuracy in this study was positively correlated with accuracy of the verbal description prior to recognition. Based on these observations, Meissner et al. proposed a recording interference account that assumed verbalization rendered the representations less accurate (compared to visual representations), thus impairing subsequent visual recognition.

Second, Kitagami, Sato, \& Yoshikawa (2002) revealed that verbal overshadowing is also sensitive to the degree of similarity between targets and distractors (manipulated with a morphing technique). Specifically, verbalization impaired subsequent visual recognition only when distractors were highly similar to the target (using a 9-alternative choice task with a "not present" response choice), but the impairment disappeared when similarity was low. It is also worth noting that this manipulation involved a change in the distractors, but not in the target picture itself. We revisited the original data and revealed that accuracy was impaired due to the more frequent choice of a distractor (a false alarm) rather than an incorrect choice of "not present" (a miss). Schooler (2002) explained this result with the transfer inappropriate processing shift hypothesis. This hypothesis assumes that verbalization induces a processing shift from visual to verbal, and that a shift to verbal processing makes finegrained non-verbal information about faces unavailable. This non-verbal information is crucial for discriminating the target from others (see also, Maurer, LeGrand, \& Mondroch, 2002), especially in a high-similarity condition (Kitagami et al., 2002). Although Schooler's hypothesis does not necessarily assume a correlation between recognition accuracy and verbal description accuracy (see also Kitagami
et al., 2002; Fallshore \& Schooler, 1995), this hypothesis and the recording interference hypothesis by Meissner et al. (2001) share two ideas: First, both assume that fine-grained non-verbal information is necessary for face recognition. Second, both expect that a verbal representation which is generated during verbalization lacks such fine-grained information, thus impairing visual recognition.

More recently, Clare and Lewandowsky (2004) introduced an alternative hypothesis, arguing that verbalization shifts the criterion threshold such that participants say "The target is not present in the display" more frequently when in fact the target is present. Although this account can explain a range of existing data, two issues deserve consideration. First, even when a "not present" response was disallowed (that is, responses were forced choice), verbal overshadowing was observed in some studies, especially when elaborative verbalization was encouraged (Fallshore \& Schooler, 1995). Second, the shifting criterion hypothesis cannot explain the fact that false alarm is more susceptible to verbalization than hit rate (Kitagami et al., 2002; Meissner et al., 2001). Thus, as Clare and Lewandowsky also speculated, there may be two mechanisms by which verbalization impairs subsequent visual recognition: One is shifting-criterion (Clare \& Lewandowsky, 2004), and the other is degradation (Meissner et al., 2001) or unavailability (Schooler, 2002) of fine-grained non-verbal representations crucial for face recognition, especially when a distractor is visually confusing. This study focused on the latter possibility, and investigated how the nature of representations changes upon verbalization, and how this affects subsequent visual recognition. Computational modeling is an effective approach for this purpose. An explicitly implemented computational model allows a modeler to directly look at the nature of computations/representations that are underpinning a simulated behavior. The PDP model here was trained for three facial processing tasks: One was to represent the retinotopic input of a face in a non-verbal format (visual encoding/recognition); a second was to activate the correct units for verbal labels upon the same retinotopic input of a face (verbal encoding); the third was to represent a face in a non-verbal format upon verbal inputs (the mental imagery of a face upon verbal cues). After being trained for these tasks, the model was forced to activate some verbal units (i.e., verbalization), and we investigated how this forced activation changed the nature of the computed representation in the model, and how it affected subsequent visual encoding of a retinotopic input.

## Method

## Model Architecture

Figure 1 shows the architecture of the PDP model, built with LENS software (http://tedlab.mit.edu/~dr/Lens/). Three peripheral layers were connected bi-directionally with a single hidden layer. In order to reduce the computational

Figure 1: Architecture of the model (Hinton diagram).
demand in this large model, units between layers were connected sparsely, such that a unit was not connected with others if the external input/target value of that unit was always zero (e.g., a unit in the top-left corner). The bottom layer was named the retinotopic layer, and its activation patterns represented a filtered (Gaussian noise) face stimulus. The left layer was named the verbal layer, and each unit in this layer represented a verbal label for facial features in a localist manner. The right layer was named the visual image layer, and its activation pattern represented a non-filtered (without Gaussian noise) face stimulus. With this architecture and the representations in each layer, we trained the model for the three tasks described below.

## Tasks

Visual encoding of a face from a retinotopic input (visual recognition). In this task, retinotopic face pattern was hardclamped onto the retinotopic layer. Then, the network was trained to activate the non-filtered, unique visual face information of the same person in the visual image layer (individuation or visual recognition - see later).

Verbal encoding of facial features from a retinotopic input (verbalization). In this task, the input was the same as the previous visual recognition task, but the network was trained to activate the correct verbal units for each presented face. For example, if the face had slanted eyes, then the model had to turn on the unit for "slant eyes", and had to turn off the unit for "drooping eyes".

Mental imagery upon verbal cues. In this task, the verbal labels of facial features were presented onto the verbal layer, and the network was trained to activate the visual face information in the visual image layer. As we will explain later, the accuracy for this task never reached 100\% because different faces sometimes shared the same verbal labels (i.e., different targets from the same input pattern).

Recognition. A standard experimental task on human recognition memory employs a N -alternative forced choice task to probe recognition process, particularly when examining verbal overshadowing. The model, however, was not trained for making an explicit N -alternative forced
"choice". Therefore, we should adopt a proper measure to probe the model's recognition. It is one of the most debatable issues in cognitive psychology regarding what process/mechanism is underpinning recognition. Following previous studies (e.g., Plaut \& Behrmann, 2011), we examined whether the model could represent item-specific information (i.e., unique face) as an approximation of recognition process. If the model computes item-specific information of an "old" face in the visual layer from a "new" retinotopic (noisy) input, then it can be considered the model identifies this input as old face by mistake (especially after a verbal label for the old face was activated). In this way, we can at least measure false alarm safely, which is the target of the current study with this procedure.

Figure 2: Four examples of the training patterns. Note that two examples within each half share the same verbal labels, and thus the same pattern activations in the verbal layer. (However, they are different faces with different specific features as shown in the parentheses).

## Representations (face stimuli)

Figure 2 shows examples of the face pictures that we created using montage software (http://www1.mahoroba.ne.jp/~matumoto/nitaroS.html). Sixty-four face pictures were created by combining four types of eyes, four types of nose, and four types of mouth (see the bottom row of Fig. 2 for the possible features) in the following steps. First, we selected two verbal labels for each part of the face - slant eyes, drooping eyes, long nose, button-shaped nose, downturned mouth, and thick lips. Next, we selected two specific types for each verbal label (e.g., slant -eyes [thin] and slant eyes [big] for the label slant eyes, as shown in the right two faces in Fig. 2). In this way, we created four types of eyes, nose, and mouth, resulting in 64 different faces by combining 4 by 4 by 4 . In order to make the model trainable, we did not include other features such as hair. Finally, the size of each picture was $70 * 60$ pixels, and the color information in each pixel was binarized (i.e., black pixel $\rightarrow 1$; white pixel $\rightarrow 0$ ). The resultant 4200-bit vector pattern was used as the target pattern of the visual image layer in the visual recognition tasks (see second row of Fig. 2).

The original bit patterns were transformed into the retinotopic input pattern by smoothing with Gaussian convolution ( $S D=0.5$ ) ( Plaut \& Behrmann, 2011). The original bit patterns were smoothed by Gaussian convolution ( $S D=0.5$ ). In summary, the model had to map a noise-filtered retinotopic input (top row of Fig. 2) into a clearer visual representation (second row of Fig. 2), which is necessary for visual recognition.
The pattern activations in the verbal layer represented the verbal labels in a localist manner (third row of Fig. 2). For example, when presented with a retinotopic pattern of the drooping-eyes, long-nose, and thick-lip face, then the model had to activate the first, second, and third units of the verbal layer (the left two cases of Fig. 2 show these examples). In the mental imagery upon verbal cues task, the same units in the verbal layer were turned on, and the network was trained to activate the visual images in the internal image layer. The accuracy in this task can never be $100 \%$ because sometimes a different target should be generated from the same input pattern (i.e., the same verbal labels). For example, slant eyes (thin) and slant eyes (big) shared the same verbal label, slant eyes. Therefore, the same unit (slant eyes) was turned on for these two cases, but different output patterns (thin or big eyes) should be generated in the visual image layer. This is true to humans: We can imagine various kinds of faces but cannot specify a unique face by simply hearing "slant eyes, long nose, and thick lips". A small amount of Gaussian noise ( $\mathrm{SD}=0.2$ ) was added to the input for the hidden layer to encourage this layer to adopt more polarized outputs.

## Training

Among the 64 face patterns, only 55 patterns were presented during training, and the remaining nine untrained patterns were used to evaluate the network's generalization performance. Furthermore, this allowed us to investigate how differently the model behaved with the trained faces ('old' items) and untrained faces ('new' items), as it was crucial for us to investigate the effect of verbalization before the recognition phase (described later in more detail).

In each trial, units in the corresponding layer (retinotopic or verbal layer) were hard-clamped to their input values, and the network was allowed to cycle 10 times. In each time step, the activation spread to the next layer, gradually being scaled by the values of the interconnecting weights, and then the network would settle into the steady state (an attractor). After 10 cycles of updates, the discrepancy between the output activation pattern generated by the network and the correct target pattern was calculated, and the connection strength was adjusted to reduce the discrepancy. The model was trained with a learning rate of 0.05 , and with a decay parameter set to 0.0000001 . When we evaluated the final performance, we used a strict criterion such that the output was scored correct if the discrepancy was within 0.5 in every unit of the target layer (i.e., the activation was less/more than 0.5 if the target was zero/one for each unit respectively).

Given that young infants recognize their parents easily, it would be natural to assume that visual recognition skills are acquired earlier than an ability to verbalize facial features, or to imagine a face upon verbal cues.Thus, all 55 of the face stimuli were first trained for the visual recognition task. After learning to generate a steady state for more than $50 \%$ of the training items in this task, the other two languagerelated tasks were included in the training schedule.

## Results

## Training tasks

Five independent simulations were run with different random seeds, and we confirmed consistent results across five cases. The training finished after 2837 epochs of training (in each epoch an item appeared once for each task in a random order), at which point the network's performance reached $100 \%$ in both the visual recognition and the verbalization tasks from a retinotopic input for both trained and untrained items (i.e., generalization). The accuracy in the visualization task from verbal labels was $0 \%$ (see above for the reason).

## Visual recognition with/without verbalization

In order to investigate the visual recognition process of a retinotopic input after/without verbalization, we recorded the activation patterns in the visual image layer (right column of Fig. 3) when the network settled on 10 cycles after the retinotopic input presentation (left column of Fig. 3). The upper two rows of Fig. 3 show the pattern activations for a trained ('old') face (drooping eyes [thin], long nose [high], and thick lip [bottom big]) and for a visually-similar, yet untrained ('new') face (drooping eyes [big], long nose [high], and thick lip [bottom big]), respectively. Both retinotopic inputs were correctly mapped onto every unit of the visual image layer. This means that two visually-similar faces were successfully discriminated (see the bigger eyes represented in the second row), unless they were preceded by the verbalization process (100\% accuracy in computation of the individual-specific face information for all the nine untrained items). Next, the middle two rows of Fig. 3 show the activations for the same two items as the upper rows but after verbalization. Specifically, we simulated the following situation: Imagine that the network had encountered the 'old' face shown in top row of Fig. 3 (drooping eyes [thin], long nose [high], and thick lip [bottom big]), and the network had verbalized the correct labels (drooping eyes, long nose, and thick lip). To simulate this situation, the three verbal units for these labels were manually turned 'on' (generating the outputs of 1.0 ) and the network was allowed to cycle 10 times, during which the activations spread into the other layers (it updated its internal status 10 times). After 10 cycles, a retinotopic input for the trained face ('target') and that for the visuallysimilar, yet untrained face ('new') were presented respectively, and the network was allowed to update its status 10 times until each input pattern was mapped onto a

Figure 3: Activation patterns in the visual image layer (right) upon retinotopic inputs (left) for trained 'old' face and for untrained 'new' face in the visual recognition task. Upper two rows: without verbalization. Middle two rows: after verbalization of a similar 'old' face. Bottom row: after verbalization of a dissimilar 'old' face.
steady pattern in the visual image layer (right column). A visual inspection reveals the retinotopic input for the visually-similar 'new' face (drooping eyes [big]) was mapped onto the pattern for the 'old' face (slant eyes [thin]) in the visual image layer (false alarm). Euclid distance of the output pattern from the target "new" face was larger than that from the lure "old" face (i.e., similar to the "old" face pattern). This means that the model actually computed the item-specific information of the "old" face (false alarm). The same analysis was conducted for all the nine "new" items (against its visually-similar "old" face, respectively),

Activations immediately after verbalization of an 'old' face

Similar 'old' face
(drooping eyes, high nose, thick lip)

Dissimilar 'old' face
(slant eyes, button nose, downturned mouth)

Correct recognition
Figure 4: Internal activation patterns in the hidden layer (Hinton diagram: more white units denote higher activation values than black units) at the various kinds of time point (see main text).
and averaged across the five individual simulations. The resultant recognition accuracy was $60 \%$ ( $40 \%$ false alarm), $S D=14.9 \%$, which was significantly lower than $100 \%(t)$ $=5.99, p=.003$ ). This confirms that the example result in Figure 3 is generalized across other patterns. In contrast, the retinotopic input for the 'old' item was mapped onto the correct pattern (drooping eyes [thin]) in the visual image layer, though less weakly than when presented without verbalization (top row). Taken together, these results confirm that false alarm was more susceptible to verbalization than hit rate. Finally, the bottom row of Fig. 3 shows the simulated result in the condition where the distractor was dissimilar to the target. Specifically, the activation patterns were taken from the same untrained 'new' face (drooping eyes [big], long nose [high], and thick lip [bottom big]), but after activations of the irrelevant verbal units (slant eyes, button-shaped nose, and downturned mouth). Thus, the model had encountered a dissimilar person, and verbalized the dissimilar labels before visual recognition of a 'new' item. As a result, the network did not settle into the pattern of the dissimilar target face (slant eyes and downturned mouth), but the represented pattern was more similar to the correct pattern (drooping eyes and thick lip). In other words, the model did not confuse the presented retinotopic input (the 'new' face) with the previously encountered 'old', yet dissimilar face, thus avoiding false alarm in this low-similarity condition (Kitagami et al., 2002).

Finally, in order to understand the mechanism of verbal overshadowing, the pattern activation in the hidden layer was measured at the various kinds of time point (Figure 4). First, the Hinton diagrams at the top row of Figure 4 show
the internal activation patterns when the network successfully discriminated two visually similar 'old' and 'new' faces, respectively (shown in the upper panels of Fig. 3). A visual inspection reveals these two representations are very similar. This concurs with the idea that fine-grained representations are crucial in face recognition (Maurer et al., 2002), without which one would be easily mapped to the other, incorrect, face pattern in the visual image layer (i.e., incorrect recognition).

Next, the left diagram of the middle row of Figure 4 shows the activation pattern immediately after verbalization of 'drooping eyes, high nose, and thick lips'. As a result, this internal representation immediately after verbalization was neither identical with that for visual recognition of the 'old' face (top left) nor that for visual recognition of the 'new' face (top right), concurring with the idea that verbalization generates the representation that lacks finegrained information crucial for face recognition (Maurer et al., 2002). Though lacking such detailed information, it was nonetheless closer to the representation for the 'old' face (top left) than that for the 'new' face (top right). In other words, the model's internal status had already moved towards the pattern for the 'old' face. We will explain later why this representation increased the false alarm of the model when the distractor was similar to the target.

## Discussion

The present computer simulation examined how internal representations changed upon verbalization and how this affected subsequent visual recognition. Without verbalization, the model represented the correct and unique pattern activation for each old face and for a visually-similar new face, respectively, in the visual image layer. This confirms that the model did not confuse two visually-similar retinotopic inputs. On the other hand, the model failed to represent the correct pattern for a new face following the forced activation of verbal units for an 'old', visuallysimilar face (i.e., verbalization). Instead, the represented pattern in the visual layer assimilated to that for the visually-similar 'old' face, suggesting that the model could not differentially recognize the 'new' face from the 'old' face (a false alarm). Importantly, this assimilation was weakened when the preceding verbalization included the features of an 'old', yet dissimilar face. Therefore, these results mirrored Kitagami et al. (2002), who found that participants' false alarm increased upon verbalization when the distractors were similar to the target.

Explicit implementation of a computer model allowed us to directly look at the internal representations to understand why the model behaved in this way. In a normal situation (without verbalization), the model computed very similar, yet unique, internal representations for retinotopic inputs of visually-similar faces. This fact is consistent with the idea that fine-grained representation is necessary for visual recognition of faces (Maurer et al., 2002), especially when discriminating a target from similar distractors. When the model verbalized the facial features, this internal
representation changed such that it was neither identical to that of an 'old' face, nor that of a ''new' face, supporting the argument that verbalization either degrades the finegrained representation (Meissner et al., 2001), or renders it unavailable (Schooler, 2002). Nonetheless, it was closer to the representation for the verbalized 'old' face than to that of a 'new' face. In order to understand why this representation induced a false alarm for a visually-similar face, it is useful to describe the general activity of PDP models here. During training, a PDP network finds a unique attractor state (a unique abstract pattern in the hidden layer) associated with each input pattern. Therefore, generating a correct output is sometimes described as if the internal activity of the hidden layer falls into its unique attractor basin. Though they are unique, similar inputs are associated with similar/neighboring attractor basins (as shown in the top two panels of Fig. 4). Consequently, if the internal representation of the model is degraded for some reason, a similar input can incorrectly drift and fall into the wrong attractor basin, generating an incorrect output. In the current model, verbalization generated the internal representation that lacked fine-grained information crucial for visual recognition (middle-left row of Fig. 4). Though it lacked such information, it was nonetheless closer to the representation of the 'old' face (the top and middle left rows are similar in Fig. 4). In other words, the model's internal status had moved towards the attractor basin for the 'old' face by verbalization. In such a situation, a similar retinotopic input, which would have settled into a unique, yet similar/neighboring attractor basin without verbalization (top-right of Fig. 4), was easily captured by the attractor for the 'old' face. The resultant (captured) internal activation pattern is shown in the left bottom row of Fig. 4, which was more similar to the top-left pattern than the top-right pattern (i.e., incorrect recognition). This is the mechanism by which verbalization impairs subsequent recognition, especially when the distractor is similar to the 'old' face. In contrast, when the dissimilar (inconsistent) labels were verbalized before visual recognition, the hidden layer activation pattern was very different to that for a subsequent 'new' face (i.e., the top and middle right rows are not similar). In this case, the network is not captured by this dissimilar attractor basin, as is shown in the bottom right diagram of Fig. 4.
In summary, as the present study has demonstrated, a computer simulation is a useful tool for investigation of verbal overshadowing. It is difficult to examine verbal overshadowing empirically, given that the standard paradigm involves a single-trial measurement. Therefore, many participants are necessary for detecting a reliable effect, and it is difficult to systematically manipulate a variable as a within-subject factor. In such a situation, it is worthy to implement a computational model in order to understand the mechanism and to provide a theory-driven question that can be empirically testable in human experiments. Of course, any computational modeling should be concerned whether the model's representation/process is the same as the human's, but previous studies have
demonstrated that investigating the internal representation of a model is a useful approach to advance the cognitive theory (e.g., Plaut \& Behrmann 2011). Furthermore, the current model can be extended to other types of perceptual stimuli (not just face). Thus, we expect that the present study would be an important step to clarify the relationship between language and perception in general. Finally, one issue deserves consideration: The current model simulated the increase in false alarm upon verbalization (Kitagami et al., 2002; Meissner et al., 2001), rather than a missed response. Although some studies failed to detect a significant difference between these two measures (Schooler \& Engstler-Schooler, 1990, a recent experimental and computational study (Clare \& Lewandowsky, 2004) suggested that it was actually the increase in "not present" responses, a response type that was not implemented in the current model. A future modeling target would be to understand the mechanism by which verbalization increases both "not present" responses and false alarms, of which the latter particularly occurs when the distractors and targets are similar.

# The effect of " Trust dynamics " : Perspective taking during collaborative problem solving 

Yugo Hayashi (hayashi.yugo.gp@u.tsukuba.ac.jp)<br>Faculty of Library, Information and Media Science, University of Tsukuba<br>1-2, Kasuga, Tsukuba, Ibaraki, 305-8550, Japan

#### Abstract

We investigated the influence of reflections on self/others' trust within group-based problem solving. We assessed the role of trust dynamics on perspective-taking activities within conflictive groups, extending the experimental framework used by Hayashi (2012) and including conversational agents for controlling participants' interactions related to trust dynamics and perspective taking behavior. Results showed that (1) reflections of self/other trust in conflictive groups may influence trust towards other members, and (2) reflections of trust by members with conflicting perspectives may facilitate trust and perspective taking. This suggests that the level of trust dynamics facilitates trust and can function to manifest perspective taking within cooperative groups.

Keywords: Trust dynamics; perspective taking; collaboration; group dynamics.

## Introduction

Conflict is inevitable in human interactions, even within ingroup activities. We investigated the mediating factor of group dynamics on "perspective-taking activity" within conflictual situations, focusing on how social cognitive factors, such as reflections of " trust dynamics," could facilitate the interaction process. Multiple conversational agents were used to control for group members' interactions, such as perspective-taking and social dynamics.

## Perspective taking and conflicts in groups

Perspective taking is an essential activity for social interaction. It perspective taking requires higher-level cognition and is rife with unintended errors and difficulties (Keysar, Barr, Balin, \& Brauner, 2000; Hayashi \& Miwa, 2009). Perspective taking plays an important role in establishing common ground between adult speakers. Keysar et al. (2000) points out that this activity includes complicated cognitive operations, and people tend to have egocentric biases that hinder such activities. Hayashi, Miwa, and Morita (2006) showed that an individual's egocentric biases constrains perspectivetaking activities during a cooperative task.

Within cooperative group activities (e.g., scientific research groups), perspective taking also plays an important role in discovering new solutions and knowledge. For example, Dunbar (1995) and colleagues investigated the use of inductive reasoning within a scientific research group and proposed the concept of distributed reasoning, where group members achieve their goals by taking charge of different types of inferences. Other studies have also investigated the nature of learners collaboratively working on complex problems while focusing on explaining such activities, role sharing, and reflective interactions (Okada \& Simon, 1997). In
these studies, perspective taking promotes the facilitation of conceptual change for gaining a deeper understanding. However, in such activities, we have to consider the effects of conflicts that occur during interactions. Conflicts occur due to disagreements among group members concerning ideas and opinions about the task being performed (Jehn, Greer, Levine, \& Szulanski, 2008). Overcoming such conflicts not only is important for establishing common ground but also can provide an opportunity for new discoveries. On the basis of these studies, we investigated the effects of a type of social dynamic that is expected to facilitate an "exocentric" perspective for overcoming group conflict.

## Influence of trust dynamics in groups

Organizational and social network studies have shown that the perception of "trust in other member(s)" within the group is important for facilitating group performance (Kramer, 1999; Castellano, Fortunato, \& Loreto, 2009). Within-group perspective taking is an interactive social process that could be mediated by the level of trust and respect within that group. Unfortunately, few studies have investigated how the perception of such dynamics affects cognitive processes during cooperative group activities.

Here, we briefly review what we mean by "trust" and reframe the term for our study. Mayer and Davis (1995) conceptually defines trust as " a willingness of a party to be vulnerable to the actions of another party based on the expectation that the other will perform a particular action important to the truster." Yamagishi and Ymagishi (1994) propose that trust is based on profit and loss to the individual. To reach a solution to the problem, cognitive operations move from the initial unsolved state to the goal state. In group-based problem-solving activities, partners play important roles in providing information to members, and members use that information on the basis of how valuable it is in attaining the goal. The level of belief, such as the trust towards group members, is very important during collaborative group activities. Thus, we define trust as "a belief that the perspective of that person will lead toward a good problem solving outcome."

Trust has several benefits for organizations and their members. When the level of trust is increased, a group is expected to experience superior group processes (e.g., higher levels of cooperation) and higher performance, and vice versa (Dirks, 1999). Parks, Henagar, and Scamahorn (1996) examined how low- and high-trust individuals respond to messages of intent from other participants in a social dilemma task. They
found that low-trusters reacted to a competitive message by decreasing cooperation but were unaffected by a cooperative message. In contrast, high-trusters reacted to the cooperative message by increasing cooperation but were unaffected by the competitive message. In another study, the authors investigated the effects of trust on decision makers' responses to fear during social dilemmas (Dirks \& Ferrin, 2001). They found that high-trusters cooperated more than low-trusters when fear was present but cooperated at the same rate when fear was absent. Klimoski and Karol (1976) investigated the dynamics of interpersonal trust during group creative problem solving with members placed into high-trust, low-trust, or control (no trust) conditions. The high-trust and control groups outperformed the low-trust group on each of 3 tasks based on the number of ideas each group generated.

In sum, shared trust among members enhances individuals’ willingness to engage in various forms of spontaneous sociability, thereby facilitating task performance. However, most past studies have only focused on the direct effect of trust on task performance. We focused on the cognitive process of how reflection of the trust dynamics influences perspectivetaking activities. Figure 1 shows our research framework. Members on the left (with high trust) end up with an exocentric perspective, while members on the right (with low trust) end up with an egocentric perspective.

Figure 1: Research frame work.

## Goal and hypotheses of the current study

The present study investigated the impact of social dynamics on perspective taking activities within conflictive groups. By extending an experimental methodology from Hayashi (2012), we investigated the following two hypotheses.

H1 Reflections of self/other trust in a conflictive group may influence trust towards other members.

H2 Reflections of trust by members with conflicting perspectives may facilitate trust during the perspective-taking process.

## Method

## The rule discovery task: Bistable objects

For the main task, the participants' goals were to count a series of objects presented on a computer display and discover its sequential rule by cooperating with other"participants." Materials for the objects were several sets of random patterns containing several figures on a $6 \times 6$ grid (colored black or white; see Figure 2). In each set, a pattern consisting of combined square blocks was shown against the background of either black or white colors. The background color was controlled to derive, through a Gestalt effect, the change in the problem-solver's perspective (Koffka, 1935).

Figure 2: Experimental stimuli used in the study.
Each set consisted of several "objects" (or patterns) in black or white, each of which consisted of a single block or multiple blocks. As shown in Figure 2, one of the paired objects has a total of 10 " components" (4 black and 6 white). When a participant focuses on white components inside a black background, the white components become the figure, and the six components pop out.

In the present study, a group of four participants collaboratively worked on the problem-solving task through computer terminals connected via a local network. All members exchanged text-based messages to discuss their opinions as to the number of objects and the sequence of the target rule. As shown in Figure 2, four participants saw the objects with either a black background (white perspective) or a white background (black perspective). Two members saw a black and two saw a white background, and each member counted the number objects that were "popping out." For each trial/objects, a square outer-box was shown on the display for one second, which was followed by a stimulus picture presented inside the box frame. Participants were required to send one message per trial to the other members as part of a secondary task (explained in the following section). Participants were told that they had to count the number of objects inside this box frame. The number of white components and black components was controlled, and the total number of components presented to the participants varied between six and twelve. The sequential pattern (Target rule) of the sums of black components and white components was repeatedly presented during each trial (i.e. $6,8,10,12$ or $6,8,10,12$; see

Figure 3). In the initial stage of the task, the local black/white numbers were controlled to be the same. Experiments from a past study showed that participants are fixated to the figure perspective, and participants try to search for the target rule based on his/her perspective (Hayashi et al., 2006; Hayashi \& Miwa, 2009; Hayashi, 2012) . On trial 9, we controlled the trials for differentiation in responses so that participants would report different numbers. Through this manipulation, participants experience conflict.

Figure 3: Example sequence of the objects.
Previous studies show that even though participants confront this conflictual stage, they are biased to their own object/perspective and behave egocentrically (Hayashi et al., 2006). To discover the rule for this task, the participant has to look at the different colored objects and integrate the other two members' perspectives. In the present study, one human participant and three conversational agents acted as human partners. Participants were informed that they would conduct the task with real humans and were told not to chat about anything else related to the task. Two agents were programmed to export messages based on a different perspective (object).

## Group members' behaviors: Conversational agents

In the present study, we set up a text-based chat communication platform by using one server and three clients, including one chat engine and three conversational agents(Figure 4). The system was similar to one used by Hayashi (2012) and developed by Java. On the Server side, a broadcast mechanism was used to distribute all the messages simultaneously. When messages were sent to the Server, they were re-distributed to all Clients and/or Agents.

The conversational computer agents were designed by a typical rule-based system. Based on pre-defined rules, the system can respond to sentences that were inputted by the participants (Figure 4). All three agents were implemented by the rule shown below. All agents autonomously responded to each other's text messages as independent interlocutors.

The conversation agent extracts keywords from the sentences that were distributed by the participant and other agents. The most frequent keywords that are used during this task are related to the (1) number of objects, (2) colors of objects, and (3) rules about the sequence. The agent contains a temporary working memory storage to represent the current status of the input messages from the (1) keywords of the participant, (2) keywords from the agents, and (3) objects

Figure 4: Communication platform.
that were presented on the screen. A rule base, in an "ifthen " format, defined all responses from the agents. When the agent detects keywords of (a) numbers, (b) colors, and (c) the hypothesis, working memory is updated. Then, a patternmatching strategy is used for binding the rules. In the present study, the agents were programmed to respond based on the numbers or colors of the objects that were set for its perspective (Agent A responded based on the black objects, Agent $B$ and $C$ responded based on white objects). The following shows the summarized version of the basic rules utilized in the study:

```
    \(<\) Rules \(>\)
Trials \(<8\)
(agent \(A, B, C\) )
\(->\) numbers \((\) white objects)
Trail \(>8\)
(agent A)
IF : "color(any)" - > colors(white)
ELSE IF : "rules" - > rules
ELSE - > numbers(white)
(agent B,C)
IF : "color(white)"AND "agentBorC" NOTcolor"
\(->\) numbers(black)AND color(black)
ELSE IF : "rules" - > rules
ELSE - > numbers(black)
```

For example, outputs of numbers (black) and colors (black) could be, "Oh, I think there are 6 black objects," "So you see 3 ? I see 3 of them in black, " etc. The server will distribute the messages to each agent in a randomized order with a delay for appropriate turn takings.

## Trust dynamics diagram interface

On each trial, participants were required to work on a secondary task, which was to evaluate and receive results of self/others' evaluations of "trust." This was done to provide reflections regarding trust dynamics of the group members.

Participants were asked to "evaluate each member based on the belief that his/her information will lead to a good outcome for the group." Figure 5 shows an example of the trust dynamics network diagram interface. The participants' representation (node) was located in the center, and the other members (partners A, B, and C) were located above and below. There were four nodes and 12 links for evaluating each member. Each arrow addresses the evaluation towards a particular member. A" + " indicates that the participant evaluated him/her as trustworthy, and a " - " mark means that the participant evaluated the member as untrustworthy. Within the interface, there were three arrows pointing from the participant to Partners A, B, and C. Participants were required to select trust $(+)$ or distrust (-) by using a pull down selection box. Prior to the experiment, all participants completed a training session in order to become familiar with the trust dynamics network diagram interface. During the experiment, participants were required to evaluate other members ( $\mathrm{A}, \mathrm{B}$, and C) during each trial. All members' (agents') outputs were controlled to simulate a pattern of trust dynamics due to each experimental condition.

Figure 5: Trust dynamics network diagram interface.

## Procedure

Seventy-five undergraduate students from a humanities course participated in the experiment (trust condition, $n=$ 27; distrust condition, $n=26$; no-trust condition, $n=22$ ). The experiment took place in a room with 12 laptop computers. Participants performed 32 trials (average time $=35$ minutes). After the task, participants worked on a writing test. In the trust condition, when a conflict occurred on the 9th trial (see Figure 3), the partners/agents were controlled to gradually generate trust towards the members with conflicting perspectives. Conversely, in the distrust condition, there were no such adjustments, and partners/agents kept generating distrust towards members with different perspectives.

Figure 6 shows the simulation of the trust dynamics during the experiment. For trials 1 to 6 , all agents' evaluations were
programmed to select distrust $100 \%$ of the time. On trials 7 to 11 , all agents were programed to generate trust with $80 \%$ variability. After the 12th trial, members with the same perspective ( $\mathrm{C}->\mathrm{B}, \mathrm{B}->\mathrm{C}, \mathrm{A}->$ participant) were programmed to generate trust $100 \%$ of the time. Other's evaluations were weighted to gradually select distrust until the 17th trial (see Figure 6). This was done to manipulate a situation where members evaluated others negatively after the conflict occurred during the main task. In the trust condition, responses were weighted to recover gradually from the 18th trial. However, in the distrust condition, there were no adjustments made. The no-trust condition was the baseline condition, and there was not a trust dynamics diagram provided to the participant.

Figure 6: Results of the agent simulation on trust dynamics.

## Dependent variables

We had two main dependent variables of interest. First, we analyzed the degree of trust towards other members during the following four task stages: (1) Initial Stage (trials 1 to 8), (2) Conflict Stage 1 (trials 9 to 16), (3) Conflict Stage 2 (trials 17 to 24), and (4) Conflict Stage 3 (trials 25 to 32). Evaluations of Participants (agents) A, B, and C were collected based on these stages and coded as follows: (1) trust as 1 point and (2) distrust as -1 point. At each stage, the average score was calculated for each participant and used as a representative value. We then calculated the average of each partner within each trial stage. Next, we analyzed participants' dialog data during the task. This was done to evaluate participants' change in perspective. If the conversation data included a description that referred to the background color, it was counted as "a change in perspective." If a participant's data did not include such information, it was counted as "no perspective change."

## Results

## Evaluations of trust towards other members

Figure 7 shows the trust dynamics results in the trust and distrust conditions. The vertical axis represents the average ratio of trust, and the horizontal axis represents the experimental trials.

Figure 7: Results of the evaluations of the trust to partners.

First, we analyzed the trust condition. We performed a 4 $\times 3$ within-subjects factorial ANOVA with the four evaluation trial-times (Initial Stage vs. Conflict Stage 1 vs. Conflict Stage 2 vs. Conflict Stage 3) and the three partners (Partner (agent) A vs. Partner (agent) B vs. Partner (agent) C) as independent variables. There was a significant interaction between the two factors $(F(6,156)=3.0, p<.01)$. We conducted further analyses to deconstruct this interaction.

First, a simple main effect analysis was conducted on each trial time. In the Initial Stage (trials 1 to 8), Conflict Stage 2 (trials 17 to 24), and Conflict Stage 3 (trials 25 to 32) there were no differences between conditions $(F(2,208)=0.063$, $p=.94),(F(2,208)=2.014, p=.14,(F(2,208)=1.142, p$ $=.32)$ ). However, in Conflict Stage 1 (trials 9 to 16), there were significant differences between conditions $(F(2,202)=$ 8.316, $p<.01$ ). Multiple comparisons using Ryan's method were conducted for Conflict Stage 1. Results indicated that the average score of partner A was higher than partners B and C respectively ( $p<.01 ; p<.01$ ). There were no differences between partners B and $\mathrm{C}(p=.75)$. Next, we examined the distrust condition. We performed the same factorial ANOVA as in the trust condition. There was a significant interaction between the two factors $(F(6,150)=10.110, p<.01)$. Again, we conducted further analyses to deconstruct this interaction.

A simple main effect analysis was conducted on each trial time. In the Initial Stage (trials 1 to 8 ), there were no differences between conditions ( $F(2,200)=0.018, p=.98$ ). However, there were significant differences in Conflict Stage 1, Conflict Stage 2, and Conflict Stage $3(F(2,200)=20.355$, $p<.01, F(2,200)=14.559, p<.01, F(2,200)=21.615$, $p<.01$ ). We conducted multiple comparisons, again, using Ryan's method. For Conflict Stage 1, results indicated that the average score of partner A was higher than that of partners B and C, respectively ( $p<.01 ; p<.01$ ). There were no
differences between partners B and C $(p=.74)$. For Conflict Stage 2, results indicated that the average score of partner A was higher than that of partners B and C , respectively ( $p<$ $.01 ; p<.01$ ). There were no differences between partners B and $\mathrm{C}(p=.26)$. Finally, for Conflict Stage 3, results indicated that the average score of partner A was higher than that of partners B and C, respectively ( $p<.01 ; p<.01$ ). There were no differences between partners B and $\mathrm{C}(p=.53)$.

## Perspective Taking Process

Figure 8 shows the results of the dialogue process of changing perspectives. The vertical axis represents the ratio of perspective change, and the horizontal axis represents the experimental condition. The numerals shown on the cylindrical bars indicate the number of participants in each condition. A chi-square analysis was conducted to check the difference in the number of problem solvers who integrated perspectives during the task. Results indicated that there were significant differences among the conditions ( $\chi^{2}(2)=6.132, p<.05$ ). Next, a multiple comparison was conducted on the two conditions using Fisher's exact test. There were significant differences between the trust condition and the distrust condition and between the trust condition and the no trust condition, respectively ( $p<.01, p<.01$ ). Conversely, there were no differences between the distrust and the no trust condition ( $p$ $<.10$ ). This suggests that a group that interacted with trustbased dynamics were taking into consideration the perspectives of others more frequently than a group that did not.

Figure 8: Results of the perspective taking performance.

## Discussion and Conclusions

We investigated the influence of social cognitive factors, such as trust dynamics during perspective taking activities, in group based problem solving. We investigated how reflections of self/others' trust can facilitate the level of trust toward others and, thus, motivate perspective. Results from the trust dynamics paradigm show that participants felt distrust toward others during the initial stage of the interactions. However, participants gradually constructed trust towards others over time. As the interaction proceeds, trust became stronger. However, when participants perceived members with conflictive perspectives, trust dropped compared to those without a conflicting perspective. This indicates that trust was de-
pendent on whether conflicting information provided by the members was present. Regarding reflective feedback from other members, we found different types of evaluations of trust towards other members (participant $->\mathrm{A}, \mathrm{B}, \mathrm{C}$ ). When participants received a recovery of trust from members with conflictive perspectives (partner B \& C), trust recovered to the same level of trust that was present with the member (partner A) who did not have a conflictive perspective. This shows that reciprocal behavior might have occurred through the interaction process. It is interesting that even if participants experienced conflict from other members, if trust is later presented, he/she will generate feelings of trust. Conversely, if participants do not receive such reflective trust (distrust condition), trust never recovers. These results support H1 and indicate that reflective feedback was influential in building trust towards other members. These results may differ from other types of reflective feedback, such as when you know that others can see everyone's evaluations. This type of feedback might have hindered our results. Furthermore, we found that certain reflections of trust feedback could influence the perspective-taking process. Participants in the trust conditions communicated with others based on conflicting perspectives more so than those in the distrust condition. This supports H2. These results suggest that the level of trust dynamics facilitates trust and can function to manifest perspectivetaking activities within cooperative groups.

The present study provides new implications for cognitive studies on perspective taking during group communication. Specifically, our results capture a trust dynamics factor that could gradually influence the process of trust and exocentric perspectives towards conflictual members. As described earlier, a few studies have investigated the nature of trust in groups and trust's influence on task performance. Some studies investigated the nature of perspective taking in risky dilemma situations. One study Evans and Krueger (2011) observed that in high-risk situations, people heuristically chose distrust; trust increases when costs decrease and benefits increase. However the present study focused on a cooperative situation; our results help elucidate how trust is mediated by problem solving interactions. Some studies (e.g., Klimoski and Karol (1976) ) have investigated the nature of trust on creative problem solving. Unfortunately, there are not many investigations assessing what kinds of trust dynamics are effective in the cognitive process of such activities.

Our present results can contribute to future studies modeling cognitive systems for supporting collaborative activities in groups. Reflections of trust dynamics, and the positive level of trust, are effective in facilitating higher trust towards others, as well as enhanced perspective taking. This model potentially can be used in collaborative learning activities, such as computer-based learning activities with large groups where perspective taking plays an important role. These trust dynamic mechanisms during collaborative learning can motivate learners to work on tasks/materials and be cognizant of the useful contributions of other members.

# How listeners respond to speaker's troubles 

Patrick G. T. Healey, Mary Lavelle, Christine Howes, Stuart Battersby, Rose McCabe<br>ph@eecs.qmul.ac.uk<br>Queen Mary University of London,<br>Cognitive Science Research Group,<br>School of Electronic Engineering and Computer Science, London E1 4NS, UK

#### Abstract

Listeners normally provide speakers with simultaneous feedback such as nods, "yeah"s and "mhm"s. These 'backchannels' are important in helping speakers to talk effectively. Two factors are known to influence when a backchannel is produced; if the speaker is looking at the listener or if the speaker is presenting new information. We investigate a third factor: whether the speaker is having trouble speaking i.e. self-repair. If dialogue is an active collaborative process then listener's responses should be especially critical when trouble is encountered. Using data from a corpus of three person dialogues we show that speaker's rate of self-repair is a better predictor of listener responses than speech rate. We also show that listeners respond strongly to speaker troubles independently of whether the speaker is looking at them. We argue that it is the points at which conversation threatens to go off-course that are most significant for coordination. Keywords: Gesture; repair; dialogue

## Introduction

Listening in conversation is not a passive activity. As Goffman (1955) noted, what listeners do while being addressed has important consequences for the way that speakers produce their turns. Goffman distinguished between two general kinds of listener feedback; displays of attention and understanding of what is said and the signalling of interactional functions such as a desire to speak next. Yngve (1970) introduced the term 'backchannel' to describe these uses of simultanous feedback that provide speakers with concurrent information about how their turn is being received.

In a series of experiements examining the effects of listener response behaviours Bavelas and colleagues were able to show that the fluency and effectiveness of a speaker's turns depends directly on the level of feedback they are getting from their addressees (J. B. Bavelas et al., 2000; J. Bavelas et al., 2006). People telling stories to listeners who are engaged in a distractor task speak less fluently and are less compelling than those whose listeners are attending more carefully.

Given the importance of listener responses for successful interaction a key question is what prompts a listener to produce them? Many of the most common backchannel signals, such as nods and smiles, use the visual channel which avoids potential competition with concurrent speech. One common finding in the literature is that addressee responses are reliably correlated with speaker's
gaze. Goodwin (1979) observed that speakers will periodically check whether addressees are attending by looking at them and if they get no response may restart or switch to a new addressee mid-turn. J. B. Bavelas et al. (2002) found that listener responses in their 'close call' story telling task were significantly more likely to occur in a 'gaze window' i.e. when a speaker is looking at a listener than when they are not.

A second common observation in the literature is that backchannels are also associated with the introduction of new information into a dialogue such as the introduction of a new referent or proposal that may warrant some signal of interim acknowledgement or acceptance before the speaker's turn is completed (J. Bavelas et al., 2006; Clark \& Wilkes-Gibbs, 1986; Yngve, 1970). In this case it is the information update that prompts the use of a backchannel to signal understanding 'so far' (Goodwin, 1981).

In this paper we explore the effects of a third factor on listener responses: the degree of difficulty a speaker has in producing their turn. Few conversational turns are produced without some form of online revision or reformulation during their production. Sometimes referred to as disfluencies these self-repairs are indicative of some sort of trouble producing a turn. If conversation is a collaborative process in which each turn is co-produced (Goodwin, 1979; Clark, 1996) then this leads to the hypothesis that the points at which the speaker shows signs of getting into trouble ought to be especially critical for collaborative reponses. This paper tests this hypothesis by investigating the relationship between nodding, speech rate and repair rate in a corpus of three person dialogues.

## Methods

Experimental work on listener backchannel responses has focussed only on dyadic, i.e. two person, interactions. However, natural interactions frequently involve more than two people (Goffman, 1981; Eshghi, 2009). For current purposes three-way interactions also have the practical advantage that they make it possible to compare two kinds of listener depending on who the speaker is looking at while they talk. Given the importance of speaker gaze to the production of backchannels this provides a useful opportunity to compare the responsiveness
of two fully ratified, active participants who differ only in whether they are being looked at while the speaker produces their turn. Note that this differs from the work of Schober \& Clark (1989) who investigated the behaviour of side participants and overhearers whose ability to provide concurrent feedback was restricted.

## Participants

Fifty four participants (30 Male, 24 Female) were recruited to the study through advertising on local community websites. Of those who responded to the advertisement, $40 \%$ participated. Participants within each group had not met prior to the study.

## Procedure

Participants were brought into the laboratory in threes and seated in a triangular formation so that each participant had good visual access to each of the others (see Figure 1). The researcher read aloud a fictional moral dilemma scenario called 'the balloon task' to the seated group. The scenario states that there are four people in a hot air balloon, which is losing height and about to crash into some mountains killing all on board. One person must jump from the ballon to their certain death in order to save the other three. Participants were instructed to debate the reasons for and against each person being saved, and reach mutual agreement about who should jump. The group was provided with an opportunity to ask questions before the researcher left the interaction space and the task began. Interactions ended when participants reached a joint decision. Groups that failed to reach an agreed decision had their interaction terminated at approximately 450 seconds ( 7 minutes 30 seconds).

Figure 1: 2-dimensional image of participants engaged in triadic interaction, wearing the reflective markers

All interactions were recorded in a human interaction laboratory fitted with an optical based Vicon motioncapture system, consisting of 12 infrared cameras and Vicon iQ software. Participants wore a top and a cap with 27 reflective markers attached. Cameras detected the markers at 60 frames per second, resulting in a highly accurate 3D representation of participants' movements over time (see Figures 1 and 2).

Figure 2: The wire frame representation of the interaction in 3-dimensional space

## Data Analysis

For each interaction, speech was transcribed from the 2D video in the annotation tool ELAN (Crasborn \& Sloetjes, 2008). These transcripts, together with the motion capture data were used to produce three measures, speech rate, rate of self repair and rate of nodding for each participant.

Measures of Self-Repair Automatic processing of the transcripts identified, for each turn, the number of words, the number of filled pauses (e.g. er, um) and the number of unfilled pauses, defined as pauses between segments of speech by the same speaker of greater than 200 milliseconds (following e.g. Zellner, 1994, a.o.). Since self-repairs often involve the repetition of words, usually close together, a normalised within-turn repeated words value was calculated, by identifying repeated words in a turn and the distance between them and applying a decay function. Examples of turns including selfrepetition, and their word repeat value are shown below, from a low repeat score in example 1 to a high repeat score in example 3. Repeated words are shown in bold, and their repetition in italics.

[^294](2) Trust me his wife if he's if he's a pilot his wife knows how to do it [1.25]
(3) And and they they said that she said that they emptied the balloon to make it lighter [2.98]

To check validity, this measure was also calculated on a corpus of 52 clinical dialogues which had been handannotated for self-repair (McCabe et al., in preparation). For the 15,191 turns analysed, the within-turn repeated words measure was positively correlated with the handannotated self-repair measure ( $r=0.57, p<0.001$ ) and is therefore used as an index of self-repair. All values were normalised by number of frames in the turn, and mapped to the frame-by-frame motion capture data.

Nodding Head movement was derived from the vertical movement of participants front left head marker. Head nodding was approximated in a two-step process. Firstly, low frequency movements ( 1 Hz and below) and high frequency movements ( 4 Hz and above) were eliminated, in accordance with those described as the parameters of normal head movement in the British Journal of Ophthalmology (Gresty et al., 1976) and fall within the range of ordinary head movement as described by Hadar et al. (1983). Secondly, in line with previous studies (Cerrato \& Svanfeldt, 2006), head nods were identified as vertical movements at a speed $>0.3 \mathrm{~mm} /$ frame, with 7 frames between the top and bottom of the movement.

Figure 3: Indexing dialogue role through speaker head orientation

Speaker Orientation and Recipient role The speech transcript was synchronized with the 3D motion capture data, identifying the identity of the speaker(s) in each frame of interaction. In order to identify the speaker's primary addressee at each point in the dialogue the technique described in Healey \& Battersby (2009)
was used. For each frame of data the speakers' head orientation is calculated using the coordinates of their four head markers. The orientation of the speakers' head is compared to a centre line falling between the speakers' two interacting partners, bisecting the interaction space (Figure 3). Head orientations falling within two degrees of the centre line are excluded. If the speaker's head orientation falls on one side of this line the person on that side is coded as the primary recipient i.e. the person the speaker is primarily orienting to at that point in the dialogue. The other participant is coded, by default, as the secondary recipient. The identity of the speaker (based on hand annotated speech) and the primary and secondary recipients (based on speaker head orientation) is coded for each frame of data. Although in principle head orientation is independent of gaze direction it is nonetheless a reliable indicator of speaker's attention and gaze, especially in multi-party dialogue (Healey \& Battersby, 2009; Jokinen et al., 2010; Loomis et al., 2008).

## Results

Following Boker et al. (2002), windowed crosscorrelations were used to determine the degree of coordination between the head nodding of each participant (i.e. speaker, primary recipient and secondary recipient) and the speaker's speech and repair rates. This method directly compares the rates of speakers' speech and repair at each frame with the head movement of each participant on a lagged frame-by-frame basis within each 30-second window providing: (i) the correlation between speakers' rate of self-repair/speech and participants' nodding, and (ii) the temporal offset at which they occur. Consecutive windows were overlapped to minimize the chance of significant correlations being undetected. Windowed cross-correlation analyses assume local stationarity within each window. Although this may not always be the case, any violations will produce a downward bias of correlation and lag, providing a conservative measure of the magnitude of the effects (as discussed in Boker et al., 2002).

Figure 4 shows the results of the cross-correlation of nodding with speech rate, at lags of up to $\pm 240$ frames (4 seconds). At zero offset speakers nod most, primary recipients nod less and side participants nod least. The Friedman comparisons in Table 1 shows this global pattern of differences between roles is reliable. As the Figure shows, the difference in roles is greatest at zero offset. This is consistent with a pattern in which speakers nod most, primary participants produce some feedback through nods and secondary participants supress their nodding, as indicated by the negative correlation. Since all participants take all roles in this task these effects are only due to differences in who the speaker is looking at.

The cross-correlation of nodding with repair rate, illustrated in Figure 5, shows a different pattern of timing

Figure 4: Cross-Correlation of Speech Rate and Rate of Nodding. Horizontal grey lines indicate the $95 \%$ confidence interval.
and level of responses to repair rate than to speech rate. As Table 1 shows speakers still nod more than primary or side participants in turns that include repairs, however both people in the recipient role at the time the of the repair nod significantly more than they would otherwise. Especially in the 1-3 second offset, i.e. towards the end of the turn involving a repair.

| Pairwise comparison | Friedman's test stat |  |  |  |
| :--- | :--- | ---: | ---: | ---: |
|  |  | Raw | Std | p |
| Repair Rate | Speaker Primary | -0.784 | -6.497 | $<0.001$ |
|  | Speaker Side | 1.042 | 8.634 | $<0.001$ |
|  | Primary Side | 1.825 | 15.131 | $<0.001$ |
| Speech Rate | Speaker Primary | 0.574 | 4.757 | $<0.001$ |
|  | Speaker Side | 1.757 | 14.562 | $<0.001$ |
|  | Primary Side | 1.183 | 9.806 | $<0.001$ |
| Repair vs Speech | Primarer | -0.287 | -2.378 | 0.261 |
|  | Side | 1.071 | 8.875 | $<0.001$ |
|  | 0.428 | 3.550 | 0.006 |  |

Table 1: Non-parametric test results for crosscorrelations by role and speech or repair rate pairwise comparisons

Friedman pairwise comparisons show no reliable difference in speakers nodding as predicted by speech rate or repair rate but both recipient roles show a significantly stronger response to repair rate. Secondary participants, in particular, shift from suppressing their nodding be-

Figure 5: Cross-Correlation of Repair Rate and Rate of Nodding. Horizontal grey lines indicate the $95 \%$ confidence interval.
haviour while the speaker is addressing someone else to a profile much more similar to that of a primary participant especially at offsets of between 1 and 3 seconds.

## Discussion

Despite the fact that all three people involved in the balloon task dialogues are active, ratified participants who are free to respond at any time, the results indicate that there are clear differences in levels of responsiveness depending on who the current speaker is attending to as indexed by theier head orientation. This is consistent with previous work by Goodwin (1979) and J. B. Bavelas et al. (2000); J. Bavelas et al. (2006) who emphasise the importance of speaker gaze in eliciting listener responses.

The results reported here extend existing findings in two ways. Previous experimental work has focussed on the behaviour of listeners in dyadic i.e. two-person dialogues. Here we extend this to three person dialogues. A pragmatic feature of three-person dialgoues is that it becomes harder to judge who is speaking to whom and, as a result, more difficult to co-ordinate the roles of speaker and addressee.

Our results demonstrate that in this context there are concurrent differences in people's levels of responsiveness that depend on whether the speaker is currently oriented to them or to someone else in the conversation; indepen-
dently of what is being said. This replicates findings reported by Healey \& Battersby (2009), for a different corpus, which indicated that listerners who are not oriented to by the speaker, i.e. secondary recipients, are normally less responsive than primary recipients.

Consequently, it is not merely exposure to the content of what is said that determines responsiveness. Interestingly, these results also show for the first time that secondary participants actually suppress non-verbal feedback i.e. their head movements are substantially negatively correlated with the speaker's speech. It appears likely that this is because they are, in a sense, actively displaying their non-recipiency.

Importantly, the present results also suggest the influence of a new factor on overt levels of response; selfrepair or speaker troubles. Although there is no overall effect on Speaker's nodding, Listeners in both the primary and secondary recipient roles respond more strongly to turns in which there is evidence that the speaker is having trouble formulating or articulating their message. This is significant, in part, because selfrepairs are relatively common, occuring in at least a third of turns in natural dialogue even on conservative estimates (Colman \& Healey, 2011). The effect is more marked for secondary recipients who switch from suppressing their responses to producing a profile much closer to that of the primary recipient.

The implication of these differences in patterns of repsonsiveness is that it listener feedback is primarily organised around the successful construction of a turn, not the content of that turn. This strengthens the view that conversation is an active, collaborative process in which people make concerted use of the resources available to them, including speech, gesture and head movements, to produce each turn. However, it also suggests that these resouces are most actively used to help speakers recover from problems in the production of their turn and not, as normally assumed, for acknowledging or 'grounding' new information.

#### Abstract

Memory reconsolidation, the re-stabilization of consolidated memories after reactivation-induced destabilization, has received considerable attention in recent years. Nevertheless, the neural processes underlying the phenomenon remain elusive. With the aim of contributing to the development of a theory in this area, we here present a computational model of reconsolidation at the "systems" level. The model is an extension of TraceLink, which has previously been used to account for a range of memory phenomena related to consolidation.

Keywords: Memory reconsolidation, neural network, connectionism.

## Introduction

The phenomenon of memory reconsolidation, the restabilization of consolidated memories after reactivationinduced destabilization, has received considerable attention in recent years with the publication of a series of studies on both animals and human subjects (Nader \& Einarsson, 2010; Nader \& Hardt, 2009). While several computer simulations have modeled consolidation after initial learning, (McClelland, McNaughton, \& O’Reilly, 1995; Murre, 1996), only one model of cellular reconsolidation has been published (Osan, Tort, \& Amaral, 2011), and - to our knowledge - no simulation of systems reconsolidation (Debiec, LeDoux, \& Nader, 2002). In order to fill this gap, we developed an extended version of a previously published computational model of memory consolidation, TraceLink (Murre, 1996), incorporating features that enable it to also account for reconsolidation.
We begin with a brief introduction to the phenomenon of memory consolidation, followed by a description of the TraceLink model. We then discuss the mechanisms believed to underpin systems memory reconsolidation, describe how we implemented them in the model, and, finally, report our simulation results.

## Memory Consolidation

Forgetting and amnesia. The ability to recall acquired memories normally diminishes with time elapsed since learning. Although there is disagreement about the precise shape of the forgetting curve (Anderson \& Tweney, 1997), it is often represented as an exponential so-called Ebbinghaus (1885) forgetting curve, as in Figure 1.

Figure 1: Idealized normal forgetting curve.
In contrast with normal forgetting, memory loss after trauma affects recent memories more than remote ones (McClelland et al., 1995; Scoville \& Milner, 1957; Squire \& Alvarez, 1995), resulting in a curve with the opposite slope, as in Figure 2.

Figure 2: Idealized Ribot gradient.
This graph shows that the ability to recall material learned shortly before onset of amnesia is strongly impaired, whereas older memories are relatively spared. The curve is commonly known as the "Ribot gradient", after the French psychologist Ribot who first postulated it (Ribot, 1882). This temporally graded amnesia gave rise to the idea that a
consolidation process stabilizes newly acquired memories older memories were less affected in amnesia because they had had more time to stabilize.

Types of consolidation. Researchers distinguish between two types of memory consolidation, "systems" consolidation and "synaptic" or "cellular" consolidation (Dudai \& Morris, 2000). Systems consolidation is a process that transitions initially hippocampus-dependent memories to a hippocampus-independent state. In the mammalian brain, the hippocampal formation is involved with the consolidation of "episodic" memories, explicit memories of experienced events. Animal studies as well as human cases of brain damage have shown that memories initially depend on the hippocampus, but gradually become hippocampusindependent. According to the "standard model of systems consolidation" (McClelland et al., 1995; Squire \& Alvarez, 1995), hippocampal memory traces are quickly created but only persist for a limited time, during which they support the more time-consuming construction of neocortical memories. On this view, the temporally graded amnesia observed after hippocampal lesions is due to the fact that older memories have had more time to consolidate in the neocortex, while newer memories are still only weakly represented there (McClelland et al., 1995; Squire \& Alvarez, 1995). This process is called "systems consolidation" because it involves interaction between two brain systems, the hippocampus and the neocortex. In contrast, the so-called "cellular" or "synaptic" consolidation process concerns the stabilization of memories within a single system.

## The TraceLink Model of Memory Consolidation

TraceLink is a connectionist model of systems memory consolidation (Meeter \& Murre, 2005; Murre, 1996). The model has two layers representing hippocampus (HC) and neocortex (NC), respectively. The HC layer has 42 units and the NC layer has 200 units. Each layer is fully connected, i.e. there are independent (asymmetric) connections in both directions between each pair of units, and the two layers are also fully interconnected. Connection weights have values in the range 0.0 to 1.0 . The units have discrete activation levels, either 0.0 (inactive) or 1.0 (active), and a stochastic asigmoid activation function:

$$
\begin{equation*}
P_{j}=\frac{1}{1+e^{-\frac{n e t_{j}}{\text { temp }}}} \tag{1}
\end{equation*}
$$

where $P_{j}$ is the probability that unit $j$ will become (or remain) active, net $_{j}$ is the net input to unit $j$ and temp is a parameter that controls the steepness of the asigmoid function, i.e. the amount of randomness in the model. (For small values of temp, $P_{j}\left(\right.$ net $\left._{i}\right)$ approaches a deterministic step function; for large temp, $P_{j}\left(\right.$ net $\left._{i}\right)$ is close to 0.5 everywhere, i.e. equal probability of becoming active or inactive regardless of net $_{i}$.). A temp value of 0.2 was used in all simulations. The net input $n e t_{j}$ in equation [1] is calculated according to the following formula:

$$
\begin{equation*}
\text { net }_{j}=\sum_{i} w_{i j} a_{i}-\text { inhibition }_{L} \tag{2}
\end{equation*}
$$

where $w_{i j}$ is the weight of the connection from unit $i$ to unit $j$, and $a_{i}$ is the activation level of unit $i$. The term inhibition $n_{L}$ is a layer-specific inhibition quantity that simulates the effect of inhibitory synapses. It is calculated by a feedback algorithm that drives the number of active units in each layer towards a configured equilibrium value, which is also the number of active units in training patterns for the layer. For example, each training pattern for the NC layer has ten active units, and the inhibition mechanism makes the layer preferentially settle into states with that number of active units.

The learning rule is Hebbian with an anti-Hebbian "interference" term that accelerates forgetting of previously learned patterns, especially in the smaller HC layer, where there is more pattern overlap:

$$
\begin{equation*}
w_{i j}(t+1)=w_{i j}(t)+\mu_{T}^{+} a_{i} a_{j}-\mu_{T}^{-}\left(1-a_{i}\right) a_{j} \tag{3}
\end{equation*}
$$

where $w_{i j}(t)$ is the connection weight between units $i$ and $j$ at time $t, a_{i}$ is the activation level of unit $i, \mu_{T}^{+}$is the Hebbian learning rate, and $\mu_{T}^{-}$is the interference or "unlearning" rate. The learning rule strengthens connections between units that are both active, and weakens connections from inactive to active units. Learning rates are specified per "tract" (hence the $T$ subscript). A tract is a set of connections with the same source and destination layers: all the connections from HC units to NC units form one tract, all connections internal to the NC layer form another tract, etc. A tract's learning rates ( $\mu_{T}^{+}$and $\mu_{T}^{-}$) may take on different values during initial acquisition versus consolidation. This simulates the effect of neuromodulation, for example, an increased learning rate in hippocampus in the presence of novel stimuli (Meeter \& Murre, 2005; Murre, 1996).

Initial acquisition. The TraceLink system is trained by presenting a training pattern to both layers ${ }^{1}$ and applying the learning rule to adjust connection weights. The intra-HC and NC-HC tracts have high learning rates and learn patterns well in a single presentation. The intra-NC tract has a much lower learning rate, and as a result a single training cycle only creates a weak trace there.

Recall. To test recall of a training pattern, a subset of the pattern's active NC units (a "cue pattern") are held ("clamped") in the "on" state, and the rest of the units in both layers are randomly set to either the active or inactive state, with equal probability. The whole system is then repeatedly cycled by executing the activation function for all the unclamped units in random order and updating their activation levels accordingly. At the end of each cycle, the inhibition algorithm adjusts the inhibition coefficients of both layers. After a configurable number of such cycles (we

[^295]used 70 in all simulations), the activation pattern into which the system has settled is compared to the original training pattern. Recall accuracy is measured as the percentage of non-cued NC units in the training pattern that have been successfully turned on.

Lesioning. Hippocampal lesion is simulated by simply disconnecting the HC layer (setting all inter-layer connections weights to zero). After initial training, the intact system can normally recall patterns quite well, because the $\mathrm{NC}-\mathrm{HC}$ and $\mathrm{HC}-\mathrm{HC}$ connections provide linkage between the pattern's NC units, but after virtual lesioning recall is poor, because the NC-NC connections are not strong enough to independently enable the system to complete the pattern correctly.

Consolidation. Memory consolidation is simulated by randomly setting each unit's activation level to either 0.0 or 1.0 , letting the system "settle" in the same manner as for recall (but without any cue pattern), and reinforcing whatever state it settles into by applying the learning rule in the NC layer. Because the system is more likely to settle into trained patterns (Hopfield, 1982), this procedure gradually strengthens those patterns in the NC layer. After a pattern has been reinforced in this manner a sufficient number of times, its NC connections become strong enough that the pattern can be recalled even after HC lesioning.

Simulations. In a typical TraceLink simulation, a series of training patterns are presented, one per simulated "day", each followed by a number of consolidation cycles (Meeter \& Murre, 2005; Murre, 1996). Because of interference, especially in the smaller HC layer where patterns overlap more, earlier patterns are gradually overwritten by newer ones. When recall is tested after training a number of patterns, a forgetting curve can be observed: older patterns are recalled less successfully than newer ones. The model is thus able to account for normal forgetting (the idea that interference plays a major role in hippocampal forgetting may be debatable (Hardt, Nader, \& Nadel, 2013)).
While patterns are slowly forgotten in the HC layer, they are gradually strengthened in the NC layer due to consolidation. If the HC layer is "lesioned" after a number of days, the earlier training patterns, which have had more time to consolidate and therefore have a stronger NC representation, are recalled more successfully than the newer ones. The model is thus also able to account for the Ribot gradient observed after hippocampal lesion. See Meeter \& Murre (2005), for more details about the TraceLink model, including accounts of simulations that reproduce a range of human memory phenomena.

## Memory Reconsolidation

It has been shown that reactivating a consolidated memory can return it to a labile state, from which it needs to reconsolidate in order to persist (Nader \& Hardt, 2009). During the period of instability, the so-called "reconsolidation window", memory impairments may be
produced by the same types of intervention that can interfere with initial consolidation, such as lesions and protein synthesis inhibition (Debiec et al., 2002; Nader, Schafe, \& Le Doux, 2000). Some have suggested that that such postreactivation plasticity allows knowledge to be modified when new information is acquired (Hardt, Einarsson, \& Nader, 2010; Lee, 2009). As is the case with memory consolidation, memory reconsolidation has been documented at both the systems and cellular level. The former type, systems reconsolidation, is "the demonstration that reactivation of a remote memory returns the trace to being hippocampus dependent again for a period of time before once again becoming independent of hippocampus" (Debiec et al., 2002).

## Method

Although the physiological events underlying systems memory reconsolidation are not known, researchers have proposed hypothetical mechanisms that could explain the observed phenomena. The present work is a neural-network model of such a hypothesis (Debiec et al., 2002; Hardt et al., 2010; Nadel \& Hardt, 2010; Nader et al., 2000). According to this hypothesis, (1) consolidation renders remote memories hippocampus-independent; (2) reactivation of a consolidated neocortical memory creates a temporary hippocampal trace (or strengthens the existing but decaying trace); (3) the hippocampal trace stimulates the neocortical trace through back-projections; (4) this stimulation has the effect of initially destabilizing the neocortical synapses, making them susceptible to decay and/or modification; (5) continued hippocampal reinforcement prevents decay of (or even strengthens) the neocortical trace while it restabilizes. The model thus provides an explanation for the observed fact that reactivation followed by hippocampal lesion produces amnesia, but neither reactivation nor lesion alone causes memory loss.

## Implementation

In order to model this hypothesis, we implemented a twolayer network along the lines of TraceLink, but with a few additional features: (a) connections have a plasticity attribute; (b) connection weights are subject to time-based decay (Hardt et al., 2013); and (c) the simulation now includes a "reactivation" phase to trigger memory reconsolidation.

Plasticity. The plasticity attribute has a value between 0.0 and 1.0 , representing minimum and maximum plasticity, respectively. Our new learning rule takes plasticity into account:

$$
\begin{equation*}
w_{i j}(t+1)=w_{i j}(t)+p_{i j}\left(\mu_{T}^{+} a_{i} a_{j}-\mu_{T}^{-}\left(1-a_{i}\right) a_{j}\right) \tag{4}
\end{equation*}
$$

where $p_{i j}$ is the plasticity of the connection from unit $i$ to unit $j$. Thus the plasticity affects a connection's sensitivity to training and also its susceptibility to interference.

Connections are created with a $p_{i j}$ value of 1.0 (fully plastic), which subsequently decreases exponentially over simulated time, as expressed by the following formula:

$$
\begin{equation*}
p_{i j}(t+1)=p_{i j}(t) \cdot\left(1-p d r_{T}\right) \tag{5}
\end{equation*}
$$

where $p d r_{T}$ is a plasticity decay rate specific to the tract to which connection $i j$ belongs. In the simulations reported here, the $p d r_{T}$ value was 0.1 for the NC-NC tract, and 0.0 for the other tracts, i.e. plasticity variations in hippocampus were not simulated.

Decay. Connection weights are subject to exponential decay at a rate that is configurable on a per-tract basis. A connection's weight decays by its decay rate modulated by its plasticity, according to the following formula:

$$
\begin{equation*}
w_{i j}(t+1)=w_{i j}(t) \cdot\left(1-p_{i j} w d r_{T}\right) \tag{6}
\end{equation*}
$$

where $w d r_{T}$ is the weight decay rate specified for the tract to which the connection belongs. Thus, as a connection becomes less plastic, it becomes more resistant to decay (Hardt et al., 2013).

Reactivation. In addition to TraceLink's "Acquisition" and "Consolidation" phases, our model has a "Reactivation" phase, during which one or more previously trained patterns are activated, the learning rule [4] is applied, and the plasticity between active units is restored to its maximum value 1.0. Following reactivation, a number of consolidation periods may be executed, as after initial learning.

## Simulations

The following simulations were carried out:
A. Consolidation

1. Train a single pattern.
2. Execute 40 consolidation periods (simulated "days"). At each day, test recall in the intact system and with "lesioned" (deactivated) HC layer.
B. Reactivation/Reconsolidation

Same procedures for training, consolidation and testing as in simulation A , but on day 20 , reactivate the trained pattern, then continue daily consolidation and testing.
C. Reactivation and HC lesion

Same procedure as in simulation B, but on day 21, permanently lesion the HC layer.
The same parameter settings were used in all three simulations, as indicated in Table 1.

An explanatory note about the daily recall tests with intact and "temporarily lesioned" HC : these tests are performed without affecting the continued evolution of the system. No learning or (re)consolidation takes place, and HC is turned back on after testing. The simulation then continues as if the tests had not taken place. Researchers with live subjects, of course, do not have this luxury; in an analogous experiment, they would only be able to get one data point from each subject.

Table 1: Parameter values used in the simulations

| Parameter | Values |  |
| :--- | :--- | :--- |
|  | NC | HC |
| Learning rate during initial acquisition | 0.06 | 0.4 |
| Learning rate during consolidation | 0.02 | 0.0 |
| Learning rate during reactivation | 0.0 | 0.2 |
| Unlearning rate | $75 \%$ of learning |  |
|  | rate |  |$|$| Weight decay rate | 0.1 | 0.1 |
| :--- | :--- | :--- |
| Plasticity decay rate | 0.1 | 0.0 |
| Number of units | 200 | 42 |
| Active units at equilibrium (=pattern size) | 10 | 7 |
| Cue pattern size (units) | 5 | 0 |

The values in the "NC" column apply to the NC layer and intra-NC tract. The values in the "HC" column apply to the HC layer, intra-HC tract and inter-layer tracts.

## Results

## A. Consolidation

Figures 3 a and 3 b show the weight and plasticity of a representative individual connection in the $\mathrm{HC}-\mathrm{HC}$ and NC NC tracts, respectively, during the consolidation simulation. Each of the two monitored connections joined two units that were simultaneously active in the training pattern, i.e. they were connections where significant Hebbian learning took place.

Figure 3: Consolidation. a) Connection weight of a hippocampal connection. b) Weight and plasticity of a neocortical connection. c) Recall performance (averaged results from fifty simulations). Each point on the "lesioned" curve shows the performance with deactivated HC , i.e. as if HC had been lesioned on that day. Vertical bars show standard error.

As expected, HC connections quickly learn the presented pattern, and then decay exponentially. NC connections, on the other hand, quickly become very plastic, but learn only gradually. Around day 17 the HC trace has become too faint for any further consolidation to take place, and the NC trace starts to decay somewhat, but the decay slows down as the plasticity diminishes further and the trace becomes stabilized.
Figure 3c shows the recall performance during the simulation. The upper curve, representing recall in the intact system, shows normal forgetting. The lower curve, recall performance with disabled HC layer, shows a gradient during the consolidation "window", followed by constant performance. These results are similar to those obtained with the original TraceLink model (Meeter \& Murre, 2005); the difference is that forgetting there was purely interference-based, whereas in this simulation it is caused by a combination of interference and decay. (Interference plays a role even though only a single pattern is trained, because the patterns reinforced during (re)consolidation may differ from the trained pattern.)

## B. Reconsolidation

As shown in Figure 4, if the pattern is reactivated on day 20, then (a) the hippocampal trace is rapidly strengthened, (b) the necocortical trace is quickly destabilized and then gradually strengthened and restabilized in a round of reconsolidation, and (c) the recall performance is somewhat improved after the reminder.

Figure 4: Reconsolidation. a) Connection weight of a hippocampal connection. b) Weight and plasticity of a neocortical connection. c) Recall performance (averaged results from fifty simulations).

## C. Reactivation followed by HC lesion

When the HC layer is permanently lesioned after memory reactivation, the results are as illustrated in Figure 5: (a) The
hippocampal trace decays after initial training as in the previous simulation and is boosted by the reactivation

Figure 5: HC lesioning following reactivation. a)
Connection weight of a hippocampal connection. b) Weight and plasticity of a neocortical connection. c) Recall performance (averaged results from fifty simulations). The points on the "intact" curve after day 21 show the performance of the lesioned system.
on day 20. The plot ends at the hippocampal lesion on day 21. (b) The neocortical trace evolves as in experiment B until day 20, the day of reactivation. Following the HC lesion on day 21, instead of being strengthened by reconsolidation, the destabilized NC trace rapidly decays. (c) The recall performance shows rapid onset of amnesia after the hippocampal lesion.

## Discussion

In spite of a growing number of studies on both humans and animals, the neural mechanisms underlying memory reconsolidation are not well understood. The present paper seeks to contribute to the development of a theory by introducing a computational model of reconsolidation.

The key finding in system memory reconsolidation studies is that lesioning after reactivation produces amnesia, whereas neither reactivation alone nor lesioning alone causes memory impairment (Debiec et al., 2002; Nader \& Hardt, 2009). With this in mind, it is interesting to compare Figures 3-5. Figure 3c shows that, once a memory is consolidated in the model, hippocampal lesions without preceding memory reactivation have little effect on it, whereas Figure 5c illustrates that post-reactivation lesions lead to a dramatic drop in recall performance. The cause of this difference is that, after reactivation, the plasticity of the neocortical trace is high, allowing for rapid decay. In Figure 4 c , on the other hand, where hippocampus is left intact after
reactivation, reconsolidation more than compensates for the decay, resulting in moderate strengthening of the memory trace after reactivation.
The neural network model presented here is able to reproduce the empirical results by simulating microprocesses that have been hypothesized to underlie memory reconsolidation - controlled variability in synaptic plasticity and plasticity-dependent synaptic decay rates - and thus demonstrates that these mechanisms in fact can account for the observed effects.
An interesting aspect of this model is that it introduces decay-driven forgetting, in contrast with the TraceLink simulations, where all forgetting was due to interference (Meeter \& Murre, 2005). It is likely that both types of mechanism play important roles in the consolidation and maintenance of memories (Hardt et al., 2013), and we are planning to apply the model to further investigate the relationship between the two. In particular, work in progress includes simulations with multiple training patterns, which will allow us to study the combined effects of decay and even greater interference.
Another direction in which we are planning to extend this work is to apply the model to manifestations of reconsolidation other than amnesia after hippocampal lesions. These include the effects of protein synthesis inhibition (Debiec et al., 2002; Nader et al., 2000) and interference training in the reconsolidation window (Hupbach, Gomez, Hardt, \& Nadel, 2007; Hupbach, Gomez, \& Nadel, 2009; Walker, Brakefield, Hobson, \& Stickgold, 2003).

# Expert Blind Spot in Pre-Service and In-Service Mathematics Teachers: Task Design moderates Overestimation of Novices' Performance 

Katharina Hellmann (katharina.hellmann@ezw.uni-freiburg.de)<br>Matthias Nückles (matthias.nueckles@ezw.uni-freiburg.de)<br>University of Freiburg, Department of Educational Science, Instructional and School Research<br>Rempartstraße 11, 79098 Freiburg, Germany

#### Abstract

To act efficiently in the classroom, teachers need to be able to judge the difficulty of problems from a novice's perspective. However, research suggests that experts use their own knowledge as an anchor, adjust estimations for others to their own knowledge and thus underestimate the difficulty that a problem may impose on novices. Similarly, experts should underestimate the benefit for novices of task designs derived from Cognitive Load Theory (CLT), as - following the expertise reversal effect - these should be rather disadvantageous for experts. We investigated pre-service and in-service teachers’ competencies in estimating the difficulty of mathematical tasks for novices. Thirty-four pre-service teachers and thirteen experienced teachers solved tasks that varied in instructional design (optimized for novices following CLT versus non-optimized). Participants solved each task and then estimated how many students of a fictional $9^{\text {th }}$ grade class would be able to solve that task. Solution frequencies were collected from fifty-two $9^{\text {th }}$ grade students. In both expert groups, overestimation was clearly more pronounced for non-optimized than optimized tasks, suggesting an expert blind spot that can be explained in terms of an expertise-reversal effect. The experts failed to adequately take into account the benefits of didactic task variation for novice learners. However, whereas pre-service teachers' overestimations of student performance were large and significant both for non-optimized and optimized tasks, in-service teachers' overestimations were generally small and failed to approach statistical significance. In contrast to preservice teachers, in-service teachers seem to have a better mental model of what a student is able to achieve, thus making better judgments of student performance.

Keywords: expert blind spot; perspective taking; expertise reversal effect

## Theoretical Background

## Expert Blind Spot

Peoples’ judgements of others are very often based on their self-assessment and are therefore cognitively biased (e.g. Tversky \& Kahneman, 1974). In line with this, research in the area of expertise has repeatedly shown that experts tend to misjudge novices' knowledge, achievement, or time on task, amongst others, to a certain degree (e.g. Herppich, Wittwer, Nückles \& Renkl, 2010; Hinds, 1999; Lentz \& de Jong, 2006). This effect has also been found to apply to teachers (e.g. Nathan \& Koedinger, 2000). Teachers, usually referred to as being domain experts in their content area, as they possess a high level of specialized knowledge, are considered to be prone to an expert blind spot (Nathan \&

Petrosino, 2003) when evaluating the difficulty of mathematical problems for students

Following Nickerson’s (1999) anchoring model, teachers may be inclined to use their specialized knowledge as an anchor when assessing the difficulty of problems for students. As a result, they are not able to take the student perspective adequately.

Figure 1: The process of perspective taking through anchoring and adjustment (adapted from Nickerson, 1999)

According to Nickerson (1999, see Figure 1), people tend to build an inaccurate mental model of the potential knowledge of general or specific others. They fail to take into account the specificity or exclusivity of their own knowledge, therefore unconsciously using it as an anchor when estimating other persons’ knowledge. As a result, teachers might underestimate the difficulty that a problem will impose on a student, and overestimate students’ performance.

However, the ability to adequately assess the difficulty of tasks for students is a crucial aspect of teaching expertise. It is necessary for communicating efficiently with students as well as for adapting teaching behaviour in and outside the classroom (e.g. selecting problems for homework, lessons or exams). Teachers should be able to take a novice's perspective and judge task attributes independently of their own perception of difficulty or effortlessness (Helmke, Hosenfeld \& Schrader, 2004).

## Cognitive Load Theory

Cognitive Load Theory (CLT; e.g. Sweller, 2005; Sweller, van Merrienboer \& Paas, 1998) can help to understand how and why experts and novices differ in their perceptions of
task difficulty and how one could deal with these discrepancies.

Working Memory Capacity And Perceived Task Difficulty According to CLT, every learning process is associated with cognitive mental load. The extent, to which a learner experiences this mental load, depends on the degree of the learner's expertise regarding the subject. Experienced learners use already existing knowledge structures, so called schemas. Schemas serve as patterns that help to structure and integrate incoming information (Sweller, 1994). But often, new information is being processed that needs the learner's full working memory capacity. If cognitive schemas do not exist and yet have to be built, working memory, the capacity of which is limited, is loaded to a high extent.
Perceived task difficulty according to CLT should mainly be a function both of the intrinsic mental load imposed on the learner (i.e., the complexity or difficulty of a task) and the amount of extraneous mental load (i.e., the load induced by an ineffective instructional design of the task). Generally, extraneous load has been shown to be an important factor hindering effective learning (e.g. Paas \& van Merrienboer, 1994). Intrinsic load cannot be influenced, as it is inherent to the task itself and can only be moderated by the amount of a learner's prior knowledge. In contrast, extraneous load can and should be reduced. Once working memory is disburdened of extraneous load, more working memory capacity is available for understanding and schema acquisition.

Instructional Techniques Reducing Extraneous Mental Load Novice learners should be provided with learning material designed according to principles derived from CLT. The main principles are: integrated-format (Sweller, 2005), step-by-step-guidance (Kalyuga, Chandler \& Sweller, 2001) or worked examples (Renkl, 2005). Tasks following these design principles substantially reduce the amount of extraneous load imposed on the learner.
An integrated-format in task design as compared to a split-attention design (Sweller, 2005) facilitates learning, as the learner does not have to search and integrate relevant information by himself, before passing on to the solution. With this procedure, information is presented close to each other and allows for an easier processing. A step by step guidance (e.g., Kalyuga, Chandler \& Sweller, 2001) helps the learner to solve a problem without struggling to find all needed solution steps in a correct order. Instead, a processing guideline is given, leaving more working memory capacity available for the understanding of the single steps. Worked examples (e.g., Renkl, 2005), as compared to traditional problem solving techniques, consist of a problem, elaborated solution steps and the solution itself. Again, working memory capacity is free from extraneous load, as no potentially irrelevant trial and error processes are performed. This, once again, results in better schema acquisition and deeper understanding.

Expertise Reversal Effect It is important to emphasize that the effects of the just mentioned CLT principles are only prevailing with regard to novice learners. The positive learning outcome of material that is designed for novice learners may, in contrast, be reversed for experts. The guidance or additional information given by optimized learning material (from now on, the term optimized will be used with regard to learning tasks that are designed in favour of novice learners) can interfere with experts’ advanced cognitive structures and schemas that have already been built. Kalyuga (2007) named this phenomenon expertise reversal effect. He described that an optimized learning tasks is experienced as being more difficult to process and causes a redundancy effect, when presented to expert learners. This results in increased extraneous load and worse performance.
From this follows that the same learning material may cause reversed effects for novice and experienced learners. However, as experts may perceive optimized tasks as being more difficult than non-optimized tasks, they may also be subject to an expert blind spot when assessing the potential difficulty of the tasks for novice learners. This prediction is in line with Nickerson's anchoring and adjustment model (1999). Experts judge optimized learning material as being difficult to solve, use that judgement as an anchor for estimating novices’ performance and thus underestimate novices' performance on these tasks. The opposite is true for non-optimized items, resulting in an overestimation of novices’ performance.

Teachers as domain experts and educators should be knowledgeable of this expertise reversal effect and able to estimate the difficulty of tasks for students as novice learners independently of their own experienced mental load. In the present study we investigated whether this assumption is true for two groups of mathematics experts.

## Research Questions and Predictions

In the present study, we investigated whether pre-service as well as in-service mathematics teachers are subject to an expert blind spot when judging the difficulty of problems for students and whether the two expert groups differ in their estimations. Differences in estimations can be expected due to different levels of teaching experience. The tasks presented to the expert groups varied in instructional design according to CLT, but were comparable in complexity, thus keeping intrinsic cognitive load stable.

Following our theoretical assumptions, both pre-service and in-service teachers should use their expert knowledge as an anchor and underestimate the difficulty of the tasks for novice students in general.

1) Therefore, we predicted that both expert groups would generally overestimate the amount of tasks that novice students would be able to solve correctly (overestimation hypothesis).
An anchoring effect should manifest itself in highly correlated ratings of one's own perceived mental load and estimated task performance of novice learners.
2) Hence, we predicted that the correlation between the experts' self-rated mental load and estimated task performance of novice learners is significantly larger than the correlation between estimated student performance and students' actual performance (anchoring hypothesis).
Following expertise reversal effect, we further expected that the experts would experience less mental load when solving non-optimized than optimized tasks.
3) Consequently, the overestimation of novices' performance should be significantly larger with regard to non-optimized tasks as compared with optimized tasks (expertise reversal hypothesis).

## Method

## Participants

Thirty-four pre-service teachers majoring in mathematics (mean study time being 6.12 semesters, $S D=3.18$ ) and 13 in-service mathematics teachers (mean time of working experience being 12.85 years, $S D=9.13$ ) participated in the study. Two different expert groups were chosen to allow for possible conclusions regarding experience levels. Whereas pre-service teachers usually do not have school teaching experience, the amount of in-service teachers' teaching experience could become evident in their ratings of students performance.

Both expert groups’ estimations were compared to solution frequencies collected from $549^{\text {th }}$ grade high school students (mean age being $14.26, S D=.52$ ). All participants attended the study on a voluntary basis and received financial compensation.

## Study design

We used level of expertise (pre-service teachers vs. inservice teachers vs. novices) and the instructional design of the task (non-optimized vs. optimized mathematical problems) as independent variables. Dependent variables encompassed experts' perceived mental load and performance, their estimations of novices' performance and novices' actual performance on a number of mathematical tasks. Estimations were compared to students’ actual performance

## Instrument and measures

Two mathematics experts created ten tasks on algebra, geometry and trigonometry. To achieve a high level of curriculum validity, contents of the tasks were chosen to meet the requirements expected from pupils on that $9^{\text {th }}$ grade school level (e.g. calculation of area, theorem of Pythagoras, angular sum). Each task was designed in a nonoptimized and optimized version. Tasks without didactic optimization were adapted from mathematics problems currently used in school. Tasks optimization was achieved by using one of the following CLT design principles (the latter being the optimized design): either split-attentionformat vs. integrated-format; or traditional problem solving
vs. step-by-step-guidance; or traditional problem solving vs. worked examples. A task on angular sum, for example, was either designed with help of a diagram and angular degrees being spread over the working sheet making it difficult to match needed information, or presented with a diagram and angular degrees being close to each other (optimized; integrated format). So, whereas each task covered exactly the same mathematical problem (keeping intrinsic cognitive load stable), the design of the task (extraneous cognitive load) varied, allowing for the measurement of differences in mental load and performance due to task design.

Perceived mental load was assessed by the following question adapted from cognitive load literature: "How difficult did you find working on the task?", and measured on a six-point rating-scale ranging from "not at all difficult" to "very difficult".

Teachers' estimations of student performance were collected by using a prototype description of a fictional $9^{\text {th }}$ grade high school class: "Imagine that you are the teacher of a class with 30 students, all having different achievement levels; there are very good, average and very poor students. Now, you want to use the same task that you have just worked on for an exam. How many students of this class will presumably solve the task correctly?"

Participants' task performance was measured as the number of correctly solved tasks (the maximum score being ten). Each of the participants' solutions was rated by two independent mathematics experts as being correctly or falsely solved. When no accordance could be initially found, the two experts discussed their different ratings and agreed on one in a second step.

## Procedure

Each participant received a booklet with ten tasks. Five of the tasks were presented in a non-optimized version and five were presented in an optimized version, balanced within the booklet. Furthermore, each task presented in its nonoptimized version (e.g. angular sum, split-attention-format) had a corresponding item in its optimized version (e.g. analogous angular sum task, integrated-format), placed elsewhere in the booklet. Using this method, repetition effects by having the participants solving the same task twice were avoided, but still estimations based on both task designs were collected.

The participants solved each mathematical problem within a fixed period of time. The time constraint should prevent ceiling effects from occurring. Experts, given unlimited time to solve the tasks, perceive only little to no mental load, as enough working memory capacity is free for solving most tasks correctly, no matter which design is presented. Under these circumstances, an effect of task design on experienced mental load can no longer be detected (Paas, Renkl \& Sweller, 2003).

After having solved each task, participants rated their perceived mental load on a six-point rating scale. Then, they estimated how many students of the fictional $9^{\text {th }}$-grade class would be able to solve the tasks they have just worked on
correctly. After having finished the rating process, participants continued with the next mathematical problem. At the end, demographic data was collected.

## Results

In a first step, we compared pre-service teachers' and inservice teachers' perceived mental load and performance for both item types. For this purpose, each participant's ratings and performance data was aggregated (five for nonoptimized and five for optimized tasks) and then compared with a paired t-test.
In line with CLT, pre-service teachers experienced significantly more mental load when solving optimized ( $M$ $=2.33, S D=0.67$ ) than non-optimized tasks ( $M=2.11, S D$ $=0.58), t(33)=-2.08, p<.05$. However, pre-service teachers did not significantly perform worse on optimized ( $M=75.88 \%, S D=20.17 \%$ ) than on non-optimized tasks ( $M=78.82 \% S D=16.29 \%$ ), $t(33)=0.82$, ns.

In-service teachers experienced no significantly different degree of mental load for optimized ( $M=2.72, S D=0.72$ ) and non-optimized tasks ( $M=2.59, S D=0.94$ ), $t(12)=$ 1.13, ns. Also, performance for optimized ( $M=76.92 \%, S D$ $=17.97 \%$ ) and non-optimized tasks ( $M=73.85 \%, S D=$ 18.94\%) did not differ significantly, $t(12)=-.56$, $n s$.

In a second step, students' solution frequencies were analysed. In line with CLT, the $9^{\text {th }}$-grade students solved more optimized ( $M=51.11 \%, S D=26.51 \%$ ) than nonoptimized tasks ( $M=44.07 \%, S D=24.69 \%), t(53)=2.38, p$ $<.05$ (all performance data are presented in Figure 2).

Finally, performance data between the participant groups were compared in a repeated measures ANOVA. Both preservice $(F(1,86)=44.08, \mathrm{p}<.01)$ and in-service teachers $(F(1,65)=16.69, \mathrm{p}<.01)$ solved significantly more tasks than students did, whereas performance between the expert groups $(F(1,45)=.16, n s)$ did not differ significantly.

## Overestimation Hypothesis

To test the overestimation hypothesis, we computed difference scores. Students' real solution frequencies for each item were subtracted from pre-service and in-service teachers' estimations of how many students would be able to solve this corresponding task correctly. A positive difference score thus indicated an overestimation and a negative score indicated an underestimation. Each participant's difference scores were then aggregated for item type (five scores for non-optimized and five for optimized tasks) and used for further analysis.
As predicted, pre-service teachers overestimated students' performance both on non-optimized tasks, $t(33)=6.29, p<$ .01 , and optimized tasks, $t(33)=2.34, p<.05$ (one-sample t-test). However, in-service teachers’ general overestimation of student performance did not reach statistical significance both for non-optimized $(t(12)=1.21, n s)$ and optimized tasks $(t(12)=-.13, n s)$. Overestimation scores between the expert groups did not differ significantly, $F(1,45)=3.19$, ns. (estimation data for pre-service and in-service teachers are presented in Figure 2).

Figure 2: Pre-service teachers’ (P) and in-service teachers (I) performance and estimation of student performance and students' (S) performance as function of task design (\%)

## Anchoring Hypothesis

To test for an anchoring effect, we computed and compared Fisher z transformed individual correlations. Pre-service and in-service teachers' mental load ratings for each item were correlated with their estimation of student performance for that particular item. Further, the estimation of student performance for each item was correlated with students’ actual performance on that item. This procedure allowed analysing whether experts' estimations were closer to their perceived mental load or to students' actual performance. Experts' perceived mental load (as compared to experts' actual performance on each task) was used for the analysis. Whereas performance on a task cannot be determined immediately by the participants (as it remains unclear whether they solved a task correctly or not), mental load served as adequate and approximate measure of task difficulty. The individual correlations were aggregated (five correlations for non-optimized and five for optimized tasks) and then compared in a repeated measures ANOVA.

As predicted, results showed a significant difference between both correlation types, thus indicating an anchoring effect. Pre-service teachers' estimations of students' performance were significantly more strongly correlated with own perceived mental load than with students' actual performance, $F(1,33)=169.45, \mathrm{p}<.01$. A very similar pattern was found for in-service teachers' correlations, $F(1,12)=35.64, \mathrm{p}<.01$ (correlation coefficients for both expert groups are depicted in Figure 3). It can be concluded that both expert groups used their own perceived mental load as an anchor to estimate the difficulty that the tasks would impose on the students.

Figure 3: The anchoring effect in both expert groups

## Expertise Reversal Hypothesis

As predicted by the expertise reversal hypothesis, both expert groups' overestimations were moderated by the instructional design of the tasks. Pre-service teachers’ overestimation of student performance was significantly larger for non-optimized ( $M=15.88 \%, S D=14.74 \%$ ) than optimized tasks ( $M=7.15 \%, S D=17.81 \%$ ), $t(33)=4.21 ; p$ < .01. Also, in-service teachers' overestimation was significantly larger for non-optimized ( $M=5.63 \%$, $S D=$ 16.82\%) than optimized items ( $M=-.62 \%, S D=16.77 \%$ ), $t$ (12) $=2.54 ; p<.05$ (see Figure 2 for mean scores). Both expert groups seem to have failed to take into account the benefits of didactic optimization of the learning material for novice learners. As was already described in the "Overestimation Hypothesis" section, differences in overestimation scores did not to reach statistical significance for both expert groups.

## Discussion

In the present study, we investigated whether pre-service and in-service mathematics teachers are subject to an expert blind spot, when judging the difficulty of tasks for students. The tasks were designed in accordance with didactic principles derived from CLT, which have differential effects on the learning outcome of experts and novices. Whereas novice learners experience a relief from extraneous mental load when being presented optimized learning material, thus having more working memory capacity available for schema acquisition and therefore performing better on those tasks, the opposite is true for expert learners. These learners, being presented with optimized tasks, experience increased extraneous mental load (due to a redundancy effect) and judge those tasks not only as being more difficult to work on for themselves, but also as being more difficult to solve for novice learners. The reason for this misjudgement lies in an anchoring effect, as experts generally use their own knowledge base and estimations as ground for judging the difficulties that other persons (in this case: novices) may have. To test these assumptions, experts' mental load ratings while working on mathematical tasks and their estimations of novice performance were compared to real solution frequencies obtained from novices.

Results indicate an egocentric bias, as the experts' general estimations for student performance were highly correlated with their own experienced mental load. Especially, the overestimation of students' task performance was significantly larger for non-optimized than optimized items,
indicating an expert blind spot that can be interpreted in terms of an expertise reversal effect. Experts failed to adequately take into account the beneficial or detrimental effects of didactical variation in task design. Rather, they judged both non-optimized and optimized mathematical tasks as being equally difficult for students, which in fact was not the case in our student sample.

However, only pre-service teachers’ general overestimation of student performance was significant, whereas in-service teachers' overestimation failed to reach statistical significance. Relating to Nickerson's (1999) anchoring and adjustment model, in-service teachers seem to have a more accurate mental model of students' knowledge than pre-service teachers do. Teaching experience seems to have had a debiasing effect on an egocentric bias, thus resulting in better judgements of student performance.

Nevertheless, there are certain limitations to the present study. The first one concerns the yet small sample size of inservice teachers compared to pre-service teachers. The results obtained so far should be further consolidated by equalizing sample sizes for both expert groups, thus allowing for a better comparability and generalizability. This would allow for a detailed analysis of the variability in teaching experience between in-service teachers and its effects on the estimations of student performance. Also, though in-service teachers showed no different estimation pattern for both item types than pre-service teachers do, the overall level of overestimation was a different one. With a bigger sample size, this issue could be further investigated and possible influencing variables could be detected.

Another limitation concerns the actual level of expertise in both teacher groups. As presented in the results section, pre-service and in-service teachers solved significantly more tasks correctly that students did. This allows the conclusion that both teacher groups have more specialized knowledge as compared to students and can indeed be called experts. Also, it is not necessarily surprising that pre-service teachers, not yet having gained teaching experience and being presented with learning tasks obtained from school books, do not solve the mathematical tasks in large part. However, it remains unclear why in-service teachers with a high level of specialized knowledge as well as teaching experience only show similar performance rates on the mathematical problems instead of solving almost all of them correctly.

Finally, the present study does not allow for a detailed insight into participants' estimation processes. After having rated each mathematical task, participants had the opportunity to answer an open-format question and give additional information on what they thought made each tasks difficult or easy. This possibility was barely used, thus not allowing for any further insights into participants' cognitive processes while judging the difficulty of the tasks for students.

Future research will address the just mentioned issues and explore ways in which teachers' ability to see the difficulty
of tasks from a student's perspective can be improved and be emphasized already in teacher education. To the authors' knowledge, no research so far has examined experts estimations of novices' performance using instructional design principles derived from CLT. Subsequent studies with different participant groups shall shed more light on anchoring and adjustment processes in experts. Experts’ cognitive processes while solving the mathematical tasks shall be further investigated. Also, longitudinal designs could be conducted in order to analyse effects of intervention programs on teachers' perception of learning material.

# The Recognizability of Authenticity 

Madeleine Henderson (madeleine.henderson@gmail.com) and Liane Gabora (liane.gabora@ubc.ca)<br>Department of Psychology, University of British Columbia<br>Okanagan Campus, 3333 University Way, Kelowna BC, V1V 1V7, CANADA

#### Abstract

The goals of this research were to (1) determine if there is agreement both amongst viewers, and between viewers and the performer, about the extent to which performances are authentic, and (2) ascertain whether or not performers and/or viewers can distinguish between authenticity and skill. An authentic performance is one that is natural or genuine, while an inauthentic performance feels faked, forced, or imitative. Study participants were asked to rate the authenticity and skill level of a series of videotaped performances by dancers and stand-up comedians. Performers also rated their own performances. Authenticity ratings amongst viewers were significantly positively correlated. Ratings between viewers and performers were not significant but all positive. A higher correlation between ratings of both authenticity and skill of performances for viewers than for performers suggests that viewers make less of a distinction between authenticity and skill than performers. The relationship between authenticity and creativity is discussed.

Keywords: authenticity; comedy; creativity; dance; expertise; fake; genuine; individual differences; performance; skill.

## Introduction

With increasing frequency there are calls for research aimed at a synthetic account of how the components of a cognitive system function in synchrony to generate behavior in everyday situations. We propose that the construct of authenticity has an important role to play in such an account. Authenticity refers to the ability to be genuine, to accurately reflect who one really is, and be true to the situation one is in. Writers speak of discovering one's own authentic voice. In theatre research the term 'authentic' is used in discussion of the extent to which a performer gives a performance something personal that goes beyond the script (Lavy, 2005). In the dance community the term 'authentic movement' refers to the strengthening of identity through uninhibited movement of they body in a social context (Goldhahn, 2009). In an area at the intersection of anthropology and tourism research, the term 'authenticity' is used to refer to the extent to which current creative works in a given genre, such as Native American or First Nations art or dance, employ the same tools, techniques, styles, and so forth, as were traditionally used (Daniel, 1996; Maruyama et al., 2008). Thus an authentic performance is one that seems natural, or true to an underlying essence, while an inauthentic performance feels faked, forced, or imitative.

Authenticity is important for many reasons. It feels highly gratifying to both the performer and the observer. It is relevant to many domains of life, including the generation of artistic works and performance (e.g., art, acting, music, and dance), non-artistic performances (e.g., teaching and
newscasts), and everyday social interactions with friends and family. However, despite that performers, viewers, and the general public regularly voice opinions about authenticity, and despite that in the scholarly community authenticity is assumed to be a genuine construct about which viewers and performers are in agreement (e.g., Goldhahn, 2009; Kogan, 2002; Lavy, 2005; McClary, 2007; Nemiro, 1997; Sawyer, 1992; Warja, 1994), we were unable to locate any empirical research that supports this assumption. Indeed we found no empirical evidence for consensus as to which performances are authentic and which are not, either amongst members of an audience, or between a performer and an audience.

## Authenticity and Skill

Audiences without artistic expertise emphasize skill over originality in assessments of visual art, while the reverse is true for audiences with expertise (Hekkert \& van Wieringen, 1990a, 1990b, 1996). This suggests that originality-which might be related to authenticity-can be confused with skill. However, there is evidence that skill and authenticity are distinct constructs (Kogan, 2002). While being skilled in a domain may facilitate authentic performance, it does not guarantee it, nor is it a necessary prerequisite. For example, a dancer may have perfected her craft, and be technically skilled, permitting a wide range of means for selfexpression, but not immerse herself in the work, or simply imitate the instructor, yielding a performance void of authentic style. Conversely, a performer lacking in technical skill may exude personality or detectable "creative release", yielding a performance that comes across as authentic. In short it remains an open question whether viewers confuse a skilled performance with an authentic one.

## Goals of Current Study

Although it would be difficult to pinpoint the potentially myriad factors that contribute to authenticity or a lack of it, it is possible to make headway toward determining whether authenticity is a genuine construct by assessing the extent to which viewers of a performance, and performers themselves, agree in their assessments of authenticity. Thus a first goal of this study was to determine if there is a correlation amongst viewers' assessments of the authenticity of a given performance. A second, related goal was to determine whether there is a correlation between viewers' assessment of the authenticity of a performance and the performer's self-assessment of the authenticity of that performance. We hypothesized that an audience can detect an authentic or inauthentic performance, and that
performances that feel authentic to a performer come across as authentic to an audience, and vice versa.

A third goal was to determine whether authenticity and skill are distinct constructs in the eyes of the performer and/or viewers. Since it is possible to be skilled but perform in an inauthentic manner, or to perform authentically but not be skilled, we hypothesized that both performers and viewers could distinguish between the two constructs.

A final goal was to determine what factors facilitate authentic performance. Previous research on this is inconclusive (e.g., McClary, 2007; Nemiro, 1997; Rhodes, 1999; Sawyer, 1992; Warja, 1994). By asking performers open-ended questions about authenticity we hoped to shed light on this seemingly elusive phenomenon that would pave the way for further studies of the relationship between authenticity and the therapeutic value of creative endeavors.

## The Study

## Participants

Three trained dance performers were recruited from a local dance studio. Dancer A was 25, Dancer B was 29, and Dancer C was 23. Each dancer had between 10 to 12 years of dance experience, and took part in dance at least once per week. Each trained dancer was paid $\$ 30$ for their participation in the study. They met with the experimenter for a video recording session of three hours duration. A four year old child with no formal dance training was also recruited as a dance performer.

Three comedians were also recruited for the study. The first was a 36-year old experienced stand-up comedian with eight years of stand-up comedy experience. He was located from a local directory. The second was a 24 -year old amateur stand-up comedian who had just started doing stand-up comedy one month prior to the study. She was recruited through a psychology of humour class at The University of British Columbia. The third was a 23 -year-old 'social comedian' known to the experimenter. He had no stand-up comedy credentials, but had years of experience being the center of attention for his humour in social situations. None of the comedians were compensated for their participation.

158 University of British Columbia undergraduates were viewers of the performances. 45 were recruited through the SONA system, which enables participation in university research in exchange for credit in a psychology class. 50 students were recruited through psychology of creativity and psychology of humor classes. They were not given incentives to participate. The remaining participants were recruited through online university class message boards, and were also not given incentives to participate. The only exclusion criterion was severe visual impairment, such as blindness. Females accounted for approximately $58.2 \%$ of the sample ( $\mathrm{n}=92$ ) and males accounted for the remaining $41.8 \%(\mathrm{n}=66)$. Most $(83.1 \%, \mathrm{n}=128)$ were between the ages of 17-25, and in a Bachelor of Arts $(64 \%, n=96)$ program.

## Procedure

The experienced dancers were filmed practicing original choreographed dance routines in their dance studio. They were told that the study was about the psychology of movement. They met at the dance studio one hour prior to filming to learn two different modern dance routines. Both routines were choreographed to music and lasted one to two minutes in duration. For one, the music was a quick, highenergy piece, while for the other it was slow and sombre.

After the hour-long practice, each dancer individually performed the fast dance five times. After all dancers had finished, they individually performed the slow dance five times in the same order as the first. Each dance performance was videotaped using a high-definition video camera.

Once the first dancer had completed all her dances, she was directed to a laptop where footage of her routines was uploaded. She was debriefed about the specific reasons for conducting the study, and given a definition of authentic performance. She was then asked to watch her own ten performances in the order in which they were performed, and given a questionnaire with the following items based on each performance:

> Please rate how authentic you felt this performance was based on how you felt you were coming across or how you felt inside during the performance" (Not authentic at all / Somewhat authentic / Neutral or Don't know / Quite authentic / Very authentic)

How would you rate your performance in regards to technical skill?" (Very poor / Poor / Okay / Good / Very good)
This was repeated for the other dancers. All dancers were also asked to fill out an open-ended portion of the questionnaire, which asked the following questions concerning factors that facilitate or hinder authenticity:
(1) Do you feel as though authenticity and technical skill are the same thing or different concepts? Please explain.
(2) Are there particular situations or environments in which you are able to produce your most authentic performance? If so, please tell us about it.
(3) Do you believe that people become more able to find their authentic style with experience?
(4) Was there a known time in your career where you felt that you had made a transition to being more able to express yourself? If yes, describe that transition.

The child dancer was filmed using a high-definition video camera in her home. Filming began when she spontaneously began dancing to upbeat dance music. The camera was not hidden from view and the child was aware she was being filmed. The footage was divided into two video clips of two minutes each. Due to her age, she was not asked to assess how authentic or skilled her performances were, nor to respond to the open-ended questions.

The experienced stand-up comedian was asked to submit between five and ten previously taped performances that he had acquired over his career. We requested that each video clip be under two minutes duration, and that together they
portray a range of authenticity. He was also asked to rate the authenticity and skill of each performance using the same five-point Likert scale administered to the dancers. He submitted six videotaped live performances and his ratings for each.

Video footage was collected from the amateur stand-up comedian without an audience (except for the experimenter). She was asked a series of questions that would potentially promote humourous responses, such as "what was your most embarrassing moment?" or "what is the strangest thing you have seen on campus?" She was also asked to run through segments of her stand-up routine which were narrative in nature, tell funny jokes (not necessarily her own), or make up funny stories and deliver them as though they were real. After approximately 30 minutes of recording, she was asked to look through the footage on a laptop and rate the authenticity and skill of each joke/story segment on the five-point Likert scale. Video footage of the social comedian was collected in the same manner as with the amateur stand-up comedian.

The video clips were loaded onto an online questionnaire using www.surveymonkey.com with the exception of those from Dancer C. Her performances were omitted due to extreme homogeneity in her responses to the Likert items. (Since her performances did not exhibit variation in selfrated authenticity, they were not useful for this study.) Her responses to the qualitative questions were retained.

Viewers were given the following definition of authenticity:

> Authenticity in the performing arts commonly refers to the ability of a performer to perform in such a way that they are able to remain true to who they really are or to the character they are trying to play. Conversely, a performer who is not performing authentically is merely giving a performance that seems artificial or imitated.

Viewers were asked whether they felt they understood the construct of authenticity, and if they did not, further discussion ensued until it was clear to them what authenticity refers to. After each video clip, viewers were required to rate it on the same five-point Likert scales that the performers used. In order to minimize potential order effects, the ordering of the performances was randomly altered every time ten students had completed the survey. Video clips belonging to the same performer were kept together, but the order of the performers and the order of the clips belonging to each performer were randomized.

The students who were recruited from the psychology of creativity and psychology of humor classes were shown the video clips on a projector screen, and they received a paper version of the questionnaire. They were given 30 seconds to rate each performance before the next one commenced. The type of psychology class and the week in which the study was conducted determined the types of performances that were shown. For example, the psychology of creativity class was approached earlier in the study, and was shown the clips of the dancers and the experienced stand-up comedian because these performances were the only ones available at
that time. The psychology of humour class saw only the comedians' performances because dance performances were not relevant to the class content.

## Analysis and Results

The means and standard deviations for the authenticity ratings of the performances are given in Table 1. The highest authenticity ratings were for the dancing child ( $M=$ $4.52)$ and the social comedian $(M=4.05)$.

Table 1: Mean authenticity ratings by viewers and performers for all performances.

| Performer | Viewer ratings <br> $M($ SD $)$ | Performer <br> Self-ratings |
| :--- | :--- | :--- |
| Experienced stand- <br> up comedian | $3.68(1.07)$ | 3.33 |
| Amateur stand-up <br> comedian | $3.19(1.31)$ | 2.50 |
| Social comedian | $4.05(1.08)$ | 4.33 |
| Dancer A | $3.18(1.12)$ | 3.80 |
| Dancer B | $3.27(1.18)$ | 3.30 |
| Dancing child | $4.25(1.01)$ | $\mathrm{N} / \mathrm{A}$ |

## Recognizability of Authenticity

Between-Viewer Ratings To determine whether the viewers agreed as to which performances seemed authentic, the intraclass correlation coefficient $\left(R_{i}\right)$ was calculated. The $R_{i}$ statistic is more appropriate for this study than the widely-used Pearson product moment correlation because the latter ignores the extent to which independent raters agree on any single rating (Cicchetti, 1991). The $R_{i}$ coefficients for the extent of agreement amongst viewers about the authenticity of the performances of each performer are presented in Table 2. All values are statistically significant at the .05 level with the exception of those for Dancer A, and they are all statistically significant at the .01 level with the exception of those for Dancer A and the dancing child.

Table 2: Agreement of authenticity amongst viewers $\left(R_{i}\right)$, and between viewers and performer $(r)$.

| Performer | $\boldsymbol{R}_{i}$ | $r$ |
| :--- | :--- | :--- |
| Experienced stand-up comedian | $.965^{* *}$ | .712 |
| Amateur stand-up comedian | $.890^{* *}$ | .120 |
| Social comedian' | $.858^{* *}$ | .609 |
| Dancer A | .340 | .061 |
| Dancer B | $.879^{* *}$ | .520 |
| Dancing child | $.822^{*}$ | $\mathrm{~N} / \mathrm{A}$ |

${ }^{*} p<.05 ; * * p<.01$

Agreement Between Viewers and Performers. To determine if there was agreement between viewer and performer ratings of authenticity, we merged the multiple viewer ratings to obtain the average composite rating for
each performer. A Pearson product moment correlation was conducted to see if the composite rating is in agreement with the performer's ratings of authenticity. These values are also presented in Table 2.

The highest agreement was between the viewers and the experienced stand-up comedian, followed by the social comedian, Dancer B, the amateur stand-up comedian, and Dancer A. There was considerable variation amongst the performers with respect to the degree to which their assessments of the authenticity of their performances were correlated with the viewers' assessments. While none of the correlations were statistically significant, all were positive. Moreover, significance was based on a small number of performances for each performer. The lack of power from the small $n$ 's indicates that the significance tests were highly prone to type II errors (failure to find a significant difference when one exists). In such situations it may be prudent to focus on the magnitude of the observed effect or relationship instead of the significance tests (Gliner, Leech, \& Morgan, 2002; Serline \& Lapsey, 1993; Wilkinson \& the APA Task Force on Statistical Inference, 1999).

Qualitative Results. To better understand what factors facilitate the expression of authentic creative style we conducted a content analysis of the open-ended questions. There were recurring responses as well as individual differences. Responses to the question, "Is the development of an authentic voice related to experience?", suggest that experience facilitates the development of authentic style, but that this happens differently for different performers. Compare the responses of two dancers:

Experience is what helps one explore his or herself to
discover what authenticity means for them. discover what authenticity means for them.

I have found that by taking a number of different dance styles with a number of different instructors that I have developed (and continue to develop) my own personal style. The more experience that I've gained the more comfortable I've become with myself and my movement and the more ideas that I can "pull out of my hat".

The performers put forward several factors that interfere with the authenticity of their performances: excessive focus on technical perfection, performing in front of large audiences, or audiences that include friends or acquaintances, performing while injured or tired, performing content that is unfamiliar or that does not "lean towards [one's] natural expression", and working with a choreographer that has a different style. The performers also put forward many factors that enhance with the authenticity of their performances. The most commonly cited factor was feeling safe from judgment. Other factors were being in a performing mood, feeling inspired, and teaching choreography. Interestingly, while some performers claimed that having an audience increases the authenticity of their performance, others claimed that it has the opposite effect.

## Distinguishing Authenticity from Skill

Quantitative Results. There was a modest but significant Pearson correlation between mean ratings of authenticity and mean ratings of skill as assessed by viewers. The Pearson correlation for the performers' mean ratings of authenticity and skill was lower but significant. These results are presented in Table 3. Thus although authenticity and skill appear to be related for both performers and viewers, performers made a stronger distinction between them than viewers.

Table 3: Pearson correlation between mean ratings of authenticity and mean ratings of skill $(r)$.

|  | $r$ |
| :--- | :--- |
| Viewers | .641 |
| Performers | .547 |

${ }^{*} p<.001$
Qualitative Results. The qualitative data indicates that the performers unanimously view authenticity and skill as distinct concepts. For example:

Technical skill - is where you learn how to move and hold yourself properly for the desired discipline. Authenticity - is the feeling and expression that you can add to your technical skill to create the "entire picture".

Anybody can master technical skills with enough practice but if you don't have charisma as an artist - or better yet as a stand-up comedian, people won't think you're very funny.

Responses suggested that skill can facilitate authenticity:
Technical skill opened the door of possibilities for me to further express my emotions.

Once I know how to do a proper "plie" and the barre, it is much easier for me to add some expression or feeling because I'm not thinking nearly as much about how the plie should be done and can focus on making it look "pretty."
However, one performer's answers suggested that acquiring skill may interfere with authenticity:

> Sometimes a lot of technical training can make it difficult for the dancer to separate their own authentic style from the teachers. It all comes down to how they have been trained, if their teacher demands uniformity and discourages personal exploration it will be harder. If they have a good teacher who knows how to pull out creativity and massage it, then the experience will benefit their discovery of an authentic style.

The performers claimed that skill can facilitate authentic performance by freeing them from concern with technical details so they could be more fully immersed in the creative process. A preoccupation with skill, however, can prevent a performer from reaching a deeper connection with the task. These qualitative responses, in conjunction with the quantitative results, support the hypothesis that authenticity and skill are related, yet distinct concepts.

## Discussion

The results of this study shed light on the seemingly elusive construct of authenticity. The agreement amongst viewers as to which performances were authentic, a result obtained across a variety of performance types and situations, suggests that authenticity is indeed a real concept as opposed to existing in the eye of the beholder.

The variability in the correlations between authenticity ratings for viewers and performers indicate that when a performance feels authentic to a performer it may or may not come across that way to others. This was addressed by one of the dancers, who noted:

> Some people have very 'quiet' personalities so when they are authentically displaying anger they might be so quiet about it [that] an audience would not see it. Those dancers might be rated 'less authentic' because they are less obvious.

This comment suggests to us that the reason for the low agreements between the amateur stand-up comedian and Dancer A and the viewers is that outward manifestations of their personalities may be subtle for the viewers to detect them. Analyzing how the personality of an artist interacts with the recognizability of authenticity in performance is an interesting direction for future research.

Although the variety of performance types and settings contributed to the generalizability and ecological validity of the findings, caution must taken in drawing conclusions that involve comparisons across performers or performance settings, because differences such as 'in a studio' versus 'at home' could be potential confounds. With this warning, we offer some speculative discussion of between-performer differences. There are several possible explanations for the high agreement amongst viewer authenticity ratings of the experienced comedian. First, over time he may have solidified a strong authentic voice that is readily detectable when present, making an inauthentic performance stand out in contrast. Second, his performances were the only ones that were filmed before he knew he would be rated. Some research indicates that the pressure of knowing one is going to be evaluated can inhibit creative expression (Nemiro, 1997; Rhodes, 1999), so it is possible that the rest of the performers who knew they were going to be evaluated gave performances that were more uniform with respect to authenticity, giving viewers less opportunity to detect differences amongst performances. It would be interesting to investigate whether expertise can entail becoming skilled at faking authenticity, i.e., whether there exist performers for whom expertise is inversely correlated with agreement between performer and viewer authenticity ratings.

The dancing child's high authenticity ratings may reflect in part the stereotype that children are authentic in whatever they do. However, the fact that the social comedian's performance was also rated as highly authentic suggests that these high ratings reflect instead the spontaneity of their performances. While the other performers' performances (though to a lesser extent the amateur comedian) were choreographed or scripted, those of the child and social
comedian were not. This interpretation is consistent with findings that freedom facilitates authenticity (McClary, 2007; Nemiro, 1997; Sawyer, 1992; Rhodes, 1990, Warja, 1994). This explanation is further reinforced by the fact that the experienced stand-up comedian's highest rated performance for authenticity was the only one in which he was forced to improvise (due to verbal feedback from the audience). This points to a weakness of the study. Since most performers knew they would be judged, they may have been less able to release inhibitions and be authentic. Another weakness is that because dancers were confined to rehearsed, choreographed routines, differences between performances of the same dance may have been too subtle for viewers to detect, thus limiting the range of authenticity scores. Future studies will focus on spontaneously improvised performances, which allow authenticity to be expressed through content as well as delivery.

Another direction for future research is to investigate whether there is a difference in the capacity to detect authenticity in live versus videotaped performances. Previous research indicating that there is a constant interaction between a performer and a live audience (Arnold, 1991; Bindeman, 1998; Nemiro, 1997) suggests that viewers may be better able to detect cues or indications of authenticity from a live performance than from a performance on a television or computer screen.

This study of authenticity arose in the context of an interest in what factors affect how the various components of a cognitive system come together to produce overt thought and behavior. It seemed reasonable that an authentic response is one that genuinely reflects the state of one's associative network, including not just one's internal model of the world (including self-understanding) but one's way of seeing and being. We refer to this dynamical structure as a worldview (Gabora, 1999, 2000, 2001). We speculated that: (1) authenticity entails being entirely present and thereby available to detect unresolved questions or issues, and open to change, (2) a lack of authenticity may indicate that elements of one's worldview are repressed or misrepresented because this interferes with the capacity to detect unresolved questions or issues, and be open to change, (3) authentic performance facilitates the process by which one's worldview self-organized into more stable state, while unauthentic performance does not. However, before we could address these issues it was necessary to address the more fundamental question of whether authenticity is a real construct.

The findings reported here, and in particular the key finding that authenticity is recognizable, opens up many questions and perspectives. It led us to speculate that perhaps one is being creative even when not engaged in an overtly creative activity if one responds to a new situation or emotion in a way that authentically reflects how it affects ones' worldview. This is consistent with the honing theory of creativity, according to which creative behavior arises because one's worldview tends to self-organize in response to perturbation to achieve a more stable state, regain
equilibrium, or resolve dissonance (Gabora, 2005; Gabora, Ranjan \& O'Connor, 2012). The creative product or performance is viewed as an external reflection of this internal transformation. This conceptualization of creativity is consistent with the anecdotal evidence obtained in the qualitative portion of this study that authentic performance can be therapeutic. It is also consistent with the notion that personal performance style is the result of inner transformations (Kogan, 2002) and the view that creative performance involves interaction and tension between the creator's conscious and subconscious which impact the creator's identity (Sawyer, 1992).

#### Abstract

Tutoring gives tutors the opportunity to engage in interactive strategies that help them to assess a tutee's understanding. However, tutors without teaching experience often do not engage in interactive strategies and, thus, have difficulty with accurately assessing a tutee's understanding. We conducted an experiment with 39 tutor-tutee dyads to test whether tutors who received training in interactive strategies would become more interactive and more accurate in assessing a tutee's understanding. Results showed that trained tutors provided a more interactive style of tutoring than untrained tutors. However, due to being more interactive, trained tutors produced less accurate assessments than untrained tutors. This suggests that changing the style of tutoring to implement interactive strategies puts a high burden on a tutor's cognitive capacity. Hence, there is obviously little cognitive capacity left that could be used to assess a tutee's understanding. Training methods that automate strategy use might enhance a tutor's assessment accuracy.

Keywords: one-on-one human tutoring; training; tutoring interactions; assessment accuracy

## Introduction

In one-on-one tutoring, tutors have the possibility to engage in interactive tutoring strategies such as asking questions or providing hints. When a tutee responds to a tutor's interactive tutoring strategies, for example, by answering a question, a tutor can learn what a tutee does and does not know (Chi, 2009; Hmelo-Silver \& Barrows, 2006). Thus, in the course of tutoring, a tutor has the opportunity to collect a multitude of information that can be used to summatively assess a tutee's understanding after tutoring session. This summative assessment may also help a tutor to prepare the next tutoring session by choosing material that is suited to a tutee's individual level of understanding (e.g., Chi, Jeong, \& Siler, 2004; Kalyuga, 2007; cf. also the discussion of the
concept of interim assessments for the school context by Perie, Marion, \& Gong, 2009).

However, research has shown that inexperienced tutors, that is, tutors who are not trained in teaching (Chi et al., 2001; Graesser, D'Mello, \& Cade, 2011), often do not engage in interactive tutoring strategies. Instead, they frequently dominate tutoring by providing lengthy explanations (e.g., Chi et al., 2001; Cromley \& Azevedo, 2005). In addition, inexperienced tutors regularly fail to assess a tutee's understanding accurately (Chi et al., 2004; Herppich et al., 2013b).

Against this background, we conducted an experimental study to test whether inexperienced tutors who received training in interactive tutoring strategies would be able to implement an interactive style of tutoring. We were interested in whether a more interactive style of tutoring would benefit a tutor's assessment of a tutee's understanding after tutoring.

## Tutoring Strategies of Experienced and Inexperienced Tutors and Their Influence on Assessment

In contrast to inexperienced tutors, experienced tutors are trained or experienced in teaching (cf. Cromley \& Azevedo, 2005; D'Mello et al., 2010; McArthur, Stasz, \& Zmuidzinas, 1990). Research shows that experienced tutors tend to provide a different style of tutoring than do inexperienced tutors. More specifically, experienced tutors more often engage in interactive tutoring strategies than inexperienced tutors. For example, they frequently scaffold a tutee by providing hints or asking questions (Cade et al., 2008; Chi, Roy, \& Hausmann, 2008; Cromley \& Azevedo, 2005). Scaffolding is a genuinely interactive tutoring strategy because it elicits constructive responses from a tutee (Hmelo-Silver \& Barrows, 2006). In this vein,

Herppich et al. (2013a, 2013b) found that experienced tutors caused tutees to utter more knowledge deficits, that is, incomplete beliefs, incorrect beliefs, or misconceptions, in the course of tutoring than inexperienced tutors. In addition, experienced tutors were more accurate in assessing a tutee's understanding after tutoring than inexperienced tutors. The results suggest that a tutee's uttered knowledge deficits are diagnostically informative because they indicate what a tutee does not know (cf. Chi, et al., 2004; Cromley \& Azevedo, 2005). Thus, tutors might derive information from these knowledge deficits that can be used to assess a tutee's understanding after tutoring.

## Training Inexperienced Tutors

To test whether training inexperienced tutors in interactive tutoring strategies would improve their style of tutoring, we developed a training method that aimed at prompting inexperienced tutors to abstain from giving lengthy explanations and, instead, to engage in more interactive tutoring strategies such as scaffolding (cf. Chi, et al., 2008). As a result of implementing more interactive tutoring strategies in the course of tutoring, tutors were assumed to more intensively engage in collecting diagnostically relevant information that could be used to assess a tutee's understanding after tutoring.

Based on what is known about effective training methods in the domain of learning strategies (Mandl \& Friedrich, 1992), the development of our training method was guided by several principles. First, training methods should inform about the advantages associated with the strategies targeted in the training. Second, training methods should directly convey knowledge about the strategies that need to be trained. Third, training methods should help to practice the targeted strategies (Klauer, 1988; Mandl \& Friedrich, 1992). Research has shown that training methods that are in accordance with these principles are particularly effective (Dignath, Buettner, \& Langfeldt, 2008; Leutner, Leopold, \& Elzen-Rump, 2007).

By now, little attention has been given to training methods that aim at fostering an interactive tutoring style in the service of improving assessment accuracy. However, existing research on training tutors with the aim of enhancing a tutee's learning has well documented that tutors are often able to spontaneously implement the strategies that are targeted in training. Yet, tutors have difficulty with changing their style of tutoring in the long run (King, Staffieri, \& Adelgais, 1998). Moreover, even though tutors are able to change their tutoring strategies, this might not necessarily increase the effectiveness of tutoring (Chi et al., 2001). In their review on tutoring-based instruction, Graesser et al. (2011) summarized research on tutor training in the following way:
...it is difficult to train tutors to adopt particular strategies. They rely on their normal conversational and pedagogical styles.... it is difficult to force the human tutors to adopt changes in their language and discourse,
particularly those levels that are unconscious and involuntary. (p. 422).

## Hypotheses

In this study, we tested the effectiveness of a training method that aimed at helping tutors to implement a more interactive style of tutoring. We addressed the following hypotheses:

1) Trained tutors engage in more interactive tutoring strategies in the course of tutoring than untrained tutors.
2) Trained tutors are more accurate in assessing a tutee's understanding after tutoring than untrained tutors.
3) The more interactive style of tutoring explains why trained tutors are more accurate than untrained tutors in assessing a tutee's understanding after tutoring.

## Method

## Sample and Design

A total of $N=39$ dyads of tutors and tutees participated in the experiment. The topic of tutoring was the human circulatory system. All tutors were university students majoring in biology with a mean age of 22.38 years ( $S D=$ 2.47). Thirty-five tutors were female and 4 tutors were male. Twenty tutors received training in interactive tutoring strategies (= trained tutors), whereas 19 tutors received no training (= untrained tutors). As indicated by a multiplechoice test, all tutors had sufficient knowledge about the human circulatory system. There was no significant difference in knowledge between trained tutors ( $M=8.45$, $S D=2.26)$ and untrained tutors $(M=8.26, S D=1.78), F(1$, 37) $=0.81, p>.05, \eta^{2}<.01$ (small effect). Moreover, trained (mean rank $=18.88$ ) and untrained tutors (mean rank $=21.18$ ) did not differ in their previous experience in providing tutoring, coded as $1=$ no experience, $2=$ sporadic tutoring, $3=$ regular tutoring, $U=167.50, z=-0.69, p>$ $.05, r=-.11$ (small effect). Tutees were seventh-grade students from the middle track of the German school system (i.e., from Realschulen). Of the tutees, 9 were female and 29 were male; one tutee did not indicate gender.

Tutors were randomly assigned to the two experimental conditions (training vs. no training) and tutees were randomly assigned to tutors. The dependent variables in this experiment were the extent to which a tutor elicited knowledge deficits from a tutee in the course of tutoring and the accuracy with which a tutor assessed a tutee's understanding after tutoring.

## Materials

Textbook Passage (Tutees and Tutors) In the tutoring session, the tutor-tutee dyads engaged in a dialogue based on a passage about the human circulatory system. We adapted this passage from the study by Chi et al. (2001). The passage consisted of 59 sentences and each sentence was printed on a separate sheet of paper. The sentences were presented to the tutor and the tutee in a ring binder.

Concepts Test (Tutees and Tutors) We used a shortened version of a test that was employed by Herppich et al. (2013b). This shortened version consisted of 16 multiplechoice items that assessed a tutee's understanding of concepts about the human circulatory system. For example, it included the following item: What is the task of the heart in the human organism? (1) The heart pumps the blood. (2) The heart cleans and filters the blood. (3) The heart supplies the blood with oxygen. (4) Don't know. The items of the original test were adapted from tests developed by Sungur and Tekkaya (2003) and by Michael et al. (2002) or constructed on the basis of the literature on misconceptions of the human circulatory system (e.g., Pelaez et al., 2005). A correct answer indicated a scientifically correct understanding of the concept. Each of the incorrect answers indicated a specific type of incorrect understanding of the concept. Hence, a tutee could achieve a maximum number of 16 points in the concepts test.

To examine the accuracy with which the tutors assessed a tutee's understanding of the human circulatory system after tutoring the tutors were also administered the test.

Training in Interactive Tutoring Strategies (Trained Tutors) The trained tutors received training in interactive tutoring strategies. The training took about 45 minutes and was presented on a computer screen. The training aimed at helping the trained tutors to adopt interactive tutoring strategies that would enable them to elicit knowledge deficits from a tutee. The training consisted of two building blocks. In the first building block, the trained tutors were informed about the problem that tutors often are not interactive and, thus, cannot accurately assess a tutee's understanding (Brown, Campione, \& Day, 1981). Subsequently, the trained tutors were provided with information about three strategies, namely, (1) abstaining from giving lengthy explanations, (2) intensifying question asking, and (3) increasing scaffolding in response to a tutee's contribution (Cade et al., 2008, Chi et al., 2008; Herppich et al., 2013a). To learn about the three strategies, the trained tutors first read an explanatory text and then watched two videos of fictitious tutoring sessions. The first video presented a tutor who failed to engage in interactive tutoring strategies and, thus, to receive information about a tutee's understanding. The second video, in contrast, presented the same tutor who did engage in interactive tutoring strategies, which helped the tutor to receive information about a tutee's understanding (cf. Renkl, 2005). In the second building block, trained the tutors also watched videos that presented positive and negative examples of tutoring strategies. This time, however, the tutoring strategies were not explained to the trained tutors. Instead, the trained tutors were prompted to self-explain what constituted the difference between the positive and negative examples. More specifically, the trained tutors were asked to provide information about the tutoring strategies that they saw in the videos and about the effects of such tutoring strategies for assessing a tutee's understanding (cf. Renkl,
2005). Finally, the trained tutors were required to indicate what they would do in order to change the tutoring strategies that they saw in a negative example. This was done to actively stimulate the application of the to-belearned strategies (cf. Klauer, 1988).

Introductory Text (Untrained Tutors) Instead of receiving training in interactive tutoring strategies, the untrained tutors read a short text. The text provided information about the effectiveness of tutoring and about problems associated with assessing a tutee's understanding. However, the untrained tutors did not receive any instruction on how to solve these problems. Instead, they were asked to provide tutoring in whatever manner they assumed appropriate.

## Procedure

Each tutoring session was divided into three phases: pretest phase, tutoring phase, and posttest phase. On average, a tutoring session lasted about 3 hours.

In the pretest phase, each tutee and each tutor individually read the passage about the human circulatory system. Afterwards, the trained tutors received training and the untrained tutors read the text.

In the tutoring phase, tutor-tutee dyads jointly read the passage about the human circulatory system sentence-bysentence and engaged in a dialogue about each sentence. All tutoring phases were videotaped.

In the posttest phase, the tutees completed the concepts test. The tutors also received the items of the concepts test and were asked to indicate for each item which of the given response options the tutee would choose.

## Codings and Analyses

Elicitation of Knowledge Deficits (Tutors) As an indicator of engaging in interactive tutoring strategies, we coded the knowledge deficits that a tutor elicited from a tutee. To do so, we used a coding scheme adapted from Chi et al. (2004). Every knowledge deficit that a tutee uttered was coded from its beginning to its end (event sampling procedure).

We coded a knowledge deficit whenever a tutor elicited from a tutee an utterance that (1) contradicted a piece of knowledge stated in the textbook passage, that (2) was incomplete, that (3) was vague, that (4) was incorrect and not addressed by the textbook passage, or when the tutee (5) did not utter a certain piece of information at all, that is, the tutee obviously missed this piece of information. In one tutoring session, for example, the tutor asked: "Why does the blood need to go to the lung? What does the lung do?" And the tutee answered: "Yes, um, yes, the lung filters the blood." This answer was coded as utterance of a knowledge deficit because it represents a normatively incorrect understanding. To standardize coding, the coder used a written instruction. For each tutor-tutee dyad, we summed up the number of elicited knowledge deficits.

Summative Assessment (Tutors) To examine the accuracy with which a tutor assessed a tutee's understanding of the human circulatory system after tutoring, we compared a tutee's responses in the concepts test with a tutor's estimations of a tutee's responses in the concepts test. To do so, we made the comparison on an item-by-item basis (cf. Hoge \& Coladarci, 1989). Hence, a tutor could achieve a maximum score of 16 points. Higher scores indicated a higher assessment accuracy.

Mediation Analysis To test our hypotheses, we performed a mediation analysis. We calculated total, direct, and indirect effects in accordance with our hypotheses by applying regression-based path analysis. To test for the statistical significance of an indirect effect, we derived 95\% confidence intervals for indirect effects as well as standard errors for indirect effects via bias-corrected bootstrap (for guidelines, see, e.g., Hayes, 2009, 2012). This approach resolves some methodological problems associated with the Sobel test (Hayes, 2009).

## Results

For all analyses, we used an alpha level of .05 . For directional hypotheses, we used one-tailed tests. In the analyses, trained tutors were coded as 1 and untrained tutors were coded as 0 . As effect size for indirect effects in the mediation analysis, we report $\kappa^{2}$. According to Preacher and Kelley (2011), effects are small when $\kappa^{2}=.01$, medium when $\kappa^{2}=.09$, and large when $\kappa^{2}=.25$. All analyses were performed using SPSS 20.0.0, the PROCESS macro for SPSS introduced in Hayes (2012; to perform the mediation analysis), and AMOS 20.0.0 (to receive standardized path coefficients for the mediation analysis). Table 1 shows the means and standard deviations of the dependent variables.

Table 1: Means and standard deviations (in parentheses) of the experiment's dependent variables

| Variable | Trained | Untrained | All |
| :--- | :---: | :---: | :---: |
|  | Tutors | Tutors | Tutors |
|  | $M(S D)$ | $M(S D)$ | $M(S D)$ |
| Elicited Knowledge | 71.30 | 32.11 | 52.21 |
| Deficits | $(40.46)$ | $(28.63)$ | $(40.01)$ |
| Assessment | 8.05 | 8.21 | 8.13 |
| Accuracy | $(2.54)$ | $(2.30)$ | $(2.40)$ |

## Impact of Training on Implementing Interactive Tutoring Strategies

Our first hypothesis stated that trained tutors would more often engage in interactive tutoring strategies than untrained tutors. Thus, trained tutors should elicit more knowledge deficits from their tutees than untrained tutors. As can be seen in Figure 1, trained tutors elicited more utterances of knowledge deficits from their tutee than did untrained tutors, $R^{2}=.25, F(1,37)=12.08, p<.05,95 \%$ CI $[.26, .74]$. Hence, the trained tutors in fact engaged in more interactive tutoring strategies than the untrained tutors.

Figure 1: Mediation model for the effect of tutor training on assessment accuracy explained by the number of expressed knowledge deficits a tutor elicited from a tutee. Numbers represent standardized path coefficients for direct effects and, in parentheses, the total effect of the independent variable on the dependent variable. ${ }^{*} p<.05$.

## Impact of Training on Summative Assessment

Our second hypothesis stated that trained tutors would more accurately assess a tutee's understanding after tutoring than untrained tutors. However, as the total effect depicted in Figure 1 shows, there was no significant difference in assessment accuracy between trained tutors and untrained tutors, $R^{2}<.01, F(1,37)=0.04, p>.05,95 \%$ CI [-.31, .24]. Hence, if only zero-order relations are taken into account, training tutors to implement interactive tutoring strategies failed to exert an influence on assessment accuracy.

## Interactive Tutoring Strategies as Mediator

Our third hypothesis stated that the higher number of a tutee's elicited knowledge deficits would explain why trained tutors assessed a tutee's understanding after tutoring more accurately than untrained tutors. To statistically test this hypothesis, we computed the indirect effect even though the total effect (i.e., the effect of training on assessment accuracy) was not significant (cf. Hayes, 2009; Shrout \& Bolger, 2002). To test the indirect effect, we constructed a bias corrected $95 \%$ bootstrap confidence interval as well as bootstrap standard errors from 10000 bootstrap samples. We found a significant negative indirect effect indicating that implementing interactive tutoring strategies as a result of receiving training decreased assessment accuracy with a standardized point estimate of $-.27(S E=.10), 95 \%$ CI [-.46, -.12], $\kappa^{2}=.26$ (zero-order correlation between elicited knowledge deficits and assessment accuracy: $r=-.43$, $p<.05$ ). Translated to unstandardized estimates, the number of items correctly estimated by trained tutors was 1.28 points ( $S E=0.54$ ) lower (and not higher) than the number of items correctly estimated by untrained tutors as mediated by the number of elicited knowledge deficits.

## Discussion

This study examined the effectiveness of a training method that aimed at helping tutors to engage in interactive tutoring strategies in the course of tutoring. It was assumed that engaging in interactive tutoring strategies would benefit a tutor's assessment of a tutee's understanding after tutoring.

First, we found that trained tutors in fact showed a more interactive style of tutoring than untrained tutors. Hence, even though the duration of our training was rather short, it was obviously sufficient to help the tutors to implement more interactive tutoring strategies. As a result, tutees tutored by trained tutors more often uttered knowledge deficits than tutees tutored by untrained tutors. This finding is consistent with the results obtained by Herppich et al. (2013a).

Second, however, the trained tutors failed to assess a tutee's understanding more accurately than the untrained tutors. The trained tutors were even less accurate than the untrained tutors. As show by the mediation analysis, this result was explained by the greater extent to which trained tutors engaged in interactive tutoring strategies as a result of receiving training. This effect was probably not observable in the zero-order analysis because the two paths making up the indirect effect were opposite in sign (cf. Hayes, 2009).

An explanation for why trained tutors and untrained tutors did not differ in assessment accuracy, as indicated by the total effect in the mediation analysis, is that the changes in the tutoring strategies due to receiving training might not have been sufficient to produce changes in assessment accuracy. This explanation would be in accordance with the results obtained by Roscoe and Chi (2007), who found that strategies of tutors can only be influenced to a certain extent. Hence, in the context of the present study, the information gained from being more interactive might not have been enough to generate more accurate assessments (cf. Graesser et al., 2011).

However, it still remains an open question as to why the elicitation of knowledge deficits was detrimental for assessing a tutee's understanding after tutoring, as indicated by the indirect effect in the statistical analysis. First, it might be that trained tutors and untrained tutors differed in the types of knowledge deficits they elicited from a tutee. Eliciting a larger number of scientifically incorrect utterances as compared to missing knowledge pieces, for example, might have been more informative for the summative assessment. This is because the incorrect response options in the concepts test were based on common types of incorrect understanding of a concept (e.g., Pelaez et al., 2005). However, the relative number of knowledge deficits elicited per category did not differ significantly between trained tutors and untrained tutors for any of the five categories of knowledge deficits coded.

Second, the detrimental effect of eliciting knowledge deficits on summative assessment might be related to our measure of summative assessment accuracy. During the training, the tutors were repeatedly informed that a tutor should get a picture of a tutee's understanding. As a consequence, the trained tutors might have conceived a tutee's understanding on a more global level than on the level of conceptual understanding. Thus, after having completed the training, being more interactive and receiving more information from the tutees could have drawn the tutors’ attention away from the knowledge they were to
assess in the concepts test. This conjecture could be tested in future research that uses measures of assessment accuracy that are as manageable for tutors as a multiple-choice test on conceptual knowledge but that would tap different levels of a tutee's understanding.

Third, another explanation refers to the fact that the tutors in this study did not possess teaching experience. Hence, the interactive tutoring strategies targeted in the training might have been quite unfamiliar to the tutors. As a result, implementing interactive tutoring strategies during tutoring might have put a fairly high burden on a tutor's cognitive capacity (Feldon, 2007). Thus, there might not have been enough cognitive capacity left to derive information from a tutee's utterances of knowledge deficits as a basis for assessing a tutee's understanding after tutoring.

This interpretation is in accordance with results from research on the acquisition of memory strategies. Often, learners can spontaneously implement a newly learned memory strategy but experience a so-called utilization deficiency (Miller, 1990). That is, implementing the strategy does not immediately improve recall or even hinders it. It is argued that using a newly learned strategy, which is not yet automated, demands most of the cognitive capacity of a learner. Thus, there is little capacity left to spend on processing the material to be recalled (e.g., Miller \& Seier, 1994).

Given this interpretation, it seems to be important to develop training methods that increase the automaticity with which interactive tutoring strategies are executed (Klauer, 1988). When interactive tutoring strategies occur more automatically, there might be more cognitive capacity available that can be used by tutors to assess a tutee's understanding (Feldon, 2007). Future research is encouraged to test whether training methods that target the automaticity of interactive tutoring strategies in fact improve assessment accuracy.

#### Abstract

Accurate judgments and decisions are crucial for success in many areas of human life. The accuracy of a judgment or decision depends largely on the cognitive process applied. In research on judgment, decision making, and categorization, two kinds of cognitive processes have often been contrasted: exemplar-based processes, which use similarity to previously encountered items to make judgments, decisions, and categorizations, and rule-based processes, which use abstracted cue knowledge. Although most cognitive models of judgment and decision processes assume that people rely on both processes, they differ in whether they assume that one process is selected or that both processes are blended into a single response. The present research takes a functional perspective and investigates what kind of interaction between the two processes leads to accurate responses. Based on crossvalidated simulations in real-world domains, it shows that blending rule- and exemplar-based processes generally leads to better judgments than does choosing between them, suggesting that the default strategy should be a blend of both processes, which is abandoned only when feedback justifies it.

Keywords: accuracy; multiple-cue judgments; decision making; categorization; exemplar models; rules; cognitive models; mixtures of experts; simulation.

## Introduction

Judging quantities, making decisions, and categorizing items are crucial elements of successful human behavior. A vast and diverse literature in cognitive science and judgment and decision making has investigated how people achieve these tasks (e.g., Ashby \& Maddox, 2005; Gigerenzer, Hertwig, \& Pachur, 2011; Kruschke, 2008; Payne, Bettman, \& Johnson, 1993). The many different models and strategies proposed can be broadly classified into two categories with reference to the cognitive processes they assume: exemplarbased processes, which use similarity to previously encountered items to make judgments, decisions, and categorizations, and rule-based processes, which use abstracted cue knowledge (Hahn \& Chater, 1998).

Extensive research has compared the proposed models' ability to describe human behavior. Furthermore, the performance of judgment and decision making strategies in predicting real-world criteria has been thoroughly investigated (e.g., Gigerenzer et al., 2011; Todd, Gigerenzer, \& the ABC Research Group, 2012).

To our knowledge, however, research in cognitive science and judgment and decision making has not previously investigated what kind of interaction between exemplar- and rule-based processes leads to accurate judgments, decisions, and categorizations: relying on just one of the two processes or using both? If both are considered, is it better to choose between them depending on the structure of the task, for instance (Rieskamp \& Otto, 2006), or to blend them into a joint response? This paper presents first answers to these questions.

A functional perspective on the interaction between exemplar- and rule based processes may be useful for at least three reasons. First, examining cognitive models' ability to predict external real-world criteria goes a step further than comparing their ability to describe human behavior in idealized laboratory tasks, by adding a further evaluation criterion. If one class of cognitive models were superior to another in terms of predictive performance, this would make them more attractive as plausible models of human behavior (Chater \& Oaksford, 1999). Second, many cognitive models are inspired by or share similarities with models from research fields interested in predictive performance (such as statistics, artificial intelligence, computer science, and machine learning; see e.g., Jäkel, Schölkopf, \& Wichmann, 2009; Marling, Sqalli, Rissland, Munoz-Avila, \& Aha, 2002), and a functional perspective provides a common ground that serves to re-connect cognitive models with such fields. Third, knowledge of how to profit from the complementary strengths of the two processes could offer prescriptions for improving human judgment, decision making, and categorization by instructing decision makers on when and how to use the two processes.

## Models of Judgment, Decision Making, and Categorization

There are two general approaches to modeling human cognition. First, single general-purpose models have been proposed (e.g., Lee \& Cummins, 2004). For instance, judgment and categorization models assume either only exemplar-based (e.g., Juslin \& Persson, 2002; Kruschke, 1992) or only rule-based processes (e.g., Ashby \& Gott, 1988; Brehmer, 1994). Second, toolbox approaches have been proposed. These assume that people draw on multiple,
different processes to solve the same task (e.g., Gigerenzer \& Selten, 2001). The toolbox approach posits that people adaptively select a tool (i.e., strategy) likely to succeed in the task at hand from a repertoire of strategies: the "toolbox" (Gigerenzer \& Selten, 2001; Payne et al., 1993; Rieskamp \& Otto, 2006; Scheibehenne, Rieskamp, \& Wagenmakers, 2013). Toolbox approaches have gained popularity particularly in decision making (e.g., Gigerenzer \& Selten, 2001; Rieskamp \& Otto, 2006). Yet also in categorization and judgment research, it is frequently assumed that people chose the process that is better suited to solving a task (Ashby, Alfonso-Reese, Turken, \& Waldron, 1998; Juslin, Karlsson, \& Olsson, 2008; Nosofsky, Palmeri, \& McKinley, 1994; von Helversen \& Rieskamp, 2008). For example, COVIS assumes that similarity-based and rulebased processes "race" for an answer, with the faster one determining the response (Ashby et al., 1998).

Although toolbox approaches often assume competition between processes, it is also possible that the processes cooperate. Hybrid or blending models assume that, instead of "choosing" a process for a task, two or more processes are executed simultaneously and their responses are integrated. For instance, the categorization model ATRIUM (Erickson \& Kruschke, 1998) combines both exemplar- and rule-based processes. Inspired by the "mixtures-of-experts" approach from machine learning (Jacobs, Jordan, Nowlan, \& Hinton, 1991), ATRIUM assumes that people have two "experts" in their mind: an exemplar-based and a rule-based one, whose outputs are processed by a gating mechanism. This gating mechanism can "choose" between these modules or "blend" their outputs by averaging their responses. In addition, ATRIUM can learn to rely more strongly on the more successful module (in terms of the probability of choosing or weighted averaging)-either for the whole task or depending on the item presented (i.e., depending on its location in psychological space). Modeling and experimental investigations support ATRIUM's assumption that exemplar- and rule-based processes simultaneously influence how humans categorize (e.g., Erickson \& Kruschke, 1998; Hahn, Prat-Sala, Pothos, \& Brumby, 2010). There is also evidence for such simultaneous influence in the domain of multiple-cue judgments (von Helversen, Herzog, \& Rieskamp, in press).

## Blending and Choosing Within One Mind

The combination of judgments or decisions from different sources is a vibrant topic in research fields such as psychology, judgment and decision making, cognitive science, statistics, artificial intelligence (AI), machine learning, biology, and economics (e.g., Krause, Ruxton, \& Krause, 2010; Kuncheva, 2004; Larrick, Mannes, \& Soll, 2012; Lee, Zhang, \& Shi, 2011; Marling et al., 2002). Combining diverse sources (e.g., forecasts from different experts) generally improves accuracy because different sources often compensate for each other's shortcomings. Depending on the circumstances, either choosing between
("competition") or blending different sources ("cooperation") may lead to better performance.

On the one hand, choosing a specific strategy allows the overall decision process to be adapted to environmental regularities and thus facilitates good performance (e.g., Todd et al., 2012). On the other hand, "blending" (i.e., averaging) different sources can often improve accuracy because errors of different signs cancel each other out. This "wisdom of crowds" phenomenon (Surowiecki, 2004) has recently also been applied to individual minds (e.g., Herzog \& Hertwig, 2009, 2013; Vul \& Pashler, 2008). Combining exemplar- and rule-based processes can be seen as an implicit "crowd within," where the two processes constitute two "experts" in one mind that either compete or cooperate in giving a response. To the extent that exemplar- and rulebased processes complement each other in the errors they commit, combining them may be a successful strategy (Herzog \& von Helversen, 2013).

In the following simulation study, we compare the merits of single purpose models, a competitive toolbox approach, and a cooperative toolbox approach. We focus on exemplarbased and rule-based processes as examples of distinctive cognitive processes because of the prominent distinction between the two in the cognitive literature (Ashby et al., 1998; Hahn \& Chater, 1998; Nosofsky et al., 1994; Persson \& Rieskamp, 2009).

## Different Levels of Interaction: Task or Item

Besides differentiating between choosing (competition) and blending (cooperation) of cognitive processes, we also consider on which level the interaction takes place: the task or item level. In the ecological rationality and adaptive toolbox approach (Todd et al., 2012), it is (implicitly) assumed that the selection of strategies happens on the task level-that is, that all the decisions within the same task are solved using the same strategy (once learning has completed). However, strategy selection (or integration) can also happen on the item level-that is, some items may be better solved by a rule, whereas others require memorization (Nosofsky et al., 1994). To account for this level of interaction, we compared competition and cooperation on the task and the item level.

## Simulation Study: Should Judgments Be Based on Exemplars, Rules or Both?

We investigated the performance of different ways to use exemplar- and rule-based processes in predicting a continuous criterion based on multiple cues. To this end, we conducted cross-validated simulations, informed by ATRIUM's (Erickson \& Kruschke, 1998) cognitive architecture, in five real-world domains. We addressed the following three questions. First, is it better to be equipped with both exemplar- and rule-based processes or is one process enough to achieve accurate judgments? Second, if both processes are used, is it better to choose between them

Table 1: Characteristics of the real-world datasets (adapted from Table 1 in Dana \& Dawes, 2004).
$N=$ number of cases, $k=$ number of cues, $\rho=$ correlation between target variable and predicted values from a multiple linear regression, $\mathbf{v}$ Vector $=$ zero-order correlation between target variable and cues, $\varnothing r_{x i x j}=$ mean correlation among cues.

| Dataset | $N$ | $k$ | $\rho$ | $\mathbf{v}$ Vector | $\otimes r_{x i x j}$ |
| :--- | ---: | ---: | :---: | :---: | :---: | ---: |
| Abalone | 4,177 | 7 | .73 | .63 .58 .56 .56 .54 .50 .42 | .89 |
| NFL | 3,057 | 10 | .54 | .46 .43 .37 .34 .33 .27 .21 .07 .05 .05 | .21 |
| ABC | 955 | 5 | .35 | .32 .20 .06 .04 .02 | .08 |
| NES | 1,910 | 6 | .35 | .26 .17 .15 .15 .13 .12 | .11 |
| WLS | 6,385 | 5 | .20 | .13 .11 .10 .10 .10 | .15 |

(competition) or to blend them (cooperation)? Third, for either choosing between or blending the two processes, is it better to treat all items the same (i.e., integration on the task level) or to treat individual items differently (i.e., integration on the item level)? Item-level integration implies choosing between the processes for each item (in the competitive approach) or weighting the two processes differently for each item when blending (in the cooperative approach).

## Datasets

We analyzed datasets previously used to compare the performance of proper and improper linear models (Dana \& Dawes, 2004). The datasets pertain to five domains: biology, sports, public opinion, political sentiment, and occupational prestige. In all datasets, a continuous target variable was predicted by several cues. For instance, the ABC dataset was derived from a 2002 poll of 955 U.S. households. Respondents' confidence that Osama bin Laden would be captured or killed was predicted by five cues, including the respondent's age, education, gender, and patriotism. See Table 1 for details of the statistical structure.

## Cognitive Models

Exemplar Model To represent an exemplar-based judgment process, we used an exemplar model for multiple-cue judgments (Juslin et al., 2008). The model assumes that judgments are based on the similarity to exemplars stored in memory, where the judgment is an average of the criterion values of the stored exemplars weighted by their similarity to the target item. We used a simplified exemplar model with one single free parameter determining the similarity gradient (see von Helversen \& Rieskamp, 2008).

Rule Model To represent a rule-based process, we used a multiple linear regression model. Such models have been widely used to model human judgment (Brehmer, 1994); they assume that judgments can be understood as the sum of weighted cue values. The model has a free parameter for every cue plus an intercept.

## Simulation Setup

For each simulation run, we randomly drew a learning sample and a test sample. We then fitted the free parameters of the exemplar and the rule model to the learning sampleminimizing the root mean square error (RMSE) between model predictions and criterion values-and used the
estimated parameter values to make predictions for the items in the test sample (for six different strategies described below). We measured estimation accuracy in the test sample using the RMSE between the model's predictions and the criterion values, a commonly used measure of absolute goodness of fit. Seven different sizes of learning samples were used $(20,40,60,80,100,200$, and 500 items) to vary the amount of experience with a domain; all test samples consisted of 250 items. For each dataset and each of the sizes of learning samples, we ran the simulation 1,000 times and averaged the results.

## Using the Rule and Exemplar Models

We tested six strategies for using rule- and exemplar-based processes to make predictions for the test sample.
"Exemplar Model" and "Rule Model" The first two strategies used just one of the two processes exclusively.
"Choosing-Task" and "Choosing-Item" The third and fourth strategy chose either the exemplar or the rule model.

On the task level, "choosing-task" selected in each simulation run the model that was superior in the learning sample and used it for all items in the test sample. To account for differences in model complexity, we used the Bayesian Information Criterion as a selection criterion.

On the item level, "choosing-item" selected in each simulation run and for each item in the test sample the model that was more likely to be superior for this particular test item-based on the performance on similar items in the learning sample. Specifically, for each test item we calculated the RMSE that the exemplar and the rule model had on similar items in the learning sample (i.e., we weighted the RMSE values of each training item using the similarity gradient of the exemplar model). The process with the lower weighted RMSE was then selected and its prediction for this test item was used.
"Blending-Average" and "Blending-Item" The fifth and sixth strategy blended the outputs of the exemplar and the rule model to make a joint prediction.

On the task level, "blending-average" computed for each test item the arithmetic mean of the predictions of the rule and the exemplar model.

On the item level, "blending-item" used in each simulation run and for each item in the test sample a

Figure 1: Cross-validated estimation accuracy (Root Mean Squared Error, RMSE) of six strategies in five domains (for learning samples of different sizes). The upper left panel averages the normalized data across domains; the RMSE values were divided by the largest average RMSE value in each domain. The strategies are explained in the text.
weighted average of both models' predictions-using the same similarity-weighted RMSEs as in "choosing-item." The item-specific weight for the exemplar model was calculated as the proportion of the rule model's weighted RMSE relative to the sum of both models' weighted RMSEs (i.e., the worse the rule model, the larger the weight on the exemplar model).

## Results \& Discussion

Figure 1 shows the generalization performance of the different strategies as a function of the size of the learning sample for the five domains. Because the datasets differed in their range of criterion values, which in turn affected the scale of the RMSE, it was necessary to normalize the RMSEs before aggregating them across datasets. To this end, we divided each RMSE by the largest average RMSE value within the respective domain, so that each RMSE value could be understood as the relative increase in fit. We then constructed a summary learning curve by averaging the normalized RMSEs across the five domains (see Figure 1, upper left panel).

Four results are noteworthy. First, "blending-average" was generally more accurate than either the exemplar or the
rule model; the exemplar model was somewhat better than the averaged predictions of both models only for very small learning samples (i.e., 20 items). Second, "blendingaverage" was generally more accurate than choosing the better model based on its performance in the respective learning sample ("choosing-task"), although choosing was slightly better for very small learning samples (i.e., 20 items) in two of the five datasets. Third, when choosing or blending, it did not pay off to tune one's use of the models to the type of item. Weighting both processes when blending ("blending-item") was less or equally accurate than was giving them equal weights ("blending-average"); similarly, choosing the process depending on the item ("choosing-item") was less or equally accurate than was using the same process for all items ("choosing-task"). Fourth, the differences between strategies decreased as the size of the learning samples increased.

Let us now answer the three questions motivating this simulation. First, in the datasets we investigated, it was generally better to be equipped with both exemplar- and rule-based processes than with just one of the two processes. Second, if both processes were used, it was generally better to blend them than to choose between them. Third, when
choosing between or blending the two processes, it was generally better to treat all items the same (and not to choose or blend, respectively, depending on the type of item; i.e., depending on how much "expertise" the exemplar- and rule-based processes had about a specific part of the psychological space).

## General Discussion

Many cognitive models of judgment, decision-making, and categorization assume that people can use both exemplarand rule-based processes (e.g., Erickson \& Kruschke, 1998). Yet it remained unclear whether using both processes provides a performance advantage over using just one process and, when both processes are available, whether it is better to choose one process depending on the task (i.e., competitive toolbox approach) or to blend their responses (i.e., cooperative toolbox approach). Our simulations in the domain of multiple-cue judgments suggest that combining the two processes (either by choosing between or blending them) leads to better judgments than does relying on just one of them, and that a simple blend (i.e., equal weighting) of both processes leads to accurate judgments. This latter point is consistent with the success of naïve equal weighting strategies (e.g., Dawes, 1979). In another set of simulations, we investigated the combination (i.e., choosing or blending) of exemplar- and rule-based processes in the context of making categorizations (using 38 machine learning benchmark datasets; Herzog \& von Helversen, 2013). Further broadening the scope of the present analysis, we found that blending the outputs of an exemplar- and a rulebased process led to successful categorizations.

Our results resonate with research in AI and machine learning that demonstrates how combining different representations is often beneficial (Kuncheva, 2004; Marling et al., 2002). More specifically, our results suggesting that combining exemplar- and rule-based processes can often increase accuracy in human cognition dovetail nicely with the successful combination of casebased and rule-based reasoning systems in AI (e.g., Marling et al., 2002; Prentzas \& Hatzilygeroudis, 2007).

Besides the general question of whether exemplar- and rule-based processes should be "blended" or "chosen" among, our simulations suggest that it does not pay off to tune one's use of exemplar- and rule-based processes to the type of item one wants to generalize to. This conclusion seems inconsistent with empirical studies suggesting that participants successfully choose between processes in categorization tasks (e.g., Erickson, 2008). Yet these experimental tasks may be unrepresentative of real-world situations. In many experimental studies-especially in categorization research-there is little (or no) doubt about which process is better suited to solving the whole task (or responding to a specific item), and a participant can thus learn to choose between or differentially use the two processes. We speculate that deviating from a simple blending strategy is generally worthwhile only in domains in which one process is clearly superior to the other, both
processes make similar errors, and this statistical structure can be ascertained with enough confidence (see Soll \& Larrick, 2009). However, we would argue that this is typically not the case in real-world domains. It would thus seem prudent that human judges and decision makers, as modeled, for example, by ATRIUM (Erickson \& Kruschke, 1998), start with a simple blend of both processes and deviate from this approach (e.g., by choosing or itemspecific tuning) only when feedback justifies it.

Why is combining exemplar- and rule-based processes so successful in multiple-cue judgment tasks? The use and the performance of exemplar- and rule-based processes in multiple-cue judgment tasks seems to depend on the statistical structure of the task-in particular, the functional relation between cues and criteria (Juslin et al., 2008; von Helversen \& Rieskamp, 2008). If the criterion can be approximated by a linear additive combination of the cues, rule-based processes predominate. In multiplicative tasks, by contrast, exemplar-based processes perform better and are used more frequently. Simulations using artificially created domains (Herzog \& von Helversen, 2013) suggest that the five real-world domains we analyzed in the present simulations represent a mixture of these two kinds of statistical structures (i.e., additive and multiplicative). Consequently, neither of the two processes in isolation was able to capture their statistical structure. To the extent that this result generalizes to decision making and categorization, it suggests one reason why people are equipped with and use both exemplar- and rule-based processes: because only a combination of the two allows people to make successful judgments, decisions, and categorizations in the real world.

#### Abstract

The present research investigates semantic priming with an adapted version of the word fragment completion task. The letter decision task, as we will call it, holds some advantages over the traditionally used lexical decision task in that it eliminates retrospective semantic matching effects, it avoids the need to construct pseudowords, it is more engaging for participants and it enhances semantic processing, which in turn allows for a more fine-grained investigation of semantic activation. The letter decision task requires participants to complete words, from which one letter was omitted like lett_ce (lettuce), as fast as possible. The study found that words are completed faster when the preceding trial comprised a semantically related fragment like tom_to (tomato) than when it comprised an unrelated fragment like guit_r (guitar). Furthermore, the study provides insight in the nature of the priming effect. It demonstrates that priming effects are larger for strongly associated prime-target pairs.

Keywords: Semantic priming; Letter decision task; Associative strength.

## Introduction

Semantic priming is the finding that the processing of targets (e.g., a picture, a word,...) preceded by a semantically related prime (also a picture, a word,...) is enhanced. For instance, the presentation of the word cat facilitates processing of the subsequently presented word dog. One of the debates in the semantic priming literature concerns the source of the priming effect (Hutchison, 2003; Lucas, 2000). The (unresolved) issue revolves around the type of relation between concepts that is necessary for priming to occur. That is to say, words can be associatively related, as evidenced by association norms (De Deyne, Navarro \& Storms, 2012) or because both concepts share certain features. Returning to the cat-dog example, both cats and dogs have four legs, two eyes, are pets, etc. and thus they are related in terms of feature overlap (e.g., McRae \& Boisvert, 1998). Moreover, the strongest associate of cat is dog hence both concepts are also associatively related. Whether priming is driven by word associations or feature overlap (or even something else) is an important question
since it has significant repercussions for theories about the organization of the mental lexicon. Consequently, a lot of research has been devoted to this topic.

The most frequently used paradigms to examine these issues are the lexical decision task, in which participants have to decide whether letter strings form existing words or not, and, to a lesser extent, the pronunciation task, in which participants read aloud words (see the reviews of Hutchison (2003), Lucas (2000) and Neely (1991)). The experimental designs further vary in the degree to which they allow automatic and controlled processes. These latter processes are conscious and strategic and they come into play when the prime-target coupling (e.g., cat-dog) is made explicit (Jones, 2010). This is for instance the case in the standard lexical decision task where participants are required to respond only to the second item of the pair (i.e., the target $d o g$ ) and not to the first (i.e., the prime cat). Strategic effects are volatile and vary over subjects, whereas automatic processes are ubiquitous. Thus, automatic processes are thought to reliably reflect the structure of the mental lexicon (Lucas, 2000). Hence, considerable effort has been put into developing methodologies that prevent controlled processes. One method to reduce strategic effects is the continuous lexical decision task (McNamara \& Altarriba, 1988; Shelton \& Martin, 1992). Here, prime-target pairs are decoupled by asking participants to respond not only to the target but also to the prime.

In the present study, we took a different approach. It was (partly) motivated by the fact that there is little consensus regarding the nature of semantic priming. A possible explanation for the divergent and sometimes unreplicated findings (see Hutchison (2003) and Lucas (2000)) is that the experimental paradigms are not sensitive enough to detect or tease apart subtle effects. The widely used lexical decision task may rely more on superficial processing of words, whereas deeper semantic processing may be necessary to fully uncover the structure of the mental lexicon. Hence, in this study, we used a different method to examine semantic priming. It is an adaptation of the word fragment completion task, a task that has mainly been used in implicit memory studies (i.a., Bassili, Smith \& MacLeod,

1989; Challis \& Brodbeck, 1992; McDermott, 1997; Roediger \& Challis, 1992; Weldon, 1993). There are several variants of the word fragment completion task, but the general idea is that participants are presented with words from which one or more letters are omitted (e.g., r_d or _orn_d_). Participants then are assigned to fill in the gap(s). In some experiments, the dependent variable of interest is the actual answer participants give. Put differently, the question is whether participants complete $\mathrm{r}_{-} \mathrm{d}$ as red or as rod. In other experiments, there is only one correct answer and the crucial dependent variable is the proportion correct responses within a certain time interval or alternatively, the time required to give the correct solution. Concretely, how many participants accurately identify _orn_d_ as tornado and/or what is the average reaction time? In this study, we examined semantic priming using a modification of the latter type. But instead of difficult words with many blank spaces, we opted for relatively simple stimuli with only one blank space. Furthermore, participants were told that the missing letter was always a vowel. The task conceptually resembled a continuous lexical decision task in that participants had to complete both prime and target words (and also unrelated filler items). For instance, on trial $n$ participants got the fragment tom_to (it should be completed as tomato) and on trial $n+1$ they got lett_ce (it should be completed as lettuce). For the sake of clarity, we will therefore coin the term continuous letter decision task to refer to the experimental paradigm in this study. As in a (continuous) lexical decision task, the main dependent variable is reaction time since accuracy will be near perfect. Hence, it is expected that lett_ce is completed faster when it is preceded by a semantically related stimulus like tom_to than when it is preceded by an unrelated stimulus like guit_r (it should be completed as guitar).

We believe that there are some advantages of the continuous letter decision task over the continuous lexical decision task. First of all, in the lexical decision task participants may endorse a retrospective semantic matching strategy. Neely and Keefe (1989) argued that participants might use information about whether the considered letter string is semantically related to the preceding letter string to reduce their response time. Concretely, when there is a semantic relation between two consecutively presented letter strings, the correct answer for the latter letter string is always "word". If there is no such relation, the second letter string is a word or a non-word. In fact, when the proportion of non-words in the experiment is high then the absence of a relation between two consecutive letter strings indicates that the second letter string is more likely to be a non-word. It is possible that participants notice these contingencies, which in turn yields strategic priming effects that are inseparable from (interesting) automatic priming effects. However, the continuous letter decision task introduced here does not suffer from a semantic matching strategy. That is to say, a semantic relation between two words on consecutive trials is not predictive for the correct response to the latter word fragment. The fact that tomato and lettuce are related does
not give information about which vowel is missing in the fragment lett_ce.

A second advantage of the letter decision task with respect to the lexical decision task is that it obviates the need to construct pseudowords. Besides practical convenience, it has also theoretical implications since previous research suggested that the nature of the pseudowords and their similarity to real words modifies priming (Shulman \& Davison, 1977) and also the word frequency effect (Stone \& Van Orden, 1993). Such issues are avoided in the letter decision task.

Thirdly, it is not far-fetched to argue that the letter decision task is more challenging, without becoming burdensome, than the lexical decision task. Although participants may not exactly be filled with joy when performing the experiment, the task is more engaging, which in turn enhances the intrinsic motivation of participants (Deci \& Ryan, 1985).

Finally and perhaps most importantly, the letter decision task presumably involves a deeper semantic processing. In the lexical decision task, shallow processing of letter strings may be sufficient to discriminate words from non-words (Rogers, Lambon Ralph, Hodges \& Patterson, 2004), thereby limiting the facilitatory effect of a related prime. Because the letter decision task is more effortful, a related prime has more potential to exert its influence.

Taken together, it may be fruitful to use the letter decision task to examine semantic priming. Hence, the first goal of the present study was to establish whether a priming effect could be obtained with this task.

A second goal was to examine the nature of the priming effect. Every crucial target like lett_ce (lettuce) was either preceded by a related prime (tom_to, tomato) or an unrelated prime (guit_r, guitar). As is traditionally the case in priming research, one could consider relatedness as a dichotomy (i.e., tomato-lettuce are related whereas guitarlettuce are not). However, one could argue that relatedness is not an all or none matter, but rather that there is variability in the strength with which two words are related (for a similar proposal, see Hutchison, Balota, Cortese \& Watson, 2008). For instance, thunder-lightening has a stronger forward association than tomato-lettuce, meaning that more people give lightning as an association for thunder than lettuce as an association for tomato (based on the large scale Dutch Word Association Database from De Deyne et al., 2012). Thus, one might hypothesize that the priming effect for thunder-lightening is stronger than the effect for tomato-lettuce. The second goal of this study was to examine this prediction.

## Method

## Participants

Participants were 40 first-year psychology students of the University of Leuven ( 7 men, 33 women, mean age 18 years), who participated in return for course credit. All participants were native Dutch speakers.

## Materials

A total of 76 related prime-target pairs like tom_to-lett_ce (tomato-lettuce) were constructed. All stimuli were Dutch word fragments. Primes and targets were always category coordinates. Categories ranged from fruits and music instruments to mammals, tools, professions, etc. Moreover, prime-target pairs had a forward association strength that ranged from $3 \%$ to $30 \%$. These and other measures of association strength were derived from the Dutch Word Association Database (De Deyne et al., 2012). In addition, 76 unrelated filler pairs were constructed.

All word fragments were generated by omitting one vowel from a Dutch noun. Only word fragments that had a unique correct response were used. Of the 76 crucial targets, 16 required an "a" response, 22 an "e" response, 18 an " $i$ " response, 13 an "o" response and 7 a "u" response.

Two lists were created such that a random half of the 76 crucial targets were preceded by their related prime in List A, whereas in List B they were preceded by an unrelated word, and vice versa. The 38 unrelated pairs for each list were constructed by randomly recombining primes and targets, with two limitations. The first is of course that the resulting prime-target pairs were no category coordinates and indeed unrelated, as evidenced by a lack of a forward and backward association between prime and target. Second, a fraction of the related prime-target pairs were response congruent, meaning that the same vowel is missing in both the prime and the target. The unrelated pairs were created in a way that they match in terms of response congruency. When a related pair is response congruent so is the corresponding unrelated pair and the other way around. So for example, there where pa_rd (to be completed as paard, Dutch for horse) was preceded by zebr_ (to be completed as zebra) in List A, it was preceded by t_rwe (to be completed as tarwe, Dutch for wheat) in List B, which was actually the prime for me_l (to be completed as meel, Dutch for flour) in List A. Hence, each list consists of 76 critical prime-target pairs ( 38 related pairs and 38 unrelated pairs) and an additional 76 unrelated filler pairs.

## Procedure

Participants were randomly assigned to one of the two lists. Twenty participants received List A and 20 List B. The task itself was a continuous letter decision task. The continuous nature of the task breaks the 152 pairs down to 304 trials. On each trial, participants were presented with one word fragment. Primes were always shown on odd-numbered trials and targets on even-numbered trials. The order of the pairs within the experiment was random and varied over participants.

On every trial, participants saw a word from which one letter was omitted. They were informed that the missing letter was always a vowel. Participants had to complete the word by pressing either "a", "e", "u", " i ", or "o" on an AZERTY keyboard. The instructions stressed both speed and accuracy. Every word fragment was displayed in the center of the screen and remained present until a response
was made. The inter-trial interval was 500 ms . Before the experimental phase, participants did 20 practice trials. The practice trials were identical to the experimental trials except that 20 new semantically unrelated word fragments were utilized. The experiment was run on a Dell Pentium 4 with a 17.3-inch CRT monitor using Psychopy (Peirce, 2007). It was part of a series of unrelated experiments and took approximately 15 minutes.

## Results

First, the split-half reliability of the response times to the 76 crucial targets was calculated using the Spearman-Brown formula. Split-half correlations for List A and List B separately were obtained for 10,000 different randomizations of the participants. The resulting reliabilities, averaged over the 10,000 randomizations, were .92 for List A and .88 for List B, which is rather high for response times. Note that all analyses were performed only on the 76 crucial target trials.

Erroneously completed targets ( $3.3 \%$ of the data) and targets preceded by an incorrectly completed prime were not included in the analysis ( $5.3 \%$ of the data). Furthermore, responses faster than 250 ms and slower than 4000 ms were removed after which an individual cut-off value for each participant was computed as the mean response time plus 3 standard deviations. Response times exceeding this criterion were also excluded (another $3.9 \%$ of the data was discarded). The exclusion criteria are similar to regular priming studies using the standard lexical decision task, except for the exclusion of target trials following incorrect prime completion. This has to do with the continuous nature of the task: post-error slowing and/or subpar prime processing conceivably obscure target response times and/or priming effects. It should be noted though that the results were qualitatively the same if different exclusion criteria were used.

The log-transformed response times were then fitted using a mixed effects model with a random intercept for participants and items (i.e., the 76 crucial targets). The response times were regressed on 4 predictors: one critical predictor called Relatedness, which is a binary variable indicating whether the target (lett_ce, lettuce) was preceded by a related prime (tom_to, tomato) or an unrelated prime (guit_r, guitar), and three covariates, namely, Contextual Diversity of the target (CD Target ${ }^{1}$, acquired from Keuleers, Brysbaert \& New, 2010), Word Length of the target in number of characters (Length Target) and the logtransformed response time to the prime (RT Prime). To facilitate the interpretation of the effects, CD Target, Length Target and RT Prime were z-transformed. Furthermore, Relatedness was coded such that targets preceded by a related prime served as a baseline. Thus the intercept should be interpreted as the expected response time to a target with

[^296]an average length ( $\approx 6$ characters) and an average contextual diversity ( $\approx 2.4$ ) that was preceded by a related prime with an average response time ( $\approx 1103 \mathrm{~ms}$ ). The analyses were carried out in R (version 2.15.2) ( R development core team, 2011), employing the lme4 package (Bates \& Sarkar, 2007). Markov Chain Monte Carlo p-values (pMCMC) and 95\% highest posterior density intervals (HPD95) were obtained with the pvals.fnc() function of the languageR package, with 10,000 iterations (Baayen, 2008).

The results are summarized in Figure 1, which depicts the $95 \%$ highest posterior density interval for the fixed effects. Note that the HPD95 of the intercept, which ranged from 6.76 to 6.85 , is not presented because it would have distorted the x-axis. Figure 1 shows that all predictors have a HPD95 that excludes zero. Hence, there is a significant priming effect ( $\mathrm{pMCMC}<.001$ ). To grasp the magnitude of the effect, one can derive model predictions based on the point estimates of the fixed effects (i.e., the dots in Figure 1; the estimate of the intercept was 6.8). The expected response time for the average participant and the average target following an average related prime equals 904 ms . This response time increases to 944 ms when the target is preceded by an unrelated prime. In other words, there is a priming effect of 40 ms .

In the previous analysis, Relatedness was a binary predictor. However, a continuous variable is needed to examine whether a stronger relation between word pairs yields a larger priming effect. To this end, five predictors that capture the associative strength between two words were derived from the Dutch Word Association Database (De Deyne et al., 2012). The five predictors are Forward Association Strength (i.e., how often is the target given as an associate to the prime; FS), Backward Association Strength (i.e., how often is the prime given as an associate to the target; BS) and three semantic relatedness measures. Semantic relatedness was calculated by computing the distributional overlap of the vector of association response counts between a pair of words as the cosine between these vectors (S raw). In addition, two variations were included, where (a) the counts were logarithmically transformed (S $\log$ ) or (b) weighted using point-wise mutual information which is often used in semantic vector models (S pmi) (Church \& Hanks, 1989; Turney \& Pantel, 2010). Both related and unrelated prime-target pairs get a score for all five variables. For unrelated pairs, FS and BS values are all zero, but the presence of shared associates results in cosine values for $S$ raw, $S \log$ and $S$ pmi that are often somewhat larger than zero.

A model comparison approach was adopted to assess the merits of these continuous predictors with respect to the binary predictor. In a first step, the same mixed-effects model from the previous analysis was used, but now the binary predictor Relatedness was replaced by one of the five continuous variables. This results in six models of which the fit indices are reported in Table 1. The AIC and BIC scores reported in Table 1 evaluate the goodness of fit against the number of parameters of the model (Akaike, 1974; Schwarz,
1978). Lower values are indicative of a better fit. Since the models compared here are non-nested, AIC and BIC scores were used to assess which model, and thus which predictor, best fits the data. The results show that all continuous measures were better than the binary predictor. The best continuous predictor was $S$ log.

In a second step, we started from the model with S log and added the other continuous variables to investigate whether they can explain the remaining variance. It turned out that only BS was a significant predictor $(\mathrm{pMCMC}=$ $.011)$ besides $S \log (\mathrm{pMCMC}=.006)$.

Figure 1: 95\% highest posterior density intervals of the four regression weights. The dots represent the point estimates of the weights.

Table 1: AIC and BIC scores for the six mixed effects models. Models only differ in the predictor that captures the nature of the prime-target relations (the first column).

| Predictor | AIC | BIC |
| :--- | :--- | :--- |
| S log | 138.8 | 185.9 |
| S raw | 145.1 | 192.2 |
| S pmi | 141.8 | 188.8 |
| FS | 150.8 | 197.9 |
| BS | 140.1 | 187.1 |
| Relatedness (binary) | 152.8 | 199.9 |

## Discussion

The present research proposes a different method, that is, the letter decision task, to examine semantic priming. In this task, participants are shown words from which one letter (i.e., a vowel) is omitted. Participants have to fill in the missing letter as fast as possible. Word fragments were selected such that there was only one correct completion possible, thereby making the task conceptually comparable to the lexical decision task. As argued in the introduction,
there are several advantages over the lexical decision task. Concretely, the letter decision task eliminates retrospective matching effects, it does not require experimenters to construct pseudowords, it is more engaging than the lexical decision task and it involves deeper semantic processing. Crucially, this study shows that the continuous letter decision task can capture semantic priming effects. Hence, the present task is a viable alternative to examine semantic priming in future research. The employed methodology greatly reduces strategic priming effects, although it is theoretically possible that (some) participants engaged in expectancy generation despite the low relatedness proportion ${ }^{2}$. To completely disentangle automatic and strategic processes one might use a standard letter decision task with a short stimulus onset asynchrony. In this paradigm a briefly presented complete prime word is quickly replaced by a to-be-completed target. The short interval prevents expectancy generation (but not retrospective matching in a lexical decision task, see e.g., Shelton and Martin, 1992), while the letter decision task eliminates retrospective matching. In addition, one could manipulate the relatedness proportion in the continuous letter decision task to check whether expectancy generation plays a role. Our lab is currently investigating these issues.

Furthermore, this study provides evidence for the hypothesis that priming effects are greater for strongly related prime-target pairs. Models that regard relatedness as a continuous rather than a binary variable fitted the data better. More specifically, semantic relatedness and backward association strength were shown to predict the response times to the target word fragments the best. Thus, the stronger prime and target words are associated, the faster participants completed the target word. The fact that backward association strength plays a role seems to indicate that the benefit is larger for reciprocally associated primetarget pairs. These findings also highlight the value of the letter decision task. Because this task enhances semantic processing, it allows for a more detailed analysis of semantic activation, which may not be possible with a classic lexical decision task.

The method to assess the merits of continuous predictors over a binary predictor may seem a bit odd. Here, a model comparison approach was used, whereas it might be intuitively compelling to average over participants to obtain a priming effect for each separate item. Indeed, one could look at the average response time of the participants who got the related pair (e.g., tom_to-lett_ce, tomato-lettuce) and subtract it from the average response time of the participants who got the unrelated pair (e.g., guit_r-lett_ce, guitarlettuce) and this for all 76 crucial targets. The resulting 76 priming effects could be regressed on continuous measures like forward association strength, backward association

[^297]strength,... (see Hutchison et al., 2008 for such an approach). However, several researchers have argued against averaging over participants because it inflates type 1 error (Baayen, Davidson \& Bates, 2008; Lorch \& Myers, 1990; Quené \& van den Bergh, 2008). Nevertheless, the results from this study are largely consistent with those from Hutchison and colleagues (2008).

It should be noted that the present research only considers associative strength of prime-target pairs. As described in the introduction, it is debated whether semantic priming is primarily driven by associations between words or by similarity in terms of feature overlap between prime and target. Although this research did not directly address this issue, it does hint at the importance of associations. But we immediately hasten to point out that all related pairs in the experiment were category coordinates, hence there will be considerable feature overlap between related primes and targets as well. Future research incorporating a continuous measure for feature overlap can provide further insight on this matter.

# Topological Similarity of Motor Coordination in Rhythmic Movements 

Shohei Hidaka (shhidaka@jaist.ac.jp) Tsutomu Fujinami (fuji@jaist.ac.jp)<br>Japan Advanced Institute of Science and Technology, 1-1 Asahidai, Nomi, Ishikawa 923-1292, Japan

#### Abstract

Recognition of motion is vitally important to any animal. Vision research has proposed a number of algorithms applicable to action recognition. However, unlike successes in early visual perception, the past studies have not yet established the computational theory of action recognition. In the present study, we employ a dynamical systems approach and hypothesize that motions are encoded cognitively as a topological structure abstracted from physical particulars. We investigated whether a common topological nature could be found in a type of rhythmic movement. The topological nature of action dynamics showed a striking similarity, which could not have been identified with other analyses where physical properties were retained. The result suggests that the dynamical perspective serves as a theoretical basis in studying complex human movements.

Keywords: Actions Recognition; Motor Coordination; Dynamical Systems; Invariant Measures

## Recognition of Actions

Recognition of motion is vitally important to any animal. Detection of another animal, whether predator or prey, or a conspecific, and subsequent detailed identification of the other and how it may behave is essential to taking any emergent actions (Johnson, Bolhuis, \& Horn, 1985). Not surprisingly, our visual system is highly specialized to recognize others' actions. How do we recognize bodily movements? Our main focus is that, despite much of the advances, we still miss a parsimonious explanation of "what is an action" or a computational theory of actions. The goal of the present study is, thus, to propose a computationaltheory level description of actions which abstract identities beyond physical particulars. We briefly review psychophysical findings and theoretical works on action recognition.

The past experimental literature has explored the capacity of motion perception using point-light displays (Johansson, 1973) in which the point-lights attached to major joints are only visible in the dark background. The available information is point-wise kinematic motion of multiple body parts. Despite the limited information, people can recognize identity (Troje, Westhoff, \& Lavrov, 2005), gender (Kozlowski \& Cutting, 1977; Troje, 2002), emotions (Pollick et al., 2001; Atkinson; 2009; Hobson \& Lee, 1999), dynamics such as the weight of a lifted object (Bingham, 1987) of actions from point-light displays. Accumulating empirical studies on action perception have suggested that velocity and its higher order derivatives in single or multiple body parts characterize actions: duration of action (Pollick et al., 2001), velocity (DeMeijer, 1989), acceleration (force
or the second order time derivatives) (Chang \& Troje, 2008; 2009), jerk or the third order time derivatives (Cook, Saygin, Swain, \& Blakemore, 2009), and pairwise counter-phase oscillation (Chang \& Troje, 2008; 2009).

Consistent with these empirical findings, most of the theoretical approach employs statistical regularities among motion profiles (Hidaka, 2012). According to a recent review (Troje, 2008), perception of biological motion involves multi-level processing on local and global motion properties. Feature processing consists of four layers from early (low-level) to late (high-level) processing: life detection, structure-from-motion, action recognition, and style recognition. The system detects an autonomous agent, and constructs body structure from its detailed analysis, then is followed by more detailed action analysis.

A couple of models have been proposed for structure-from-motion and action recognition (Giese \& Poggio, 2003; Lange \& Lappe; 2006). In the model of structure-frommotion and action recognition, the model identifies body structure, and subsequently recognizes actions from the pixel-based visualization of point-light displays. In Giese \& Poggio (2003), the model was built based on neurophysiological findings in the visual cortex, and was applied to recognition of action types and action direction in normal, masked, or scrambled point-light displays.

Despite the accumulated empirical evidence and theoretical works, its computational level account attributed to Marr (1982) - a description of function, i.e., set of inputoutput pairs in action recognition - is still missing. The two models above constructed algorithms which recognize a class of actions or properties of actions through processing the features of human bodily movements. However, in general, algorithmic models formalize specific procedures, but their meaning is not often readily apparent. First, a complex model typically loses transparency of mechanism as a cost of generality (For example, multi-layered physiologically-plausible model, Giese \& Poggio, 2003). A drawback of complex models (using nonlinear filters or feature decomposition technique) is that the estimated parameters do not necessarily offer a clear interpretation on which attributes are informative in the recognition processes. Second, such a complex model often outperforms human recognition (Troje, 2002; Davis. \& Geo, 2004; Pollick \& Paterson, 2008) rather than explaining it. It is thus dubious whether those models can explain the action recognition of human beings.

We are interested in the computational level of action recognition rather than in the algorithmic level. We study actions, that is, how our multiple body parts are coordinated
in performing particular tasks. Our human body consists of over two hundreds bones, numerous muscles, and billions of neurons in the central and peripheral nerve systems controlling them with feedback loops. Obviously, making a smooth action requires integrated control across all levels of these interactive systems. Given this complexity in motor control process, it is unrealistic to compute the inverse transformation (as supposed in early vision) from end-point visible actions to its intrinsic motor control patterns. Therefore, instead of such inverse computation, we hypothesize that the goal of action recognition is to compute "dynamical invariances" under smooth transformation. This hypothesis views motor control underlying human movements as a set of dynamical systems, that is, a sequence of interactions between elements involved in controlling movements such as body joints, muscles, neural systems, etc. Our hypothesis can be best understood in the context of the dynamical system perspective on the motor coordination (Shaw et al., 1996; Turvey, 1998; Smith \& Thelen, 2003). The properties retained in dynamical systems for long term can be captured with invariant measures such as attractor dimension or Lyapnov exponent (Kantz \& Schreiber, 1997).

We define a higher dimensional space, i.e., phase space, within which all possible combinations between elements involved in controlling movements can be found. An action is then defined as a trajectory on the space. Trajectories can be projected onto lower dimensional spaces, e.g., actual movements observable from outside. In our study, we collect motion data to reconstruct the dynamical systems by embedding the time series in a higher dimensional space. For graphical examples, Figure 1 illustrates attractors, or the state space which the system may take in the three theoretical dynamical systems, the Hennon map, Rossler system, and Lorenz system (Figure 1 (a-1), (a-2), (a-3)). A univariate time series (as imperfect observation of the system) is shown in Figure 1 (b) for each of these systems. Since the original systems live in two or more dimensions, these univariate time series do not have full information due to missing dimensions. Thus, we need to "reconstruct" the phase space instead of studying the degenerated patterns. By taking the time delay vector (e.g., $\{x(t), x(t+\delta)\}$ ), the topological nature of the phase space is reconstructed (Figure 1c). In Figure 1 (c-1)-(c-3), the time-delay embedding (a map from low to high dimensional space) successfully recovers similar topological structure shown in Figure 1 (a-1)-(a-3) only from the degenerated data Figure 1 (b-1)-(b-3). Although the original phase space is unknown for empirical bodily movements, we expect the intrinsic topological nature can be reconstructed in the same way as the theoretical dynamical systems (Figure 1 (b-4) and (c-4)). See Kantz and Schreiber (1997) for a detailed description of these procedures for nonlinear time series analysis.

To study dynamical invariances, we investigated topological similarities of motor coordination. The rationale for the approach is found in observations such that one can mimic other's behaviors no matter how different their
individual appearances. Topology abstracts over physical particulars such as distance, speed, etc., to extract some dynamical invariances independent of these physical properties. Specifically, we examined the dynamical properties of rhythmic movements for two main reasons. First, rhythmic movements are not just a period but with fluctuating accents, and this is expected to show complexity to some extent neither too simple nor too complex. Second, actions which an actor can maintain continuously and produce a substantial amount of datasets are necessary for characterization of dynamical invariances.

Figure 1: Phase space of (a-1) the Hennon map, (a-2) the Rossler system, (a-3) Lorenz System, and (a-4) the body model and attached markers (filled circles: analyzed, open circles: attached but not reported in this study). (b1-3) A univariate time series from the original phase space in (a1-3) (b-4) An x-axis phase of the Shaker 1 in the expert player in the $60-\mathrm{bpm}$ trial (blue circles) with the estimated noisereduced time series (black dots). (c1-4) The reconstructed phase space from the low dimensional observed time series in (b1-4).

## Chacterizing Complex Rhythmic Actions

The data was originally obtained in order to analyze the levels of expertise in the samba music plays (Yamamoto, Ishikawa, \& Fujinami, 2006; Yamamoto \& Fujinami, 2008). The dataset consists of five players, and each player performed basic samba shaking actions in five different tempos (60, 75, 90, 105, and 120 beats per minute, and each trial lasted 97.4 seconds on average) by being cued with a metronome. While playing, three dimensional motions of 18 markers, attached on body parts and musical instruments, were recorded at 86.1 Hz of sampling rate (Figure 1a-4). As well as the original study, here we aim to find the relationship between dynamical properties among bodily actions. For simplicity, we limited ourselves to analyze a subset of the original datasets, 3190 samples (74.1 seconds long) of four markers attached on the right wrist, right elbow, and two sides of the musical instrument (shaker), having the right shoulder as a reference point (Figure 1a-4). These were the essential parts of the samba actions making sounds directly, and we
expected that dynamic coordination among them would be crucial to characterize the dynamical properties of the samba.

## Preprocess and phase space reconstruction

In the analysis, after down-sampling the original data to 46.05 Hz , the first 250 samples ( 5.81 second long from the beginning of the recording) were excluded as initial setup of the actions, and 3250 samples ( 75.5 second long) of velocities were analyzed for each subject. In order to reduce measurement noise, for each movement of the markers, the local linear projective method was performed after phase space reconstruction of each time series on the 31 dimensional time delay space with 46 msec (i.e., $\{\mathrm{t}, \mathrm{t}+\Delta \mathrm{t}, \mathrm{t}$ $+2 \Delta \mathrm{t}, \ldots, \mathrm{t}+30 \Delta \mathrm{t}\}$ where $\Delta \mathrm{t}=46 \mathrm{msec}$ ) (Takens, 1981). This technique is a nonparametric and unsupervised method which, in principle, reduces observation noise independent of the time series intrinsically generated from a nonlinear dynamical system. Figure 1 (b-4) shows the original data (open circles) and its noise-reduced data (filled circles) after applying the local linear projective method. Due to digitalization in the motion capture system, the original data only takes certain discrete values which may be potential sources of observational noise in the measurement. As the result of the noise reduction, we obtained the 31 dimensional phase space of 3220 points for each coordinate of three dimensional positions of each marker movement in each subject and trial. An example of the reconstructed phase space is shown in Figure 1 (c-4).

## Estimating symbolic dynamics

For each estimated phase space (Figure 1c-4 and Figure 3), a symbolic dynamic is estimated by the symbolic false nearest neighbor method (Buhl \& Kennel, 2005; See also Hidaka \& Yu, 2010). In this algorithm, a symbolic state is assigned to each data point in the given phase space by minimizing the error in the one-to-one correspondence between spatial nearest neighborhood and symbolic nearest neighborhood. After convergence of the iterative minimization procedure, we obtained the series of binary symbolic states for the trajectory in the high dimensional phase space. Each symbolic series of length 5 (e.g., the subsequence " 01100 " as a state) is reported as a state in the present study, but we found the similar results consistently with the symbol length from 5 to 8 . It means that the state transition in each phase space is analyzed by partitioninig into 32 (i.e. $2^{5}$ ) distinct states.

## Results

In order to see the rhythmic properties as phase shifts in repeating actions, we analyzed the temporal profiles of the velocities in the right arm and wrist. Figure 2 shows the histogram of phase differences between body parts with the right shoulder as the reference point. Since the right elbow and wrist are the major body parts playing the shaker, their temporal structure was expected to reflect the rhythmic charateristics. However, not as expected, the five musicians showed quite different distributions in terms of phase shifts among body parts, even for the right wrist and elbow
movement to play the shakers to the same tempo. The peaks found for the elbow and wrist are sharp for musicians A and D, compared with those found in the other musicians. As for A, the peaks of the elbow and wrist come to the same phase, but the peak is less visible for the wrist. As for D , the peaks of the elbow and wrist come later than that of the shoulder. For the other musicians, no obvious feature is found. The frequency uniformly varying over the phase angle shows large fluctuations in arm movements for each musician. The histograms revealed both within-musician fluctuations and individual differences rather than similarity among actions. The results suggest that charaterization of the "same" action (i.e., playing to the samba rhythm) on the levels of physical properties may lead quite different patterns across subjects. Needless to say, changing physical properties such as tempos also directly changes phase differences. The level of physical properties is not sufficient for characterizing actions even if the major parameter of the actions (i.e., tempo) is well controlled.

Next, we analyzed the properties of actions by looking into the dynamical systems underneath body movements. A basic technique to characterize dynamical properties from an empirical time series is phase space reconstruction. A phase space reconstructed by time-delay embedding is visualied as a three dimensional subspace projection (Figure $1 \mathrm{c}-4$ ). The phase space is originally a set of velocity vectors of the four markers including two sides of the shakers, right wrist and elbow. The trajectory on the reconstructed phase space shows an attractor or the state space the system may take. The phase space is 124 dimensional space consisting of 31 time-delay copies of the four dimensional time series. First we analyzed the dimensionality of the attractors as one of invariance for the dynamical system. It is formally measured by correlation dimensions (Kantz \& Schreiber, 1997), and we found the correlation dimensions varying from 1.8 to 2.4 across five musicians and five conditions. These results suggested the state space of the samba rhythm is rather restricted on a low dimensional space.

Since the dimensions of the attractors are lower than three, it allows us to visualize them in the three dimensional space without losing much information. Figure 3 shows the attractors estimated for all five musicans on the five conditions. Visual inspection of the samba attractors grasps the gist of commonalities among the attractors. Consistently across most of the attractors, they share a similar shape of trajectories - a twisted double circle (which may appear different due to a specific visual angle of each attractor). These similar "shapes" of trajectories indicate that the topological nature of the attractors is similar.

In order to quantify the similarity among attractors, we performed analysis based on symbolic dynamics (Buhl \& Kennel, 2005). Symbolic dynamics offers a way to analyze a topological property of a dynamical system by constructing a homeomorphism (map preserving the topological nature) from the original space to a symbolic space. If two state spaces are homeomorphic (topologically identical), we find identity between their symbolic dynamics
as well. Importantly, it is easier to compute similarity between two symbolic spaces than that between two highdimensional phase spaces. This mathematical property is applied in our data analysis. By estimating the symbolic dynamics for each of the samba attractors, we estimated the probability of state space transition on the estimated symbolic space (Figure 4). Each of the top left two-by-two panels shows a probabilistic distribution (stationary distribution) of the symbolic states for each musician and condition. Each symbolic state is defined by a binary symbol series of length 5 (e.g., " 01100 "), and the distribution over its 32 possible states is shown in the figure.

In Figure 4, we show the analysis concerning a pair of musicians and conditions as representative results. Each distribution of symbolic states reflects the topological nature of the underlying dynamical systems - transitivity or connectivity of states in the system. As shown in Figure 4, the distribtions of state spaces are quite similar across subjects ( $\mathrm{R}=0.784$ and $\mathrm{R}=0.962$ ) shown in the panels of Figure 3 and across conditions ( $\mathrm{R}=0.959$ and $\mathrm{R}=0.803$ ) shown in the panels in Figure 2. Across all the pairs of five subjects and five conditions, the average correlation of distiribution is 0.831 . This means that the topological nature of the complex actions as dynamical systems were quite robust across different musicians and different playing tempos.

As a baseline comparison, we performed cross correlation analysis of the physical movements of the shaker (the major axis of the 3D motions with the most variance). By taking a time lag maximizing correlation, the average cross correlation was 0.453 across musicians and trials ( 0.462 across musicians (the same tempo) and 0.478 across tempos (the same musicians)). These results showed the temporal correlation of the shaker movements were not as high as the correlation of the symbolic state space ( 0.831 ) even with the time lag optimally adjusted and the playing tempo being held constant. This result means that the similarity of movements as physical properties cannot explain the topological similarities shown above.

Figure 2: The distribution of phase shift (radian) of right elbow (gray) and right wrist (white).

Figure 3: The reconstructed phase space embedding in three dimensional time delay space in Musician A-E playing at tempo $60,75,90,105$, and 120 BPM. The velocity of the trajectory in the three dimensional space is shown as RGB color code for its visibility.

Figure 4: Stationary distributions of states in each of symbolic dynamics (four top left panels) and their correlations between musicians and conditions (four right side and bottom panels).

The result -- higher similarity between topolgoical properties of the state space -- is quite surprising with consideration to the individual differences on the physical level charateristics (Figure 2) and low cross correlations in the physical movements. The results suggest that the topological properties of the attractors were quite similar across different musicians and tempos, while their physical realizations of the actions differed from person to person.

## Discussion

One of the challenges to the theory of action recognition is formalizing the possible attributes of characteristic actions. In the present study, we hypothesize that an intrinsic topological nature of actions as dynamical systems
characterizes a similarity between actions. This is meant to describe actions on the basis of invariances under nonlinear transformations, rather than the specific features (coordinate systems) the actions have. In other words, this is to abstract the actions from their physical properties. In order to test the hypothesis, we investigated the samba playing action, which is repetitive rhythmic movement. The samba rhythm fluctuates within a certain range, showing a complex accent pattern, even if an auditory cue is given to keep the tempo constant (Figure 2). No common property was found in movements across musicians in physical movements of the right arm.

Subsequently, we analyzed the same data from a perspective of actions as dynamical systems. In the analysis, we define a higher dimensional space in which the action is mapped as a trajectory. We analyzed time-delay vectors, which embed the time series of movements, i.e., lower dimensional data, into higher dimensional space.

The analyses revealed topological similarities in the reconstructed phase space among the musicians and among the different playing conditions. The analyses using the symbolic dynamics quantified the similarities in terms of their topological structures. In sum, these results supported our hypothesis that human actions can be characterized on the basis of invariances as dynamical systems. This invariant nature of the dynamical property can serve as a possible basis for our perception of actions, and offers an explanation of why we perceive them as "the same actions." Interestingly, the patterns revealed in the current analysis (Figure 3) are not just abstract-level depiction, but they also correspond with the introspective view of the samba rhythm (Figure 5: obtained from the most experienced musician A in the post-experiment interview). His drawing represents a general periodic motion with accents at a particular part of the trajectory. The geometric shape of the trajectory closely corresponds with the reconstructed phase space (Figure 3).

Finally, we briefly mention the implications to the two relevant research fields. One is the imitation of bodily movements. It is necessary to map from the body of the self to the body of the other in order to imitate the other's actions (Breazeal \& Scassellati, 2002). One of the traditional approaches to this problem is to compute inverse kinematics (estimating the motor control parameters from the perceived actions) upon which a number of robotics applications have been based (for example, Wolpert, Doya, \& Kawato, 2003). This approach, however, does not offer a sufficient explanation for neonatal imitations (Melzoff \& Moore, 1977) and how actions are identified, because neonate do not have opportunity to learn the cross-modal identity of the action (i.e., visual patterns of the other's action and motor control of the self). In turn, topological similarity of actions revealed in the present study may potentially offer a cross-body identity of actions regardless of their differences in physical particulars.
The present study proposes the dynamical perspective of actions in which it is essential to characterize topological similarities of actions as attractors. It is viewed as a
paradigm shift from cognition as inverse computation for an ill-posed problem to the computation of invariances under smooth transformations.

Figure 5: A drawing by the expert in his introspective explanation of the samba rhythm.

# Eye Movements Reveal Interplay Between Noun Capitalization and Word Class During Reading 

Sven Hohenstein (sven.hohenstein@uni-potsdam.de)<br>Department of Psychology, University of Potsdam,<br>Karl-Liebknecht-Str. 24/25, 14476 Potsdam, Germany

Reinhold Kliegl (kliegl@uni-potsdam.de)
Department of Psychology, University of Potsdam, Karl-Liebknecht-Str. 24/25, 14476 Potsdam, Germany

#### Abstract

Subjects' eye movements were recorded while they read sentences for comprehension. Sentences were presented with capitalized nouns-in agreement with German spelling rules-or completely in lowercase. Overall reading speed was not influenced by the manipulation of capitalization, but fixation durations were affected by the interplay between capitalization and the word classes of the fixated and the succeeding word. As expected, fixations were shorter for capitalized than lowercase nouns, but unexpectedly they were longer when the upcoming word was also a noun. This modulation was reduced when all words were printed completely in lowercase. We interpret the results as evidence for distributed processing across several words.

Keywords: eye movements; reading; corpus analysis; capitalization; parafoveal processing

## Introduction

The uptake of visual information is critical for the process of reading. Most visual receptors are located in the foveathe central $2^{\circ}$ of the visual field. As distance from the fixation location (and thereby from the fovea) increases, acuity decreases across the parafoveal region. Hence, it is necessary to move our eyes to obtain visual information of the words in a sentence. Foveal information of the currently fixated word is most essential for word processing. There is much evidence for the effect of, among others, orthographic, phonological, and semantic features of the currently fixated, foveal word as well as of the not-yet fixated, parafoveal word on fixation durations. Some of the parafoveal effects are still under dispute (for a recent review see Schotter, Angele, \& Rayner, 2012). The resolution of such disputes is critical for our understanding of eye-movement control during reading, because arguably parafoveal word processing is the primary source of information for guiding the eyes to the next fixation location.

## Capitalization

Although many studies have demonstrated the relevance of low-level orthographic features on eye movements during reading, little is known about the role of capitalization. In languages based on the Roman alphabet, the first words of a sentence and proper nouns are capitalized, that is these words are spelled with an initial capital letter. Additionally, German script has an unusual characteristic: the capitalizat-
ion of all nouns. Therefore, the frequency of capitalized words in German texts is relatively high, making it an ideal language for studying the impact of initial capital letters during natural reading.

Capitalized characters in parafoveal vision may be salient and attract attention to the preview word. Furthermore, German capitalization may reduce the cost of lexical processing. From the first letter alone, readers of German script obtain the word-class information (i.e., whether the next word is a noun vs. non-noun). Deeper lexical (e.g., semantic) processing of the word may start faster than in other languages because of the early availability of word-class information. Preprocessing of parafoveal words appears to be more likely in German than in less transparent orthographies (Laubrock \& Hohenstein, 2012).

There is research demonstrating a beneficial influence of capitalization on reading rate in German (Bock, 1989; Bock, 1990; Bock, Augst, \& Wegner, 1985; Bock, Hagenschneider, \& Schweer, 1989; Gfroerer, Günther, \& Bock, 1989). When uppercase and lowercase letters were used improperly, the reading rate was lower than when the German capitalization rules were observed (Bock et al., 1985). When Dutch subjects were asked to read German texts, they showed the same pattern of reading speed despite the absence of capitalization in Dutch (Bock et al., 1989). These effects were also reflected in eye-movement measures (Gfroerer et al., 1989). Furthermore, German subjects' reading rates for English texts were the same whether the rules of capitalization applied were based on German or English spelling (Bock et al., 1989), indicating that German readers transferred their familiar capitalization rules to text in a different language.

The advantage of capitalization increases with reading skill (Bock, 1990). For $10^{\text {th }}$-grade students, the effects of violations of German capitalization rules are similar to those obtained with adult readers. The same pattern was also present for $7^{\text {th }}$-grade children, but differences were less pronounced. Violation of the capitalization rule had no reliable effect on the reading speed of $3^{\text {rd }}$-grade children. In addition, on the basis of several experiments, Bock (1989) argued that the function of German capitalization rules for reading is independent of word shape, and that they allow differentiating between nouns and non-nouns without analyzing a word's meaning.

There is also evidence for the importance of capitalization in Italian. In Italian, like in most languages based on the Roman alphabet, proper names are spelled with an initial capital letter, whereas common nouns are spelled in lowercase. Peressotti, Cubelli, and Job (2003) demonstrated that reaction times in a lexical-decision task are reduced if proper names are presented capitalized compared to noncapitalized presentation and common nouns. The authors provide an orthographic cue hypothesis that an initial uppercase letter helps pre-activate lexical units corresponding to proper names.

Furthermore, Müsseler, Nisslein, and Koriat (2005) reported an influence of German capitalization rules on the missing-letter effect. Typically, when subjects are asked to underline a certain target letter, the letter is more difficult to detect in function words than in content words. In their study, this missing-letter effect was eliminated when function words within a sentence were capitalized indicating that unfamiliar orthography facilitates the extraction of single letters.

Finally, nouns are best recognized when they are presented with an initial uppercase letter (Jacobs, Nuerk, Graf, Braun, \& Nazir, 2008). In this study, subjects had to type single words that were presented briefly ( 50 ms ) and then followed by a mask. Words were presented with all letters in lowercase, with all letters in uppercase, or with an initial uppercase letter. Accuracy for non-nouns was best when they were presented with an initial uppercase letter or completely in lowercase (both types of presentation are common in German texts due to the capitalization of words at the beginning of a sentence).

Hohenstein and Kliegl (in press; Experiment 2) manipulated capitalization in an eye-movement study of semantic processing of parafoveal words. They asked subjects to read single German sentences for comprehension. Employing the gaze-contingent boundary paradigm (Rayner, 1975), the parafoveal preview for a critical target noun (wool) was semantically either related (silk) or unrelated (soap) to the target and was replaced with the target word during the saccade to the target location. Fixation durations on the target noun were shorter for related compared to unrelated previews, indicating parafoveal semantic information extraction. Most importantly, this effect was not modulated by capitalization: There was no significant difference between sentences presented completely in lowercase and sentences presented in agreement with the German capitalization rules (i.e., with capitalized nouns).

Hohenstein and Kliegl (in press) also analyzed the effect of capitalization on fixation durations on the target word, which was always a noun, and on the pretarget word, which was any of a number of different parts of speech, but never a noun. Whereas the violation of German noun-capitalization was reflected in longer target fixations, the pretarget was fixated more briefly if the sentence was presented completely in lowercase. This inverse effect of capitalization on pretargets and targets could not be explained by either (1) a general reading-speed benefit associated with a presentation
in which nouns are capitalized-a common result of past studies-or (2) a unique effect of capitalization on reading nouns, but not words which are always presented in lowercase. We hypothesize that the obtained effect is due to an interplay of capitalization and the word classes (nouns/nonnouns) of fixated and parafoveal words.

Here we report an eye-movement corpus analysis of German sentences, which were presented either completely in lowercase or with capitalized nouns (following the German spelling rules). The focus will be on the interaction between the word class of the preceding, current, and upcoming word and capitalization.

## Method

This is a reanalysis of the study of Hohenstein and Kliegl, (in press; Experiment 2). We describe the main features of the experiment, judged to be relevant for an appreciation of the present article; for further technical details we refer to the original article.

## Subjects

Thirty-two subjects ( 20 women, 12 men ) participated in the experiment. Their age was between 16 and $39(M=23$, SD $=4.8$ ). All were native speakers of German with normal or corrected-to-normal vision.

## Apparatus

Sentences were displayed on a single line at midscreen height on a 21 -inch monitor. Subjects were seated 24 inches in front of the screen. Sentences were presented in black, boldface, 20-point Courier New font on a white background. Each character was 12 pixels wide- $0.45^{\circ}$ of visual angleat a screen resolution of $1024 \times 768$ pixels. The refresh rate of the monitor was 150 Hz .

Eyes were monitored using an EyeLink II system with a sampling rate of 500 Hz , an instrumental spatial resolution of $0.01^{\circ}$, and an average accuracy of better than $0.5^{\circ}$. Recording was binocular. Heads were positioned on a chin rest to minimize head movements.

## Material

We used the material developed by Hohenstein, Laubrock, and Kliegl (2010). All sentences were constructed around a critical target region and ranged from six to thirteen words. In 100 sentences, the target word was a noun and the preceding word (i.e., the pretarget) was a non-noun. In 24 additional sentences, targets were non-nouns. The sentences did not include any punctuation except the period at the end. Word lengths ranged from two to eighteen characters.

Sentences were presented in two conditions: capitalized and non-capitalized. In the capitalized condition, the sentence's first word and all nouns were spelled with an initial capital letter. In the non-capitalized condition, all words were spelled in lowercase.

## Procedure

Subjects were naive concerning the purpose of the experiment. They were instructed to read single sentences for comprehension. A random sample of one third of the sentences was followed by a three-alternative multiple-choice question that was answered by clicking on one of the response alternatives. Ninety-five percent of all questions were answered correctly, indicating no serious comprehension problems.

At the beginning of the experiment, subjects were instructed that the experiment consisted of two parts. One part of the sentences was presented following the German capitalization rules and the other was presented completely in lowercase. Each part comprised 62 sentences, preceded by six practice sentences, which were not included in the analyses. Subjects were informed about the start of the second part.

When a sentence was initially presented, the preview (related or unrelated) occupied the target location. An invisible boundary located directly after the last letter of the pretarget word was present in each sentence. When either eye crossed the boundary, the preview word on the target position was replaced with the target word. The sentence remained in this final form until the end of the trial. The manipulation of the preview has no relevance for the present study.

## Measures and Selection Criteria

Data from sentences with a blink or loss of measurement was used only until the point in time preceding the first loss and only if the loss occurred after the target region. Saccades were detected with a binocular velocity-based algorithm (Engbert \& Kliegl, 2003; Engbert \& Mergenthaler, 2006). Analyses were based on right-eye fixations.

This first level of screening led to a pool of 39,646 fixations. In a second level of data screening, we excluded the first and last fixations in sentences $(7,830)$ and fixations on the first or last words of sentences $(9,608)$. We used firstpass fixations only (i.e., excluding 5,930 fixations). This second level of screening left us with 24,302 valid withinsentence reading fixations. Our selection procedure is similar to data filtering in a large eye-movement corpus study (Kliegl, Nuthmann, \& Engbert, 2006). We included all nontraining trials. Results were not affected by the exclusion of trials with subsequent comprehension errors.

We computed gaze durations (the sum of all first-pass fixations), first-fixation durations, and single-fixation durations (for a definition of these measures, see Inhoff \& Radach, 1998) for each word. Additional measures included refixation probability and relative landing position (i.e., the position of the first fixation). Furthermore, we calculated reading speed (words per minute) for each sentence.

## Statistical analysis

Inferential statistics for effects on fixation durations are based on linear mixed models (LMMs) specifying subjects and sentences as crossed random factors (Baayen, Davidson, \& Bates, 2008; Kliegl, Masson, \& Richter, 2010). LMMs
are much more resilient to data loss than the classical analysis of variance. Thus, these analyses are very powerful even for datasets with differences in the number of observations between subjects and items. Effects in models with continuous dependent variables were estimated with the lme 4 package (Bates, Mächler, \& Bolker, 2012) in the $R$ environment for statistical computing (version 2.15.2, 64-bit build; R Development Core Team, 2012). LMMs were fitted using the restricted maximum likelihood method.

We specified varying intercepts for both subjects and items. Furthermore, we included varying slopes associated with the effect of capitalization-the only experimental factor in the present study. The full model including variance components for all terms of the experimental design is preferred for statistical analyses (Schielzeth \& Forstmeier, 2009). Coverage probability of confidence intervals associated with fixed effects is better for LMMs including random slopes than for models including intercepts only (Schielzeth \& Forstmeier, 2009; Barr, Levy, Scheepers, Tily, 2013). With the additional inclusion of correlation parameters, models did not longer converge. Hence, these parameters were excluded. In a recent simulation study, Barr et al. (2013) demonstrated that models without random correlations are very similar to full models with respect to coverage probability and power. The authors rank both kinds of models in the first position of desirable model designs.

The primary fixed effects in the analyses were capitalization and the interactions between capitalization and the word classes of the preceding, the current, and the next word. Following the work of Kliegl et al. (2006), we included several additional covariates (word frequency, word length, saccade length, second-order polynomial of relative landing position), which have an influence on fixation durations in reading. The inclusion of these covariates reduced potential confounding for the word class predictors.

Continuous predictors were centered at their mean; relative landing position was centered at .5 ; the factor capitalization (capitalized presentation vs. non-capitalized presentation) entered the analysis as treatment contrast with capitalization as reference category ( 0 vs. 1 ) and the factors for word class (non-noun vs. noun) were specified as sum contrasts ( -0.5 vs. +0.5 ).

We report regression coefficients together with $p$ values based on Markov chain Monte Carlo sampling with 10,000 samples (Baayen et al., 2008). Based on analyses of model residuals, we decided to use the (natural) logarithm of all fixation-duration measures.

## Results

## Global Reading Speed

The analysis of reading speed tested only the effect of capitalization. Mean reading speed was 208 and 207 words per minute in the capitalized and non-capitalized condition, respectively. This difference was not significant ( $\beta=0.85 ; p$ $=.78$ ). The result differs from findings in earlier studies, in
which subjects read reliably slower if capitalization rules were not followed (e.g., Bock et al., 1985).

## Fixation Durations

The analysis of gaze duration ( 20,768 observations), firstfixation $(20,816)$, and single-fixation duration $(17,775)$ revealed the same pattern of effects. We present a detailed analysis of gaze durations only. Table 1 displays the results of an LMM analysis with gaze duration as dependent variable. There were several significant effects associated with word frequency, word length, landing position, and saccade length (see Table 1 for details).

The violation of German capitalization rules did not significantly influence gaze duration as a main effect, but there were several significant interactions associated with it. If the capitalization rules were followed, nouns were fixated more briefly than non-nouns. Interestingly, the word classes of the previous and the next word also had an effect on gaze duration: If the previous word was a noun, fixation time was shorter; if the next word was a noun, gaze duration was longer.

Most importantly, the interaction between capitalization and word class was significant both for the current and the next word. Figure 1 displays these interactions. As expected, a noun was fixated longer if the presentation was non-capitalized and thus with unfamiliar orthography. This trend was reversed with respect to the word class of the word to the right: Fixation duration was reduced if the next word was a noun and presented completely in lowercase. As is apparent from Figure 1, compared to reading under normal German capitalization conditions, fixation durations in sentences presented completely in lowercase are less modulated by properties of the fixated and surrounding text. These interactions were also significant for either first-fixation duration or single-fixation duration as dependent variable.

## Additional Analyses of Reading Behavior

There was a small effect of capitalization on saccade length: Saccades were shorter by 0.157 characters $(p=.003)$ if all words were presented in lowercase compared to the presentation following the German capitalization rules (means values: 6.20 vs. 6.35 ). The interactions between capitalization and words class had no significant effect on saccade length (all $p \mathrm{~s}>.07$ ). Initial landing position, skipping probability, regression probability, and refixation probability were not significantly influenced by capitalization or the interactions between capitalization and word class (all $p$ s $>.18$ ).

## Discussion

In the present study, subjects were asked to read sentences for comprehension. Sentences were presented in one of two capitalization conditions: In the capitalized condition, all nouns were spelled with an initial capital letter (following the German spelling rules); in the non-capitalized condition, all words were presented completely in lowercase.

Table 1: Estimates (regression coefficients) with associated standard errors and $p$-values as well as random-effect variances of a linear mixed-model corpus-analysis with log gaze duration as dependent variable.

| Fixed effects | Dependent variable: log gaze duration |  |  |
| :---: | :---: | :---: | :---: |
|  | Estimate | SE | $p$ |
| (Intercept) | 5.43494 | 0.026 | <. 001 |
| $\log _{10}$ frequency |  |  |  |
| Previous word | -0.02305 | 0.003 | <. 001 |
| Current word | -0.07392 | 0.003 | <. 001 |
| Next word | -0.00005 | <0.001 | . 100 |
| Length ${ }^{-1}$ |  |  |  |
| Previous word | -0.03763 | 0.039 | . 334 |
| Current word | -0.41590 | 0.048 | $<.001$ |

| Capitalization $\times$ word class |  |  |  |
| Previous word | 0.00183 | 0.013 | . 883 |
| Current word | 0.05577 | 0.014 | <. 001 |
| Next word | -0.07686 | 0.013 | $<.001$ |
| Random effects | Variance |  |  |
| Sentences |  |  |  |
| (Intercept) | 0.00154 |  |  |
| Capitalization | 0.00000 |  |  |
| Subjects |  |  |  |
| (Intercept) | 0.02003 |  |  |
| Capitalization | 0.00129 |  |  |
| Residual | 0.13397 |  |  |

Note. All continuous predictors were centred. Frequencies were $\log _{10}$ transformed. For length, the reciprocal was employed. "Current", "previous", and "next" indicate variables associated with the fixated word, the preceding word, and the succeeding word, respectively. The $\times$ symbol indicates an interaction.

Neither fixation times nor reading speed was significantly affected by the violation of capitalization. This result is in contrast to findings in earlier studies (Bock, 1989; 1990; Bock et al., 1985; 1989). We hypothesize the different result is due to changes in communication technology over the last 20 years. The earlier studies were conducted in the 1980s, a time in which text messaging, e-mail, and virtual chat rooms

Figure 1: Gaze duration on the current word as a function of capitalization and word class of the previous, the current, and the next word. Error bars indicate standard errors. All random effects and all fixed effects except the intercept, capitalization, and word class (including interactions) were removed from the data. The removal of effects was applied to each panel separately.
were less widely used than they are today. The use of short text messages with cellphones, in particular, is easier when all words are typed in lowercase. Indeed Schloblinski et al. (2001) found that most German text messages by students do not follow the German capitalization rules. Furthermore, texts in lowercase could be found in e-mails and social networks too (e.g., Schnitzer, 2012). In the present study, participants were young adults. Hence, we suppose our subjects were more proficient in reading text without capitalization than subjects in the earlier studies.

The most important findings are the interactions between capitalization and the word classes of the fixated and the next word. We demonstrated that the effects in a critical target region (Hohenstein \& Kliegl, in press) generalize to reading behavior throughout sentences. If German capitalization rules were followed, nouns were fixated more briefly than non-nouns. Interestingly, the effect was reversed for the upcoming word. We observed an effect of the parafoveal word on the current fixation duration. Parafoveal-on-foveal effects are an indicator of distributed processing of words
during reading (e.g., Kliegl et al., 2006). The case of a word's first character is easy to extract due to the saliency of an uppercase letter in a string of lowercase letters. The direction of the effects could be explained by a segmentation hypothesis: The words preceding nouns are often highly associated with those nouns (e.g., articles, adjectives). Perhaps, when a non-noun is fixated and the next word is a noun, both words are processed during the fixation on the non-noun (the word-group hypothesis; Kliegl, 2007; Radach, 1996). This results in a slowdown if the next word is a noun. Once the noun is fixated, it has already been preprocessed and hence fixation time is reduced.

When all words were presented in lowercase, the effects of word class were significantly reduced. Reading was less modulated by the word class and appeared to be more homogeneous. Although reading speed is comparable in both capitalization conditions, the reading strategy is different because salient orthographic cues are missing when capital letters are not present. This finding is evidence for the importance of parafoveal processing in reading.

In summary, the results reveal an impact of orthographic and visual word features on distributed processing during reading. Furthermore, readers are very flexible in adapting to different reading situations. That said, our results do not generalize to older readers who might encounter problems in the unfamiliar reading situation. Besides age differences, future research should focus on how non-native speakers of German use capitalization cues for their reading strategies.

## Acknowledgments

This research was supported by Deutsche Forschungsgemeinschaft (grants no. KL 955/6-1) as part of Research Group 868 "Computational Modeling of Behavioral, Cognitive, and Neural Dynamics".

#### Abstract

In human face-to-face communication, language comprehension is a multi-modal, situated activity. However, little is known about how we combine information from these different modalities, and how perceived communicative intentions, often signaled through visual signals, such as eye gaze, may influence this processing. We address this question by simulating a triadic communication context in which a speaker alternated her gaze between two different recipients. Participants thus viewed speech-only or speech+gesture object-related utterances when being addressed (direct gaze) or unaddressed (averted gaze). Two object images followed each message and participants' task was to choose the object that matched the message. Unaddressed recipients responded significantly slower than addressees for speech-only utterances. However, perceiving the same speech accompanied by gestures sped them up to a level identical to that of addressees. That is, when speech processing suffers due to not being addressed, gesture processing remains intact and enhances the comprehension of a speaker's message.

Keywords: language processing; co-speech iconic gesture; eye gaze; recipient status; communicative intent; multi-party communication.

## Introduction

Human face-to-face communication is a multi-modal activity and often involves multiple participants. Despite this, language comprehension has typically been investigated in uni-modal (i.e., just speech) and solitary (i.e., one passive listener) contexts. The present study investigates language comprehension in the context of two other modalities omnipresent during face-to-face communication, co-speech gesture and eye gaze. Moreover,
it explores the interplay of these modalities during comprehension in a situated, dynamic social context involving multiple interlocutors in different roles.

There is, by now, a plethora of empirical evidence demonstrating that speech and co-speech gestures are semantically integrated during comprehension (e.g., Holle \& Gunter, 2007; Holle, Gunter, Rüschemeyer, Hennenlotter, \& Iacoboni, 2008; Kelly, Özyürek, \& Maris, 2010; Özyürek, Willems, Kita, \& Hagoort, 2007; Willems, Özyürek, \& Hagoort, 2007, 2009). However, only two recent studies have begun to explore to what extent this integration is automatic, and to what extent it is controlled and influenced by the pragmatics of communication, such as the perceived intentional coupling of gesture and speech (e.g., when observing a gesture performed by one person accompanying speech produced by another) (Kelly, Ward, Creigh, \& Bartolotti, 2007; Kelly, Creigh, \& Bartolotti, 2010). The findings suggest that the semantic integration of gesture and speech is indeed sensitive to the intentional coupling of the speech and gesture modalities.

A question that remains is whether this holds when we situate speech and gesture comprehension in a context that is much closer to natural communication, such as in a face-to-face context, where speech and gesture are accompanied by additional nonverbal social cues, such as eye gaze. Due to the saliency of the sclera and the contrast it forms with the iris in the human eye, gaze direction is not only omnipresent but also an extremely powerful social cue in human face-to-face interaction (Senju \& Johnson, 2009). While some studies have investigated speech and gesture comprehension in the presence of eye gaze, they have typically done so without manipulating eye gaze direction as an independent cue (e.g., Green, Straube, Weis, Jansen, Willmes, Konrad, \& Kircher, 2009; Kelly, Kravitz, \&

Hopkins, 2004; Skipper, Goldin-Meadow, Nusbaum, \& Small, 2009; Straube, Green, Jansen, Chatterjee, \& Kircher, 2010; Wu \& Coulson, 2005, 2007).

One exception is a recent study by Holler, Kelly, Hagoort, and Özyürek (2012). Their study involved one speaker alternating her gaze between two recipients, thus rendering one of them addressed and the other unaddressed during each message she communicated. Despite this study involving multi-modal messages consisting of speech and gesture, the study was designed to primarily yield insights into the influence of eye gaze direction on the processing of the gestural component of bi-modal utterances. Thus, while showing that addressed and unaddressed recipients process gestures differently, the findings revealed no effect of eye gaze on the processing of speech. However, as the authors state themselves, this does not necessarily mean that addressed and unaddressed recipients do not differ in how they process speech; one reason being that the paradigm applied in their study required participants to focus attention on the verbal modality to make judgements about the speech they heard. This explicit attentional focus might have masked effects of eye gaze on speech processing that may be revealed in other contexts.

There are some studies that provide us with good reasons to assume that this is indeed the case. For example, Schober and Clark (1989) showed that overhearers process speech less well than addressees in a referential communication task. While this study did not involve a manipulation of eye gaze direction (nor a face-to-face context), it demonstrates that recipient status can have a significant impact on how we process language. This evidence is complemented by more recent studies that did investigate speech processing in the context of gaze. For example, Staudte and Crocker (2012) showed that a robot's eye gaze towards objects in the interlocutors' environment influenced participants' reference resolution, while Knöferle and Kreysa (2012) demonstrated that a person's eye gaze towards objects influences how participants process speech with respect to thematic role assignment and syntax.

Based on this earlier research, we predict that social eye gaze, indicating communicative intent and recipient status in conversation, also influences the processing of speech. Thus, the present study investigates how, in a multiparty setting, different types of recipients (as signaled through a speaker's eye gaze direction) process speech, and speech accompanied by gestures. To do so, we developed a visually focused paradigm that avoids explicit attention to speech to allow us to better observe potential differences in addressed and unaddressed recipients' processing of both uni-modal speech-only and bi-modal speech-gesture utterances.

Like Holler et al. (2012), we implement our task in a situated, triadic communicative setting. However, in our task, participants watched a speaker conveying speech-only or speech + gesture utterances referring to objects (e.g., 'he prefers the laptop'). The gestures accompanying these
utterances in the bi-modal condition were always iconic in nature and depicted a typical feature of the object (such as its function, e.g., a typing gesture). These messages were followed by two object images, one of them having been mentioned in the utterance. The task was simple - speakers were asked to indicate as quickly as possible which of the two images was related to the speaker's preceding message. This paradigm allows us to test, firstly, how different types of recipients process speech when it is the only modality carrying semantic information, and, secondly, how they process semantic messages that are communicated bimodally, via speech and co-speech gesture.

More specifically, we are also interested in seeing whether the findings from our study are in line with the Competing Modalities Hypothesis proposed by Holler et al. (2012). This hypothesis states that unaddressed recipients focus more on gesture than do addressed recipients, since they are processing information from fewer (visual) modalities overall (i.e., no eye gaze, since the speaker's eyes are averted to the other participant). They can therefore devote more cognitive resources to the gestures, and, as a consequence, they process the gesturally depicted meaning more than addressees. In contrast to Holler et al. (2012), whose paradigm was designed to tap primarily into cospeech gesture processing, we here test this hypothesis in a paradigm that allows us to measure the processing of both gesture and speech. That is, if, in the present study, we do observe an effect of recipient status on the processing of speech in a way that is in line with past research (e.g., Schober \& Clark, 1989) - meaning unaddressed recipients process speech less well - then the enhanced processing of co-speech gestures may benefit unaddressed recipients' comprehension of the speaker's message and compensate for some (or even all) of the speech processing disadvantage.

As an alternative, Holler et al. (2012) proposed the Fuzzy Representation Hypothesis. This hypothesis predicts that unaddressed recipients perceive gestures as being less intended for them than for the gazed at recipient. They therefore process gestures less clearly than addressees, and, as a consequence, end up with a fragmented, or fuzzy, representation of the gesturally depicted meaning. If the Fuzzy Representation Hypothesis is true, then we should see no benefitting effect of gestures on the processing of speech. Rather, unaddressed recipients might be slowed down even more when trying to process bi-modal utterances, since not only the speech poses difficulties for them, but also the gestures.

The present study aims to tease apart which of these two hypotheses may best explain how addressed and unaddressed recipients (as indicated by the speaker's eye gaze direction) comprehend multi-modal language in a pragmatically much richer communication context than has been traditionally investigated, that is, in a context that bears somewhat more resemblance to the kind of joint activity that human communication is (Clark, 1996).

## Method

## Participants

32 right-handed, native German speakers (16 female) participated in the experiment (mean age 24.5 yrs ).

## Design

We used a $2 \times 2$ within-participants factorial design, manipulating the gaze direction of the speaker (direct gaze/addressed recipient condition vs. averted gaze/unaddressed recipient condition) as well as the modality of presentation (speech-only vs. speech+gesture).

## Materials and Apparatus

Video clips 160 short sentences of a canonical SVO structure were constructed. Sentences always referred to an object combined with a non-action verb (see below for more detail), e.g. 'he prefers the laptop' ('er bevorzugt den Laptop'). The iconic gestures accompanying the sentences always referred to the object that was mentioned in speech and provided information about its shape, function, or size (see Fig.1, for a gesture depicting the act of typing).

In order to guarantee that the gestures unambiguously referred to the objects mentioned, verbs were carefully selected to be as neutral as possible and were never action verbs. Hence, rather than more commonplace constructions like 'he types on the laptop' where the typing gesture could refer to both 'typing' and 'laptop', verbs like 'prefer' ('bevorzugen'), 'like' ('mögen'), or 'see' ('sehen') were used in the sentences. Our manipulation of both gaze direction and modality of presentation required each sentence to be recorded in four versions: 1. direct gaze (addressed) speech-only, 2. direct gaze (addressed) speech+gesture, 3. averted gaze (unaddressed) speech-only, and 4. averted gaze (unaddressed) speech + gesture (Fig. 1).

Figure 1: Four different versions of the 'laptop' stimulus. $\mathrm{AR}=$ addressed recipient, $\mathrm{UR}=$ unaddressed recipient.

Object pictures We created a total of 320 object pictures. 160 of these were pictures of the objects mentioned in the

160 stimulus sentences (e.g., a picture of a laptop), and an additional 160 pictures were selected to serve as unrelated pictures, such that the 'laptop' would be presented alongside a 'towel', for example (Fig. 2). Object pictures were searched via Google Images and further edited in Adobe Photoshop to have all objects presented in the same quality and size on a white background.

Prior to testing, all 320 pictures were judged by two raters (female native German speakers who did not participate in the main experiment) for their ease of identification.

Figure 2: Example of a pair of object pictures.
Each participant saw each of the 160 video clips in one of the four conditions exactly once, resulting in 160 experimental trials per participant ( 40 trials per condition), plus 24 filler trials, yielding 184 trials overall. To avoid confounding effects of the order in which the pictures were presented on the screen, this order was counterbalanced.

Videos and object pictures were presented on a 15 " laptop screen using Presentation software (http://www.neurobs.com). The audio signal of the videos was presented via high quality Sennheiser headphones.

## Procedure

Participants were tested individually. At the beginning of each testing session, participants were familiarised with the experimental set-up and the course of the experiment, and were seated in front of the experiment laptop where they received their instructions.

Participants were told that they would see a number of pre-recorded video clips of a speaker (in fact a confederate) who, they were told, spontaneously formed short sentences based on line drawings and single words displayed on a screen not displayed in the video shot. They were also told that during the recordings, a second person was present in the room, sitting diagonally across from the speaker. The speaker was supposedly instructed to sometimes address this other (fictitious) participant when producing her utterances (averted gaze condition), and to sometimes address the (actual) participant via a video camera positioned straight across from her (direct gaze condition). Participants were instructed that following each video clip, they would see two pictures of objects on the screen, and that it was their task to indicate via button press which of the two pictures best matched the speaker's message (left button for the left-hand picture, right button for the righthand picture). They were asked to react as quickly and as
accurately as possible. Reaction times of participants' left/right responses were recorded via a button box, as were response accuracies.
In order to ensure that participants were actually watching the video clips and not basing their decision on the spoken part of the message only, they were explicitly asked to look at the screen during the entire course of the experiment. This was further enforced by the presence of a surveillance camera (our checks showed that no participant had looked away), which all participants agreed to be videorecorded with during the experiment.
Before the beginning of the experiment proper, participants completed a total of six practice trials. As in the actual experiment, each trial consisted of a video clip, followed immediately by the two object pictures, which stayed onscreen until the participants pressed a button. After their response, participants saw a fixation cross for a random time interval between 2 and 5 seconds before the next trial started.

## Results

A total of six trials from two participants were excluded from the analysis beforehand because of a technical error. An alpha value of .05 was used throughout our statistical analyses. All p-values reported are two-tailed.
For the analysis of the reaction times ${ }^{1}$, we excluded all incorrect responses, 83 in total ( $=1.62 \%$ of all trials). Also excluded from the analysis were responses more than 2.5 SD above or below each subject's mean reaction time (this resulted in 118 responses being excluded: 40 in the speechonly condition, direct gaze, 31 in the speech-only condition, averted gaze, 23 in the speech + gesture condition, frontal gaze, and 24 in the speech + gesture condition, averted gaze).
Figure 3 shows the reaction time data for the 2 (gaze direction: direct vs. averted) x 2 (modality of presentation: speech-only vs. speech + gesture) repeated measures ANOVA. The results yielded a significant interaction, $\mathrm{F}(1,31)=5.947, \mathrm{p}=.021$. The main effect of modality was not significant, $\mathrm{F}(1,31)=3.431, \mathrm{p}=.074$, and neither was the main effect of gaze, $\mathrm{F}(1,31)=.464, \mathrm{p}=.501$.
In line with our hypotheses, we calculated two a priori contrasts (using paired-samples t -tests), comparing addressed and unaddressed recipients' processing of unimodal speech-only utterances, as well as their processing of the bi-modal speech+gesture utterances. The first comparison showed that unaddressed recipients ( $\mathrm{M}=$ 542 ms ) were significantly slower than addressees ( $\mathrm{M}=$ 530 ms ) at processing speech-only utterances, $\mathrm{t}(1,31)=$ $2.547, \mathrm{p}=.016$. The second comparison, however, showed that unaddressed ( $M=525 \mathrm{~ms}$ ) and addressed $(M=531 \mathrm{~ms})$

[^298]recipients did not differ in their processing of speech + gesture utterances, $\mathrm{t}(1,31)=1.112, \mathrm{p}=.275$.

Figure 3: Addressed recipients' (AR) and unaddressed recipients' (UR) reaction times (ms) in the speech-only and speech + gesture conditions (error bars represent SE ).

## Discussion

This study investigated multi-modal language processing in a situated, socially dynamic communication setting involving multiple parties. The specific question we tried to answer is how different types of recipients, as signaled through a speaker's eye gaze, process speech and speech accompanied by iconic gestures, in a triadic communication scenario. The findings revealed a significant interaction between modality and recipient status. More precisely, they show, first and foremost, that the processing of speech-only utterances is indeed affected by recipient status in our task, since unaddressed recipients were significantly slower in this condition than were addressed recipients. Crucially, addressed and unaddressed recipients did not differ in their processing of speech+gesture utterances. That is, unaddressed recipients significantly benefitted from the information depicted in the gestural modality, allowing them to perform at the same level as addressees when perceiving bi-modal rather than uni-modal utterances.

The findings are thus very much in line with the Competing Modalities Hypothesis (Holler et al., 2012). Unaddressed recipients appear to focus their cognitive resources on the processing of co-speech iconic gestures. At the same time, the findings allow us to further refine this hypothesis; because we found that unaddressed recipients do not process speech more quickly than addressed recipients, the competition effect seems to apply to the visual modalities (gesture and gaze) only. In other words, due to not having to process eye gaze, unaddressed recipients can focus more on gesture and, as a consequence
process this information more. Their increased processing capacity due to the absence of direct gaze does not, however, affect their processing of speech-only utterances.

The reason as to why, in contrast to Holler et al. (2012), we found a numerical but no reliable difference between addressed and unaddressed recipients' processing of bimodal utterances (i.e., unaddressed recipients were slightly faster in the bi-modal condition than addressed recipients were, but not significantly so) is likely to be due to our change in paradigm. As argued in the Introduction, the explicit attentional focus on the verbal modality in Holler et al.'s (2012) study might have masked differences in the processing of speech - an assumption that we were able to corroborate here. In the present study, we purposefully shifted participants' attention towards the visual modality (by asking them to identify pictures) in order to uncover potentially previously masked differences in speech processing, while being aware that this shift in paradigm might, in turn, reduce differences in the processing of visual (i.e., gestural) information between addressed and unaddressed recipients. The present study thus complements that by Holler et al. (2012) nicely. Together, they offer us a more comprehensive insight into how different recipients process uni-modal and bi-modal utterances in the presence of eye gaze.
What remains to be investigated are the exact cognitive mechanisms underlying our Competing Modalities account. Currently, we are unable to determine whether the iconic co-speech gestures benefit unaddressed recipients' processing of speech because they are semantically integrated with the verbal information - thus leading to a richer, unified mental representation of the concept of 'laptop', for example - or whether they lead to a stronger memory trace due to receiving related information from two different input streams (visual and verbal), with this information being associated but stored separately and not as a unified representation (much like a dually-coded representation à la Paivio (1986)). Future studies, preferably involving on-line measures suitable for dipping directly into semantic integration processes, are needed to answer this question.
In conclusion, the present study has brought together three different modalities in a language processing paradigm, and it advances our understanding of how perceived communicative intent, as signaled through a speaker's eye gaze, influences the interplay of these modalities during comprehension in a situated, face-to-facelike (rather than solitary) setting. The findings are striking since we have shown that the ostensive cue of eye gaze has the power to modulate how different recipients process semantic information carried by two concurrent modalities, speech and co-speech gestures. Moreover, we have shown that in situated face-to-face settings involving multiple recipients, the gestural modality can benefit unaddressed recipients - when speech processing suffers, gestures help.

## Acknowledgments

We would like to thank the University of Rostock for their provision of testing space, the Radboud University and MaxNet initiative for financial support, the Neurobiology of Language Department and the Gesture \& Sign Research Group at the Max Planck Institute for Psycholinguistics for helpful feedback during discussions of this study, and the European Commission for funding this research (JH was supported through a Marie Curie Fellowship \#255569, and through ERC Advanced Grant \#269484INTERACT).

#### Abstract

Previous research indicates learning words facilitates categorization. In the current study, we investigated whether learning about a category facilitates word learning (retention) by presenting 2 -year-old children with multiple referent selection trials to the same object category. Children either encountered the same exemplar repeatedly or encountered multiple exemplars across trials. All children did very well on the initial task. However, only children who encountered multiple exemplars retained these mappings after a short delay. Overall, these data provide strong evidence that providing children with the opportunity to compare across exemplars during referent selection facilitates retention.

Keywords: word learning; fast mapping; categorization; multiple exemplars

Learning the names for object categories is necessary for children to make sense of their world and to communicate about it effectively. Perhaps it is not surprising, then, that children's early vocabularies are dominated by names for object categories (Samuelson \& Smith, 1999; Waxman, 2003). Previous research has demonstrated a close relationship between vocabulary acquisition and categorization (e.g., Gopnik \& Meltzoff, 1992; Thom \& Sandhofer, 2009). However, although several studies have demonstrated knowing more words facilitates categorization, it remains unclear how experience with object categories may facilitate word learning.

Word learning is a complicated process, involving both fast and slow mapping (McMurray, Horst, \& Samuelson, 2012). The first time a novel name is encountered, the child quickly forms an initial, rough hypothesis of the word's meaning-hence the term fast mapping (Carey, 1978). For example, when presented with a boat, a cup and a novel black-and-white stuffed animal and asked for the penguin, a 2-year-old child can reliably determine that penguin refers to the animal (PENGUIN). However, simply forming this initial mapping does not mean that the child has really learned the word-that is, that the child could recall the name-object association after a delay or in a new context, for example with other novel toys (Horst \& Samuelson, 2008; Riches, Tomasello, \& Conti-Ramsden, 2005, Waxman \& Booth, 2000). Indeed, processing demands
might prevent young children from learning the correct name-object association after only a single exposure (Mather \& Plunkett, 2009).

In contrast to fast mapping, full word learning emerges gradually during a period of slow mapping (Capone \& McGregor, 2005; Carey, 1978; Horst \& Samuelson, 2008). During this phase repeated encounters allow the child to strengthen the name-object association such that it can be recalled after a delay. Importantly, the penguin-PENGUIN association will be strengthened each time the child hears the word penguin and sees the animal in a new situation. For example, a child might see a stuffed penguin at daycare and then later play with a penguin and other animals during bath time at home. Across such situations children learn about the statistical regularity with which the names and their referents co-occur (cross-situational word learning; Munro, Baker, McGregor, Docking \& Arculi, 2012; Smith \& Yu, 2008). Clearly, then, repeated exposures are critical for word learning.

However, children do not only learn names for individual items, but also learn names for object categories. Categories are collections of items which share common features (e.g., Quinn, Eimas \& Rosenkrantz, 1993; Rosch, 1975), but which are still discriminable from each other. In the PENGUIN category, for instance, the majority of members share the common features of black-and-white coloring, two legs and the ability to swim, but the individual members are discriminable. For example, a child can discriminate between a stuffed penguin and a plastic penguin bath toy. Importantly, during early word learning, children not only encounter the same category exemplar repeatedly but may encounter multiple, different exemplars over time.

When children are presented with multiple exemplars across situations, they may compare across items, which induces categorization by helping children to detect both the commonalities and differences between the category members, both of which are critical for categorization (e.g., Kovack-Lesh \& Oakes, 2007; Oakes \& Ribar, 2005). Kovack-Lesh and Oakes (2007) have reported that simply providing the opportunity to compare across exemplars during the transition between trials is enough to help infants form a category they otherwise do not form when presented
with the same items in the same sequence. This is especially important because it demonstrates that young children are able to compare between exemplars across trials.

Namy and Gentner (2002) as well as others (e.g., Casasola, Bhagwat, \& Burke, 2009; Waxman, 2003) have previously argued that applying a common name to multiple exemplars invites children to compare across items and draws their attention to shared commonalities. For example, when two objects are given the same name, children will extend this common name to new objects that share the same perceptual features with the named exemplars (e.g., Samuelson \& Smith, 1999). Importantly, these findings demonstrate that exposing children to multiple, variable exemplars labeled with a common, novel name allows children to detect the similarities between objects and therefore facilitates categorization.

However, it remains unclear whether comparison facilitates children's ability to retain category names because the existing studies on the effect of presenting multiple category exemplars on word learning have focused largely on generalization. For example, in a longitudinal category training study, toddlers who encountered multiple perceptually variable exemplars experienced a significant acceleration in vocabulary growth and were able to generalize novel names to novel exemplars from the same categories, in contrast to children who encountered perceptually similar exemplars (Perry, Samuelson, Malloy, \& Schiffer, 2010).

The current study examines whether providing children with the opportunity to compare across exemplars facilitates their ability to learn and retain names for novel object categories. We tested 2-year-old children because they can complete multiple trials without becoming overly tired and enjoy this particular task. We provided children with multiple fast mapping by mutual exclusivity trials to better understand how encountering multiple exemplars facilitates cross-situational word learning. Further, while previous studies have investigated how encountering multiple exemplars effects children's generalization of novel names, the current study explores the effect on retention. Specifically, children encountered each novel object category across three referent selection trials. Half of the children were repeatedly presented with the same exemplar across trials and half of the children were presented with multiple exemplars across trials. If providing the opportunity to compare across exemplars facilitates crosssituational word learning, then children who fast-mapped multiple exemplars should demonstrate better retention.

## Method

## Participants

Twenty-four children aged 2;6 (13 girls, $M=2 ; 6 S D=43.19$ days; range $=2 ; 4-2 ; 8$ ) with a mean productive vocabulary of 563.75 words $(S D=81.91$ words, range $=391-668$ words) and no family history of colorblindness participated. Children were from predominantly middle class homes. Half of the children were randomly assigned to the single
exemplars condition and the other half were randomly assigned to the multiple exemplars condition. Children's ages and productive vocabularies did not differ between conditions. Data from two additional children were excluded from analyses due to fussiness and experimenter error. Parents were reimbursed for travel expenses and children received a small gift for participating.

Figure 1: Novel stimuli

## Stimuli

Eighteen known objects, chosen because they are highly familiar to 2-year-old children, served as familiar objects: bird, chicken, elephant, fish, giraffe, lion, boat, bus, car, motorcycle, plane, train, block, chair, comb, cup, toy mobile phone and spoon.

Nine novel objects from three categories, chosen because they are not easily named by 2-year-old children, served as the target objects (see Figure 1). Consistent with other studies (e.g., Vlach, Sandhofer, \& Kornell, 2008), the objects in these categories varied in color and texture, but shared the same shape.

The doff category consisted of slightly transparent, plussign shaped tops in yellow, green and red. The cheem category consisted of plastic rods with small balls on one end in blue/orange, orange/blue and yellow/green. The hux category consisted of rubber balloons with elastic strings hanging down in blue/orange, yellow/blue and green. The balloons kept their shape because they had foam balls inside them. All objects were similar in size ( $5 \mathrm{~cm} \times 8 \mathrm{~cm} \times 10 \mathrm{~cm}$ ). Stimuli were presented on a white tray divided into three even sections. A digital kitchen timer was used to time the 5-minute break.

## Procedure and Design

Before the experiment began, the experimenter showed the parent color photographs of the known and novel objects to ensure they were known and novel to the child, respectively (which they were for all children). During the experiment, children were seated in a booster seat at a white table across from the experimenter. Parents sat next to their children and completed a vocabulary checklist and were instructed to
avoid interacting with their children, but to encourage them to respond during the warm-up trials if necessary. None of the children needed parental encouragement after the warmup trials.

Warm-up trials Each session began with three warm-up trials to introduce children to the task. On each trial, children were presented with three randomly selected known objects. First, the experimenter set the tray of objects on the table and silently counted for three seconds to give the child an opportunity to look at the objects (see also, Horst, Scott, \& Pollard, 2010). Then, the experimenter asked the child to select an object by naming it twice (e.g., "Can you find the block? Can you get the block?") before sliding the tray forward. Children were praised heavily for correct responses and corrected if necessary. Between trials the experimenter replaced the tray on her lap and arranged the objects for the next trial out of the child's view.

The same objects were presented on each warm-up trial, but object positions (left, middle, right) were pseudorandomized across trials. Thus, children were asked for a different object in a different position on each trial. These stimuli were later used as known objects during the referent selection trials (see also, Horst \& Samuelson, 2008).

Referent Selection Task. Referent selection trials immediately followed the warm-up trials and proceeded in the same manner except that children were neither praised nor corrected.

Each child was presented with nine sets and saw each set once on a known name referent selection trial and once on a novel name trial for a total of 18 referent selection trials (see Figure 2 for examples). Known name trials were included to ensure that children were mapping the names to the requested targets and not simply mapping novelty to novelty (Horst, Samuelson, Kucker \& McMurray, 2011).

Figure 2: Trials on which a doff exemplar was present

Each set included two familiar objects (e.g., boat and cup) and one novel object (e.g., top). Children in the multiple exemplars condition saw a different novel exemplar in each set. For example, a child might see the green top with the block and lion, the red top with the chair and train and the yellow top with the bus and fish (see Figure 2). Children in the single exemplars condition saw the same exemplar in each set. For example, a child might see the green top with the block and lion, and again the chair and train and once more with the bus and fish. Thus, the only difference between conditions was whether children saw one or three exemplars from each category.

Referent selection trials were presented in three blocks. For example, one child completed all trials with the doff category, then all trials with the cheem category and finally all trials with the hux category. Block order was counterbalanced across participants using a Latin Square design. The order of known and novel trials was pseudorandomized in each block such that the same set (e.g., green top, lion, block) was never presented on two consecutive trials and no more than two trials of either type (i.e., known or novel) were presented sequentially. Object position (left, middle, right) was randomly determined on each trial. Between the referent selection task and the retention task the child remained at the table and colored pictures during a 5minute delay period, which was included to ensure that children's retention was based on long-term memory representations for the novel name-object associations formed during the referent selection phase rather than shortterm maintenance (for a similar argument see, Horst \& Samuelson, 2008).

Retention Task The retention task was the same in both conditions. First, to re-engage children in the task, a new warm-up trial with three different known objects was presented. This was immediately followed by three retention trials, during which children saw three novel exemplars: one from each novel category (top, rod, balloon). The same exemplars were presented on all trials for a given child. In the single exemplars condition, children were presented with the same exemplars encountered earlier. In the multiple exemplars condition, children were presented with one of the three exemplars encountered earlier, with each exemplar (e.g., green top) being presented equally often across children. Object positions were randomized across trials and children were asked for a different novel object in a different position on each trial.

Coding. Children's responses were coded offline from DVD. Responses included touching and picking up objects (see Horst et al., 2011, for a deeper discussion of possible responses on this type of task). A naïve coder coded $20 \%$ of the sessions for reliability. Inter-coder agreement was high, $M=98.08 \%, S D=3.44 \%$ (range $=92.31 \%-100.00 \%$ ). Overall, $90 \%$ of the target words were included in the analyses of children's retention as, like prior studies, only the words that a child correctly fast-mapped at least once
during the referent selection trials were included in subsequent analyses. There was no evidence of group differences in interest/attention during the experiment.

## Results

We first compare children's performance to chance levels and then compare children's performance between conditions. As can be clearly seen in the left panel of Figure 3 , children in both conditions were very accurate at choosing the target object during the initial referent selection task. On known name referent selection trials, 11 children in each condition chose the target on every trial, and one child in each condition chose the target on $8 / 9$ trials. Thus, children's proportion of target choices was the same for both conditions and greater than would be expected by chance (.33), $t(11)=71.73, p<.0001, d=20.60$ (all $p$ s are two-tailed). On novel name referent selection trials, children's proportion of target choices was also greater than expected by chance (.33) both for children in the multiple exemplars condition, $t(11)=6.57, p<.0001, d=2.38$ and for children in the single exemplars condition, $t(11)=4.59$, $p<.001, d=.84$. Again, there was no difference between conditions, $t(22)=.345$, ns. Thus, whether children encountered multiple exemplars or the same exemplars repeatedly during referent selection did not influence children's performance on either known or novel name referent selection trials.

Our main question in this experiment was whether encountering multiple exemplars or the same exemplars repeatedly during referent selection influenced retention. As can be seen in the right panel of Figure 3, only children in the multiple exemplars condition retained more names than expected by chance (.33), $t(11)=5.00, p<.001, d=1.46$. Children in the single exemplars condition failed to retain more words than expected by chance, $t(11)=1.47, n s, d=$ .44. An unpaired $t$-test confirmed that children who encountered multiple exemplars retained more words than children who encountered the same exemplars repeatedly, $t(22)=2.06, p \leq .05, d=.16$.

Figure 3: Children's proportion of correct choices. Dotted line represents chance (.33). Error bars represent one standard error. ${ }^{* * *} p<.0001,{ }^{* *} p<.001,{ }^{*} p \leq .05$.

Table 1: Number of words retained as a function of number of correct referent selection trials. N in parentheses. Exact binomial probabilities, ${ }^{* * *} p<.0001, * * p<.01, * p<.05$.

|  | Correct Number of Trials per Word During Referent Selection |  |  |
| :---: | :---: | :---: | :---: |
|  | One Trial | Two Trials | Three Trials |
| Multiple | 2 (6) | 6 (9)* | 15 (18)*** |
| Exemplars |  |  |  |
| Single | 1 (6) | 3 (8) | 11 (17)** |
| Exemplars |  |  |  |

To further understand how multiple exemplars influence children's ability to retain newly fast-mapped names we also explored retention as a function of number of successful referent selection trials. As can be seen in Table 1 , when children only successfully fast-mapped on one of the three trials, they were unable to retain that name over a 5-minute delay, regardless of whether they saw the same or different exemplars on their two unsuccessful trials. When children successfully fast-mapped twice, they were able to retain that category name if they encountered multiple exemplars but not if they encountered the same exemplar repeatedly. Finally, when children successfully fast-mapped three times, they were able to retain that name whether they had mapped the name to multiple exemplars or to the same exemplar repeatedly. Taken together, these data confirm that multiple exemplars facilitate word learning via fast mapping and that sufficient encounters with the same exemplar can also lead to retention.

## Discussion

The current study explored how providing the opportunity to compare across multiple category exemplars facilitates children's ability to learn and retain names for novel object categories. We presented 2 -year-old children with multiple referent selection trials with the same object category. Children either encountered the same exemplar repeatedly or multiple exemplars across trials. Overall, all children did very well on the initial referent selection task. However, only children who encountered multiple exemplars retained the previously fast-mapped novel names after a delay. Further, these children demonstrated significantly better retention than children who only encountered the same exemplar repeatedly.

Overall, these data demonstrate that experience with multiple exemplars facilitates word learning, specifically retention of fast-mapped names for object categories. Other studies that have explored the relationship between vocabulary and categorization have typically tested children over a long time scale, such as several weeks (Ellis \& Oakes, 2006; Perry et al., 2010). However, the current study reveals that exposing children to an object category, rather than a single category member, facilitates children's ability to learn the name for that category within minutes (see also Kemler Nelson, O'Neil, \& Asher, 2008).

These findings also add to the literature demonstrating that comparison facilitates categorization (e.g., Gentner \& Namy, 1999; Kovack-Lesh \& Oakes, 2007) and that applying a common name to multiple exemplars invites children to compare across items, drawing their attention to shared commonalities (Casasola et al., 2009; Gentner \& Namy, 1999; Namy \& Gentner, 2002; Plunkett, Hu \& Cohen, 2008). It is likely that children also learned from encountering the same exemplars repeatedly, but that this learning was not robust enough to withstand a short delay.

The current study also demonstrates that behavior is the product of nested timescales, consistent with dynamic systems theory (Thelen \& Smith, 1994). Specifically, in the current study, children's ability to retain words emerged as a product of their present (what they were currently seeing), their just previous past (how many exemplars they had just fast-mapped) and their past (their developmental history of learning about names and categories).

Importantly, these data clearly indicate that encountering multiple exemplars led to better novel name retention. We believe that children who encountered multiple exemplars retained words at greater rates because each encounter with a new exemplar invited them to compare the new exemplar to their stored memory representations for that object category, thus enabling them to encode additional information. That is, as each exemplar was encountered children's stored memory representations were updated and elaborated. This explanation is consistent with exemplar theories of categorization (e.g., Murphy, 2002; Medin \& Schaffer, 1978; Nosofsky, 1984), which argue that individual representations are formed each time an exemplar is encountered.

Previous research that has investigated how multiple exemplars influence children's word learning has done so by presenting multiple exemplars at test. After encountering a single exemplar from the target category, children are typically presented with one of two types of test trials. Using referent selection tasks, children are tested with another exemplar from the same category, a completely novel foil and known foils (e.g., Mervis \& Bertrand, 1994; Golinkoff, Hirsh-Pasek, Bailey \& Wenger, 1992). Children are very good at selecting the target as opposed to a completely novel object. However, any delay is minimal (e.g., 1-2 trials later), thus we cannot be sure that we are testing children's long-term memory for new words rather than short-term maintaince.

Using naturalistic play situations, children are tested after a short delay, but they are tested with the same previouslyencountered exemplar, another exemplar from the same category and a novel foil (e.g., Jaswal \& Markman, 2003; Waxman \& Booth, 2000). Children are very good at selecting the previously-encountered exemplar, however, it is not clear that we are testing generalization if the same exemplar is presented again. In addition, these tasks do not control for novelty differences between the test alternatives, which can have a profound effect on children's responses (Horst, et al., 2011).

The current study is different. Specifically, we presented multiple exemplars during referent selection to provide an opportunity to compare across exemplars during fast mapping to investigate the effect of comparison on full word learning. Note, other studies that have tested children's retention for name-object associations learned via referent selection have only included one exemplar for each category (e.g., Horst \& Samuelson, 2008; Kucker \& Samuelson, 2011), although, recently Ankowski, Vlach and Sandhofer (2012) presented multiple exemplars to demonstrate that simultaneous presentation facilitates abstraction and generalization for new category members better than spaced presentation. In addition, the relative novelty of the test alternatives was controlled as each had previously served as a target and each had been encountered the same number of times. Thus, although previous research has tested the strength of children's newly formed nameobject category associations by presenting different exemplars at test, the current study is the first fast mapping study to explore the role of comparison in word learning by manipulating the strength of children's name-object category associations formed during referent selection across encounters with multiple exemplars.

Overall, then, the current study adds to a growing body of evidence that experience with multiple exemplars and within-category variability influences young children's word learning. Importantly, this study demonstrates that categorization can have a profound effect on children's word learning over a short time scale. Thus, the current study is among the first to systematically investigate the interplay between category variability and cross-situational word learning, and as such provides important groundwork for further research in the area, as well as informs our understanding of category learning and cognitive development, more generally.

## Acknowledgments

We thank the parents and children who participated and members of the Word Lab for their administrative assistance. We would also like to thank Emma Axelsson, Karla McGregor, Sammy Perone and Larissa Samuelson for helpful discussions related to this research.

#### Abstract

In cognitive science there is a paradox: Researchers studying decision making have repeatedly shown that people employ simple and often less than optimal strategies when integrating information from multiple sources. However, researchers working in fields such as categorization, memory, and perception have had great success using optimal models to account for information integration. Is this conflict due to the use of different materials and procedures? We test the hypothesis that stimuli requiring more controlled information integration lead to suboptimal performance, while stimuli that lend themselves to more automatic processing produce more optimal integration. We test for one canonical example of sub-optimal information integration, the dilution effect, using stimuli more commonly found in perception experiments. Dilution was indeed reliable across several conditions. The largest effects occurred in stimuli manipulated so as to discourage automatic processing. We use the Multicomponent Information Accumulation model to explain how stimulus presentation influenced cognitive processing.

Keywords: dilution effect; information integration; models

## Introduction

Information integration is the combining of evidence from multiple sources. Many tasks, from speech comprehension to medical decision making, require such integration. Each source of information on its own provides some evidence, but integrating all information yields the best performance. This article investigates the manner in which information is combined. While the literature provides numerous examples of near-optimal information integration, there are just as many examples where it is far from optimal. The types of stimuli and procedures used often determined the pattern of results. Tasks involving quantitative stimuli, like probability judgments (Tversky \& Kahneman, 1974), seem to implicate heuristic strategies, more than perceptual tasks, like speech comprehension (Oden \& Massaro, 1978). Our research tests the hypothesis that even perceptual information can produce suboptimal integration if it is displayed in a way that discourages automatic processing.

## Suboptimal Integration in Decision Making

Many studies of judgment and decision making suggest that information from multiple sources is integrated via simple heuristics. Sometimes these studies produce behavior approaching optimal decision making (Gigerenzer \& Todd, 1999), but in many other cases, performance is well short of
optimal (Gilovich, Griffin, \& Kahneman, 2002). The conjunctive fallacy, unpacking effects, and the dilution effect are just a few of the many common findings that violate normative models of information integration. These deviations from rational behavior are so numerous that it is now common to assume sub-optimal integration as a starting point for theories of decision making.

## Optimal Integration in Perceptual Domains

In contrast, there are numerous successful applications of optimal or rational models of information integration in domains such as perception (Oden \& Massaro, 1978; Tenenbaum, 1999), categorization (Ashby \& Maddox, 1990, 1992; Nosofsky, 1986), and memory (Anderson, 1991; Shiffrin \& Steyvers, 1997). Researchers in these more perceptual fields begin with an assumption of optimal integration and only later investigate sub-optimal or heuristic-based strategies.

## The Dilution Effect

Although information integration is an object of study by researchers in both decision making and perceptual domains, these fields often seem to operate independently of each other. One reason is the difference in experimental paradigms. Decision making research focuses mainly on linguistic and quantitative stimuli, and is concerned with how individuals use information to form explicit inference or preferences. Perceptual research typically relies on more perceptual stimuli, and concentrates on how the information is produced from external stimulation. Even when words are used as stimuli, as in memory research, the focus of information integration often includes perceptual aspects of the stimuli. The present research aims to bridge this divide through a novel experimental paradigm that combines aspects of each research tradition.

We focus on one example of sub-optimal information integration: the dilution effect. This effect refers to a situation where adding null or weak positive evidence to what is already strong positive evidence reduces the overall belief in a hypothesis. The effect has been replicated in numerous studies (LaBella \& Koehler, 2004; McKenzie, Lee, \& Chen, 2002; Nisbett, Zukier, \& Lemley, 1981; Peters \& Rothbart, 2000), but Shanteau (1975) gives one of the clearest demonstrations of the dilution effect. In his study, an experimenter drew samples of red (R) and white (W)
beads, with replacement, from one of two boxes. Box A was $70 \% \mathrm{~W}$ and $30 \% \mathrm{R}$. Box B was $30 \% \mathrm{~W}$ beads and $70 \% \mathrm{R}$. The participants did not know from which box the beads were drawn. In one condition, the experimenter drew the sequence WWWRWR from one of the boxes. After every two beads, participants estimated the probability that the beads came from Box A. The mean judgments after WW, WWWR, and WWWRWR were $69.3 \%, 64.0$, and 60.6 , respectively. The WW sample provides diagnostic information, information that clearly points to Box A. However the subsequent samples were nondiagnostic; they could have come from either box with equal probability, and should not have changed the estimated likelihood that the entire sequence came from Box A. Yet this non-diagnostic information caused the estimated probability to drop.

## Why Faces?

Although the dilution effect has only been explored using traditional judgment and decision making stimuli, it easily lends itself to perceptual stimuli. We use weak and strong evidence from different parts of a face to investigate the effect. For example, imagine you are asked to identify a face captured on a security camera. The top half of the face is relatively clear, but the bottom half is in shadow and harder to see. The top and bottom halves of the face then lend strong and weak evidence to the decision. The primary goal of this research is to determine whether the information from these sources is combined in an optimal fashion, or sub-optimally as exemplified by the dilution effect.

A benefit of using perceptual stimuli is that issues of interpretation and language understanding do not come into play. For example, the conjunction law is violated less if participants interpret "Linda is a bank teller" to mean that she is a bank teller and not a feminist (Sides, Osherson, Bonini, \& Viale, 2002). People also often misinterpret probabilities, but perform more optimally when information is presented as frequencies (Gigerenzer \& Hoffrage, 1995). The present task employs perceptual stimuli, thereby greatly reducing any undesirable influence of language conventions.

## Testing Models of the Dilution Effect

In addition to testing for the dilution effect, we evaluate three models of information integration. The Simple Bayesian model combines evidence from the two sources of information optimally, according to Bayesian statistical methods, and predicts additive effects. The Averaging model calculates a weighted arithmetic mean of the evidence produced by each source, and always predicts dilution. Finally, we use the Multi-component Information Accumulation model to explain how information is sampled from multiple sources, and accumulates during deliberation. This model accounts for the behavior we observed in our experiment, and provides insight into how stimulus presentation affects information processing.

The goal of our experiment was to replicate the dilution effect using perceptual stimuli and to determine the role of stimulus presentation on performance. In particular, we
tested if images that encouraged more automatic perceptual integration yield reduced dilution effects than images that required more controlled combination of evidence.

In the experiment, participants categorized a test series of faces into two families (Jones or Smith). The test faces were created by morphing together two target faces (representing the patriarch of each family) along a continuum. Different parts of the faces were morphed independently, allowing us to test how individual combined various levels of evidence. In direct analogy to standard work on the dilution effect, the top and bottom halves of a face act as two sources of information. Based on the many studies showing nearoptimal combination of perceptual information it would be natural to expect two halves from the Jones side of the morph continuum to produce even stronger responses in favor of Jones. Alternatively, weak evidence might dilute strong evidence to produce a dilution effect.

To investigate factors controlling the size and reliability of the dilution effect, two manipulations differentially encouraged automatic and controlled integration of information. It is fairly common to distinguish automatic and controlled processing, both in theory and empirical research. Most often automatic processing is assumed to be fast and independent of conscious manipulation, and controlled processing is assumed to be slow and conscious. Automatic processing is usually assumed to be more robust, less prone to large errors, less based on heuristics, and closer to optimal than controlled processing. This line of thinking suggests that the dilution effect is less likely when processing is automatic, and more likely when processing is controlled. We use the automatic/controlled language of Schneider \& Shiffrin (1977) for convenience sake, rather than to make strong claims that information integration is ever entirely automatic or controlled.

In the present experiment we used conditions that manipulated face images so as to bias processing toward or away from automatic processing. In the Together condition the two half faces are shown atop one another, in a normal configuration. Because identification of faces is overlearned, this should promote automatic processing and produce less dilution. That is, weak evidence, when added to strong evidence from the same category, should increase accuracy. In the Split condition the two half faces were separated horizontally. In the Inverted condition the images were displayed upside-down. Because our perceptual systems have rarely needed to recognize split or inverted faces, each half face might be processed separately, with the results later combined using more deliberate strategies. That is, weak evidence should combine less optimally with strong evidence and produce more dilution.

## Method

## Participants

Nineteen students from Indiana University (undergraduate and graduate) were paid $\$ 16$ to participate in this study. All participants had normal or corrected-to-normal vision.

## Stimuli

All of the stimuli used in the experiment were derived from two "target faces" (A and B) selected from the FERET database (Philips, Moon, Rizvi, \& Rauss, 2000). After cropping the image to remove hair and head outline, the faces were warped so that their major facial features aligned. Once the faces are aligned, a morph is essentially a linear combination of the grayscale values of the two faces at each pixel. The cropped areas of the $256 \times 384$ pixels, grayscale images were filled with a sinusoidal grating. Upside-down copies of the two target faces were also made for the Inverted conditions. The four resulting images were used to construct all experimental stimuli.

The experiment began with two short blocks of trials that calibrated morphs levels to the individual. On each trial a half face was presented and participants chose the target that it most closely resembled. The test faces were created by morphing Target $A$ and Target $B$ together along $a$ continuum. Faces favoring $A$ and $B$ were initialized to 94.44\% Target A and 5.56\% Target A, respectively. A staircase algorithm was used to find top and bottom half face morphs for each target and each orientation that produced an intermediate level of accuracy (approximately $72 \%$ ). These morphs became the medium (M) strength half faces, while weak (W) and strong (S) morphs were derived by extrapolation. Weak halves use the morph coefficient halfway between the medium morph and 0.5 . Strong halves used the morph two thirds of the distance between the medium morph and the target.

Having calibrated all morphs levels, test stimuli were created as follows. For each orientation, the W, M, and S top half faces for Target A were crossed with the W, M, and S bottom half faces for Target A. The same procedure was followed for Target B. As a manipulation check, the W and M half faces for A were also paired with the M and W half faces for B, respectively. Whole faces were presented either in a normal configuration (directly above or below the other half face or background) or horizontally split by 60 pixels. The $\mathrm{W}, \mathrm{M}$, and S top and bottom half faces were also presented in isolation with a continuation of the background presented instead of the other half of the face. Pilot testing showed no performance differences between Together and Split half faces, so the latter were omitted. Sample stimuli are shown in Figure 1. This procedure was done separately for upright and inverted faces, yielding 56 test stimuli for each orientation.

Figure 1: Example test faces.

## Procedure

Participants completed two sessions of the experiment on separate days. They were told that they would see a series of faces, each of which belonged to either the Jones or Smith family. They were instructed to use the test face's resemblance to each patriarch to determine the correct family. After several example trials, participants completed two blocks of calibration trials. The first consisted of 72 upright half face trials, interspersed with 48 upright whole face filler trials included to discourage strategies tailored to half faces. Auditory feedback was given after each response, with a high beep for correct and a low beep for incorrect.

After calibration, participants began an integration phase consisting of two blocks of trials in Session 1 and six blocks in Session 2. Each block contained 68 trials. Each test face appeared once per block, with the exceptions of W/W, M/M, and S/S stimuli, which appeared twice. Upright faces appeared in odd numbered blocks. Inverted faces appeared in even numbered blocks.

Each trial began with a test face appearing in one of nine random positions near the middle of the screen. After two seconds the face was masked with one of two scrambled sets of features from the target faces. After 250ms the mask disappeared and the two target faces appeared, one on each side of the screen. Participants chose the family to which the test face belonged. They were then asked, "What is the likelihood that you are correct?", and responded on a 6point scale from $50 \%$ to $100 \%$. A fixed number of points were awarded for each correct choice and the individual with the highest final score received a $\$ 20$ bonus.

## Results

The present analysis focuses on participants' choice proportions, though mean confidence judgments showed a similar pattern of results. We began by removing data from trials in which individuals indicated no confidence in their decision (likelihood judgment of $50 \%$ ), or responded too fast (less than 150 ms ), or too slow (greater than 5 sec ). This procedure removed approximately $12 \%$ trials, across all participants.

Next, we labeled morphs according to the accuracy they produced on half face trials. That is for example, an individual's half face trials determined which Jones top half morphs were strong, medium, and weak. This relabeling proved unnecessary in most cases because accuracy order matched the physical morph order.

A choice response was considered correct if the test face provided stronger evidence for that target than the alternative. For half faces and most whole faces (i.e. those where top and bottom both favored the same target) this was straightforward. On trials where top and bottom halves favored opposite targets the stronger of the two halves indicated the correct response.

Orientation had almost no effect on accuracy, confirming that calibration successfully equated upright and inverted half face morphs strengths. There were also no significant effects of orientation on the dilution effect, so we present
results collapsed across upright and inverted orientation in order to concentrate on evidence level and split. Mean accuracy, collapsed across target, half (top vs. bottom), and orientation is shown in Figure 2. Accuracy tends to increase with evidence strength, providing a coarse check that the stimuli were appropriately calibrated. Accuracy with M/oW faces was below that of even the weak half faces, confirming that these opposite halves were indeed taken as evidence for the alternative category.

Figure 2: Mean accuracy across evidence levels for whole faces (bars) and half faces (lines).

Our primary research question dealt with how people would combine the two halves of a face and when they might show something akin to the dilution effect. To address this question we compared accuracy with each whole face to that with the stronger half alone. Deviation scores were calculated within individuals by subtracting the mean accuracy given the stronger half face from the response (coded as correct or incorrect) given for whole face. A value greater than 0 indicates additive integration, qualitatively in line with the predictions of a simple Bayesian model. A result less than 0 indicates a dilution effect because additional weak positive evidence decreased accuracy. Figure 3 shows mean deviation scores.

A t-test showed mean deviation scores to be significantly below $0, t(6767)=18.61, p<.01$. As expected Split faces produced greater dilution effects than Together faces. A 2 (Orientation) x 2 (Split) repeated measures analysis of variance (ANOVA) confirmed this, with a main effect of Split, $F(1,18)=12.36, M S E=.015, p<.01$. No other effects were significant. Dilution was greatest for W/S faces, where the difference in top and bottom half strengths was largest. Additive effects were largest in the W/W condition, suggesting that some near-optimal information sampling may have occurred.

Figure 3: Mean dilution scores across whole face conditions.

Figure 4: Predicted deviation scores for the McIA model.

## Discussion

These findings are rather surprising given that the dilution effect had not previously been observed in a perceptual context. The bulk of the existing literature suggested that performance would probably resemble that of a nearoptimal integration process, but we found that participants were often less accurate with two pieces of diagnostic evidence than one. Clearly sub-optimal information integration is not limited to the numerical or linguistic stimuli found in traditional judgment and decision making research. Additionally, our results provide insight into how people processed information in the task. As predicted, dilution was greater when automatic perceptual integration of top and bottom halves was made more difficult by splitting the face. Surprisingly, the dilution effect was
present to an equal extent in both Inverted and Upright orientations. Since, inversion was meant to interfere with strategies tailored to upright faces, this may suggest that participants did not treat the stimuli as they would normal faces. In contrast, the split manipulation may have operated at a lower level where splitting disrupted general purpose whole-object automatic processing in either orientation.

## Models of Perceptual Dilution

The obtained pattern of results poses problems for two of the candidate models introduced earlier. The Simple Bayesian model posits that information from top and bottom halves is combined optimally. Consequently, the model predicts additive effects in all conditions, except M/oW, and cannot account for the large dilution effects observed when a W half was paired with a S half.

The Averaging model, on the other hand, assumes that individuals always integrate top and bottom halves of face by taking the average of the evidence produced by each. The model predicts dilution effects whenever top and bottom evidence strengths are unequal, but it predicts deviations scores near 0 for conditions where top and bottom are of the same strength. Thus, the large additive effects in the W/W condition cannot be explained through averaging alone.

As an alternative we propose the Multi-component Information Accumulation model (McIA). This model represents information integration as a process of accumulating evidence to a decision threshold, $\theta$. According to the model, on each trial a participant repeatedly samples information from one of three sources of evidence: the top half, the bottom half, or the whole face. Each sample provides evidence causing preference to move toward one of two decision bounds. These boundaries represent the amount of preference required to make each response. At one moment a sample may favor the Jones response, causing the preference state to take a step toward the Jones boundary. However, the next sample may favor Smith, causing the preference state to step away from the Jones boundary and toward the Smith boundary. In this manner preference evolves as a noisy random walk process until a decision threshold for one response is reached. The model is thus capable of making predictions for both accuracy and response times.

The probability of sampling whole face evidence is a free parameter, $\alpha$, representing the likelihood that the perceptual system would automatically combine the top and bottom halves into a single whole face. Since splitting the halves apart increased the size of the dilution effect, $\alpha$, was estimated separately for Split and Together faces. The probabilities of sampling the top or the bottom half were then each $(1-\alpha) / 2$. The probability of stepping toward the correct decision boundary after a sample is given by the rate parameter, $\delta$. Since the rate of evidence accumulation should vary with stimulus strength, six rate parameters were estimated. These corresponded to W, M, and S morphs for both top and bottom half faces. For half face trials there is only one $\delta$ to sample at each moment. However, on whole
face trials one of three sources of evidence is sampled at each moment. For example, if a stimulus was comprised of a W top and S bottom, the three sources would be $\delta_{\text {Weak } T_{o p} \text {, }}$ $\delta_{\text {Strong }}$ Bottom, and whole face evidence produced by automatically integrating the two halves. If the whole face evidence is sampled, an evidence accumulation rate is calculated as the Bayesian optimal combination of top and bottom rates, assuming independence. This represents the idea that automatic perceptual integration of top and bottom halves produces additional, perhaps configural, evidence for the correct response. The value of $\theta$ proved relatively unimportant for fitting choices, and was arbitrarily set to 10 . In the future we plan to use the McIA model to simultaneously fit choices and response times, which will allow for better estimation of $\theta$.

The best fitting parameters of the McIA model are given in Table 1. Deviation scores based on the model's prediction are shown in Figure 4. The model does a remarkable job of capturing the basic qualitative patterns in the data. It produces dilution effects because deliberation is sometimes driven by the evidence in the weaker half, producing more errors than with the stronger half alone. In the W/S condition this produces very large dilution effects because, for example, $\delta_{\text {Weak Bottom }}$ is much smaller than $\delta_{\text {Strong Top }}$. However, unlike the Averaging model, the McIA model does not always predict dilution. Instead it posits that on some trials the perceptual system automatically combines the top and bottom halves into a configural whole, yielding high accuracy. This explains the additive effects for W/W, as well as the difference between Split and Together conditions. According to the model whole face evidence was sampled 63\% of time for Together faces, but only 37\% of time for Split faces. This supports our hypothesis that separating the top and bottom halves of face encourages more controlled, less optimal strategies.

Table 1: Best Fitting Drift Rate and Attention Parameters of the McIA Model.

| $\delta_{\text {Weak Top }}$ | 0.522 |
| :--- | :--- |
| $\delta_{\text {Medium Top }}$ | 0.549 |
| $\delta_{\text {Strong Top }}$ | 0.586 |
| $\delta_{\text {Weak Bottom }}$ | 0.518 |
| $\delta_{\text {Medium Bottom }}$ | 0.525 |
| $\delta_{\text {Strong Bottom }}$ | 0.594 |
| $\alpha_{\text {Together }}$ | 0.627 |
| $\alpha_{\text {Split }}$ | 0.365 |

## Conclusion

The present results represent a synthesis of two divergent trends in the extant literature. We used the stimuli and procedures of a perceptual categorization study to investigate a central decision making phenomenon. Unlike in many previous studies using perceptual stimuli, we found widespread and reliable sub-optimal integration, in the form of the dilution effect. Informative differences in the size of this effect were also found. The Together condition, which
encouraged automatic face processing, yielded relatively little dilution compared to the Split condition, which encourages more controlled integration.

Note that we do not see processing mode as a binary concept, but rather a continuum between the extremes of fully automatic and fully controlled integration. To the degree that deviation scores were higher for Together conditions than for Split conditions, we posit a greater degree of automatic integration. The McIA model instantiates this idea through a random walk process with three sources of evidence, the top half alone, the bottom half alone, and the whole face, which represents instances where the perceptual system automatically combines the evidence from the two halves. The model explains how processing was modulated by stimulus presentation. Since Together faces were more naturalistic stimuli, participants were able to sample whole face information more often, yielding greater accuracy.

We also found interesting differences in the size of the dilution effect across levels of evidence strength. For conditions where the top and bottom halves were very unequal, significant dilution was observed. The McIA model produces this result by switching attention between top and bottom halves as it repeatedly samples information. Over time, this effectively averages the evidence in each half. In contrast, additive effects were observed in several conditions where top and bottom strengths were equal. The McIA model also predicts this result because averaging the evidence strengths of these two halves (as described above), produces deviation scores near 0 . However, when whole face evidence is sampled, the probability of stepping toward the correct boundary is the Bayesian optimal combination of the two half face $\delta$ values. These whole face samples push accuracy above that of the stronger half alone.

These results pose a serious challenge to the idea that integration of perceptual information is always well described by rational models. The prevalence of dilution effects for even the most natural of stimuli suggests that there is still more work to be done to fully bridge the span between optimal integration in perceptual and sub-optimal integration in judgment and decision making. This work is a first step toward determining the conditions under which sub-optimal information integration is to be expected. In future work we plan to extend this experimental paradigm to investigate other paradoxical phenomena, such as the conjunctive fallacy, the disjunction effect, and availability effects.

# Cooperation in Prisoner's Dilemma Game: Influence of Players' Social Roles 

Evgenia Hristova (ehristova@cogs.nbu.bg)<br>Maurice Grinberg (mgrinberg@nbu.bg)<br>Iskra Georgieva (issgeorgieva@gmail.com)<br>Milena Borisova (borisova_milena@abv.bg)<br>Department of Cognitive Science and Psychology,<br>New Bulgarian University, 21 Montevideo Street, Sofia 1618, Bulgaria

#### Abstract

The paper aims to extend the findings of a previous study (Grinberg et al., 2012) exploring the impact of social relations on the cooperation in the Prisoner's dilemma game. Relations between players are manipulated by assigning different roles. The roles embodied the four basic types of human relations in line with Fiske's relational models theory (Fiske, 1991): communal sharing, authority ranking, equality matching, and market pricing (players are assigned roles of team mates, chief and subordinate, partners, and opponents, respectively). Cooperation rates, mutual cooperation, mutual defection, and payoffs gained were subsequently analyzed and compared for a series of forty games. As a result we identified that the market-pricing condition is characterized by considerably lower individual and mutual cooperation, higher mutual defection and lower payoff in comparison to the conditions impersonating the remaining three relational types.

Keywords: Prisoner's Dilemma, decision-making, cooperation, social interaction, relational models

## Introduction

## Prisoner's Dilemma Game

Games are formal tools to study social interactions. The Prisoner's dilemma (PD) game is one of the most extensively studied social dilemmas as it is considered to model interactions in many social situations and problems such as overpopulation, pollution, energy savings, participation in a battle, etc. (Dawes, 1980). It is used to study cooperation and conflict in interactions between individuals, groups, and societies (Rapoport \& Chammah, 1965).
In the PD game the players simultaneously choose their moves - to cooperate (C) or to defect (D) - without knowing the choice of the other player. The payoff table for the twoperson PD game is presented in Figure 1. The payoffs of the Prisoner's dilemma game (see Figure 1) satisfy the inequalities $\mathrm{T}>\mathrm{R}>\mathrm{P}>\mathrm{S}$ and $2 \mathrm{R}>\mathrm{T}+\mathrm{S}$. Because of this game structure a dilemma appears, as there is no obvious best move. On one hand, the D choice is dominant for both players - each player gets a larger payoff by choosing D (defection) than by choosing C (cooperation) no matter what the other player chooses. On the other hand, the payoff for mutual defection $(\mathrm{P})$ is lower than the payoff if both players choose their dominated C strategies (payoff $R$ for each player).

|  | D | 4, 1 | 2, 2 |

Figure 1: Payoff tables for the PD game with standard notation for the payoffs and an example with specific payoff values. In each cell the comma separated payoffs are the Player I's and Player II's payoffs, respectively.

As the PD game is used as a model for describing social dilemmas and studying the phenomenon of cooperation, there is a great interest in the conditions that could promote or diminish cooperation. In formal game theory players are supposed to try to maximize their payoffs in a completely selfish manner (Colman, 2003). From this point of view the dominant strategy in the game is defection (in one-shot or in repeated PD games with a fixed and known number of games). This prediction is in contrast with the behavior of the players observed in laboratory settings or in real life situations.

In human societies, people cooperate all the time and often cooperation is seen as one of the foundations of human civilization (see e.g. Gärdenfors, 2003). Sally (1995) provides a meta-review of the experiments involving PD games published between 1958 and 1995 and shows that in its iterated version (the game is played many times), cooperation choices are made in 20-50 \% of the games (mean $47.4 \%$ ) and even in one-shot games many players cooperate, although much less than in the iterated version.

Several studies have shown how cooperation can emerge from expected utility or anticipatory reinforcement models without any specific relations between the players (see e.g. Grinberg, Hristova, \& Lalev, 2010; and the references there in).

Other theories explain the cooperative behavior in PD games in terms of socially established values and stress the importance of social interaction and relationships. Reputation building theory (Kreps et al., 1982; Andreoni \& Miller, 1993) assumes that the player is building himself a reputation of a cooperative player to build herself the image of trust and thus to provoke cooperation by the other player. Trivers (1972) puts accent on reciprocity as a widespread norm and basis of societies: people reciprocate cooperation
with cooperation. Another influential theory about cooperation in PD game is based on the concept of altruism. It assumes that some players are not strictly self-interested and from an altruistic perspective, cooperation can yield higher payoffs than defection (Cooper et al., 1996).

Although these social theories of cooperation have been proposed to explain cooperative behavior unexpected by normative game theory, it is interesting to consider more general social theories that are more closely related to the game theoretic analysis of social relations. In our opinion such a theory is the relational models theory proposed by Alan Fiske (Fiske, 1991) which is trying to decompose any social interaction to four basic relations and thus seems amenable to game theoretic representation.

Moreover, as the PD game is central in the modeling of social interactions it can be used to explore the existence and limits of the relational social types as posited by relational social models (see e.g. Haslam, 2004). Exploring the potential of games like the PD game as modeling relational types is one of the goals of this paper which is a continuation of a first analysis presented in Grinberg, Hristova, \& Borisova (2012).

## Relational Models Theory

Relational models theory (Fiske, 1992; Fiske \& Haslam, 1996; Rai \& Fiske, 2011) states that there are four basic schemas that are used to build, organize and maintain relationships and interactions among individuals in a society. These models are supposed to be universal and all relations could be described by these models or by combination of them. The four types of relations generate four modes for every aspect of the interactions between people - resource allocation, moral judgments, decisionmaking, etc. These four relation models are the following (Fiske, 1992):

- Communal Sharing - relations in an undifferentiated group of people with equivalent status. Everyone in a community - which could consist of two members or could be very large - has some rights and some duties. The focus is on commonalities and not on distinctions;
- Authority Ranking - implies an ordinal ranking in society and this ranking scheme determines one's relative status. For instance, military hierarchy can be considered a prototype of such relations;
- Equality Matching - relations are based on a model of one-to-one correspondence as in turn-taking, tit-for-tat strategies, etc. The social prototype would be friendship networks, in which reciprocity is a norm which rules the distribution of wealth;
- Market Pricing - based on a model of proportionality in social relations in which people reduce their interaction to some ratios of utility measures. Examples of relations of this type are the ones governed by prices, rational calculations, expected utilities, etc.

## Social Interactions and Cooperation

In formal game theory payoffs, strategies and choices are analyzed independently from any context or meaning. Most experiments for studying PD game employ neutral presentation of the game. I order too be able to control for extraneous variables, game is presented in neutral formulation, choices are labeled as ' A ' and ' B ', or as ' 1 ' and ' 2 ', etc. Participants in the game are usually called 'players', or 'you' and 'the other' and usually are unfamiliar with one another, in most cases also a visual contact between them is avoided. This is done in order to isolate cognitive processing of information and to capture influence of other factors.

However, we think that deeper understanding of decisions in games should consider social relations involved in the interactions. People behave differently in social interactions described as formal games with similar strategies and payoffs, depending on whom they interact with, what is the situation, what are the possible choices.

Sally (2001) states that social interaction is essential and the social dilemmas like PD need to be investigated from such a perspective. In the paper the importance of closeness between players in game strategy building is discussed. According to this account, players change their choices if they perceive the other player as a friend or a stranger.

Other studies focused on the influence of game description, game title, etc. As such labels and description give different context of the interaction, it is expected that they change the behavior of the players.

Some studies explored the influence of the title given to the game. Ellingsen et al. (2012) found more cooperation when the game is labeled 'Community Game' vs. 'Stock Market Game'. Liberman et al. (2004) found a similar effect in the first round cooperation comparing the game titles 'Community Game' and 'Wall Street Game'.

Another study explored the influence of the general interpretation context (Eiser \& Bhavnani, 1974). Participants cooperate more when they are told that the experiments studies 'international negotiation' or 'interpersonal interaction' compared to 'economic bargaining' or neutral description.

Zhong et al. (2007) manipulated several factors - game label, choices labels, outcome labels and found that giving interpretative labels promotes cooperation and this is especially the case when 'trust' and 'cooperation' are used as labels.

However, in all of these studies the influence of the players' roles is not explored. In all of them the players are are labeled neutrally as 'You' and 'Other person' (Ellingsen et al., 2012; Eiser \& Bhavnani, 1974; Zhong et al., 2007) or as 'Player 1' and 'Player 2' (Liberman et al, 2004). As players' labels and roles could also serve to denote social relations, it is worth exploring their influence on cooperative behavior.

## Relational models and PD game

In a previous study (Grinberg et al., 2012), we made a first attempt to apply the Fiske's relational models theory (Fiske, 1991) to playing in PD games. In the experiment (see for details Grinberg et al., 2012), the relational models between players (communal sharing, authority ranking, equality matching, and market pricing) were operationalized by using various ways of distributing the total payoff gained by a dyad of players in a series of Prisoner's dilemma games: each player receives the total payoff (communal sharing), one of the players receives more than the other (authority ranking), each player receives half of the total payoff (equality matching), each player receives a portion of the total payoff proportional to his/hers individual payoffs (market pricing). For these four conditions, the cooperation rates, the mutual cooperation, the mutual defection, and the payoffs gained were analyzed and compared for a series of forty games. The results of Grinberg et al. (2012) showed that the market pricing distribution scheme leads to less cooperation, less mutual cooperation, more mutual defection and less total payoff than in the other three distribution schemes.

This is an interesting result taking into account the fact that in formal game theory, in many experiments, and in many real life situations, the players are perceived as individualistic beings. It is also evidence that the topic deserves further exploration and has motivated the present study.

## Goals of the Study

The goal of the present study is to explore the mapping of the Fiske's relational models theory to Prisoner's dilemma game focusing on the players' roles corresponding to the four relational models (Fiske, 1992) as follows:

- communal sharing - group of people with strong bonds, wherein everyone is equivalent to the other and all resources are common;
- authority ranking - people are ordered hierarchically and the resources are distributed according to the person's rank;
- equality matching - a balanced relationship based on turn-taking, tit-for-tat strategies and equal distribution of the resources;
- market pricing - relations based on proportionality and comparison - it is important 'how the person stands in proportion to others'
We aim to explore what is the influence of the role assigned to the player on a set of game outcomes that characterize the playing of a PD game - cooperation, mutual cooperation, and mutual defection. It is also important to check the influence of the assigned role on the overall payoffs that are received - e.g. what type of model is more beneficial in terms of payoff earned in interactions shaped by the strategic structure of the PD game.

Based on the results obtained in Grinberg et al. (2012), the cooperation rate is expected to be the highest if the players are acting in a communal sharing relation and the
lowest when the players' roles are defined according to the market pricing model. In the latter scenario, we expect a more individualistic behaviour of the players.

## Method

## Stimuli and Procedure

A sequence of 40 Prisoner's dilemma games is used in the current experiment. All of the games had the payoff matrix given in Figure 2.

Figure 2: Payoff table for the PD game used in the experiment.
Participants were tested in pairs. After receiving the appropriate instructions for the corresponding experimental condition, each dyad played 5 training games (whose results were not included in the analysis) followed by 40 games that were further analyzed. On the computer game interface, the cooperation move was labeled ' 1 ' and the defection move was labeled '2'. Matlab 7.6.0 (R2008a) was used for presenting the game and recording the choiches of the players. After each game the subjects got feedback about their own and the other player's choice and payoffs in the current game. They could also constantly monitor their own total payoff; the total payoff of the other player; and the monetary equivalent of their own total payoff.

The instructions for the experiment explained in detail the rules of the game and included several test questions to ensure that participants understood them correctly. There were five instructions that varied only in the description of the players' roles and the corresponding relations between the players in the game.

The experimenters secured that the participants had not visual, verbal and any kind of other contact between them before and during the experiment. Therefore, no player knew who the other player was before the end of the experiment. Subjects were paid real money accordingly to the final payoff in the game. Each session lasted about 20 minutes.

## Experimental Conditions

The players' roles are varied in accordance with the four relational models described above in a between-subjects design. We also added a control condition, exposed to the most common neutral presentation of the PD game. So, there are 5 experimental conditions as a total differing in how players are labeled in the instructions and on the game interface and how the sequence of games is presented (a sentence in the instruction defines the relations between players)

- Team condition - the players are labeled as 'teammates'; instruction: 'You will play a sequence of
games based on team-work between players with your team-mate' (communal sharing relational model);
- Hierarchy condition - the players are labeled as 'chief' and 'subordinate', correspondingly; instruction: 'You will play a sequence of games based on hierarchy between players with your chief/subordinate' (authority ranking relational model).
- Partners condition - the players are labeled as 'partners'; instruction: 'You will play a sequence of games based on equality (parity) between players with your partner' (equality matching relational model);
- Opponents condition - the players are labeled as 'opponents'; instruction: 'You will play a sequence of games based on competition between players with your opponent' (market pricing relational model).
- Players condition - the players are labeled as 'players'; instruction: 'You will play a sequence of games with the other player' (control condition).
The names for players' roles in each experimental condition are used consistently throughout the experimental session - in the instructions and on the game interface.

## Participants

Forty pairs ( 80 participants) took part in the experiment -8 pairs in each experimental condition. Participants were randomly assigned to their experimental condition. In the hierarchy condition, it was randomly determined which player will be in the subordinate role and which player in the chief role.

Data of one dyad was removed because one of the players reported after the game end that he has participated in a similar experiment. Thus, we ended with 7 pairs in the hierarchy condition and data of 78 participants was analyzed ( 46 female, 32 male, mean age 24 years). For this condition, although the players were asymmetrically labeled (chief and subordinate) the results are not significantly different, so they are analyzed together.

## Results

To explore the influence of the players' roles on choices and cooperation in the PD games, the following dependent variables are analyzed: number of cooperative choices for each player; number of games with mutual cooperation in a pair; number of games with mutual defection in a pair. For clarity, in the figures, the results are presented in percentages. However, the analysis is performed using the specified dependent variables.

The average payoff per game (in points) is considered a measure to assess which players' roles led to higher profits.

Each dependent variable is analyzed in ANOVA with players' roles as between-subject factor with 5 levels (team vs. hierarchy vs. partners vs. opponents vs. players).

## Cooperation

The cooperative choices (\%) are presented in Figure 3.The analysis shows a significant influence of the players'
roles on the number of cooperative moves $(\mathrm{F}(4,73)=3.44$, $\mathrm{p}=0.012$ ).

Post-hoc LSD test shows that the cooperation rate in the opponents condition is significantly lower than the cooperation rate in the team condition ( $p=0.003$ ), in the hierarchy condition ( $p=0.003$ ), and in the partners condition ( $p=0.025$ ). All other differences are nonsignificant.

Figure 3: Average percentage of cooperative choices for different players' roles. ('*' means $p<0.05$ ).

This analysis shows that the labels for the players' roles influence the cooperation rate and lead as expected to lower cooperation for players labeled as 'opponents'. In the terminology of Fiske's theory, the market pricing relational model leads to diminished cooperation in comparison to the other three relational models. While this does not seem strange for the team and partner conditions, it is to some extent for the hierarchy condition. For the latter, however, detailed analysis showed that one pair of players cooperated $100 \%$ of games which led to this strange results which is at odds with the results of Grinberg et al. (2012) for the corresponding condition.

## Mutual Cooperation

Average percentage of games in which there is mutual cooperation (both players have chosen to cooperate) is presented in Figure 4.

Figure 4: Average percentage of mutual cooperation in a pair in each distribution condition ('*' means $p<0.05$; '(*)' - marginally significant difference).

The ANOVA does not identify a statistically significant influence of the players' roles on the number of mutual cooperative game outcomes $(F(4,34)=2.03, p=0.112)$. However, the Post-hoc LSD test shows that a difference exists between the opponents and hierarchy condition ( $p=$ 0.013 ). Marginally significant differences are observed between the opponents and partners condition ( $p=0.09$ ), between the opponents and team condition ( $p=0.09$ ), and between control (players) and hierarchy condition ( $p=$ 0.074).

It turns out that mutual cooperation is the lowest ( $\sim 8 \%$ ) in the opponents condition. This result is consistent with the assumption that the competition, distinctive for the money pricing relational model, will induce an individualistic participants' behavior.

Mutual cooperation is also relatively low in the control condition - the condition with neutral description of the players' roles. The interesting result is again in the hierarchy condition for which the hire mutual cooperation is obtained ( $\sim 31 \%$ ) but as discussed earlier it is partially due to one pair of players which cooperated throughout the whole series of games.

## Mutual Defection

The average percentage of games with mutual defection (both players have chosen to defect) is presented in Figure 5. ANOVA does not identify a statistically significant influence of the players' roles on the number of games with mutual defection $(F(4,34)=2.07, p=0.106)$. However, a further conducted Post-hoc LSD test identifies significant difference between the opponents condition and partners condition ( $p=0.009$ ), and marginally significant difference between opponents condition and hierarchy condition ( $p=$ 0.066).

Figure 5: Average percentage of mutual defection in a pair in each distribution condition ('*’ means $p<0.05$; '(*)' marginally significant difference).

Therefore, it can be concluded that when the players are labeled as opponents, mutual defection is a much more typical choice. It should be noted that mutual defection leads to the lowest possible payoff for the pair. Although defection is the dominant strategy for players in one-shot PD games, here the players play 40 games and mutual defection leads to the worst collective payoff - thus the dilemma structure of the game arises as the opposition between individual and collective
rationality. However, it is interesting to note the high mutual defection in the team condition.

## Average Payoff

The payoff analysis was conducted on the basis of the average payoff per game (in points) (see Figure 6). ANOVA shows a significant influence of the distribution type on the payoff $(F(4,73)=2.50, p=0.049)$.

Figure 6: Average payoff per sequence of 40 games for a pair in each distribution condition ('*' means $p<0.05$ ).

Significant differences were established through post-hoc LSD test between the opponents and team condition ( $p=0.006$ ), between the opponents and hierarchy condition ( $p=0.001$ ), between the opponents and partners condition ( $p=0.001$ ).

The payoff for the participants is lowest when the players are opponents (compared to the other three relational models). This is an interesting result especially since the roles of opponents presumably represent the market pricing relational model, which is related to individualistic attitude and profit orientation. However, taking into account that the highest number of games with mutual defection are found in the opponents condition, the result could be explained by the lower payoff that the players get when they both defect.

## Conclusions and Discussion

The presented study aims at further examining the presumable influence of social relations over cooperative and noncooperative behavioral patterns in the Prisoner's dilemma game. Within our experiment subject were assigned different roles that corresponded to the four basic relations, defined by the Relational models theory: communal sharing, authority ranking, equality matching, and market pricing.

The results outline a clear tendency towards lower individual and mutual cooperation, higher mutual defection and lower total payoff when players are directly labeled as 'opponents' (a role model typical for the market pricing relation) in comparison to all other role sets. Simply put whenever participants are led to perceive 1) the other player as their enemy in the game; and 2) the game as a game of open competition, they cooperate less and earn lower payoff both individually and as a pair. This result, though logical and intuitive in nature, questions the actual success potential of a profit-oriented behavioral model within the Prisoner's dilemma game and real life situations reflecting this game.

As it can be concluded competitiveness may not be the best approach towards goal accomplishment whenever a mutual dependency on participants' choices is present regardless of whether we are facing a person who we deem our opponent.

Strikingly similar results were observed in a previous study (Grinberg et al., 2012) examining the effect of the payoff distribution over the cooperation levels in Prisoner's dilemma game. Lower individual and mutual cooperation, higher mutual defection and lower total payoff were observed when the joint profit was divided among players according to their individual contribution - the experimental condition impersonating the market pricing relation. In comparison, in both experiments the conditions reflecting the remaining three relational models are characterized with higher levels of individual and mutual cooperation and payoff plus lower defection rate. What can be concluded as a summary of both studies is that in line with our expectations, the relational model of market pricing, no matter how framed, "awakens" individualistic, egoistic and concurrent behavioral tendencies among subjects resulting in lower level of cooperation within the Prisoner's dilemma game. Moreover, the influence of these tendencies over individuals seems irrespective of the influence of rationality itself. This in its nature supports the idea that human relations may affect our choice of behaviors in a decisive manner irrelevant of our rational awareness.

An interesting area for exploration remains the condition comprising the authority ranking relation. As it can be seen in both studies this relation could lead to high cooperation despite the different roles of the players or the inequality in the payoffs received. Cooperation levels within the condition are more or less the same as the ones observed in the two "cooperative in nature" conditions - communal sharing and equal matching. It can be thus speculated that inequality does not trigger competition to the extent individualism and "self-sufficiency" do. Therefore such a relation of inequality may not be an obstacle for subjects to perceive the game as a game of an in-team dependency and choose a cooperative behavioral pattern.

The studies conducted produce results with broader implication potential. The research on the effect of human relations on the behavior in social dilemmas is fundamental for the understanding of complex phenomena within the field of both decision making in games and real-life situation in economy, politics, military field etc.

#### Abstract

In order to learn about the world, young children rely on information provided by social partners. Past research has shown children consider a variety of factors when learning from others, including consensus. Corriveau, Fusaro, and Harris (2009) found that in an object labeling task, children trust responses that receive majority support, and they concluded that children prefer members of a majority as social informants. However, it is possible that children prefer majority members only in domains that rely strongly on socially constructed norms, such as object labeling, where non-social information is unavailable. We formalized this prediction using a rational model of learning from testimony across tasks, and compared our model's predictions to children's responses in object labeling and causal learning tasks. We find that in a causal learning task, a domain that relies less on socially constructed norms, children rely more on their personal observations than informant testimony.

Keywords: social learning; Bayesian modeling; social cognition; consensus; testimony; epistemic trust

## Introduction

We humans are inherently social creatures, and throughout our daily interactions, we openly share our thoughts and opinions with one another. The ubiquity of our social sharing and learning is rare among animal species (Tomasello et al., 2005; Warneken \& Tomasello, 2009), and has been cited as an explanation for the robustness of human culture (Boyd, Richerson, \& Henrich, 2011). Listening to others who share their knowledge can save precious time and effort, as learning through experience can be difficult and time-consuming. In listening to others' testimony, we can instantly and effortlessly learn how to prepare a dish, where to hunt, or who to hire to fix the kitchen sink.

Learning from others is especially important for young children, who have a relatively small pool of life experiences to draw on in new situations. However, one potential drawback to social learning is the possibility of receiving incorrect or misleading information. Therefore, it would be advantageous for children to employ mechanisms to evaluate sources' reliability. Previous work has found that children use informants' past accuracy as an indicator of trustworthiness (Sabbagh \& Baldwin, 2001, Birch, Vauthier, \& Bloom, 2008; Koenig, Clement \& Harris, 2004; Pasquini et al., 2004; Corriveau \& Harris, 2009) and selectively imitate others (Gergely, Bekkering, \& Kiraly, 2002; Brugger et al., 2007; Buchsbaum, Gopnik, Griffiths, \&

Shafto, 2011; Schulz, Hooppell, \& Jenkins, 2008). On the other hand, other studies suggest children's social learning is sometimes surprisingly unselective and irrational (Lyons, Young, \& Keil, 2007; McGuigan \& Whiten, 2009).

We can learn not only from reliable individuals, but also from "crowd sourcing" information from a group of people. Adults often turn to others for advice, assuming that opinions held by many must be valid by virtue of their popularity. This intuition echoes the law of large numbers in probability theory: the more individual testimonies, the more likely the collective conclusion of those testimonies is accurate. Corriveau, Fusaro, and Harris (2009) found that three- and four-year-old children view consensus as an indication of reliability; they were more likely to endorse novel object labels that received majority support, and to choose a member of the majority group as an informant about other object labels. The authors concluded that preschoolers prefer information endorsed by the majority, and prefer members of a majority as informants.

The extent to which children prefer members of a majority as informants is still unclear. One possibility is that children prefer majority members as informants in all situations where multiple testimonies are available. In this view, children would indiscriminately weigh information from others as the most valuable source of information, perhaps prizing it above their own observations. Social psychologists have discovered that consensus opinions can override adults' existing opinions (Asch, 1956; Cialdini \& Goldstein, 2004), which can result in internalization of the consensus opinion (Kelman, 1958; Nolan et al., 2008).

However, if children are rational learners, they should not always prefer majority testimonies. Domain demands should affect the weight children place on others' testimony. When learning about domains that are heavily socially constructed (e.g. object labels or tool use conventions), testimony from others should be highly valuable because the relevant knowledge is transmitted through others, and children cannot learn this type of information on their own. By virtue of the social conventions that dictate object labeling, typically only one label is regarded as correct (Markman, 1989). Alternatively, learning about domains that are not socially constructed (e.g. causal relationships, or naïve physics), children should consider not only informants' endorsements but also their own knowledge, because this type of knowledge can be gained through personal observation and is not typically bound by social
convention. This leaves open the possibility that an effect can have multiple causes.
In this paper, we explore how children's endorsement of majority testimony varies as a function of domain type, and compare these empirical results to rational behavior as predicted by a Bayesian model of learning from testimony. Specifically, we compare children's endorsement of majority testimony in an object labeling task versus a causal learning task. We predict that when given two options - one endorsed by a three-person majority, and one endorsed by a single minority informant - children should be more likely to endorse the majority's testimony when learning socially constructed facts (object labeling) than when learning nonsocially constructed facts (causal learning).

## Modeling Testimony Across Task Domains

In order to rationally learn from others' testimony, children must consider several types of information: the testimonies themselves, their own observations, and social and pragmatic cues that can affect the interpretation of others' testimony. The specific cues and information available to children vary depending on domain, leading them to rely more heavily on pure testimony in some domains. Learning object labels is a task that is especially dependent on social conventions. Speakers of a language must implicitly agree that certain words refer to specific objects, concepts, or ideas (Clark, 1988; 1990) and use them accordingly. In contrast, causal knowledge can be gained through nonsocial cues, like personal experience, that also provide reliable information.

A Bayesian ideal observer model is a natural way to formalize our assumptions about the types of evidence available in these different domains, and about the preexisting biases and pragmatic assumptions that learners may bring to linguistic versus causal inferences. Buchsbaum et al. (2012) developed a model of how a rational learner should make causal inferences from both informant testimony and direct observations of causal outcomes. In this model, the learner receives testimony from one or more informants about the causal efficacy of one or more actions, and may also observe the causal outcome of these actions. The learner's goal is to choose a causally effective action. Here, we adapt this model to compare rational inferences from testimony in object labeling and causal tasks.

## Model Details

Our model for causal inference from testimony is very similar to the model presented in Buchsbaum et al. (2012). In this model, learners receive testimony $r_{c, i}$ from informant $i$ about whether they think candidate cause $c$ is effective. Learners can also directly observe the effects $e_{c, j}$ of those causes (with $N_{c}$ being the number of observations of the effect of cause $c$ ) Each cause $c$ has a true underlying causal strength $w_{c}$, where $p\left(w_{c}=\rho\right)=\gamma$ and $p\left(w_{c}=1-\rho\right)=1-\gamma$, where $\rho$ is a relatively high causal strength value, and $\gamma$ is the probability of a cause having high causal strength. The probability of an effect $e$ following $c$ is $w_{c}$. Each informant $i$
has knowledge about the strength of cause $c, k_{c ; i}{ }^{1}$ We assume that $k_{c, i} \in\{0,1\}$, corresponding to two possible states of knowledge of a cause: knowledgeable and naïve. If $k_{c, i}=1$ (informant $i$ knows about the causal strength of $c$ ), then $p\left(r_{c, i}=w_{c} \mid k_{c, i}=1, w_{c}\right)=1-\varepsilon-$ an informant with knowledge of cause $c$ will give correct testimony about the causal strength of $c$ with probability $1-\varepsilon$, where $\varepsilon$ is a small probability of giving incorrect testimony. In this work, we use $\varepsilon=0.01$. On the other hand, if $k_{c, i}=0$ then $p\left(r_{c, i}=w_{c} \mid\right.$ $\left.k_{c, i}=0, w_{c}\right)=p\left(r_{c, i}=w_{c} \mid k_{c, i}=0\right)=0.5-$ the informant will guess uniformly at random between the two possible actions. The probability of informant $i$ being knowledgeable about a particular cause is $p\left(k_{c, i}=1\right)=\tau$.

Figure 1: Dependencies of the variables in our Bayesian ideal observer model.

Finally, we assume $p($ choose $c) \propto p($ effect $\mid c$, obs) children choose causes in proportion to how likely they think they are to produce the effect, given the evidence. We can use this model to compute the probability that the learner should choose to perform a particular action to bring about the effect, using the dependencies defined in our graphical model shown in Figure 1 (for further details, see Buchsbaum et al., 2012). We can use the same model to infer novel object's labels from testimony. In this case, we have unnamed objects instead of causes, and instead of a causal strength, each object has a probability of corresponding to the novel label. However, unlike the causal case, there are no independent observations to incorporate into the model; you cannot "see" whether a label truly names an object.

## Model Predictions

We can examine a simple contrast between object labeling versus causal learning, where in each task, we assume two possibilities per task: i.e. two objects that could be the referent of a novel label, versus two actions to perform on a toy to elicit music. Corriveau, Fusaro, and Harris (2009) showed children three majority informants making one prediction, and a minority informant making an alternate prediction, so in a similar object labeling task, the majority

[^299]a)

b)

Figure 2: Proportion of responses endorsing majority testimony from (a) model predictions and (b) child data.
may each label Object 1 modi once, while the minority informant labels Object 2 modi three times. In a comparable causal task, the majority may all activate a toy using Action 1, while the minority informant activates the same toy three times using Action 2. Here, statements drawing attention to the demonstrated action are treated as testimony that the action is causally effective. As in the graphical model, the effect of an action is independent of the actor. We can use the model defined above to formalize some of the differences between these two tasks, then examine the model's predictions for whether rational learners should endorse majority testimony.

In labeling objects, we know that there exists a pragmatic mutual exclusivity assumption (Markman, 1989). If an informant labels Object 1 as the modi, this strongly implies that they believe that Object 2 is not a modi. In contrast, using one causal action does not necessarily imply that other actions are ineffective. We can capture this difference by having an informant's testimony that Object 1 is the modi implicitly include testimony that Object 2 is not a modi. In contrast, testimony in the causal case about the efficacy of Action 1 is left neutral with respect to the efficacy of Action 2. Instead, we treat testimony about Action 2 as unobserved for this informant (as are any demonstrations of Action 2 they might have performed).

Our remaining modeling assumptions are similar for both the causal and object labeling tasks. From previous work, we know that children assume that causes are relatively rare - most effects can only be brought about in one or two ways (Buchsbaum et., al, 2011; Bonawitz \& Lombrozo, 2012). Similarly, children generally assume that an object has only one basic-level label (Markman, 1989), so if it is a modi, it is probably not also a toma or a blicket. We can represent both of these prior biases by using a small value for $\gamma$, making multiple causes and multiple labels relatively unlikely. We also know that children are biased to assume that causes are deterministic or near-deterministic (Schulz \& Sommerville, 2006), and similarly that if an object is a modi, it is probably a modi every time, rather than occasionally something else. We can represent both of these assumptions using a high value for $\rho$. Finally, we know that children are a priori biased to assume adults are generally knowledgeable and helpful (Taylor, Cartwright, and Bowden, 1991), which can be represented by using a high value of $\tau$.

We can now look at model predictions for the simple object labeling and causal inference tasks described above. We present predictions using the example parameter values $\gamma=0.05 \rho=0.9$ and $\tau=0.8$ in Figure 2a. However, the qualitative differences in model predictions described below are robust to a wide range of parameter values, and in particular hold for any combination of values consistent with our assumptions. Given object-label testimony from a majority of three informants and one minority informant, the model predicts that learners should strongly favor the majority label. This is true not only if we explicitly force the model to consider only hypotheses where exactly one object is a modi (representing a hard mutual exclusivity constraint), but also if we remove this constraint, but continue to hold the softer pragmatic assumption that an informant who calls one object a modi is also saying that the other is not a modi.

In contrast, in the case where three informants activate a toy one way, and the minority informant activates the toy in another, the model predicts that after observing both actions bringing about the effect equally often, learners should be equally likely to choose either action themselves, despite the conflicting testimony. Finally, we examine a case where informants make causal predictions, but do not demonstrate the actions, paralleling the lack of non-testimony evidence in object labeling. In this case, we do not assume that predicting that one action is effective entails that the other action is not. Here, the model again predicts that the learner should endorse the majority's action choice, but only if they believe causes are rare. If they believe that causes are very common, they should continue to be roughly evenly split. Given our assumption that children are biased to believe causes are rare, we predict that they will again endorse the majority's demonstration in this case.

## Experiment 1: Comparing tasks

In this study, we present preschoolers with four informants' conflicting testimony about objects. In the object labeling condition, informants identify the referent of a novel label, and in the causal learning condition, they demonstrate a novel action on the object that results in a song.

## Methods

Participants Participants were 64 preschoolers, 29 male and 27 female (mean age $=4$ years 2 months; range $=36-$ 65 months). Participants were recruited in the San Francisco Bay Area by mail and phone calls or from local preschools
and museums. An additional five children were tested, but were excluded due to fussiness (4) or experimenter error (1).
Materials In the object labeling condition, stimuli were four novel objects. In the causal condition, stimuli were two plush toys, each of which contained a wireless, batterypowered doorbell chime box. The boxes played short melodies when activated by a handheld remote to create the illusion that children's actions were causally efficacious. Pre-recorded video clips of informants' testimonies were shown to children on a 13 " laptop screen.

Procedure Participants were randomly assigned to either the object labeling condition or causal condition. Each participant participated in two test trials of their condition.

In each condition, the experimenter introduced novel objects to participants and explained that they were unknowledgeable about their labels or causes. Participants then watched four video clips of four informants evaluating the objects.

Each clip began with a female informant sitting at a table with the novel objects. She visually inspected them, then picked up one of the toys and called it by the novel label (e.g. modi), or acted on the toy, resulting in the toy playing a short song. In three of the four video clips, the "majority" informants each endorsed one object as a modi or performed one action to elicit music, and the minority informant informant endorsed the other object the modi, or performed an alternate action to elicit music. The minority informant always repeated the novel label or alternate action three times so that each participant heard the label used to refer to each object an equal number of times.

After participants watched the video clips, the experimenter presented the child with the objects from the video clips and asked children to identify the referent of the novel label, or to make the toy play music. Participants' first gestural or vocal response was recorded. Participants in the causal condition were invited to activate toys three times.

Half of the video clips were mirror images of original recordings to control for the location of objects (object labeling condition) and handedness of informants when manipulating toys (causal condition). The trial presented first and identity of the minority informant were also counterbalanced.

## Results and Discussion

Participants were assigned a score $(0,1$, or 2 ) based on the number of trials in which they endorsed the majority informants' testimony (0-2) first responses in the two trials they participated in (see Table 1).

The distribution of scores in the object labeling condition was significantly different from those in the causal condition, $\chi^{2}(1, N=64)=6.72, p<.03$. The proportion of endorsements of majority testimony over the minority informant's was significantly greater in the object labeling trials $(49 / 64)$ than in causal trials $(32 / 64), \chi^{2}(1, N=128)=$ $8.61, p<.003$ (see Figure 2b). These results closely match
our model's predictions. There were no significant differences in responses based on gender or age (younger vs. older than mean age).

Table 1: Participant scores by condition.

|  | Score |  |  |
| :--- | :---: | :---: | :---: |
| Condition | $\mathbf{0}$ | $\mathbf{1}$ | $\mathbf{2}$ |
| Exp 1: Object labeling task | 4 | 7 | 21 |
| Exp 1: Causal task | 13 | 6 | 13 |
| Exp 2: Causal task (no feedback) | 2 | 3 | 12 |

In the causal condition, participants were invited to activate each toy three times. Not all participants made three attempts, but collectively, participants made a total of 179 attempts to activate toys in the causal trials. Ninety-four attempts ( $53 \%$ of total attempts) were actions performed by majority informants, 84 attempts ( $47 \%$ of total attempts) were actions performed by the minority informant, and one attempt was a novel action performed by none of the informants. All participants in this condition attempted at least one action performed by the minority informant.

As predicted by our model, these data show children were more likely to endorse majority testimony when learning socially constructed facts (object labels) than non-socially constructed facts (cause-and-effect relationships).

Though there was no formal coding scheme for children's spontaneous comments during the study sessions, anecdotal evidence suggests that children's intuitions matched our model assumptions about mutual exclusivity. In the causal condition, children's comments suggested they accepted both the majority testimony and the minority informant's testimony ("Both [actions] make it go!"). Furthermore, all children in this condition attempted an action performed by a minority informant at least once in the study, suggesting that children were open to multiple possibilities when learning about cause and effect. In the object labeling condition, however, several children expressed the belief that there was only one correct answer ("That one isn't the modi!" about the minority-endorsed object).

A possible alternative explanation of these results is that children in the causal condition did not use information gained through their observations or informants' testimony; rather, they were simply confused by the task and randomly imitated informants' responses. To rule out this possibility, we designed another causal condition in which we expected children to endorse the majority testimony.

## Experiment 2: The effect of feedback

In the causal condition of Experiment 1, children indiscriminately imitated the majority and minority informant actions, presumably because they were able to rely on their own observations, which suggested both demonstrated actions were equally effective at activating the toy. This second experiment examines how children behave when they do not have their own observations to rely on, but instead only have information from informants. We predict
that when children lack personal observations indicating the efficacy of informants' testimony, they will be more likely to endorse the majority's testimony.

## Participants

Participants were 17 preschoolers, 7 male and 10 female (mean age $=4$ years 4 months; range $=40-62$ months). Participants were recruited in the San Francisco Bay Area by mail and phone calls or from preschools. An additional three children were tested, but excluded due to fussiness.

## Materials and Procedure

The materials and general procedure of Experiment 2 were identical to those used in Experiment 1. The crucial difference between the two experiments was the content of the video clips participants watched. While in Experiment 1, children watched informants in the video clips perform actions that resulted in the toy playing music, in Experiment 2, informants in the video clips only mimed the actions they endorsed, and no music played as a result of miming the actions. In other words, children who viewed the Experiment 2 video clips received no information about the efficacy of the informants' testimony.

The script of the videos also differed from Experiment 1. Unlike the informants in Experiment 1, who did not verbally describe the action they performed, informants in the Experiment 2 video clips explicitly described their endorsed action and its hypothetical causal effect before miming the action, in order to provide context to children about why the action was being mimed: "It plays music if you pull the pink one!"

## Results

As in Experiment 1, Experiment 2 participants were given a score of 0,1 , or 2 based on their first responses (see Table 1). The number of first responses endorsing majority informants' testimony was significantly higher in Experiment 2 than in the Experiment 1 causal condition, $\chi^{2}(1, N=94)=6.84, p<.008$, and was correctly predicted by our model (see Figure 2b).

Participants in Experiment 2 were also invited to attempt to activate each causal toy three times. Participants collectively made 99 attempts to activate the toys. Of those attempts, 64 ( $65 \%$ of total attempts) were actions performed by majority informants, and 35 ( $35 \%$ of total attempts) were actions performed by the minority informant. Unlike in Experiment 1, where all causal condition participants attempted at least one action performed by the minority informant, four of the 14 participants in Experiment 2 attempted only actions endorsed by the majority.

## General Discussion

In this set of studies, we found that children do not indiscriminately endorse majority opinions; rather, their endorsement of majority opinions varies by task domain type and availability of alternate sources of knowledge. In

Experiment 1, children were significantly more likely to endorse majority testimony when learning about socially constructed facts (object labels) than non-socially constructed facts (causal relationships). Experiment 2 found that in the absence of information about the efficacy of informants' actions, children endorse majority testimony. Children's responses were predicted by a Bayesian model, suggesting that children make rational inferences from informants' testimony, and, when available, weigh other sources of information (e.g. personal observations) more heavily than testimony.

Though these results suggest children consider different sources of information in a non-socially-constructed domain, it is unknown whether they would do so in a socially constructed domain. In the causal conditions, the amount of feedback (i.e., hearing the toy play music) children received about actions' effects was easily quantifiable; however, it is less straightforward what would demonstrate positive or negative feedback about informants' endorsements in a object labeling condition. Future studies could explore how to convey feedback in an object labeling condition - perhaps showing successful or unsuccessful communication achieved through using the label - and the effect it would have on children's inferences.

Follow-up studies could also examine the effects of the informants' language in Experiment 2. In designing Experiment 2, we tried to make informants' video demonstrations as natural as possible while maintaining a similar script to Experiment 1, but creating parallel conditions proved difficult. Recall that the informants in Experiment 1 video clips performed their endorsed action without naming their actions. The informants in Experiment 2 narrated their actions and those actions' hypothetical effect ("It plays music if you pull the pink one!") to explain why informants were miming actions and to present possible actions for children to attempt at test. The hypothetical language used could imply to children that informants had prior experience with or knowledge about the toy. This prior knowledge, combined with informants' explicit demonstration, could be interpreted as evidence that informants were acting pedagogically, or upholding a social norm. Future work could examine how much of Experiment 2's effect was driven by children's lack of access to personal observations, versus pedagogical effects or social norm adherence.

Another difference between the conditions is the number of objects used in object labeling and causal conditions. In each of the causal conditions, participants saw the informants perform one of two actions on a single object, but the object labeling condition, participants saw informants call one of two objects by a novel label. A follow-up study to the object labeling condition could feature video clips with informants calling one object by two names, so that procedures of the object labeling and causal conditions would be more parallel.

In Experiment 1, we found that children's endorsement of majority testimony varies by task domain, but the flexibility
with which children incorporate conflicting information has yet to be determined. Accepting majority testimony as universally informative could potentially mislead a learner; individual members of the majority opinion could be mistaken, or the majority opinion as a whole could be flawed (see Esser, 1998 for a review on groupthink). Future work can identify the cues used to identify a reliable or unreliable majority. Children could discount informant testimony for rational reasons - for instance, if an informant is unreliable or unknowledgeable - or for less rational reasons - for instance, bias against out-group members (Kinzler \& Spelke, 2011).

Additionally, the nature of the beliefs underlying children's endorsements has yet to be examined. Children may endorse majority testimony in the moment in order to conform to societal norms, but do not truly believe this testimony correct. In social psychology, this is called compliance. It is also possible that children internalize this new social knowledge and believe it to be true. Future studies could explore whether children are merely complying with social norms in similar object labeling tasks, or whether they internalize the majority's testimony. Children could be asked to teach others the names of objects, or to recall objects' novel labels in sessions hours or days later.

Overall, the similarity between our model's predictions and empirical data suggest that young children are discerning when considering others' testimony; the extent to which they prefer majority testimony is dependent on task domain type. This work also adds to the growing body of literature that suggests children consider information from multiple sources to make rational inferences.

# Visual motion processing and perceptual decision making 

Aziz Hurzook (ahurzook@uwaterloo.ca)<br>Oliver Trujillo (otrujill@uwaterloo.ca) Chris Eliasmith (celiasmith@uwaterloo.ca)<br>Centre for Theoretical Neuroscience, University of Waterloo<br>Waterloo, Ontario, Canada N2L 3G1

#### Abstract

Perceptual decision making is a fundamental cognitive process widely studied in the behavioural sciences (Gold \& Shadlen, 2007; Wang, 2008). We present a novel, biologically plausible model of visual motion processing and perceptual decision making, which is independent of the number of choice categories or alternatives. The implementation is presented in the form of a large-scale spiking neural circuit consisting of three main processes: 1) a velocity filter that uses the principle of oscillator interference to determine the direction and speed of pattern motion using networks of V1 simple cells; 2) a retinotopic representation of motion evidence in the middle temporal area (MT); and 3) competition-less integration of sensory 'evidence' over time by a higher-dimensional attractor network in the lateral intraparietal area (LIP). The mechanisms employed in 1) and 3) are new. We demonstrate the model by reproducing behavioral and neural results from classic perceptual decision making experiments that test the perceived direction of motion of variable coherence dot kinetograms. Specifically, these results capture monkey data from two-alternative forced-choice motion decision tests. We note that without any reconfiguration of the circuit, the implementation can be used to make decisions among a continuum of alternatives.

Keywords: perceptual decision making, continuous decision making, motion processing

## Introduction

An important function of the mammalian brain is the ability to make decisions based on sensory input, and to take action based on these decisions. Organisms are constantly receiving sensory stimuli from their environment, and in order to choose sensible actions, they must sense and accumulate data over time until enough information exists to make a decision.

In this work, we offer two primary contributions in the computational modelling of a classic perceptual decision test. First, we take as our modelling starting point the visual intensity signals falling on the retina, from stimuli like those used in mammalian studies. Second, we show that the structure of the decision task is not relevant to the structure of the percept represented in the association cortex, and propose a novel mechanism to make decisions based on this structure.
A start-to-finish visual motion and perceptual decision circuit. We simulate the essential components of the primate motion perception and decision pathway using biologically plausible techniques at each stage of circuit modelling. From random-dot motion movies we generate burst signals known to occur in LGN (spatiotemporal derivatives of image intensity with noise reduced), the model then extracts velocity (direction and speed) information using a recurrently connected network of V1 simple cells, it then generates maps of optical flow in MT, and finally it integrates this evidence
in LIP using an $n$-dimensional integrator from which the representation of perceived structure emerges, regardless of task structure. Unlike motion energy models and some related proposals (Adelson \& Bergen, 1985; Rust, Mante, Simoncelli, \& Movshon, 2006; Simoncelli \& Heeger, 1998), the velocity selection mechanism we describe shows how recurrently connected spiking neurons can generate the observed spatiotemporal dynamics in V1 simple cells; that is, we show where the phase evolution of separable and inseparable Gabor-like V1 tunings comes from. Also new is our elimination of divisive normalization in the decoding of integrated vector quantities (Simoncelli \& Heeger, 1998), and the use higher dimensional integration in MT. We are not aware of any past spiking neural models that include all of these stages of processing.

Decision making from the temporal integration of structured percepts. Past work employing integrators to explain perceptual decision making assumes that scalar evidence is integrated to a threshold (Wang, 2008). Many separate scalar integrators are proposed to mutually inhibit one another to explain more complex tasks (e.g. deciding between two, four, eight, etc. possible directions of motion). Here, we propose that a single vector integrator can account for any number of directions of motion. The concept of vector addition is simple: when two opposing vectors are added, they cancel; when two similar ones are added, they reinforce. If the vectors are time-dependent, then at any point in the time course of the integration we have the current state of perception (a vector). Thus, 'competition' among alternatives is misleadingthere is no 'race' among 'competing' choice alternatives, as is typical of past models (M. E. Mazurek \& Shadlen, 2003). Moreover, the percept vector is independent of the decision structure. In other words, the number of alternatives (two choices, $n$ choices, a continuum) is irrelevant to the evidence accumulation process. Hence, the DV can be more generally interpreted as the decision radius ('DR', perhaps) of a percept vector evolving through integration in a higher dimensional sphere rather than a point on a line. The percept evolves over time as evidence accumulates, eventually crossing a decision surface ('DS', perhaps, rather than a decision threshold) if enough sensory evidence is accumulated. In the two-alternative forced choice task we use in our simulation, motion signals are integrated in two dimensions $(n=2)$ yet produce a binary decision, without reconfiguration of the circuit.

Our model suggests that the evidence that is accumulating
for perceptual decisions is a task-independent, $n$-dimensional percept structure (a vector) and not simply a task-dependent, one-dimensional category value (or decision variable, 'DV'). Since the percept structure can be interpreted as any timedependent evidence state for any sensory modality, the circuit could provide a more general approach for the analysis of integrate-to-threshold processes. It could thus be applicable to arbitrary decision processes in the brain, of which the motion evidence domain is only one example. In what follows, we provide a summary of the theoretical principles supporting the model, a description of the model itself, experimental details and results.

## Principles of model design

We use the leaky integrate-and-fire (LIF) neuron as our single cell model. The activity of an LIF neuron $a_{i}(J)$ can be thought of as the steady state firing rate of a neuron under a constant current $J$ and is given by

$$
a_{i}(J)=\left[\tau_{r e f}-\tau_{R C} \ln \left(1-\frac{J_{t h}}{J}\right)\right]^{-1}
$$

where $J_{t h}$ is the threshold current of the neuron, $\tau_{r e f}$ is the refractory period for the neuron, and $\tau_{R C}$ is the membrane time constant for the neuron. To reduce computational demands, we focus only on instantaneous firing rates, as opposed to the precise spike time information, using what are known as rate neurons. It has been shown, however, that the same computations can be performed with a slight increase in the number of spiking neurons (Eliasmith \& Anderson, 2003). Neurons in our model are coupled by a model of synaptic dynamics to give rise to biologically realistic dynamics, and hence empirically constrained timing data.

The general modelling techniques we use for building our simulation are collectively called the Neural Engineering Framework (NEF). The NEF is a method for performing large scale computations using any of a variety of simulated neurons (Eliasmith \& Anderson, 2003). The NEF characterizes the encoding of vector values by populations of spiking neurons, and computation of optimal decoders that allow the approximation of linear or nonlinear functions between ensembles of neurons. This allows us to perform arbitrary computations on vector or scalar quantities using simulated neurons. The following paragraphs go on to describe our computational methods and the NEF in more detail.

## Vector representation

Many empirical studies of mammals have found that populations of cortical neurons can encode real-world stimuli (Hebb, 2002). In the NEF, we encode vector-valued stimuli with populations of simulated neurons, or ensembles.

Encoding over neural populations. Each neuron in an ensemble is tuned to receive more ionic current $J$ when responding to a certain stimulus vector $\mathbf{e}_{i}$, known as that neuron's preferred direction vector, and receive less current the further
away the stimulus vector $\mathbf{x}$ is from $\mathbf{e}_{i}$. So given a vector stimulus $\mathbf{x}=\left(x_{1}, x_{2}, \ldots, x_{n}\right)$, we can relate the firing rate of a single neuron in the ensemble $a_{i}$ to the stimulus by

$$
a_{i}(x)=G_{i}[J(x)]=G_{i}\left[\alpha_{i}\left(\mathbf{e}_{i} \cdot \mathbf{x}\right)+J_{i}^{\text {bias }}\right]
$$

where $G_{i}$ is the nonlinear (spiking or non-spiking) function specific to our neuron model, $\alpha_{i}$ is a gain factor, and $J_{i}^{\text {bias }}$ is a background bias current.

Decoding by optimal linear estimation. In addition to being able to encode stimulus values across neural ensembles, we also would like to be able to recover the original stimulus, given an ensemble's firing pattern. Using this method, we can build a representation for arbitrary stimuli with neural ensembles (Eliasmith \& Anderson, 2003). The simplest way to do this is to make the assumption that the stimulus is a linear combination of the neural activities, which turns out to be quite accurate given enough neurons in the representation (Eliasmith \& Anderson, 2003). That is, we assume our stimulus vector $\hat{\mathbf{x}}$ can be represented by

$$
\hat{\mathbf{x}}=\sum_{i=1}^{N} a_{i} \mathbf{d}_{i}
$$

with $N$ being the number of neurons in the ensemble and $\mathbf{d}_{i}$ being a vector of decoding weights for neuron $i$. If we know $\mathbf{x}$, it is possible to find the optimal set of linear decoders $\mathbf{d}$ that minimize the squared error between $\mathbf{x}$ and $\hat{\mathbf{x}}$. This is a common problem in linear algebra, and can be solved as follows:

$$
\begin{aligned}
\mathbf{d} & =\Gamma^{-1} \mathbf{v} \\
\Gamma_{i j} & =\sum_{x} a_{i} a_{j} \\
\mathbf{v}_{j} & =\sum_{x} a_{j} \mathbf{x} .
\end{aligned}
$$

Solving for the optimal linear decoders, $\mathbf{d}$, allows us to recover an estimate of the original stimulus vector given a neural ensemble's activity. As we will see, it also allows us to directly compute the neural connection weights that perform a computation between two or more ensembles.

## Vector transformation

Now that we have defined a way of encoding and decoding stimulus values, we can perform computations between neural ensembles using our encoding and decoding vectors. Suppose we want to have an ensemble $\mathbf{y}$ encode some function of the value another ensemble is encoding, $\mathbf{x}$. i.e. $\mathbf{y}=f(\mathbf{x})$. We simply compute the decoders for $\mathbf{x}$ as above, only substituting $f(\mathbf{x})$ for $\mathbf{x}$ when computing $\mathbf{v}_{j}$. Then in order to encode our desired function, we multiply our new functional decoding weights $\mathbf{d}$ by our encoding weights for population $\mathbf{y}$, yielding a new set of weights between the populations that generate the desired transformation.

$$
\omega_{i j}=\alpha_{j}\left(\mathbf{d}_{i} \cdot \mathbf{e}_{j}\right)
$$

where $\alpha_{j}$ is a gain term associated with neuron $j$. Note that this technique works well for nonlinear functions as well as linear ones, as we are in effect projecting into a higher dimensional space than our representation, effectively turning a nonlinear function into one that is linear in the weight space.

## Population dynamics

The NEF also defines a way of computing functions defined over time, or dynamic functions. Incorporating timedependance is important in understanding and modelling neural responses, since in the real world, neural activity is dependant on time. In general, we describe a linear dynamic function by $d \mathbf{x} / d t \equiv \dot{\mathbf{x}}=A(\mathbf{x})+B(\mathbf{u})$, where $\mathbf{x}$ is the value currently being represented, and $\mathbf{u}$ is an input value from another ensemble.

One useful example of such a function is a twodimensional oscillator, defined by $A=\left(\begin{array}{cc}0 & 1 \\ -1 & 0\end{array}\right)$. To have an ensemble exhibit this behavior, we define a recurrent connection from this population to itself as described in Eliasmith and Anderson (2003). As shown there, it is possible to solve for the connection weights that allow the ensemble to exhibit the desired behavior, allowing for the implementation of arbitrary dynamical systems.

## Visual motion processing and perceptual decision making

The circuit we propose has three main information processing stages: 1) a velocity filter that uses the principle of oscillator interference to determine the direction and speed of pattern motion using networks of V1 simple cells; 2) a retinotopic representation of motion evidence in MT; and 3) competition-less integration of sensory evidence over time by an $n$-dimensional vector integrator in LIP. A schematic circuit diagram is depicted in Figure 1.

## Velocity selection using oscillating networks of V1 simple cells

The extraction of direction of motion employs the oscillator interference (OI) mechanism, depicted in Figure 2. The initial translational motion of an edge in a local region of the visual field is encoded in a burst signal at $t=t_{0}(\phi=0)$ to simulate LGN output. The signal is filtered through an input filter to control the initial phase of the oscillator. The input drives the rotation of the neurally represented state, $\mathbf{x}(t)=(r(t), \phi(t))$, through a progression of Gabor phase angles in the counterclockwise direction, with a rotation period intrinsic to the oscillator. Damping effects cause the neural representation of $\mathbf{x}(t)$ to return quickly to zero without further input. Subsequent input bursts at times $t_{i}$ add vectorially to, and thus interfere with, $\mathbf{x}(t)$. Constructive interference increases $\|\mathbf{x}(t)\|$ while destructive interference decreases it. Thus, if the direction and speed of the edge transiting the input gate of the neural oscillator are sufficiently close to the magnitude and phase of $\mathbf{x}(t)$, a resonance response occurs and $\mathbf{x}(t)$ sustains its magnitude and rotation. High responses from neurons

Figure 1: Unit circuit schematic for perceptual decision circuit. This figure details the circuit associated with each small patch of the visual field indexed by $i$. These units are repeated for each preferred direction, $\theta$. Each cluster of circles shown is a neural ensemble with $N$ LIF neurons. Index $d$ is the dimensionality of the decoded quantity encoded by the ensemble. $T$ is the period of the natural (undamped) frequency of the oscillator. Each MT ensemble pools the activities of several V1 ensembles with the same $\theta$ and $T$; likewise for LIP pooling of MT. The LIP ensemble is an $n$-dimensional integrator whose activity represents the direction of motion vector that emerges as motion evidence accumulates from all directions. In these simulations, $n=2$ as we are testing for the perceived direction of motion in a plane.
tuned to states later in the period indicate strong velocity (direction and speed) correlation for all earlier phase times after $t_{0}$. Summation of the activities of the late-phase neurons from

Figure 2: Velocity selection mechanism based on oscillator interference (OI). The velocity filter is an array of recurrently connected ensembles of direction selective V1 simple cells. The connection weights are determined using the NEF to endow the ensemble with oscillatory phase sensitivity and thus speed selectivity. The system state has components of magnitude and phase, $\mathbf{x}(t)=(r(t), \phi(t))$. The initial (rest) state is $\mathbf{x}(t)=(0,0)$. (1) An initial burst signal from the LGN is triggered by the translational motion of an edge in the receptive field, shown as a bar moving to the right inside the dotted circle, overlapping the input filter. $\mathbf{x}(t)$ begins to increase in magnitude and rotate through the phase angles. (2) Further input bursts at times $t_{1}$ to $t_{4}$ interfere constructively with the system state only if $\mathbf{x}(t) \approx \mathbf{x}\left(t_{i}\right)$. (3) The activity of neurons tuned to phases late in the period will be high only if correlation with visual input is similar earlier in the cycle. The late-phase activities drive an associated direction vector representation in MT. Other V1 oscillators associated with the same patch but tuned to different directions contribute a weight proportional to the component of motion velocity in their preferred direction (bottom, grey arrows).
the oscillator produce a scalar weight of an associated vector represented in a retinotopic field of motion evidence in area MT. This is a generic mechanism that captures motion information from any visual input.

## Motion evidence map in MT

Figure 3 shows time snapshots of sample velocity maps represented in MT. These are depictions of the stimulus motion

Figure 3: Retinotopic velocity maps in MT. Samples of vector read-out (optical flow) maps in MT for a $7 \times 7$ array of receptive fields for times $t=100,120,140 \mathrm{~ms}$ after stimulus input. The response latency was $50-65 \mathrm{~ms}$. Stimulus coherence levels are categorized by column. For all coherence levels, the stimulus produces a distribution of motion responses. The target direction is not obvious from inspection and requires temporal integration.
in the visual field for any number of directions (for clarity we depict eight directions) at the given times. Each point in the $7 \times 7$ array represents the centre of a patch that is the domain of visual signal input to each unit circuit. The scalar output of each V1 oscillator provides the weight of an associated velocity for a given patch in the field. It should be stressed here that no task-dependent categorization of the motion field is imposed.

For complex pattern motion like variable coherence dots, even at high coherence levels ( $50-100 \%$ ), the wide distribution of velocity response maps provides an indication as to why temporal integration is required for the biased direction to emerge.

## Higher dimensional vector integration in LIP

An important contribution of the model is its employment of a higher-dimensional vector integrator. The linear dynamical equation is

$$
\dot{\mathbf{x}}=A \mathbf{x}+B \mathbf{u}(t)
$$

where $A=0, B=I$ (the identity matrix), and $\mathbf{u}(t)$ is the input evidence. Using the NEF we can determine that the recurrent matrix for neurons to implement this dynamical system is

$$
\omega_{i j}=\alpha_{j} \mathbf{d}_{i}(A+I) \mathbf{e}_{j}=\alpha_{j} \mathbf{d}_{i} \mathbf{e}_{j}
$$

where $i$ and $j$ index the same population of neurons. Because the NEF is defined for vector representations, these weights will result in a neural state that represents the integration of information in the dimensionality of $\mathbf{x}$ (in this case $D=2$ ). Multi-dimensional integrators of this sort have been previously employed in neural models of working memory (Singh \& Eliasmith, 2006), but not for decision making.

## Experiment

## Model implementation

The neural system simulation package used to implement the circuit was Nengo, (http://nengo.ca). Table 1 provides the neurophysiological parameters used. A total of $2.9 \times 10^{5}$ spiking LIF neurons were used. The random-dot motion movies were generated using the Psychtoolbox-3 extensions for Matlab ${ }^{\circledR}$ (Kleiner, Brainard, \& Pelli, 2007; Pelli, 1997; Brainard, 1997). The visual input signal was in the preferred directions of the associated V1 oscillators. To simulate thalamic bursting (Butts et al., 2010), temporal derivatives of spatial overlap between the stimuli and oscillator input filter were taken at $2-\mathrm{ms}$ pulse widths.

## Decision test description

We performed a two-alternative, forced-choice, fixed duration test of 1 -second duration, using variable coherence random-dot motion movies for a single patch. The decision threshold value was held fixed and was the only parameter adjusted to fit behavioural data. The length of the percept state vector, when the average success rate of the circuit was $80 \%$, was used as the decision radius (analogous to the decision threshold use by Gold and Shadlen for the same test in monkey trials (Gold \& Shadlen, 2007). The coherence level (motion strength) was lowered progressively, decreasing motion information and stressing the signal-to-noise ratio resolving capability of the circuit. For each coherence level 10 tests were run.

## Results

The model was able to determine direction of motion in the majority of cases down to about 5\% coherency (Figure 5), and showed similar characteristics to data collected from monkeys in (Gold \& Shadlen, 2007). Particularly, as shown in Figure 4, neuron responses in area MT stayed relatively constant over time, with certain neurons showing stronger firing rates when given stronger motion evidence (higher coherency). At the same time, neuron responses in area LIP got stronger over time, particularly when nearing the decision threshold under medium to high coherency. Additionally, as shown in Figure 5, the experimental results relating to the percentage of correct decisions and time taken to make a decision over varying coherency levels were in accordance with experimental data.

## Conclusion

In the TAFC visual decision task we have used to test our model, we have shown the validity the OI velocity selection

Figure 4: Electrophysiology of MT and LIP neurons during the decision task. Recreated from (Gold \& Shadlen, 2007).

Figure 5: Psychometric performance. The circuit can discern motion direction reliably for coherence levels down to $10 \%$, below which it drops to $50 \%$ success (random guess) as motion strength approaches 0 . The disparities in reaction time between our model and the experimental data may be attributable to motor reaction time and other behavioural factors for which we do not account. Monkey data plots recreated from (Gold \& Shadlen, 2007).

mechanism and the effectiveness of integrating a percept vector over time, without any consideration of the number of choice alternatives. The percept vector evolved over time, toward the left or right direction in two dimensions, producing a binary decision. This was due to the nature of the input, the sensory processing and integration mechanisms, and not any imposed task structure. Since the OI mechanism is isometric in the visual plane, identical results would result from forced choice tasks in any direction. We have tested the same model with additional forced-choice options (e.g. 4 and 8), and it performs similarly well (results not shown). Predictably, fewer choice alternatives lead to faster decisions, since the minimum detectable difference in signal level between two alternatives is greater than if that same magnitude were distributed among 8 alternatives.

It is natural for us to consider the percept vector and its temporal integration to a DS in much higher dimensions. The approach we have presented here can likely be applied to higher order sensory or non-sensory decision making that requires integration of evidence over time.

#### Abstract

Embodied cognition studies have demonstrated that when words found in high physical locations (e.g., bird) are positioned at the top of a screen they are processed faster than when they are positioned at the bottom of the screen. The reverse effect is obtained for words found in low physical locations (e.g., fish). This concept-location facilitation effect has been argued to demonstrate that cognitive processing is fundamentally perceptual in nature. However, questions can be raised with regards to the absolute or relative location of these concept-location words We investigated whether semantic judgments were made with respect to an absolute location on the screen (embodied explanation) or with respect to a relative location in comparison to other words included in the experimental session (statistical linguistic explanation). In a response time experiment we presented participants with physical-location words from existing studies at the top or bottom, top or center, and center or bottom of the screen. For animate words we found a concept location facilitation effect for words presented at the top of the screen, at the center of the screen, and at the bottom of the screen. In addition, however, language statistics explained RTs to center words. Findings indicated that participants made judgments relative to other words on the screen and not relative to their absolute location on the screen, lending support to a statistical linguistic explanation of the findings.

Keywords: concepts; embodied cognition; symbolic cognition; concept-location facilitation; perceptual

## Introduction

Embodied cognition theories state that language is understood through perceptual representations that are grounded in modality-specific somatosensory experience (Barsalou, 1999; Glenberg, 1997; Semin \& Smith, 2008). Words become meaningful only after mentally reenacting external perceptions and experiences associated with that word. Thus, the patterns of neural activity that occur when comprehending a particular word would be similar to those patterns that occur when actually perceiving its referent (Hauk, Johnsrude, \& Pulvermüller, 2004). In other words, according to embodied cognition theories mental representations are couched in the physical and perceptual experiences of the body.

There is a wealth of evidence supporting the embodied cognition account, with evidence showing that when
experimental tasks cue participants to refer to relevant perceptual representations, language processing is facilitated (Glenberg \& Kaschak, 2002; Kaschak et al., 2005; Pecher, van Dantzig, Zwaan, \& Zeelenberg, 2009). For example, Zwaan and Yaxley (2003) demonstrated that when word pairs appeared in their expected physical locations on a computer screen (e.g., ceiling presented at the top of the screen and floor presented at the bottom of the screen), comprehension was faster than when pairs appeared in unexpected physical locations on a computer screen (e.g., floor presented at the top of the screen while ceiling was presented at the bottom of the screen). That is, it is easier to process a word when the expected physical properties of the word match its actual physical properties. Accumulating research like this tends to suggest that individuals rely on perceptual representations, especially in everyday language comprehension.

This embodied cognition account of semantic representations is often contrasted to an amodal (or symbolic) account of cognition, whereby language is represented amodally. A classical symbolic account of language representation argues that semantic information is seated in language and can be derived from relationships that exist between symbols instead of from the mental reenactment of biomechanical and perceptual experiences. In other words, meaning is represented in a linguistic structure within the brain encoded in a formal abstract language, and words are understood from their natural linguistic context instead of from their perceptual features.

Recently, several studies have argued that an extreme symbolic or an extreme embodied cognition account is untenable, and that a more plausible cognitive model includes both perceptual and symbolic processes in language comprehension (Barsalou, Santos, Simmons, \& Wilson, 2009; Louwerse, 2008; 2011a; Paivio, 1986). For instance, Louwerse (2008; 2011a) proposed the Symbol Interdependency Hypothesis. This hypothesis predicts that language encodes the perceptual information we tend to simulate. Consequently, language statistics allows for bootstrapping meaning with only minimal symbol grounding in perceptual experiences. Put differently, according to the idea of symbol interdependency embodied simulations and symbolic relationships are complementary in conceptual processes.

We also know from previous research that language statistics and perceptual simulations explain cognitive processes to different extents under different conditions. For example, linguistic representations are relatively more prominent early during processing whereas complete perceptual representations take longer to generate (Louwerse \& Connell, 2010; Louwerse \& Hutchinson, 2012). Louwerse \& Jeuniaux (2010) found that both task and stimulus influenced whether participants were more likely to rely on linguistic or perceptual information. Thus, findings reporting effects for word pairs attributed to embodied cognition (e.g., Zwaan \& Yaxley, 2003) might likely also be explained by a statistical linguistic account. For example, when participants were asked to make a semantic judgment about word pairs, the statistical linguistic frequency of the word pair best predicted RTs whereas when participants were asked to make an iconic judgment about image pairs, perceptual ratings about the pair better accounted for RTs (Louwerse \& Jeuniaux, 2010). Although both the linguistic and perceptual information about the word pair showed to be relevant in both cognitive tasks, with both verbal and non-verbal stimuli, different types of information were more, or less, important across different conditions.

These studies demonstrate that both language statistics and perceptual simulation must be taken into consideration together. After all, the Symbol Interdependency Hypothesis argues that language encodes perceptual information, making it difficult to disentangle the two variables. That is, effects attributed to statistical linguistic frequencies could also be attributed to perceptual simulation and vice versa. Furthermore, studies demonstrating a language statistics effect use word pairs as stimuli (e.g., Louwerse \& Hutchinson, 2012; Louwerse \& Jeuniaux, 2010; Tse, Kurby, \& Du, 2010).

However, evidence supporting an embodied cognition account also comes from single words, presented in different locations on a computer screen. For example, Šetić and Domijan (2007) presented 'up' and 'down' words one at a time either in an expected physical location or in an unexpected physical location (e.g., butterfly would either appear at the top of the screen (expected location) or at the bottom of the screen (unexpected location)). Participants were asked to determine if the word they saw was something animate (living animal) or something inanimate (non-living entity). As expected, patricipants were faster to process concept-location matches (e.g., butterfly presented at the top of the screen) than conceptlocation mismatches (e.g., butterfly presented at the bottom of the screen). Unlike experiments comparing word pairs, findings for words in isolation, such as those in Šetić and Domijan (2007), are more difficult to also explain with a statistical linguistic account. That is, unigram word frequency does not explain congruency effects, as the set of 'up words' are not all more orless frequent than the set of 'down words'. In fact, when comparing how frequently the 'up words' and 'down words' occurred in a massive corpus of the English language (the Web IT 5-gram corpus; Brants \& Franz, 2006), no difference was obtained between the frequencies of 'up words' and 'down words' inform the

Šetić and Domijan (2007) study, $t(153.37)=0.64, p=.52$. Consequently, the concept-location word results only seem to support an embodied cognition account and are argued to be due to the congruency of the presentation location and the perceptual features of the word: butterfly is processed quickly at the top of the screen because a mental simulation of a butterfly involves perceptual and spatial information about where a butterfly is found in the actual world (above the ground/at the top). This poses a challenge to an account that argues for both linguistic and perceptual simulations factors in conceptual processing, such as proposed by the Symbol Interdependency Hypothesis.
Although it seems straightforward to conclude that these effects must be due to the mental simulation of words, there are alternative explanations. Lakens (2011a; 2011b) argues that such effects might instead be due to polarity correspondence. Proctor and Cho (2006) found that in binary classification tasks, concepts can be processed faster when their polarity matches the response polarity. In other words, when a stimulus and a response are coded as either both positive or both negative, processing is facilitated, e.g., butterfly is processed quickly at the top of the screen because its location is positive (up), as is the response to whether or not it is found in the sky (yes). In order to rule out a polarity correspondence explanation for the results, in a similar experiment, Pecher, van Dantzig, Boot, Zanzolie, and Huber (2010) asked participants to respond to the question Is it usually found in the ocean? or to the question Is it usually found in the sky?. They argued that for a polarity correspondence explanation to be valid, yes responses would be expected to be processed faster at the top of the screen, regardless of the question being asked, and regardless of word meaning. For instance, when being asked if an animal is found in the ocean, one would expect butterfly to be processed faster at the bottom of the screen because it is not found in the ocean, a hypothesis contrary to an embodied cognition explanation and a hypothesis that was not supported. Instead, the results showed just the opposite, i.e., when being asked if the animal is found in the ocean, butterfly was still processed faster at the top of the screen. In a response, Lakens (2011b) still suggested that perhaps butterfly is processed faster at the top of the screen, even when participants are making an ocean judgment because the judgment becomes a relative assessment with down as the default response (as all comparisons are made with reference to the ocean, which is down).
Lakens (2011b) goes further to point out that alternative explanations for data explained solely by perceptual simulations should not be overlooked. In addition, Lakens (2011b) and Louwerse (2011b) both suggest that results from Pecher et al. (2010) might likely also be explained by a statistical linguistic account. That is, although Pecher et al. (2010) concludes that mental simulation accounts for responses in the sky/ocean task, linguistic frequencies do contribute to word meaning and should also be considered. To illustrate, Louwerse (2011b) found that ocean animal names paired with the word ocean occur more frequently than ocean animal names paired with the word sky (and vice versa for sky animal names) and that these frequencies
account for subject RTs. In sum, findings previously attributed to mental simulation accounts can also be explained by a statistical linguistic account, as was also demonstrated in earlier research (Louwerse \& Jeuniaux, 2010). These findings illustrate that task instructions might influence response times because ocean and sky are more or less linguistically associated with the stimuli. In other words, linguistic explanations for these findings should also be explored.

But it remains difficult to offer a linguistic explanation for results when words are presented in isolation. Although task instructions might influence the speeded responses, the frequency of butterfly - sky is only able to account for faster RTs for congruent word categories and tasks while still leaving mental simulations to offer the only explanation for the facilitative effect of the congruency of the presentation location and the perceptual features of the word (as unigram word frequency cannot account for these RTs). Perhaps linguistic information might play a role explaining these concept-location effects for isolated words after all. Although words are presented in isolation on the screen (i.e., one word is presented at a time), it is possible that decisions might be made relative to the other words presented in the other trials of the experiment. Such an explanation would suggest that instead of making judgments relative to the congruency between the concept and the absolute position of the word on the screen (i.e., top of the screen or the bottom of the screen), participants are making judgments relative to the other words in the experiment. That is, participants might show a conceptlocation facilitation effect not because the words are presented on the top and bottom of the screen, but rather because words are asynchronously presented relatively above and below one another throughout the duration of the experiment.

To explore this possibility, in this study we presented participants with isolated words at either the top or bottom (to replicate the original results), top or center, or center or bottom of the screen. According to an embodied cognition account, if responses are faster because word meaning and world location are congruent, we would expect the same high and low words, presented in the center of the screen to show no concept-location facilitation effect because the presentation location is not congruent with the physical and spatial properties of the simulated word. In other words, when butterfly is presented in the center of the screen, processing should not be facilitated.
Alternatively, if decisions are based on the relationship between one word relative to the other words in the experiment (as opposed to being relative to the presentation location of the word; a linguistic explanation), then we might find that high words presented in the center of the screen (concept-location mismatch) will still show a concept-location facilitation effect if low words are presented at the bottom of the screen. That is, when butterfly is presented in the center of the screen, processing will be facilitated if other words in the experiment are 'below' a butterfly. Similarly, we might find that low words presented at the center of the screen would show a concept-location facilitation effect if high words are
presented at the top of the screen. In essence, if conceptlocation facilitation is found when words are presented in relative positions on the screen (i.e., above/below one another) as opposed to absolute positions on the screen (i.e., at the top/bottom of the screen), it might be the case that perceptual simulation (concept-location facilitation effect) is not entirely accounting for RTs but rather, participants are making decisions about words presented in isolation by comparing those words to the group of words included in the experiment.

## Method

## Participants

Eighty-seven undergraduate native English speakers at the University of Memphis participated for extra credit in a Psychology course. Participants were randomly assigned to each of the three conditions (words presented at either a) the top of the screen and the center of the screen, b) the center of the screen and the bottom of the screen, or c) the top of the screen and the bottom of the screen).

## Materials

The experiment consisted of 48 living animal words that could be found in a low spatial location, (such as the ground or ocean, $n=24$ ) or found in the sky (a high spatial location, $n=24$ ). The remaining 48 words consisted of nonliving objects that could also be found in either high ( $n=24$ ) or low ( $n=24$ ) physical locations. Words were extracted from both Pecher et al. (2010) and Šetić and Domijan (2007).

## Procedure

The procedure was almost identical to Pecher et al. (2010) and Šetić and Domijan (2007). Participants were asked if words presented on a $1280 \times 1024$ computer screen were either living or nonliving. This task has the advantage that it does not bias participants to consciously judge the physical location of a word. The center of the screen was positioned at eye level. Similar to Pecher et al. (2010) and Setić and Domijan (2007), each trial began with the presentation of three fixation crosses appearing on the screen for 300 ms . Fixation crosses were presented either at the top, center, or bottom of the screen, depending on where the proceeding word would appear on the screen. This occurred in order to notify participants where the next word would appear.

Words were presented at either the top and the center of the screen, the center and bottom of the screen, or - as in the original Šetić and Domijan (2007) study the top and bottom of the screen, depending upon the between participants condition. Upon presentation of a word, participants indicated whether the word was living or not living by pressing designed counterbalanced keys on the keyboard ( $f$ and $j$ keys). All words were seen once and were counterbalanced for each participant where half the high spatial location words were presented in the upper position (relative to the other presentation location, i.e., top relative to center/bottom or center relative to bottom) and
half in the lower position (i.e., bottom relative to center/top or center relative to top), likewise for the low spatial location words.

If responses were slower than $2,500 \mathrm{~ms}$ a message reading 'TOO SLOW' would appear. Participants were asked to try to be as quick and as accurate as possible in their responses. The next trial began immediately after the subject's response or after the feedback message.

## Results and Discussion

Eleven participants were removed from the analysis because $>40 \%$ of their answers were incorrect. All remaining participants were split evenly between conditions. In all analyses, we used the parameters found in Pecher et al. (2010) for outlier identification and removal. Outliers were identified as those correct responses greater than three standard deviations from the mean per subject per item. Outlier removal (as described above) resulted in a loss of $2.8 \%$ of the data. All error trials were removed, resulting in a loss of an additional $8.7 \%$ of the data.

A mixed-effect regression analysis was conducted on RTs with match/mismatch (match or mismatch between word category (low or high spatial location word) and relative presentation location (relatively high location of top or center or relatively low location of center or bottom)) as a fixed factor and participants and items as random factors (Baayen, Davidson, \& Bates, 2008). The model was fitted using the restricted maximum likelihood estimation (REML) for the continuous variable (RT). F-test denominator degrees of freedom were estimated using the Kenward-Roger's degrees of freedom adjustment to reduce the chances of Type I error (Littell, Stroup, \& Freund, 2002).

In addition to the location presentation manipulation, we investigated the source of the RT differences in this task, linguistic or embodied. An embodied account would be predict a concept-location facilitation effect, whereas a linguistic account would suggest these same effects are driven by language statistics. To further explore if participants were relying on language statistics, we ran analyses using word frequency as a fixed factor to determine if a possible additional explanation for any concept-location facilitation effects may exist. The word frequency factor was calculated as the log frequency of each word being presented obtained using the Web 1T 5gram corpus (Brants \& Franz, 2006).

Unlike Šetić and Domijan (2007), no significant conceptlocation facilitation effect was found for words appearing at the top of the screen, $F(1,2330)=1.46, p=.23$, at the center of the screen, $F(1,1599)=.10, p=.75$, nor at the bottom of the screen, $F(1,2395)=1.76, p=.19$. Just as in Pecher et al., (2010) these findings also fail to replicate the concept-location facilitation effect found in Setić and Domijan (2007). In fact, there was no interaction between location and word category for any of the three word presentation locations and experimental conditions. Pecher et al. (2010) offered the explanation that the concept location facilitation effect is not well understood, with some factors causing facilitation and others causing interference. The linguistic frequency factor did not explain

Figure 1: Average RTs in ms for the words appearing at the top of the screen.

Figure 2: Average RTs in ms for the words appearing at the center of the screen.

Figure 3: Average RTs in ms for the words appearing at the bottom of the screen.
the results either, with no significant main effects for words appearing at the top of the screen, $F(1,2330)=.0001, p=.99$, the center of the screen, $F(1,1599)=.19, p=.66$, nor the bottom of the screen, $F(1,2395)=.11, p=.74$. These current results seem to support neither an embodied cognition account (as there was no concept-location facilitation for the top-bottom condition) nor an alternative linguistic account (as there was no concept-location facilitation for either condition including the center location nor was linguistic frequency significant). In the absence of a replication in both the current study and in Pecher et al. (2010), perhaps the effects reported in Šetić and Domijan (2007) might be attributed to linguistic differences in the Hungarian stimuli. Alternatively, such concept-location facilitation effects might simply be relevant for certain groups of words and not others.

To further explore the results of the current experiment, and the possibility that words are processed relative to the words around them, we analyzed our findings mixed effects model but for animate versus inanimate words. Words that were inanimate again showed no interactions for words appearing at the top of the screen, $F(1,1172)=$. $003, p=.96$ (see Figure 1), the center of the screen, $F(1$, 787) $=.07, p=.80$ (see Figure 2), or the bottom of the screen, $F(1,1072)=.92, p=.34$ (see Figure 3). Linguistic frequency was also not significant for words appearing at the top of the screen, $F(1,1172)=1.53, p=.22$, the center of the screen, $F(1,787)=.62, p=.43$, nor the bottom of the screen, $F(1$, 1072)=.002, $p=.96$.

However, words that were animate did show significant interactions. Words appearing in any given location (top, center, and bottom) were processed faster when that location was relatively the same as the word category. 'Up words' presented in the center were processed faster in the center-bottom condition, whereas 'down words' presented in the center were processed faster in the top-center condition, $F(1,789)=6.10, p<.02$. Figure 2 clearly illustrates RTs for matched and mismatched up and down words presented in the center of the screen, showing that words with a concept-location match are processed faster than words with a concept-location mismatch. Similarly, 'up words' presented in the top of the screen were processed faster in both the top-bottom and top-center conditions, $F(1,1134)=6.80, p<.01$, (see Figure 1). Finally, 'down words' presented in the bottom of the screen were processed faster in both the top-bottom and center-bottom conditions, $F(1,1067)=10.97, p=.001$, (see Figure 3).

In addition, to further explore the impact of linguistic frequency also significantly explained RTs to words presented at the bottom of the screen, $F(1,1067)=5.08, p=$. 02 , but only marginally for words presented in the center of the screen, $F(1,789)=3.22, p=.07$, with no effects for words presented at the top of the screen, $F(1,1134)=2.58$, $p=.10$. These findings seem to be consistent with the idea that decisions are based on the relationship between one word relative to the other words in the experiment, as 'up words' presented relatively above 'down words' still showed a concept-location facilitation effect despite these words being presented in the center of the screen.

In addition, in all conditions, words appearing relatively below other words ( $M=767.45, S D=267.40$ ) were processed significantly slower than words appearing relatively above other words ( $M=889.36, S D=421.41$ ), $t(4926)=15.36, p<.001$. That is, regardless of the absolute location of the word on the screen, where-ever the bottom position was (i.e., center of the screen or bottom of the screen), words presented in that location were processed slower than the same words presented in a relatively higher location. Consider the case of the center presentation location: when words were presented in either the center of the screen or the bottom of the screen, words took longer to process at the bottom and less time to process at the center. However, when those same words were presented in the center or the top, they took longer to process in the center and less time to process at the top. This means that the same words presented in the same location are processed faster or slower simply due to whether other words are appearing above or below them. This at least suggests that comparisons between high and low positions are biased given that the center represents both the relative top and bottom in different conditions.

Finally, to explore whether participants indeed made comparative judgments for words, we assessed whether bigram frequencies were able to account for the response times of center words. As in previous studies (Louwerse, 2008) we operationalized the bigram linguistic frequencies as the $\log$ frequency of a-b (e.g., owl-lizard) or b-a (e.g., lizard-owl) order of word pairs. Because words were presented individually on the screen, pairs were determined by the randomized presentation order. The bigram frequency of each pair was assigned to the second word in the randomly presented pair. The order frequency of all word pairs within 3-5 word grams was obtained using the large Web $1 T$ 5-gram corpus (Brants \& Franz, 2006). A mixed-effect regression analysis was conducted on RTs to center words with the bigram frequency as a fixed factor and participants and items as random factors (Baayen, Davidson, \& Bates, 2008). Bigram frequency was a significant predictor of RTs for center words only, $F(1,906)=3.99, p=.05$. This was true for all center words regardless of experimental condition, implying that participants consider past trials while making judgments about the current word in question, and implying that a linguistic frequencies explain RTs during a conceptlocation facilitation task.

## General Discussion

In three presentation location conditions (top and center, bottom and center, or top and bottom) we failed to replicate a concept-location facilitation effect as found in Šetić and Domijan (2007) for inanimate words. However, when considering animate words, words matched between the relative presentation location and word category resulted in faster RTs than words with a mismatch. This finding suggests that participants make judgments about individual words they see on the screen with respect to other words they see throughout the duration of an experiment. The absolute location of a word on a screen does not seem to impact the concept-location facilitation effect, but rather
the relative location appears to be what is important. This finding suggests that decisions are based on the relationship between one word relative to the other words in the experiment, not only based on the relationship between one word and the embodied physical and spatial properties of that simulated word. In addition, across all three conditions, we found a main effect of location, such that words presented below other words were processed slower. This finding suggested that participants made judgments relative to other words, not only relative to their location on the screen. To further determine whether participants made comparative judgments between words presented asynchronously over the duration of an experiment we also showed that bigram frequencies can predict subject RTs. These findings together indicate that it might be the case that participants are making decisions about words presented in isolation by comparing those words to the group of words included in the experiment, suggesting that findings that are easily attributed to embodied cognition (Pecher et al., 2010; Šetić \& Domijan, 2007) can also be attributed to language statistics.

#### Abstract

Research has shown that spatial referencing differs across cultures. Whether "Western" samples, specifically ones speaking the same native language, show the same referencing patterns has not been investigated thus far. Examining spatial referencing behavior across different tasks, we compared samples from four different countries speaking the same language with respect to their application of the intrinsic frame of reference (FoR) and the three variants of the relative FoR. Our findings indicate influences of factors beyond language: While the four French-speaking samples showed an overall preference for the reflection variant of the relative FoR, they differed significantly regarding the extent to which reflection and the intrinsic FoR were applied. Moreover, in all samples, characteristics of the referenced objects, namely whether they were animate or inanimate, influenced FoR use. The order of tasks also had an impact on referencing behavior.

Keywords: space; spatial cognition; frames of reference (FoRs); linguistic relativity; object characteristics; animacy; French.

## The Question of Language's Influence on Cognition

In the past decades, the debate about linguistic relativity (known as the Sapir-Whorf-Hypothesis, e.g. Sapir, 1949; Whorf, 1956), that is, whether language determines cognition, has been revived (e.g. Gumperz \& Levinson, 1996). An influential research area spurring this revival concerns frames of reference in the domain of space.

Languages differ regarding spatial referencing, that is, how they preferentially describe the position of objects in
relation to one another (e.g. Majid, Bowerman, Kita, Haun, \& Levinson, 2004; Mishra, Singh, \& Dasen, 2009). Moreover, it has been shown that across different languages, frames of reference (FoRs) covary in language and cognition (e.g. Danziger, 2011; Haun, Rapold, Janzen, \& Levinson, 2011; Levinson, 2003). However, there is still much debate on how this covariation comes about, specifically whether language determines cognition or vice versa or whether environmental factors influence both language and cognition (see e.g. the debate between Levinson, Kita, Haun, \& Rasch, 2002, and Li \& Gleitman, 2002; and see Haun et al., 2011; Li, Abarbanell, Gleitman, \& Papafragou, 2011).

In their overview of cross-cultural findings, Majid and colleagues (2004) investigated environment (urban vs. rural), habitual action (subsistence patterns) and cognitive styles (individualism vs. collectivism) as possible mediators between FoRs in language and cognition. They found that none of these factors beyond language systematically accounted for differences in non-linguistic FoR use between speakers of different languages.

Commonly, in spatial referencing research, language and culture are treated as one entangled factor (e.g. Burenhult \& Levinson, 2008). As they are closely intertwined (e.g. Kodish, 2003), differential effects of language and culture are arguably difficult to investigate. However, feasible approaches would be to investigate individuals living in the same country but speaking different languages or the other way around: individuals speaking the same language but living in different countries.

Research in this vein indicates that both language and extra-linguistic factors play a role for referencing strategies. Eggleston (2012) compared three samples, namely Spanish speakers from Barcelona and from Nicaragua and a Nicaraguan sample speaking Sumu-Mayangna. While the former two spoke the same language, the latter two lived in the same country. She found that the samples differed with respect to referencing preferences. Shared language was a stronger predictor of spatial referencing behavior than shared environment. Eggleston concludes that the two factors interact. Similarly, indicating influences beyond language, Troadec (2003) found differences in FoRpreferences between two different French speaking samples in Polynesia, in that the absolute FoR was preferred on an island while the relative FoR was preferred in a city. Taken together, these findings indicate that while language and spatial cognition covary, speaking the same language alone does not necessitate identical FoR-preference. Instead, there seem to be differing conventions between communities, at least when the language allows for application of all FoRs.

## Frames of Reference

In times of ever-increasing international cooperation it is important to know possible sources of miscommunication. Implications of research on spatial referencing thus go far beyond research offices, as illustrated by the following example: Task forces from different countries have to come up with strategies of how to enter a building in which terrorists are keeping hostages. If the order "we enter the building from the back left, you guys go in from the front right entrance" are interpreted in different manners, this may have devastating consequences. Knowledge on differences regarding how we describe where things are is one important step in the direction of successful international cooperation.

In order to describe the location of objects in relation to one another, frames of reference (FoRs) are used. They comprise several constituents (cf. Levinson, 2003): a coordinate system (e.g. front, back, left and right), a figure object whose location is to be described and a ground object in relation to which the location of the figure is described (Talmy, 1983).

Three main FoRs have been identified in the literature (Levinson, 2003): absolute, intrinsic and relative FoR. The relative FoR is subdivided into three variants: translation, reflection and rotation. The absolute FoR uses fixed bearings, such as the cardinal directions for the coordinate system. Applying this FoR, a figure object might then be described to be "northeast" of the ground object.

Applying the intrinsic FoR, the coordinate system is centred in the ground object, the figure object's position is thus described from the perspective of the ground object. Hence, this FoR can only be applied when the ground object has intrinsic front, back, left and right sides.

Using a relative FoR, the position of the figure object in relation to the ground object is described from an observer's perspective; the primary coordinate system originates in the
observer's front, back, left and right sides. This primary coordinate system is then projected onto the ground object and transformed into a secondary coordinate system in one of three possible ways: Applying translation, the secondary coordinate system results from a mere shift of the primary system into the ground object. Here, left and right remain oriented as in the observer's primary coordinate system. A figure between the observer and the ground is described to be "behind" the ground object. In the case of reflection, the primary coordinate system is reflected off the ground object. A figure between the observer and the ground is hence described to be "in front of" the ground object, left and right again remain oriented as in the primary coordinate system. In the third variant, rotation, the secondary coordinate system results from rotating the primary system and centring it in the ground as if another observer was facing the observer of the scene. Here, similar to the reflection variant, a figure between the observer and the ground is described to be "in front of" the ground object, however, left and right are also switched. Thus, between the intrinsic and the three relative FoRs, the order "we enter the building from the back left, you go in from the front right entrance" can be interpreted in at least four different ways. However, individuals are mostly unaware of ambiguities in their spatial descriptions (cf. Grabowski \& Miller, 2000).

## The "Western" Bias

Research investigating the link of language and cognition by means of spatial referencing has almost exclusively focused on comparing "Western" (North-American and European) with "Non-Western" (Indigenous) samples. It has been shown that while "Westerners" preferentially use egocentric (relative) referencing strategies, many "Non-Western" cultures use allocentric (absolute) referencing, some even exclusively (e.g. Levinson, 2003). While there is a prevalent implicit assumption that "Westerners" are all the same (e.g. Pederson, 1993), empirical findings comparing referencing behavior within and between Western cultures are scarce. Those studies attempting to do so (e.g. Grabowski \& Miller, 2000; Flaherty \& Richardson, 1996) found that there are differences regarding the application of at least two distinctive FoRs commonly used by speakers of European languages: The intrinsic and the relative FoR. Importantly, the variants of the latter have received very little attention in past research efforts on spatial referencing. In research, the reflection variant is commonly treated to be "the" relative FoR and the only one investigated. However, use of the other two variants has also been reported (e.g. translation in Tongan and Hausa: Bennardo, 2000; Hill, 1982; translation and rotation to some extent in Chinese, Tongan and Farsi speaking samples: Beller, Hüther, Singmann, \& Bender, subm.; Beller, Singmann, Esfandiari, \& Bender, subm.; Bender, Rothe-Wulf, Hüther, \& Beller, 2012). Accounting for the different ways individuals can reference from their own perspective, we found that FoR-preferences of two "Western" populations speaking different languages, namely US-Americans and Germans, differ regarding the
extent to which variants of the relative FoR are applied (Beller et al., subm. [a]; Bender et al., 2012; Hüther, 2010). In the current study, we examined if referencing differences would also occur between Western cultures speaking the same language, namely French.

## Determining the Role of Situational Aspects

The French language allows for the application of all described FoRs. While a preference for the relative FoR is assumed in native speakers of French (e.g. Mishra et al., 2009; Pederson, 1993), there are no empirical investigations of speakers of French regarding the variants of the relative FoR and the intrinsic FoR.

To shed light on the issue of language versus other factors influencing referencing preferences in Western populations, we compared four samples speaking the same language but living in different countries: Belgians, French, Québécois and Swiss. Thus, we kept native language constant while the environment (country) varied between samples. If language alone were the main determinant of referencing preferences, the different groups of French native speakers should not significantly differ in their use of FoRs, irrespective of where they live. However, if FoR-use is a matter of conventions within communities, samples from different countries may differ despite their speaking the same language. Moreover, testing for possible situational factors influencing FoR-use (as suggested by Li \& Gleitman, 2002), we varied whether the referenced objects were animate or inanimate. We assumed a stronger preference for the intrinsic FoR with animate objects. The intrinsic orientation of living beings may be more salient than that of inanimate objects thus making the application of the intrinsic FoR easier. Also, one may be more likely to take, say, a bird's perspective than that of a pencil. We thus assumed influences of the given spatial task at hand, in that intrinsic referencing would occur more often with animate than with inanimate objects.

Considering the three variants of the relative FoR as well as the intrinsic FoR, we set out to answer the following questions: Which referencing preferences can be observed in native speakers of French from France, Switzerland, Belgium, and Canada? Are there inter-individual differences within the countries, indicating variations in FoR-use within communities? Do the samples differ with regard to their preferred FoR, indicating that language is not the only determinant of referencing preferences? And finally, are individuals' referencing choices intra-individually consistent across different situations or do situational influences such as differences in animacy of the to be referenced objects correspond to different FoR-use?

## Method

FoR-use of the four French speaking samples was assessed using an online questionnaire in French. We developed the questionnaire using the Questback software. Within each sample, two versions of the questionnaire were administered in order to control for sequence effects.

Participants A total of 186 students ( 131 female) of the social sciences completed the questionnaire. The Belgian sample consisted of 55 students ( 46 female; mean age 21.8 years, $S D=4.82$ ) from the University of Liège. The French sample consisted of 46 students ( 34 female; mean age 22.5 years, $S D=4.51$ ) attending different universities. The Canadian sample consisted of 57 students ( 29 female; mean age 25.5 years, $S D=6.07$ ) from the University of Montreal. The Swiss sample consisted of 28 students ( 22 female; mean age 24.3 years, $S D=4.27$ ) from the University of Geneva. All participants indicated that French was their native language. Participation was voluntary and was not compensated.
Materials and Procedure All materials were presented in French. After being informed about the procedure and indicating their consent, each participant filled out a questionnaire comprising 40 tasks. Each task contained one of the following eight descriptions:

- The candle [the starfish] is located behind and to the right of the pencil [the bird].
- The candle [the starfish] is located in front and to the left of the pencil [the bird].
- The candle [the starfish] is located behind and to the left of the pencil [the bird].
- The candle [the starfish] is located in front and to the right of the pencil [the bird].
Each of the eight descriptions was presented five times, every time with different pictures as answer options. Out of eight photographs displaying different configurations of animate (starfish and bird) or inanimate (candle and pencil) objects, participants were asked to choose the one that best fitted the description. The photographs differed regarding the direction into which the ground object (bird or pencil) was facing and regarding the position of the figure (starfish or candle). In each task, four of the depicted object configurations corresponded to a distinct FoR (the three relative FoR variants or the intrinsic FoR); choosing one of the other four pictures did not indicate application of one of the FoRs. Animate and inanimate object configurations were presented as two blocks. An example item is shown in Figure 1. Here, choosing b) corresponds to the reflection variant of the relative FoR, c) to the rotation variant, h) corresponds to the translation variant, and selecting d) indicates application of the intrinsic FoR.

Figure 1: Example of an item with configurations of animate objects. The task was to select the photograph corresponding to the description "The starfish is located in front and to the left of the bird."

Table 1: Percentages of FoR choices in the four samples considering object animacy and order of tasks.

|  | ( $N=46$ ) | Total | 52.0 | 3.6 | 3.7 | 35.5 | 5.4 | 46.2 | 5.2 | 4.0 | 37.3 | 7.6 |
| Canadian |  | A | 80.0 | 0.8 | 7.8 | 7.7 | 3.8 | 56.7 | 1.6 | 5.6 | 30.5 | 5.6 |
|  | ( $\mathrm{N}=25$ ) | B | 60.4 | 3.0 | 5.8 | 29.0 | 1.8 | 41.6 | 5.0 | 7.2 | 41.8 | 4.4 |
|  | ( $N=57$ ) | Total | 70.2 | 1.9 | 6.8 | 18.4 | 2.8 | 49.2 | 3.3 | 6.4 | 36.2 | 5.0 |
| Swiss | ( $\mathrm{N}=14$ ) | A | 84.6 | 8.6 | 0.7 | 2.1 | 3.9 | 69.6 | 8.9 | 1.8 | 15.4 | 4.3 |
|  | ( $\mathrm{N}=14$ ) | B | 79.6 | 1.8 | 1.4 | 13.2 | 3.9 | 65.4 | 4.6 | 2.1 | 24.6 | 3.2 |
|  | ( $\mathrm{N}=28$ ) | Total | 82.1 | 5.2 | 1.1 | 7.7 | 3.9 | 67.5 | 6.8 | 2.0 | 20.0 | 3.8 |

Note: Percentages are aggregated across participants and 20 items per block (animate and inanimate); order A: inanimate-animate, order B: animate-inanimate; ref. indicates application of the reflection variant of the relative FoR, rot. $=$ rotation, trans. $=$ translation, int. $=$ intrinsic FoR and the n.c.p. (no clear preference) column denotes the percentages of answers that did not correspond to one of the investigated FoRs (i.e. choices of one of the other four answer options).

Participants were randomly assigned to one of two questionnaire sequences: Approximately half of each sample answered the 20 tasks with inanimate objects first (A), the others started with the 20 animate items (B). After completion of all 40 tasks, demographics were requested and participants were thanked and debriefed.

## Data Analysis and Results

To answer our research questions, we combined descriptive and inferential statistics in analyzing FoR-use in the four samples. As evident in Table 1, albeit to differing extents, in all four investigated French speaking countries the reflection variant of the relative FoR was predominantly used, followed by the intrinsic FoR.

In order to be able to test for significant differences in the samples' FoR-use, we first identified for every participant how often they applied the different FoRs in the two blocks (the possible maximum being 20 per block, indicating application of the same FoR on every item). We then conducted a repeated measures ANOVA with FoR (reflection, rotation, translation, intrinsic, and no clear preference) and block (animate vs. inanimate) as within-subjects-factors and nationality (Belgian, French, Canadian or Swiss) and block order (animate or inanimate items first) as between-subjects-factors. Aside from the expected main
effect of FoRs $\left(F(1.360,242.041)=159.4, p<.001, \mathfrak{y}_{\mathrm{p}}^{2}=\right.$ .472), it revealed a significant interaction of FoRs $x$ nationality $\left(F(4.079,242.041)=2.7, p=.029, \mathrm{y}_{\mathrm{p}}^{2}=.044\right)$. For all analyses, Greenhouse-Geisser corrected values are reported. As apparent in Table 1, the main differences between the samples from the different countries concerned the extent to which the intrinsic FoR and the reflection variant of the relative FoR were applied. Aggregating the data over all items and participants, we found that in the French sample, while the reflection variant of the relative FoR was applied the most ( $48.1 \%$ ), the intrinsic FoR was applied in over a third of the items (37.3\%). In the other three countries, the reflection variant dominated much more clearly over the other referencing options: in the Canadian sample, $60.8 \%$ of the aggregated answers corresponded to the reflection variant ( $26.2 \%$ intrinsic), in Belgium 62.2\% ( $27.3 \%$ intrinsic) and the Swiss sample showed the clearest preference with $74.8 \%$ of the answers corresponding to the reflection variant (only $13.8 \%$ intrinsic).

The repeated measures ANOVA also showed a significant interaction of FoR and animacy $(F(1.411,242.041)=16.7$, $p<.001, \mathrm{y}_{\mathrm{p}}^{2}=.086$ ). As evident from Table 1, this effect was mainly due to overall increased application of the intrinsic FoR with animate objects as opposed to inanimate objects. There was also a significant interaction between

Table 2: Consistent referencing preferences in \% by nationality and object animacy.

|  | items with inanimate objects |  |  |  |  | items with animate objects |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Country | ref. | rot. | trans. | int. | n.c.p. | ref. | rot. | trans. | intr. | n.c.p. |
| Belgium ( $\mathrm{N}=55$ ) | 67.3 | 0 | 3.6 | 23.6 | 5.5 | 54.6 | 0 | 1.8 | 30.9 | 12.7 |
| France $\quad(\mathrm{N}=46)$ | 50.0 | 2.2 | 0 | 36.9 | 10.9 | 41.3 | 0 | 0 | 34.8 | 23.9 |
| Canada ( $\mathrm{N}=57$ ) | 71.9 | 0 | 5.3 | 17.5 | 5.3 | 45.6 | 0 | 1.7 | 28.1 | 24.6 |
| Switzerland ( $\mathrm{N}=28$ ) | 85.7 | 3.6 | 0 | 7.1 | 3.6 | 60.7 | 3.6 | 0 | 14.3 | 21.4 |

Note: Table displays averaged percentages of number of individuals whose FoR-choice was consistent across at least 15 of 20 items per block. N.c.p. (no clear preference) subsumes participants who were not intra-individually consistent.

FoR and order $\left(F(1.360,242.041)=11.9, p<.001, \mathfrak{y}_{\mathrm{p}}{ }^{2}=\right.$ .063): Participants who worked on the animate items first showed a stronger overall preference for the intrinsic FoR (intrinsic: 38.3\%; reflection: 48.9\%) than those who worked on the inanimate items first (intrinsic: 17.3\%; reflection: 70.5 \%).

Taking a closer look at the variance in FoR-choices within the countries, we established for all participants whether they were intra-individually consistent in their FoRuse across tasks. We considered an individual to be consistent, when he/she chose the same FoR in at least 15 of 20 items ( $75 \%$ ). Interestingly, intra-individual consistency was also affected by animacy of the items (cf. Table 2). For inanimate items, the majority of participants behaved intraindividually consistent in terms of their FoR choice (France was the exception with $10.9 \%$ of participants that were not intra-individually consistent). For animate items, FoRchoice across items was less intra-individually consistent (cf. Table 2). There were also inter-individual differences within the countries: In the Belgian, French and Canadian samples a considerable number of participants (consistently) applied either reflection or the intrinsic FoR, whereas the Swiss sample applied reflection very consistently both intraindividually (cf. Table 2), and inter-individually. All samples preferred the reflection variant over the other two variants of the relative FoR.

## Discussion

Considering the three variants of the relative FoR as well as the intrinsic FoR, we found significant differences in referencing behavior between four samples speaking the same native language but living in different countries. French allows for choosing freely between the different FoRs, thus misunderstandings occurring due to this variation in descriptions/interpretations of the same spatial array are possible. While all samples generally preferred reflection over the other variants of the relative FoR, the French used the intrinsic FoR more than the Canadian, Belgian and Swiss samples, the latter almost exclusively applied reflection. Unlike the other investigated countries, France is not officially bilingual. Since second language proficiency influences spatial referencing (cf. Flaherty \& Richardson, 1996), this may account for the French sample differing from the others. The observed general preference for reflection corresponds to our previous findings in German samples. However, indicating situational influences on referencing behavior and thus supporting our hypothesis, the intrinsic FoR was used more frequently with animate than with inanimate items. In previous studies (e.g., Beller et al., subm. [a]) we had found no significant differences with respect to object's animacy. The current study may have facilitated detection of such differences by using photographs, thus making the referencing tasks more lifelike. Another possible explanation inherent in the depicted objects is that the animate objects were bigger and the intrinsic front of the bird may thus have been more salient than that of the pencil. However, this possible effect of the
material would have affected all samples in a similar fashion and hence cannot account for the observed differences between our samples. Presenting the animate and inanimate tasks in blocks may also have had an influence (see Surtees, Apperly, \& Noordzij, 2011). Specifically, task order influenced FoR choice: when animate items came first, the intrinsic FoR was applied more on the following inanimate items as well, and the same effect appeared for the reflection variant of the relative FoR when the order was reversed. This might be explained by some sort of priming effect and/or a tendency to reference consistently (set effects). Regarding consistency, we found that differences within countries were due to inter-individual differences rather than intra-individual differences in referencing. This suggests that while miscommunication regarding the position of objects occurs between people in a given country, individuals tend to keep to their preferred referencing strategy. Note, however, that intra-individual consistency was lower with animate than with inanimate items. Overall, our findings empirically support the generally expected preference for a relative FoR in Western cultures, more specifically, for the reflection variant. However, our data show that the intrinsic FoR is also applied to considerable extents in all investigated populations. Moreover, we found that the extent to which this FoR is applied by French speakers differs both between and within countries. One cannot help but wonder why these possible sources of misunderstandings are not gradually adapted or at least made explicit within language communities, so that the same sentence will not be interpreted in different ways. How does this fit in with Sapir's (1949) famous claim that "We see and hear and otherwise experience very largely as we do because the language habits of our community predispose certain choices of interpretation"? Our findings regarding interindividual differences and differences between countries indicate that interpretation choices may not so strongly be predisposed by the language habits of our community, whether the community is defined by speaking the same language or by living in the same country. We are required to talk about things in space everyday, yet FoRs seem to still be somewhat variably applied, possibly hindering successful communication.

With respect to limitations of the current study, it must be said that our rather homogenous samples of university students majoring in the social sciences do not necessarily warrant generalizability of our findings to the entire population of the investigated countries. On the upside, however, the observed differences cannot be attributed to differences between the samples concerning factors like age or level of education. Moreover, assessing referencing preferences by means of a questionnaire may not adequately represent strategies applied in everyday settings. However, our questionnaire allowed for assessment of the different samples in their usual surroundings with the exact same measure, thus avoiding possible experimenter effects induced by specific dialects for instance. Regarding this train of thought, one might argue that different variants of

French are spoken in the investigated samples, and that differences in referencing behavior may be due to the differences in the linguistic habits of these groups. However, we used the same descriptions across all groups, and, more importantly, our tasks did not require speech production but rather interpretation of a given sentence by choosing one of eight possible depictions. This procedure diminishes possible influences of different dialects on referencing strategies as linguistic input was both minimal and held constant across groups.

In summary, our findings suggest that with respect to the FoRs commonly applied by Westerners, there are differences even between speakers of the same language that seem to be influenced, at least in part, by their living in different countries. In addition, we also found that aspects of the referenced objects had an impact on FoR-preferences. How these differences between speakers of the same language, yet living in different places, come about remains a question for further research.

#### Abstract

This study investigates whether viewing human gestures facilitates learning about non-human biological movements and whether correspondence between gesture and to-belearned movement is superior to non-correspondence. Functional near-infrared-spectroscopy was used to address whether gestures activate the human mirror-neuron-system (hMNS) and whether this activation mediates the facilitation of learning. During learning participants viewed triples of visualizations (animation - gesture video - animation). Results showed that for low-visuospatial-ability learners corresponding gestures led to higher cortical activation in the inferior-frontal cortex (part of the hMNS) and better learning outcomes, whereas for high-visuospatial-ability learners the type of gesture had no influence. Furthermore, results showed that - if presented with non-corresponding gestures - only low-visuospatial-ability learners who activated their inferiorparietal cortex (also part of the hMNS), improve their learning. Thus, activating the hMNS facilitates learning about movements and stimulating the hMNS via gestures seems to be an adequate instructional strategy to enhance learning with dynamic visualizations for low-visuospatial-ability learners.

Keywords: Learning about movements; dynamic visualizations; human mirror-neuron-system; gestures; functional near-infrared-spectroscopy.

## Learning about Movements with Dynamic Visualizations

Many contents in the Natural Sciences as well as in other domains, such as different sport disciplines or scene perception, comprise the understanding of changes in space over time. Dynamic visualizations can easily depict such changes and they may be particularly suited for instructional purposes if these changes do not occur in a discrete or linear way, but rather involve more complex continuous aspects (e.g., acceleration). However, they were not always superior to static visualizations to convey dynamic information (e.g., Imhof et al., 2012). Thus, it is crucial to understand when and for whom dynamic visualizations are beneficial to use them effectively and to exploit their potential for learning. Until now, research on the instructional use of dynamic visualizations has yielded rather heterogeneous results: Not only design factors and individual learner characteristics,
but also context factors, such as, the knowledge domain, task requirements, or additional instructional support, influence the effectiveness of dynamic visualizations (e.g., Höffler \& Leutner, 2007; Lowe, Schnotz, \& Rasch, 2011; Tversky, Morrison, \& Bétrancourt, 2002). These context factors have become a focus of research on dynamic visualizations.

## Learning with Gestures

One idea on how to support learning about movements with dynamic visualizations that is based on the embodied cognition approach and proposed by De Koning and Tabbers (2011) is the active and passive use of gesture. Empirically, Hegarty et al. (2005) showed that gestures are naturally used to express movements of depicted components and thereby also the depicted processes in mental animation problems. Moreover, it has already been shown that the production of gestures during learning is beneficial for acquiring knowledge about different scientific topics and spatial problem solving (e.g., Chu \& Kita, 2011; Cook \& Goldin-Meadow, 2006; Scheiter et al., 2012). However, learners can either produce gestures on their own or they can perceive gestures that are performed by others. In line with the proposal of De Koning and Tabbers (2011), it is also beneficial for learning to perceive gestures that illustrate the depicted contents, for instance, performed by teachers (e.g., Valenzeno, Alibali, \& Klatzky, 2003).

Underlying this gesture watching effect might be the activation of brain areas (i.e., the human mirror-neuronsystem [hMNS]; Fogassi \& Ferrari, 2011; Rizzolatti \& Craighero, 2004) that are typically used to observe, understand and imitate the actions of other persons. In a related line of research, a current hypothesis that has recently received considerable attention (e.g., Ayres et al., 2009; Van Gog et al., 2009) is that the stimulation and involvement of this hMNS might be beneficial for learning about complex continuous aspects with dynamic visualizations. The hMNS is typically activated by human movements, but may be more generally used to also represent other biological or even non-biological movements, if the observer is able to anthropomorphize
these movements (cf. De Koning \& Tabbers, 2011; Engel et al., 2008). Thus, in the domain of learning about biological movements, one effective instructional strategy to activate the hMNS might be to show learners not only the to-belearned movements via dynamic visualizations, but also gestures displaying the to-be-learned dynamics in order to trigger an anthropomorphized encoding. Hence, only showing gestures that map onto the to-be-learned movements should benefit learning about those movements.

This study addresses whether perceiving gestures in addition to dynamic visualizations is also beneficial for learning. Moreover, to investigate the role of the hMNS, the underlying cognitive processes during learning were investigated with neurophysiological methods in this study (i.e., functional near-infrared-spectroscopy [fNIRS]). Until now, to the best of our knowledge, there is no direct test of the assumption that learners' ability to recruit their hMNS during processing dynamic visualizations may influence the effectiveness of the visualizations. Moreover, it still has not been investigated whether hMNS activation can be induced by gesture-based interventions and then transferred to nonhuman movements because of mapping processes. This approach might easily facilitate the understanding of complex dynamic phenomena by implementing embodied visualizations that activate specific brain areas into instructional materials.

## Learners' Visuospatial Ability

Beyond context factors also individual learner characteristics may play a role during learning about biological movements. Because processing continuous changes requires visuospatial ability (cf. Hegarty, 1992), it is likely that learners' visuospatial ability will determine how much the learners profit from visualizations (cf. Hegarty \& Waller, 2005). Often the continuous processes do not occur only in two-dimensional but rather in threedimensional space. Thus not only visual, but also spatial aspects are important. Previous research on visuospatial ability has revealed two important results, namely that (a) learners with higher visuospatial ability outperform learners with lower visuospatial ability during learning with visualizations (see Höffler, 2010, for a meta-analysis) and moreover, there is some evidence, that (b) visuospatial ability may moderate the effectiveness of learning with different visualization formats. Higher visuospatial ability may compensate for "poor" instructions (i.e., in our case unrelated non-corresponding gestures, cf. methods section), whereas learners with lower visuospatial ability suffer from such instructions (cf. ability-as-compensator hypothesis; e.g., Hays, 1996; Hegarty \& Kriz, 2008; Höffler, 2010).

## Research Questions and Hypotheses

This study addressed by using neurophysiological methods (i.e., functional near-infrared-spectroscopy [fNIRS], which is a non-intrusive approach to gather data about cortical activation of humans) the research question whether the hMNS is activated during viewing gestures and whether the
viewing of these gestures is helpful for learning about biological movements because learners map the human movements to the non-human biological movements.

However, maybe solely the circumstance that learners see a human during learning activates the hMNS and is thus sufficient to facilitate learning about biological motions. In other words, it might be also helpful for learners to see gestures that have nothing to do with the to-be-learned content. Thus, this study investigated whether viewing gestures that correspond to the to-be-learned non-human movements facilitate learning about these movements better than unrelated non-corresponding gestures. Additionally, the moderating role of learners' visuospatial ability was addressed. Furthermore, this study tested whether the activation of the MNS mediates the facilitation of learning.

We hypothesize that viewing corresponding gestures facilitates learning more than viewing unrelated noncorresponding gestures. This might be particularly true for low-visuospatial-ability learners, whereas high-visuospatialability learners might not need this type of anthropomorphization to learn about the depicted dynamic processes (cf., ability-as-compensator hypothesis; e.g., Höffler, 2010). Moreover, we hypothesize that learners differ with regard to recruiting the hMNS for processing and that higher hMNS activation is associated with better learning outcomes than lower hMNS activation. This might again be particularly true for low-visuospatial-ability learners, as they do not have available this ability to compensate for such a hMNS actication.

## Methods

## Participants and Design

Forty-five university students ( $M=24.98$ years, $S D=4.57$; 31 females) were asked to learn how to classify different fish according to their movements based on visualizations that illustrated four different movement patterns of fish. For each movement pattern the participants saw three visualizations: Firstly, they saw an animation of the specific movement pattern. Secondly, they saw a video of a person performing gestures with his hands and arms. These gestures either did correspond or did not correspond (i.e., were unrelated) to the fish movement patterns. Therefore, at this point the experimental manipulation with the betweensubjects factor type of gesture took place. Thirdly, the learners saw the initial fish animation again.

An expert regarding fish movements performed the gestures. For the corresponding gestures this expert was instructed to display with his hands and arms representations of the respective movements as clearly as possible (see figure 1 left). For the non-corresponding gestures the expert was instructed to perform gestures with his hands and arms that were unrelated to the fish movement patterns (i.e., waving, circulating the forearms around each other, drumming, and pointing, see figure 1 right).

Each visualization was depicted for 30 s and was followed by pauses of 30 s (black screen) between all
visualizations. The learners were instructed to relax in these pauses. In the pauses, the activations of the brain areas of interest are supposed to decay to the baseline level before the next visualization was displayed.

Figure 1: Learning visualizations in triples: corresponding gestures (left) and non-corresponding gestures (right).

## Materials

Participants had to learn to discriminate four different patterns of fish movements. These movement patterns differ in terms of the body parts that generate propulsion (i.e., the body itself or several fins) and also in the manner of how these body parts move in the three-dimensional space (i.e. different wave-like or paddle-like movements). The four different movement patterns were: 1. undulation of the body; 2 . undulation of the dorsal and anal fins; 3 . oscillation of the dorsal and anal fins (and undulation of the pectoral fins); and 4. oscillation of the pectoral fins. One major challenge in identifying these movement patterns is that fish may deploy other movements in addition (e.g., to navigate), that can easily be confused with movements used for propulsion in another movement pattern.

Animations were rendered based on typical fish performing the four movement patterns. These animations were standardized in terms of the perspective, background, position in the frame, and the swimming direction of the fish. Moreover, in these deliberately designed visualizations, we were able to only show the movements performed for propulsion and omit other irrelevant movements. Beside that, the depicted movements were highly realistic, thus representing the movements of real fish adequately. The movement cycles of the movement patterns were presented in loops in the animations ( 30 s per movement pattern, 25 fps, size: $640 \times 480$ pixels) in the center of the screen.

For each movement pattern, videos of an expert regarding to fish movements were recorded who performed either a corresponding or a non-corresponding gesture. These gestures were presented in the respective conditions in loops in the videos ( 30 s per movement pattern, 25 frames per s , size: $640 \times 480$ pixels) in the center of the screen. The presentation of all visualizations was system-controlled.

## Measures

Learning Outcomes To assess learning outcomes, a movement pattern classification test was administered. This
test comprised 21 dynamic multiple-choice items consisting of underwater videos of real fish performing one of the four to-be-learned movement patterns. To choose for each item the kind of movement pattern that was depicted, learners had to identify the body parts relevant for propulsion and their way of moving. Each item was presented 7 s to the participants and immediately afterwards they had 3 s time to choose the correct answer by pressing a corresponding button. The possible answers were indicated as static screenshots from the learning animations of the four movement patterns. Each item was awarded one point for the correct answer (max. 21 points). The test items were presented in blocks of 30 s so that 3 items were grouped together. Pauses of 30 s (black screen) followed each block.

Learners' Visuospatial Ability Learners' visuospatial ability was assessed with a short version of the paper folding test (PFT, Ekstrom et al., 1976). This test measures the ability to form representations of "object location, movement, spatial relationships, and transformations" (Blazhenkova \& Kozhevnikov, 2009, p. 640) and thus is well suited to cover the domain of fish movements. The short version of the PFT consists of ten multiple-choice items, where participants have to choose the correct answer out of five options. The stimuli are depictions of stepwise folded papers that were punched in the folded state, whereas the answer options depict the punches of various unfolded papers with the punches being either in the correct or incorrect positions. A maximum of three minutes is assigned to work on the items, and each correct answer is worth one point (max. 10 points).

Cortical Activation During viewing the gestures in the learning phase, cortical activation was conducted via fNIRS measurements with an ETG-4000 (Hitachi). As probe set we used a $2 \times 22$ channel array, that was placed over the fronto-temporo-parietal regions centered at the T3-T4 and C3-C4 positions (not exactly terminating on these positions because of the fixed interoptode distances) according to the standard locations of the $10-20$ system. Changes of absorbed near-infrared light were transformed into relative concentration changes of oxygenated $\left(\mathrm{O}_{2} \mathrm{Hb}\right)$ and deoxygenated haemoglobin $(\mathrm{HHb})$. Local increases of $\mathrm{O}_{2} \mathrm{Hb}$ as well as decreases of HHb are indicators of cortical activity (Obrig \& Villringer, 2003).

## Procedure

Participants were tested individually. They first received a printed overview in which they were informed about the procedure on the different parts of the study. Subsequently, they had to answer the PFT and a demographic questionnaire. Subsequently, the fNIRS probe set was placed on the scalp of the participants and adjusted with the help of the experimenter. Then, the learning phase started and the computer-based learning materials were presented. For each of the four to-be-learned movement patterns learners were presented with the triples of visualizations
(fish animation - gesture video - fish animation). In the learning phase the experimental manipulation took place. Learners saw either the corresponding or the noncorresponding gestures. Following the learning phase (12 min ) learners performed a filler task ( 8 min ), in which they listened to music. Subsequently, learners completed the movement classification test ( 8 min ). To answer the test items participants were instructed to put both their forefingers and both their middle fingers on predefined keys. These keys were labeled with screenshots from the corresponding fish animations on the screen. In total, a single experimental session lasted approx. 50 minutes.

## Results

## Learning Outcomes

To analyze learning outcomes we conducted a multiple regression analysis with the categorical predictor type of gesture and the continuous predictor learners' visuospatial ability. We had to exclude four participants because of technical reasons (data loss) resulting in a total number of 41 participants in this analysis. Further, we had to exclude eight test items from the learning outcome measure, because participants answered them with a response rate of more than $95 \%$. The reliability analysis of the remaining 13 test items achieved a good to excellent cronbach's $\alpha$ of 85 .

For learning outcomes the predictors in the regression analysis explained a significant portion of variance ( $p=$ $.01)$. Results showed no effect of type of gesture on learning outcomes ( $p=.41$, ns), whereas there was an effect for learners' visuospatial ability on learning outcomes ( $p=.04$ ). This effect has to be interpreted in terms of the significant interaction between type of gesture and learners' visuospatial ability on learning outcomes ( $p=.04$; figure 2 ).

Figure 2. Interaction between learners' visuospatial ability and type of gesture on learning outcomes.

This interaction was resolved by a simple slopes analysis (cf. Aiken \& West, 1991). It revealed that for participants with high visuospatial ability (defined as one standard deviation above the sample mean) the type of gesture had no influence on learning outcomes ( $p=.34$, ns). As expected, for participants with low visuospatial ability (defined as one standard deviation below the sample mean) corresponding
gestures were better for learning than non-corresponding gestures ( $p=.04$ ). Thus, the corresponding gestures are beneficial for low-visuospatial-ability learners.

## Cortical Activation

To analyze the cortical activation we defined two regions of interest (ROIs) on the left hemisphere for the hMNS among the respective channels. The two ROIs were the left inferiorfrontal cortex (IFC) and the left inferior-parietal cortex (IPC, cf. figure 3). To analyze cortical activation we conducted two multiple regression analyses with the predictors type of gesture and learners' visuospatial ability. We had to exclude additional eight participants from these analyses because the data quality of these participants was too poor resulting in a total number of 33 participants in these analyses. For cortical activation on IPC the predictors in the regression analysis did not explain a significant portion of variance ( $p=.96, \mathrm{~ns}$ ).

Figure 3. Spatial arrangement of the left probeset.
For cortical activation on IFC the predictors in the regression analysis explained a significant portion of variance ( $p<.001$ ). Results showed an effect of type of gesture on IFC activation ( $p<.001$ ) and an effect for learners' visuospatial ability on IFC activation ( $p<.001$ ). These effects have to be interpreted in terms of the significant interaction between type of gesture and learners' visuospatial ability on IFC activation ( $p<.01$; see figure 4).

Figure 4. Effects of type of gesture (G) and learners' visuospatial activities (VSA) on cortical activation (left).

Again a simple slopes analysis was conducted (cf. Aiken \& West, 1991). It revealed that for participants with high visuospatial ability (defined as one standard deviation above the sample mean) the type of gesture had no influence on IFC activation ( $p=.14$, ns). For participants with low visuospatial ability (defined as one standard deviation below the sample mean) corresponding gestures resulted in a higher IFC activation than non-corresponding gestures ( $p<$
.001). Thus, the corresponding gestures helped low-visuospatial-ability learners to activate the hMNS in terms of IFC activation.

## Effects of Cortical Activation on Learning Outcomes

Finally, to address the question whether higher hMNS activation is directly associated with better learning outcomes, we conducted two multiple regression analyses with the three predictors type of gesture, learners' visuospatial ability and cortical activation in terms of IFC activation or IPC activation respectively.

For learning outcomes the predictors in the regression analysis with IFC activation did not explain a significant portion of variance ( $p=.12, \mathrm{~ns}$ ). Interestingly, the predictors in the regression analysis with IPC activation did explain a significant portion of variance for learning outcomes ( $p<$ .01). There was a three-way interaction between the predictors type of gesture, learners' visuospatial ability, and IPC activation on learning outcomes ( $p=.03$; see figure 5 ).

Figure 5. Three-way interaction between type of gesture, learners' visuospatial ability, and IPC activation on learning outcomes.

This triple interaction was resolved by simple slopes analyses (cf. Aiken \& West, 1991). Firstly, this approach revealed that for learners who saw corresponding gestures there was no two-way interaction between participants' visuospatial ability and IPC activation ( $p=.59$, ns). The following simple slopes analyses revealed that IPC activation did not predict learning outcomes for learners who saw corresponding gestures: neither for high-visuospatial-ability learners ( $p=.47$, ns), nor for low-visuospatial-ability learners ( $p=.40$, ns). However, for learners who saw non-corresponding gestures there was an interaction between participants' visuospatial ability and IPC activation $(p<.01)$. We further resolved this two-way interaction between participants' visuospatial ability and IPC activation for learners who saw non-corresponding gestures. The simple slopes analyses revealed that in the group of learners who saw non-corresponding gestures IPC activation negatively predicted learning outcomes for high-visuospatial-ability learners ( $p=.04$ ), whereas for low-visuospatial-ability learners IPC activation positively
predicted learning outcomes $(p=.001)$. Thus, for learners who saw non-corresponding gestures, but have had high visuospatial abilities at their disposal IPC activation is detrimental for learning. However, for learners who did neither have corresponding gestures nor high visuospatial abilities at their disposal, activation of their hMNS in terms of the IPC during processing the unrelated noncorresponding gesture improves their learning.

## Discussion

This study tested whether viewing gestures performed by others is helpful for learning about non-human movements and whether these gestures stimulate anthropomorphization via an activation of the hMNS. The anthropomorphization is stimulated by an external video and is not accomplished by the learners on their own. Our results showed that viewing corresponding gestures activated the hMNS particularly for low-visuospatial-ability learners. These learners achieved the same learning outcomes as high-visuospatial-ability learners. Low-visuospatial-ability learners seem to profit from being demonstrated a connection between non-human biological movements and movements of the human body that correspond to these movements. Thus, learning about biological movements can be facilitated by gesture-based interventions activating parts of the hMNS: Gestures that correspond to the to-be-learned movements and activate the inferior-frontal cortex (IFC). This activation seems to compensate missing viusospatial ability.

Furthermore, our results indicate another way of improving learning about biological movements: When looking at participants who neither have high visuospatial ability, nor received the benefit of viewing corresponding gestures, - namely, the group of low-visuospatial-ability learners who processed non-corresponding gestures - the result pattern was rather heterogeneous: Only participants who activated another part of the hMNS (i.e., the inferiorparietal cortex [IPC]) were able to dramatically improve their learning, whereas participants who did not activate this area achieved only poor results. This indicates that the activation of the inferior-parietal cortex helps participants to learn about biological movements, particularly if they have no access to other facilitating factors. In line with this reasoning, learners who have available two facilitating factors, namely high visuo-spatial abilities and an activation of the IPC, performed worse when they saw noncorresponding gestures. In this case, the two facilitators might compete and interfere with each other resulting in inferior learning outcomes. Nevertheless, higher hMNS activation is associated with better learning outcomes - at least for low-visuospatial-ability learners: for IFC activation it seems that there is a rather stepwise connection in that a certain value has to be reached, whereas for IPC activation it seems that it follows the more activation the better learning.

Stimulating the hMNS by means of gestures seems to be a promising strategy to enhance learning with dynamic visualizations for low-visuospatial-ability learners because this intervention leads to higher activation in their IFC as
part of the hMNS. However, further research needs to replicate these findings with a larger sample size and continue to disentangle the effects of this study. Particularly, our findings have to be replicated with other examples of gestures in different domains, as gestures about fish movements might not be a typical example of gestures. Furthermore, it is very important to investigate how the activation of the IPC can also be fostered by instructions.

Furthermore, gesture-based instructions that support anthropomorphization should be investigated in different instructional domains and settings that involve learning about continuous movements and processes to prove whether they are in general a suitable method to enhance learning about processes with dynamic visualizations.

Further research should also investigate whether effective and less effective dynamic visualizations differ in their ability to activate the MNS, thereby potentially explaining inconsistent results on the effectiveness of dynamic visualizations (e.g., Höffler \& Leutner, 2007; Tversky et al., 2002). The present study is one first step into this field of research and our results suggest that it is important to not only put further effort into designing better dynamic visualizations, but also in providing learners with suitable strategies to adequately process these visualizations.

#### Abstract

Models of cognitive processes often include simplifications, idealisations, and fictionalisations, so how should we learn about cognitive processes from such models? Particularly in cognitive science, when many features of the target system are unknown, it is not always clear which simplifications, idealisations, and so on, are appropriate for a research question, and which are highly misleading. Here we use a case-study from studies of language evolution, and ideas from philosophy of science, to illustrate a robustness approach to learning from models. Robust properties are those that arise across a range of models, simulations and experiments, and can be used to identify key causal structures in the models, and the phenomenon, under investigation. For example, in studies of language evolution, the emergence of compositional structure is a robust property across models, simulations and experiments of cultural transmission, but only under pressures for learnability and expressivity. This arguably illustrates the principles underlying real cases of language evolution. We provide an outline of the robustness approach, including its limitations, and suggest that this methodology can be productively used throughout cognitive science. Perhaps of most importance, it suggests that different modelling frameworks should be used as tools to identify the abstract properties of a system, rather than being definitive expressions of theories. Keywords: Language Evolution; Cultural Evolution; Robustness

## Introduction

A central question in the field of the evolution of language is whether linguistic structure is mainly a product of domainspecific genetic constraints, or of cultural transmission. However, the cultural evolution of language is difficult to study because there is little direct evidence available. Simulations ${ }^{1}$ make it possible to study of the dynamics of cultural evolution, but often include highly simplified mechanisms of learning. Human experiments obviously use a realistic learning mechanism, but present the problem that test subjects already know natural languages, and it is difficult to control for individual differences in learning. While recent work suggests that compositional linguistic structure emerges in iter-

[^300]ated learning contexts under pressures to be learnable and expressive (Kirby, Cornish, \& Smith, 2008), problems with simulations and human experiments potentially make it difficult to justify theoretical claims about the evolution of language.

We explore how the notion of 'robustness' from philosophy of science (e.g. Wimsatt, 1981; Weisberg \& Reisman, 2008) can be used to support claims in language evolution; specifically, we argue that emergent compositional structure is a robust property of iterated learning. We suggest how to extend this methodology to similar claims across cognitive science, that are based on unrealistic models, and little direct empirical evidence.

## Language Evolution

Before discussing the notion of robustness, it is first necessary to introduce work on the iterated learning model (ILM) in language evolution as this will be used as a case-study. The ILM looks at how culturally transmitted systems (e.g. a mapping between linguistic signals and meanings) change by being repeatedly transmitted through a bottleneck (Kirby, 2000). The bottleneck is a restriction of information that could be due to a finite limit on the information to be transferred or a restricted set of meanings to be described. The bottleneck causes the system to change over time, usually towards a more compressible relationship between signals and meanings. This can be interpreted as a pressure on the language to become more 'learnable' by the next generation. In the extreme case, the variation in the system reduces so that there is only one signal. Opposing this is a pressure for expressivity (e.g. a need to distinguish between meanings). A perfectly expressive linguistic system has a different signal for each meaning.

Smith, Kirby, and Brighton (2003) showed that an optimal solution under these two pressures is compositionality: the meaning of a signal is composed of sub-meanings expressed by sub-strings of the signal. This means that there are fewer signal components to be learned than individual meanings, and the signals of unobserved meanings can be re-constructed accurately. The demonstration that cultural transmission can lead to complex linguistic structure contrasts with theories that see linguistic structure as primarily deriving from innate, domain-specific constraints (Chomsky, 1965, see Kirby,

Dowman, \& Griffiths, 2007).
The initial work on the iterated learning model involved computational simulations. Instead of committing to a particular model or simulation framework, a range of computational techniques were used as tools to demonstrate the principles of the iterated learning model. These include grammar induction models (Kirby, 2000), exemplar models (Batali, 2002), neural network models (Kirby \& Hurford, 2002; Swarup \& Gasser, 2008) and self-organising maps (Worgan \& Damper, 2008).

The next step involved translating the ILM into a laboratory experiment. Kirby, Cornish, and Smith (2008) demonstrated that the emergence of compositional structure could be observed in an artificial language which was learned, produced, transmitted and then learned again by human subjects. Participants were exposed to pairings of nonsense words and meanings and asked to memorise them. The meanings were images with structured semantic dimensions: shape (circle, triangle, square), colour (red, blue, black) and movement (horizontal, bouncing, or spiraling motion). Participants were trained on a sub-set of the whole meaning space, but they were then asked to produce a label for every meaning. The labels that were produced became the training data for the next participant. This meant that the language changed as it was transmitted from participant to participant, mirroring the cultural transmission of language.
By this process, the language adapted to two pressures. A bottleneck on transmission was present, because the participants were not trained on all labels. This put a pressure on the language to become more faithfully transmitted. With only this pressure, the number of distinct labels in the language declined. These languages were easy to learn, but not expressive. To counter this, a pressure for expressivity was added by excluding homonyms from the training subset. Under both pressures, the language adapted to become learnable and expressive by becoming compositional. That is, instead of labels being distinct and holistic, sub-parts of each label consistently referred to sub-parts of each meaning. For instance, in one emergent language, all meanings which included the colour blue began with an ' $L$ ' while all meanings that included the spiralling movement ended with 'PILU’ (see Kirby, Cornish, \& Smith, 2008, p. 10684). This meant that the language was both easy to learn and could express all meanings distinctly.

The ILM experiment showed that compositional structure could emerge spontaneously due to the process of cultural transmission. The results mirrored those of the computational simulations, leading to the experiments being thought of as simulations with human participants (see Kirby, Smith, \& Cornish, 2008).

The ILM sparked a lineage of experimental simulations testing different constraints and assumptions of the original simulation, including replacing the exclusion of homonyms with a pressure for communication between two participants (Matthews, Kirby, \& Cornish, 2010; Silvey, Kirby, \& Smith,

2012; Navarro \& Perfors, 2011; Tamariz, Cornish, Roberts, \& Kirby, 2012; Verhoef \& Boer, 2012). Bringing the process full circle, principles elucidated through the human simulations motivated new computational simulations (Smith, Tamariz, Cornish, \& Kirby, 2013). There are differences between these studies, for example the precise distribution of letters in the strings that emerge is not robust across computational and human simulations since human distinctions between vowels and consonants were not built into the computational agents. However, in each case the results were compatible with the theory of structure emerging though repeated transmission through a bottleneck under pressures for learnability and expressivity.

## Problems with abstraction and transparency

Computational models have many advantages: the internal states of individuals are transparent and quantifiable; the exact amount of noise is quantifiable; and exploring the parameter space can be easier than running alternate conditions in human experiments (e.g. Reali \& Griffiths, 2010 model an infinite population). However, the abstractions inherent in computational models can be a weakness because a model's implications rely on the ability to translate between the abstractions and the real world. Computational models of the cultural evolution of language may simplify the representation of linguistic units, learning processes or psychological mechanisms. Simplifying assumptions might be made such as agents sharing an innate, conceptual space for words and meanings (Vogt, 2005) or being able to observe intended meanings (Worgan \& Damper, 2008).

In contrast, laboratory experiments with real humans include artificial languages with concrete analogues to real languages and real learning mechanisms. However, while the learning mechanisms are realistic, they are opaque. It is difficult to deduce the precise mental processes that lead to the emergence of structure. Because of this complexity, it is difficult to maintain absolute experimental control. Furthermore, the participants already have full knowledge of a compositional language. This is a potential confound since the emergent structure may just be a reflection of the participants' existing language rather than being caused by the same process that proto-linguistic humans underwent (e.g. Flynn, 2008; Chomsky, 2011). However, as we shall see below, these problems can be addressed by demonstrating that the outcome is a robust property across different models..

## Aims of models and simulations

One crucial question in this area of research is what simulations are used to learn about, and thus what kind of theoretical inferences can possibly be warranted from them. Simulations of cultural transmission are not intended as instantiations of human language learning, nor the evolution of a real language. However, the ILM is informative about systems that are transmitted through a bottleneck, and that become more structured as a result. The simulations, then, are an example

Figure 1: How simulations, models and lab experiments can contribute to theories of language evolution. Potential problems in the translation from the target phenomenon to models, simulations, and experiments (dotted arrows) are spread over many approaches, while the discovery of robust properties found across all these approaches provide support for the central theory (thick arrows).
of cultural transmission's effect on structure in cultural phenomena, where human language is one of these more general phenomena. Results from simulations of iterated learning can therefore inform the general theory of iterated learning ${ }^{2}$.

In the field of language evolution, simulations of iterated learning are used as thought experiments to show that nativist assumptions are not necessary to account for the emergence of complex linguistic structure. Computational simulations can be more powerful than traditional thought experiments because they must usually be instantiated at a more technical level, and because they allow complex interactions and structures which might be unintuitive (Bedau, 1998).

Di Paolo, Noble, and Bullock (2000) suggest a workable methodology for opaque thought experiments:

1) Exploratory phase: Explore model behaviour, observe patterns
2) Experimental phase: Formulate hypotheses that organise patterns ('explanatory organisation'). Some patterns will be explained by the model dynamics directly. Some patterns will be explained through other observed patterns ('indirect explanation').
3) Explanatory phase: Relate organisation of observations to the theories about natural phenomena, explain the consequences.
[^301]This idea is very similar to recent work in philosophy of science (particularly philosophy of economics), where models and simulations can be seen as 'credible worlds', constructed to explore general theoretical principles (Sugden, 2000, 2009). Recent work on model-based theorising (Weisberg, 2007; Godfrey-Smith, 2006), largely based on examples from population biology, incorporates similar stages of modelling, going through stages of model construction, model analysis (stage 1 and 2) and the (optional) stage of the exploration of how well the model 'fits' the target system, and thus which general principles can be learned from the model (stage 3). Here too, there are questions about how these constructed, and often highly simplified worlds relate to real world systems.

There are two main ways model-world fit can be evaluated, both found in cognitive science. One is to consider the translation from the target system to the model/simulation, for example when models and simulations are used as abstract analogues of a concrete phenomenon (e.g. eye saccades during reading). Here knowledge about the target system is used to construct the model (though of course it may involve simplification, idealisation and so on). Model-world fit is analysed by considering how different the model is from our knowledge of the target system (perhaps it fails to capture important structural or causal features).

The other way to consider model-world fit is to consider the converse; the translation from a model/simulation back to a the target system. Here, a model-simulation is constructed using relevant background knowledge of a family of targets, but not intended to represent any particular target system. Once the principles governing the model/simulation are established, the researcher then looks to see if the model/simulation actually captures any targets in the real world. If any are found, then the researcher infers that the same principles govern the model/simulation and these target systems. It is this kind of translation that is found in Weisberg and Godfrey-Smith's description of model-based science, where justifications must be given for inferences from properties found in a model to properties of a target system. In language evolution, this inference goes from the results of iterated learning paradigms to real cases of language evolution.

In order to support this inference, there are a number of ways that model-target fit can be evaluated. The role that the notion of robustness plays in these evaluations is discussed below, and linked to other cases in cognitive science.

## Model-Target Fit and Robustness

## Robust properties

Robust properties are those that are consistently found across a set of different models, suggesting that it is an 'important' property that derives not from incidental features of the model (e.g. its particular assumptions and simplifications), but from the core structure found across all the models (Levins, 1966; Wimsatt, 1981; Weisberg, 2006; Weisberg \& Reisman, 2008).

As Levins originally put it, "if these models, despite their different assumptions, lead to similar results, we have what we can call a robust theorem that is relatively free of the details of the model. Hence, our truth is the intersection of independent lies." (Levins, 1966, p. 20). As detailed above, in the case of language evolution the emergence of linguistic structure is a robust property of iterated learning systems under the pressures of expressivity and learability.

However, Weisberg and Reisman (2008) identify several (related) kinds of robustness: parameter, structural and representational robustness. First, a model can be robust (i.e. give roughly the same results) for a wide range of parameter settings. Second, a set of crucial causal components that make up the 'core structure' noted above give rise to structural robustness. Finally, representational robustness refers to the range of model descriptions (e.g. programming languages or mathematical formalisms used) for which a model still gives rise to the same results. Of most relevance in the sections below are structural and representational robustness, detailed below.

## Multi-model method

One way that robustness analyses figure in language evolution research is through the use of different types of models. Researchers in the field of cultural evolution see models as tools, not necessarily as reflections of theories (e.g. Cornish, Tamariz, \& Kirby, 2009). As tools, they need not commit the researcher to particular methodological approaches (agentbased or mathematical) nor particular theories of cognition (e.g. humans as Bayesian learners or frequentist learners).

Testing the same ideas across a range of mathematical models and computational simulations, but also across different formalisms or experimental setups within each broad method, is a standard way to explore robust properties. This corresponds to both structural and representational robustness noted above. The same core structures are found across these models, but other variables can differ (e.g. learning algorithm, size of population). That these additional variations do not affect the core finding (emergence of linguistic structure) provides support for the claim that the core structures really are the essential causal components in these models. Further, that these models can be constructed in a range of computational and mathematical frameworks, and still give rise to emergence linguistic structure, means that these results are not related to specific features of these frameworks - they are representationally robust. Both provide support for the claim that linguistic structure is a robust property of ILM models.

However, this method of constructing and comparing a range of computational and mathematical models is not widely found in current practice in cognitive science, where researchers are often wedded to particular frameworks. The field of language evolution may require this kind of approach because its precise object of study is still being identified, so the key variables and relations to consider are not yet obvious. For example, it is difficult to intuit about the abstract properties of a culturally transmitted linguistic system underpinned
by genetic constraints (Christiansen \& Kirby, 2003).

## Human simulations

Another crucial way of exploring the relations between simulations and real systems, used in language evolution, is to replace computer agents in agent-based models with human subjects (Kirby, Cornish, \& Smith, 2008). The inclusion of this much wider range of structural features (such as real biological learning mechanisms) provides a strong test for claims about the core structural features and representational robustness of ILM models. However, that subjects already know natural languages is seen as a strong confounding factor in the interpretation of human simulations. There are two standard responses to this.

Firstly, there are the experimental controls. Compositional structure does not always emerge in these simulations, only when both the pressures of expressivity and learnability are applied. Also, the human participants, far from deliberately introducing familiar linguistic structures, rarely expressed an understanding of the principles behind the experiment, most even not noticing that they were being tested on meanings that they had not been taught (Kirby, Cornish, \& Smith, 2008).
Secondly, there is an argument based on the notion of robustness. Human simulations can be seen as further explorations of structural and representational robustness, that include both actual biological mechanisms (e.g. learning), but also potentially problematic factors (subjects already know natural languages). That linguistic structure still reliably emerges from iterated learning paradigms under pressures for learnability and expressivity, even when significant variables are changed, provides more evidence that the emergence of linguistic structure is a robust property of these models.

## Summary: Learning from simulations in the ILM

Since there is little empirical evidence about the facts of language evolution, the strength of model-target 'fit' may not be most convincingly based on the comparison to the real world, but on the robust properties found under various simplicifications and idealisations of real world target systems. Even if we are not sure of how precisely to represent a target system, the fact that many highly idealised representations of the same system make a similar prediction (e.g. emergence of compositionality), can be sufficient to suggest that this is what is happening in the target system itself. In this case, theoretical claims based on robust properties already have some degree of 'fit' with target systems, purely because of the nature of robustness.

## Robustness in Cognitive Science

The sections above illustrate how to productively use robustness notions in cognitive science. Modelling the same process over different formalisms or frameworks, and over computational, mathematical and human models and simulations, can help identify general principles and core variables and constraints. Each particular model need not have high modelworld fit, but together the emergence of a robust property cuts
through these problems. However, there are of course limits to robustness approaches, and, as with any other methodology, there are no clear cut rules about its application.

First, it is not clear, in general, how many independent lines of evidence (i.e. different models/simulations) one must have in order to identify a 'real' robust property, and the core causal structure that gives rise to it. Yet this may become more clear in specific contexts. In some cases two or three very different models/simulations (e.g. containing very different assumptions) might be sufficient to warrant an inference to the existence of a robust property. Alternatively, a larger group of similar models/simulations that together survey a wide range of alternative assumptions may be required. The identification of surprising convergence across different models will always be context dependent.

Second, robustness analyses can be misleading. One might identify a robust property, and the causal structure that gives rise to it, on the basis of different models that all incorporate the same erroneous assumptions. An inference that this causal structure is also found in the world, and explains some cognitive phenomenon, would therefore be unwarranted. One might also make mistakes in identifying the robust property (perhaps it is more or less specific than found in the models), and what the relevant causal structure is.

Clearly, robustness approaches are defeasible, just as any other methods are. Yet the promotion of the use of a wide range of different frameworks found in robustness-based approaches may minimise the kind of errors identified above, or identify them earlier than approaches that stay within one modelling framework. Further, models will still be held accountable to the usual range of relevant empirical and theoretical work. Therefore robustness analyses should be seen as a additional methodological tool that can help to test and strengthen theoretical claims that are largely made on the basis of models and simulations.

Finally, one might question whether robustness analyses can not only support theoretical claims (as illustrated above), but also show when they are unfounded. In fact, it seems that criticisms of overfitting, highly parameterised models (e.g. Pitt \& Myung, 2002), often based on model comparisons that include controls for model complexity (e.g. Hansen \& Yu, 2001), do just this. Low-parameter models with a stable core of causal components tend to be favoured in cognitive science, which is entirely consistent with a preference for high levels of parameter and structural robustness.

One implication of the use of robustness analyses is that traditional debates about the validity of different modelling approaches may not be constructive. For example, researchers have debated whether 'bottom-up' or 'top-down' approaches are the most productive for researching cognition (Griffiths, Chater, Kemp, Perfors, \& Tenenbaum, 2010; McClelland et al., 2010). With a robustness approach, the question is not about which provides more realistic models or which can provide clearer analytic results, but how they can complement each other's strengths and weaknesses. In this
case, it makes sense for researchers to use both approaches to identify robust properties, and thus converge on mutually supported theories.

## Conclusion

This paper used research in language evolution to illustrate a robustness approach to modelling in cognitive science. It showed how robustness analyses support the identification of linguistic structure as robust property of the processes of cultural transmission, as modelled and simulated across a range of mathematical models, computational simulation frameworks and human experiments.
The robustness approach outlined here strongly contrasts with typical practices in cognitive science, where the aim is often to develop a single model, developed in a specific modelling framework, to account for a narrow range of data. Often, though not always, such practices generate models that lack predictive power and generality, and parameter and structural robustness. With the realisation that such models may have little to do with actual cognitive processes, pressures from new statistical methods of model comparisons are starting to force alternative methods of model construction.

A robustness approach directly promotes the development of models with high parameter, structural and representational robustness. These are often seen as positive features of models, as the output of such models can be traced to the activities of a set of core causal components, not to specific parameter settings, or to artifactual features of the modelling framework used. The use of multiple modelling/simulation frameworks also makes it easier to identify artefacts and core variables in models. Finally, robustness analyses offer a way of providing support for theoretical claims when there is little direct empirical evidence available. In this case, a robustness approach stands as a powerful alternative approach to modelling in cognitive science, and one we recommend highly.

## Acknowledgments

# Context Dependent Utility: Modeling Decision Behavior Across Contexts 

Jonathan Ito (ito@ict.usc.edu)<br>Stacy Marsella (marsella@ict.usc.edu)<br>Institute for Creative Technologies, University of Southern California<br>12015 Waterfront Drive<br>Playa Vista, CA 90094-2536 USA

#### Abstract

One significant challenge in creating accurate models of human decision behavior is accounting for the effect of context. Research shows that seemingly minor changes in the presentation of a decision can lead to drastic shifts in behavior; phenomena collectively referred to as framing effects. Previous work has developed Context Dependent Utility (CDU), a framework integrating Appraisal Theory with decision-theoretic principles. This work extends existing research by presenting a study exploring the behavioral predictions offered by CDU regarding the multidimensional effect of context on decision behavior. The present study finds support for the predictions of CDU regarding the impact of context on decisions: 1) as perceptions of pleasantness increase, decision behavior tends towards riskaversion; 2) as perceptions of goal-congruence increase, decision behavior tends towards risk-aversion; 3) as perceptions of controllability increase, i.e., perceptions that outcomes would have been primarily caused by the decision maker, behavior tends towards risk-seeking.

Keywords: Decision; Appraisal; Context; Framing; Utility;

## Introduction

Descriptive models of human decision behavior seek to accurately describe and predict the decisions people actually make. Creating these models is vital for advancing a more complete understanding of the human decision process and requires addressing the factors that systematically bias the perception and evaluation of decisions.

One significant challenge in creating accurate models of human behavior is accounting for the effect of context on decision behavior. Research has shown that seemingly minor changes in the presentation, or framing, of a decision problem can lead to drastic shifts in behavior; phenomena collectively referred to as framing effects. In a seminal study, now referred to as the Asian Disease Study, Tversky and Kahneman (1981) showed that when outcomes were described, or framed, as gains participants tended to be risk-averse; however, when the same outcomes were framed as losses participants tended to be risk-seeking. Subsequent studies involving domains as diverse as financial planning (Schoorman, Mayer, Douglas, \& Hetrick, 1994), Acquired Immune Deficiency Syndrome (AIDS) (Levin \& Chapman, 1990), Breast Self Examinations (Meyerowitz \& Chaiken, 1987), taxpayer compliance (Liu, Xia, \& Xu, 2011), and judgments of website quality (Hartmann, De Angeli, \& Sutcliffe, 2008) have also demonstrated framing effects to varying degrees. In addition to gain-loss framing, framing can also involve the role of the decision maker (Wagenaar, Keren, \& Lichtenstein, 1988), the salience of outcomes (Van Schie \& Van Der Pligt, 1995),
decision domain (Vartanian, Mandel, \& Duncan, 2011), and perceived need (Mishra \& Fiddick, 2012).

Despite the highly multidimensional nature of context, the prevalence of framing effects in numerous domains, and the profound impact they can have on the decision process, very few decision models explicitly address the multidimensional impact of context on decisions. Existing decision-theoretic approaches which do address framing and context are generally limited by a narrow, one-dimensional view of context. For instance, Prospect Theory (Kahneman \& Tversky, 1979) and Cumulative Prospect Theory (Tversky \& Kahneman, 1992) model the effect of context only to the extent that it applies to outcomes perceived as either gains or losses. Therefore, to address the multidimensional effect of context on decision behavior, previous work has developed Context Dependent Utility (CDU), a framework which seeks to explicitly model the multidimensional impact of context on decision behavior through the integration of Appraisal Theory and decision-theoretic models (Ito \& Marsella, 2011). This work extends previous research by presenting an experimental study exploring the behavioral predictions offered by CDU regarding the multidimensional effect of context on decision behavior. In particular, the results support the behavioral predictions of CDU and suggest that it can dramatically improve the modeling of human decision behavior across distinct contexts.

## Context Dependent Utility

In previous work, Context Dependent Utility (CDU) was developed to explicitly model the multidimensional impact of context on decision behavior (Ito \& Marsella, 2011). The CDU process consists of two primary components: the computational appraisal of the decision situation and an evaluation function aggregating the appraisal information into a real-valued utility.

Appraisal Theory (Lazarus, 1991) is a psychological theory which addresses the process by which emotions arise given the subjective evaluation and interpretation of a situation. Because appraisal theory provides a well-defined framework for the interpretation of features of a situation in terms of their significance, we argue that it provides the means to identify, encode, and integrate contextual information into the decision process. Appraisal as implemented by CDU consists of three distinct evaluations: pleasantness, goal congruence, and control. Each appraisal is defined over individual outcomes as a function of diminishing sensitivity evaluated with respect to some reference point. This follows from the
principle that emotions and appraisals arise primarily from the changes, relative to some reference point, associated with them rather than from any inherent properties of the outcomes themselves (Frijda, 2007). The general appraisal function is shown in (1), in which $0 \leq k \leq 1$, controls the sensitivity of the appraisal.

Pleasantness is implemented as an evaluation of value made with respect to the value of the status quo, $v_{\mathrm{sq}}$, as in (2). Goal congruence is implemented as an evaluation of value made with respect to the value of the aspiration outcome, $v_{\mathrm{ao}}$, as in (3). Control is a measure of the degree to which an outcome will be perceived to have been primarily caused by the decision maker and is implemented as an evaluation of $d e$ cumulative probability, i.e., the total probability of obtaining an outcome at least as preferred as it, made with respect to the probability of the control threshold, $p_{c t}$, as in (4). Note that the decumulative probability representation given in (5) requires that outcomes are in ascending order of value, i.e., $v_{i} \leq v_{i+1}$.

$$
\begin{align*}
\operatorname{appraise}(x, r e f, k) & =\left\{\begin{aligned}
(x-r e f)^{k} \text { if } x-r e f \geq 0 \\
-(r e f-x)^{k} \text { if } x-r e f<0
\end{aligned}\right.  \tag{1}\\
\text { pleas }\left(v_{i}\right) & =\text { appraise }\left(v_{i}, v_{s q}, k_{\text {pleas }}\right)  \tag{2}\\
\operatorname{gc}\left(v_{i}\right) & =\text { appraise }\left(v_{i}, v_{a o}, k_{g c}\right)  \tag{3}\\
\operatorname{ctrl}\left(D_{i}\right) & =\operatorname{appraise}\left(D_{i}, p_{c t}, k_{c t}\right)  \tag{4}\\
D_{i} & =\sum_{j=i}^{n} p_{j} \tag{5}
\end{align*}
$$

The decision evaluation component of CDU is implemented using rank-dependent utility (Quiggin, 1982) as seen in (6). Rank-dependent utility models allow for nonlinear decision weights while maintaining stochastic dominance. The utility function consists of a linearly weighted combination of pleasantness and goal congruence as seen in (7). Outcome weight, $\pi_{i}$, is defined in the standard rank-dependent manner as seen in (8) and (9) in which $a$ and $b$ serve to normalize the weighting function such that $w(0)=0$ and $w(1)=1$.

$$
\begin{align*}
C D U & =\sum_{i=1}^{n} \pi_{i} u\left(v_{i}\right)  \tag{6}\\
u\left(v_{i}\right) & =\left(\beta \text { pleas }\left(v_{i}\right)+(1-\beta) g c\left(v_{i}\right)\right)  \tag{7}\\
\pi_{i} & = \begin{cases}w\left(D_{i}\right)-w\left(D_{i+1}\right) & \text { if } i<n \\
w\left(D_{i}\right) & \text { if } i=n\end{cases}  \tag{8}\\
w\left(D_{i}\right) & =a\left(\operatorname{ctrl}\left(D_{i}\right)\right)+b \tag{9}
\end{align*}
$$

Since appraisals are implemented as functions of diminishing sensitivity with respect to reference points, the underlying utility function becomes increasingly concave as perceptions of pleasantness and goal-congruence increase. Similarly, the underlying weighting function becomes increasingly concave as perceptions of controllability increase. Furthermore, ac-
cording to the principles of the rank-dependent utility formalization employed in CDU, a concave utility function is associated with risk-aversion whereas a concave weighting function is associated with risk-seeking. Therefore, CDU offers the following set of behavioral predictions regarding the effects of pleasantness, goal congruence, and control on the decision process:

Hypothesis 1 As outcomes are perceived as increasingly pleasant, behavior will tend towards risk-aversion

Hypothesis 2 As outcomes are perceived as increasingly goal-congruent, behavior will tend towards risk-aversion

Hypothesis 3 As outcomes are perceived as increasingly controllable, behavior will tend towards risk-seeking

This work presents the results of an experimental framing study designed to test the hypotheses offered by the CDU framework. The study presents participants with a scenario in which they are asked to decide between two competing plans to prevent school dropouts.

## Method

## Participants

For the study, 525 participants from the United States were recruited through Amazon Mechanical Turk.

Each participant received a payment of $\$ 0.40$ for participation. The sample had a self-reported gender distribution of 319 male ( $61 \%$ ) and 206 female ( $39 \%$ ). The median age range was 22 to 34 years with $85 \%$ of participants below 45 years of age. The majority of participants self-identified as white (78\%). Approximately half of participants (50\%) have also completed a 2 year college degree or higher.

Risk propensity, measured using the Subjective Risk Assessment instrument (Dohmen et al., 2005), uses a 7-point scale in which 1 represents being very prepared to take risks, 4 represents being risk-neutral, and 7 represents very unwilling to take risks. The mean of the subjective risk assessment measure for all participants was 3.46 with a median value of 3 and a standard deviation of 1.4 representing a slight overall self-reported tendency towards risk taking.

Additionally, only 42 participants ( $8 \%$ ) self-identified as possessing some real-life expertise involving the prevention of school dropouts.

## Procedure and Design

The study was administered as an anonymous online questionnaire implemented via Qualtrics (Qualtrics Labs Inc., Provo, UT). Before presentation of the decision scenario, demographic information including gender, age, race/ethnicity, and highest level of education was collected along with a measure of subjective risk propensity. Instructions adapted from previous studies administered by Schneider (1992) were then presented to participants regarding the upcoming decision task. In addition, an embedded Instructional Manipulation Check originally developed by Oppenheimer, Meyvis,
and Davidenko (2009) was adapted and employed in the present study to ensure that the instructions were read and to encourage participant attentiveness.

The decision scenario was then presented to the participants. The scenario was based on one originally designed by Fagley, Miller, and Jones (1999) to test standard gainloss framing, but subsequently expanded in the present study to include additional considerations of context. It presented participants with two possible plans to prevent school dropouts: one plan always results in some students dropping out whereas the other plan results in either all students dropping out or no students dropping out. According to decisiontheoretic formalizations of risk, a preference for the plan which always results in the same outcome (some students dropping out) is characterized as a preference towards riskaversion whereas preference for the plan which results in one of two potential outcomes (one good and one bad) is characterized as a preference towards risk-seeking. As in most framing studies, regardless of frame, the underlying values, i.e., numbers of students dropping out or staying in school and outcome occurrence probabilities, associated with the scenario remain unchanged.

The framing of each scenario involved the explicit manipulation of the context associated with the appraisal dimensions of pleasantness, goal congruence, and control. The manipulation of pleasantness was associated with the description of outcomes as gains or losses such that outcomes described as losses were presumed to be relatively unpleasant whereas outcomes described as gains were relatively pleasant. Therefore, in the loss condition, outcomes were described by the number of students that drop out of school; for the gain condition, outcomes were described by the number of students that stay in school; for the neutral condition, outcomes were described using both the number of students that drop out and stay in school.

The manipulation of goal congruence was based on a previous study conducted by Payne, Laughhunn, and Crum (1981) and involved specifying different evaluation criteria to establish what constitutes a successful, or goal-congruent, outcome. In particular, participants were informed that their performance would be evaluated in comparison to the average retention rate, i.e., the percentage of students that stay in school, of other schools in the district. Therefore, in the low retention condition the expected retention rate was $5 \%$ (50 students stay in school or 950 drop out); in the neutral retention condition the retention rate was $40 \%$ ( 400 students stay in school or 600 drop out); and in the high retention condition the expected rate was $75 \%$ ( 750 students stay in school or 250 drop out).

The manipulation of control, derived from research on loci of control (Rotter, 1966), involved depicting the source of uncertainty as either arising from chance events or from the ability of the decision maker. Uncertainty arising from chance events suggests that outcomes are uncontrollable and therefore not caused by the decision maker whereas uncertainty
regarding the ability of the decision maker suggests that outcomes are controllable and will be perceived as having been caused by the decision maker. Therefore, in the chance condition, uncertainty was depicted as arising from the random selection, i.e., lottery, of funding applications; In the ability condition, the source of uncertainty was described as arising from the hypothetical ability of the participant to write a persuasive funding application; and the neutral condition involved a mixture of the two. A full listing of a school dropout scenario in which outcomes are described as gains, retention rate is low, and the source of uncertainty is depicted as arising from one's ability is given in Appendix .

The primary dependent variables in the decision task consisted of both a dichotomous choice between plans, as found in most standard framing studies, and a continuous strength-of-preference response, which included an option indicating indifference, as advocated by Levin, Gaeth, Schreiber, and Lauriola (2002).

After completion of the decision task, participants were asked to directly evaluate the pleasantness, goal congruence, and control of the three potential outcomes, i.e., the sure outcome of the risk-averse alternative and the two potential outcomes of the risky alternative. This served as a manipulation check to ensure that the contextual manipulations employed in the scenario were effective. Participants were then offered the opportunity to express any additional factors that may have influenced their decisions. Finally, participants were asked to indicate whether or not they perceived themselves as possessing any type of expertise relating to school dropouts.

The study was conducted as a $3 \times 3 \times 3$ between-subjects factorial in which both the presentation order of the two dropout prevention plans and the ordering of the two potential outcomes of the risky alternative were balanced. Table 1 illustrates the various factors and the number of participants that were assigned to each combination of factors. To ensure the integrity of the data, responses deemed inconsistent by an automated consistency-verification program were ignored. An inconsistent response was defined as one in which the dichotomous response regarding participant preference between plans does not agree with the associated continuous strength-of-preference measure. For example, a stated dichotomous preference for the sure alternative coupled with a strength-of-preference score favoring the risky alternative was deemed inconsistent.

## Results

As discussed earlier, two distinct but related dependent measures were assessed: a dichotomous choice between alternatives and a continuous strength-of-preference measure. According to the dichotomous measure, 327 participants ( $62 \%$ ) preferred the sure alternative while 198 participants preferred the risky alternative ( $38 \%$ ). Similarly, according to the strength-of-preference measure, in which 1 indicates very strong preference for the sure alternative, 4 indicates indifference, and 7 indicates very strong preference for the risky alternative, mean choice preference was 3.61 with a median

Table 1: Number of Participants per Condition

| Gain/Loss | Retention | Source of Uncertainty |  |  |
| :--- | :--- | ---: | ---: | ---: |
|  | Rate | Chance | Neutral | Ability |
| Loss | Low | 20 | 18 | 23 |
|  | Neutral | 20 | 26 | 18 |
|  | High | 26 | 23 | 22 |
| Neutral | Low | 20 | 18 | 17 |
|  | Neutral | 21 | 21 | 21 |
|  | High | 21 | 22 | 19 |
| Gain | Low | 20 | 19 | 15 |
|  | Neutral | 15 | 17 | 20 |
|  | High | 13 | 16 | 14 |

of 3 and a standard deviation of 1.71. This indicates a slight preference for the sure alternative.

Using the continuous strength-of-preference measure as the dependent variable, a 3-way ANOVA found significant main effects for retention rate $F(2,498)=25.99, p<0.001$, $\eta^{2}=0.09$, and source of uncertainty $F(2,498)=6.53, p<$ $0.01, \eta^{2}=0.02$, while the effect of gain/loss descriptions $F(2,498)=1.84, p=0.16, \eta^{2}=0.01$ approached significance. ${ }^{1}$ Figures 1, 2, and 3 show respectively the main effects of gain/loss description, retention rate, and source of uncertainty on mean preference strength. No significant interactions were detected.

Figure 1: Experiment 1 Effect of Gain/Loss Descriptions on Preference with $95 \%$ Confidence Intervals and Significance Levels ( 0 *** 0.001 ** $0.01 * 0.05$ )

Post-hoc $t$-tests on the effect of gain/loss description on preferences revealed a significant difference between the loss and gain conditions, $t(332.59)=2.29, p<0.05$. For the effect of retention rate on preferences, $t$-tests revealed that the

[^302]

Figure 2: Experiment 1 Effect of Retention Rate on Preference with $95 \%$ Confidence Intervals and Significance Levels ( 0 *** 0.001 ** 0.01 * 0.05 )
difference between the low and high conditions $t(340.55)=$ $-5.93, p<0.001$ and between the neutral and high conditions $t(352.21)=-6.69, p<0.001$ were significant. For the effect of source of uncertainty on preferences, the differences between the chance and the ability conditions $t(328.1)=$ 3.31, $p<0.01$ and between the neutral and ability conditions $t(347.17)=2.39, p<0.05$ were significant.

In addition to the primary dependent variables, direct evaluations of pleasantness, goal congruence, and control over each outcome were assessed to ensure that the contextual manipulations had the intended effect on their associated appraisals. A one-way MANOVA on the effect of gain/loss descriptions on appraisals of pleasantness for each of the three outcomes showed an effect approaching significance $F(6,1042)=1.74, p=0.11$. Similar MANOVAs showed significant effects for retention rate on appraisals of goal congruence $F(6,1042)=18.65, p<0.001$ and source of uncertainty on appraisals of control $F(2,1042)=16.5, p<0.001$ for each of the three outcomes.

## Discussion

The goals of the study were to examine how different aspects of context affect decision behavior and whether shifts in preference in response to contextual changes, i.e., framing effects, are consistent with the predictions offered by CDU.

The experimental results support both the multidimensional effect of context on decision behavior and the predictions offered by CDU with respect to the effects of context. In particular, the present study finds strong support that the contextual dimensions associated with pleasantness, goal congruence, and control do affect decision behavior in the direction predicted by CDU. CDU predicts that when outcomes are described as gains opposed to losses, decision makers will tend to act in a more risk-averse manner to maintain pleasantness. CDU also predicts that when the standards for success, i.e.,

Source of Uncertainty

Figure 3: Experiment 1 Effect of Source of Uncertainty on Preference with $95 \%$ Confidence Intervals and Significance Levels ( 0 *** 0.001 ** $0.01 * 0.05$ )
retention rates, are low, decision makers tend to act in a more risk-averse manner to maintain goal congruency compared to when standards of success are high. Finally, CDU predicts that when the source of outcome uncertainty is depicted as arising from ability, e.g., persuasive writing ability, decision makers tend to act in a more risk-seeking fashion to capitalize on the perceived controllability of the situation compared to when the source of uncertainty is depicted as arising from chance events.

## Conclusion

One significant challenge in creating accurate, descriptive models of human behavior is accounting for the effect of context on decision behavior. Existing approaches at modeling context and its effects on decision behavior, i.e, framing effects, are generally limited by a one-dimensional view of contextual influence and therefore lack the descriptive flexibility to account for a broad range of behavior. Therefore, this work extends previous research (Ito \& Marsella, 2011) on Context Dependent Utility (CDU), a decision framework which seeks to explicitly model the multidimensional impact of context on decision behavior, by presenting experimental data supporting the need for accurate, multidimensional models of contextual influence on decision behavior. In particular, this work presents the results of a study in which participants are asked to choose between two alternative plans (one risky and one risk-averse) to prevent school dropouts. Additionally, to examine the effect of context on overall decision behavior, the context of the decision task is varied between subjects along the following dimensions: whether outcomes are described in terms of gains or losses; the retention rate used to determine the degree to which an outcome is considered successful; and the portrayal of the source of uncertainty in the scenario, i.e., whether outcome variability depends on chance
or ability-based factors.
The present study shows strong support for all of the behavioral predictions offered by CDU regarding the impact of context on decision behavior: 1) as the overall perception of pleasantness increases, which is associated with the description of outcomes as gains rather than losses, decision behavior tends towards risk-aversion; 2) as the overall perception of goal-congruence increases, which is associated with lower retention rates implying lower standards of success, decision behavior tends towards risk-aversion; 3) as the overall perception of controllability, i.e., the perception that outcomes would have been primarily caused by the decision maker, increases, which is associated with depicting the source of uncertainty as arising from one's ability, behavior tends towards risk-seeking. In sum, the present study illustrates the need for models which explicitly represent the multidimensional affect of context on behavior, such as CDU, especially when modeling decision behavior across contextually distinct situations.

## School Dropout Scenario

## Initial Scenario Presentation

Imagine that you have been hired by the school district of a major city to combat the high number of student dropouts. It
is projected that 1000 students in your district will drop out of school during the next year if nothing is done.

## Action Description

Two plans exist to address the student dropout problem. Both plans require similar investments of money, time, and effort from your district. However, only one can be implemented. Based on other districts' experiences with these plans, estimates of the outcomes that can be expected from each plan can be made. Assume for purposes of this decision that these estimates of are accurate and are as follows:

Dropout Prevention Plan A Invest currently available funding in a smaller, relatively affordable dropout prevention program. This plan results in the following outcome:

- 400 of the 1000 students stay in school

Dropout Prevention Plan B Invest currently available funding in a larger dropout prevention program. However, the school district's current funding is insufficient to cover the full cost of this program. Therefore, its success is dependent on obtaining additional funding from the government. Funding approval for your dropout plan depends primarily on your ability to write a persuasive funding application. Historically, $2 / 5$ of your previous applications have been persuasive enough to receive funding. This plan results in one of two possible outcomes:

- $2 / 5$ chance that you are able to write a persuasive funding application. This results in sufficient funding and 1000 of the 1000 students staying in school
- $3 / 5$ chance that you are not able to write a persuasive funding application. This results in insufficient funding and 0 of the 1000 students staying in school

## Evaluation Criteria

The standard used to evaluate your performance will be the average student retention rate (the percentage of students that stay in school) obtained by other school districts in the state. Last year, the average retention rate for the other districts in the state was $\mathbf{5 \%}$. The same rate is expected this year.

If you select a dropout prevention program that ultimately leads to a higher retention rate than those obtained by other districts in the state, you will be evaluated as being successful. Of course, the higher the retention rate is in your district, the more successful you will be evaluated. On the other hand, if you select a dropout prevention plan that ultimately leads to a lower retention rate than the average rate of other districts, your own evaluation will be diminished. Again, the more retention rates are below the average level, the more diminished will be your own evaluation.

Which plan would you adopt?

# A computational exploration on the role of semantic memory in episodic future thinking

#### Abstract

Episodic future thinking refers to a human cognitive process which generates successive predictions of events that are likely to occur in a cue-specific context in the future. An emerging view is that semantic memory as well as episodic memory contributes to this process, but the exact mechanism remains unclear. We built a computational model that learned to predict the next event upon a presented event (sequence prediction model). After learning the statistical structure in the training sequence, the model was tested for generating successive self-predictions of events triggered by a cue. The generated sequence of events captured some phenomenological features of patients with semantic dementia when the semantic system of the model was damaged. The role of semantics in episodic future thinking and the usefulness of a sequence prediction model are discussed.

Keywords: episodic future thinking; semantics; paralleldistributed processing model; sequence learning

## Introduction

We can project ourselves into the future despite the fact that we have never experienced it. The term episodic future thinking refers to a human ability to envision a plausible future event in a specific time and place (i.e., a specific context) (Atance \& O’Neill, 2001; Schacter, Addis \& Buckner, 2008). Over the last decade, researchers from various fields, including psychology, neuropsychology, and neuroimaging, have investigated episodic future thinking, focusing mainly on the contribution of episodic memory to constructing episodic future thought. More recently, data from patients with semantic dementia have suggested that semantic memory may also play a role (Irish, Addis, Hodges, \& Piguet, 2012). The current study used a computational model to investigate the mechanism by which semantic memory supports episodic future thinking.

## Role of Episodic Memory

The role of episodic memory has been suggested in various studies. For example, some neuroimaging studies have revealed a common neural network involved in the remembering of past, and in imagining future events (Szpunar, Watson, \& McDermott, 2007). These data are consistent with neuropsychological studies with amnesic patients (e.g., hippocampal amnesia or Alzheimer's disease) who showed simultaneous impairments in both remembering past episodes and imagining future events (e.g., Irish et al., 2012). Based on these findings, the
constructive episodic simulation hypothesis was proposed, which assumes that imagining future events requires a system that can retrieve detailed information stored in episodic memory and flexibly recombine them into coherent representations of future events (Schacter, Addis, \& Buckner, 2008). Further support for this idea comes from experimental psychology. For example, both retrieving an episode and imagining a future event are affected by a temporal distance factor in the same manner. Specifically, Addis, Wong, \& Schacter (2008) collected both the past events that participants recalled and the future events they generated, and classified detailed information in these outputs as either internal or external. Internal details are "episodic" information, meaning specific in time and place and related to the central events (i.e., the main event described by the participant). In contrast, external details are not specific in time and place. It was found that, in both recalling of past episodes and thoughts about future episodes, internal details lessened as participants were required to produce farther events from the present in both directions. This means that as episodic future thinking goes farther in terms of temporal distance from the present, the time and place (context) of the generated events deviates from those of the central events (central topic).

## Role of Semantic Memory

More recently, the role of semantic memory in episodic future thinking has also captured attention (Irish et al., 2012). D'Argembeau and Mathy (2011) suggest that construction of episodic future thought typically involves progressive conversion from general to more specific information such that access to general knowledge (semantics) precedes retrieval of time-specific episodic information. In other words, semantic memory provides a "framework" for construction of episodic future event representations, and then episodic information from the past is integrated to form a coherent and elaborated sequence of future events. A key support for this idea came from a study with neurological patients with semantic dementia, characterized by the progressive and insidious loss of conceptual knowledge about objects, facts and the meaning of words, yet preserved non-verbal episodic memory (Irish et al., 2012). Specifically, Irish et al. (2012) found that although their patients were as good at remembering past episodes as controls, their episodic future thoughts lacked internal details. In other words, the sequence of events they generated did not maintain the time and place information (context) that was
cued by an investigator. Note that this was not due to a difference in task difficulty because Alzheimer's disease patients in this study showed simultaneous impairments in both measures. Thus, this dissociative pattern suggests that even if episodic memory is relatively intact, loss of conceptual knowledge has an impact on episodic future thinking.
Motivated by these findings, we employed a paralleldistributed processing (PDP) modelling approach to investigate the mechanism by which semantic memory contributed to episodic future thinking. As we reviewed above, human experiments have provided significant insights, but each has its own limitation: It is relatively difficult to separate the contribution of episodic memory from that of semantic memory in healthy controls. Semantic dementia patients are the best test cases but their verbal outputs are limited such that it is difficult to probe their cognitive processing in detail. In contrast, computational modelling provides an ideal situation where we can directly look at the nature of computation/representations in the model to glean further insights into how semantic memory supports other cognitive processing (e.g., Woollams, Joanisse, \& Patterson, 2009).

## Future Prediction Model

Given there is no computational model for episodic future thinking in the literature, the initial step is to make some simplified assumptions so that the target cognition can be implemented in a computational model. A standard paradigm to probe episodic future thinking involves a presentation of a cue such as time/location/object (e.g., next year's birthday, or $50^{\text {th }}$ birthday, etc.), and a participant successively generates cue-specific predictions on what is likely to happen (e.g., a birthday cake is on a plate in a dining room $\rightarrow$ I blow the candle $\rightarrow$ my friend will pick out the candle $\rightarrow$ the friend will cut the cake $\rightarrow$ the friend will serve me a cake on a plate, etc.). The nature of this generation is successive such that the order of these example sentences cannot be at random. In other words, future thinking includes at least two aspects - computing cuespecific information and successively generating future predictions based on the corresponding previous prediction. Of course, these two aspects are not enough to account for the whole episodic future thinking processing. However, once we assume that episodic future thinking taps at least an ability to generate successive predictions based on the corresponding previous prediction upon a time-/location-/object-specific cue, then there is an existing computational model by Elman (1990) that we can adopt and modify for the current purpose. This model was trained for predicting the next alphabetic letter in an artificial language. Specifically, the model received a 6-bit binary vector, which represented one of the alphabetic letters, and the model was trained for predicting the next 6-bit binary input vector. The presented sequence was not random, but there was a statistical structure regarding what was likely to come next (artificial grammar). The model learned this statistical
structure in the sequence. In later studies, human participants were trained for the same task and were able to use their statistical knowledge after training in order to generate successive predictions about the next letter following their own previous predictions upon a presented cue (Perruchet \& Amorim, 1992). Returning back to the current study, it would be possible to assume that a statistical structure exists even in the event sequence (episode) within the real world. For example, we reasonably guess that the next event would be to blow the candle when a birthday cake is served to the dinner table. Also, we know that someone will cut cake into pieces before biting into a whole cake. Thus, there is some statistical structure in the sequence of events in real world, and our working hypothesis is that the order of successive cue-specific predictions in episodic future thinking should be to some extent constrained by this statistical structure in real world. Once we assume the similarity between the future prediction of the next letter in a given language (Elman, 1990) and the future prediction of the next event in real life, then it is natural to adopt Elman's approach for modelling episodic future thinking (see below in detail). As we admit above, episodic future thinking is a complex cognitive process, but this approach is promising to capture at least the two core characteristics of episodic future thinking mentioned above.

## Method

## Model Architecture, Tasks, and Representations

Figure 1 shows the architecture of the model. Four peripheral layers (input layer, output layer, semantic layer, and recognition layer) were connected bidirectionally through a single hidden layer. The hidden layer and each of the five output layers were connected to themselves. The input layer was sub-divided into five layers, each of which represented one of the five elements of the current event (Figure 1). For example, the first layer represented the context information of the current event. If this context layer was hard-clamped to the binary vector of [100000] , then it meant the current event occurred in Context 1 (e.g., school). The remaining four layers represented the Agent/Action/Object/Instrument of the current event. Thus, if the whole input layer was hard-clamped to the 18 -bit

Figure 1: The architecture of the model (Hinton diagram).

Table 1: Sequence structure of the training set.

| sequence | context |  |  | other information |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | contex <br> t <br> label | pattern | predictabilit y | pattern |  |  |  | predictability |  |
|  |  |  |  | agent | action | object | $\begin{gathered} \text { instrumen } \\ \mathrm{t} \\ \hline \end{gathered}$ | with context | without context |
| event (1) |  |  |  | 010 | 100 | 010 | 100 | 783 |  |
| event (2) | 1 | 100000 | constant | 100 | 010 | 001 | 100 | or |  |
| event (i) |  |  |  | 010 | 001 | 010 | 010 | 100\% |  |
| $\text { event }(i+1)$ | 6 | 000001 | constant | 001 | 010 | 001 | 010 | $33,50,$ | 6 ~ 45\% |
| event (j) |  |  |  | 100 | 100 | 100 | 010 | 100\% |  |
| event $(\mathrm{j}+1)$ |  |  |  | 001 | 001 | 001 | 001 |  |  |
| $\text { event }(\mathrm{j}+2)$ | 3 | 001000 | constant | 010 | 010 | 100 | 100 | 100\% |  |

vector of [(Context) 010000 (Agent) 100 (Action) 001 (Object) 100 (Instrument) 001 ], then the current event was 'In Context 2 (e.g., home), Agent 1 (e.g., John) did Action 3 (e.g., cut) to Object 1 (e.g., cake) with Instrument 3 (e.g., knife)'. The layers in the output side had the same structure, and when presented with the input pattern of the current event, the model was trained to activate the units in the output layer that consisted of the next event (the input 18 -bit vector of the next trial). The sequence structure will be explained later.
Next, the semantic layer consisted of 15 units whose activation patterns represented the 'conceptual knowledge' of the current event (interpretation of the event) in a distributed manner. Following many parallel-distributed processing (PDP) models that incorporated a 'conceptual knowledge' system in their models (Woollams et al., 2009), no attempt was made to design semantic representations that captured the actual meanings of the input pattern (e.g., input words, action, event, etc.). Instead, like past models, artificial semantic representations were created that, nonetheless, captured core characteristics of the meaning of an event. Specifically, we assumed that the meaning of an event would be to some extent related to the action, instrument, and object information of that event (e.g., not an arbitrary mapping). Once we hear these pieces of information, we can guess what happened in that event with some confidence. In contrast, the meaning of an event would be less strongly related to information on who (Agent) did that action. For example, the meaning of cutting an apple with a knife is invariant irrespective of who did that action. Next, the context information also constrains the meaning of the event. We know that certain kinds of events rarely occur in a certain context. For example, passing $a$ ball should not occur in a restaurant. Of course, Agent information would also constrain the meaning of an event (e.g., we might know that John would never eat an apple), but to a lesser extent than context/action/object/instrument
information. Taking these assumptions together, we created the target semantic representations such that the bit-patterns in the context/action/object/instrument input layers were systematically related to part of the target vectors in the semantic layer (i.e., mapping was not completely arbitrary). Then, when presented with the current event pattern in the input layer, the network was trained for generating the correct pattern in the semantic layer in addition to predicting the next event in the output layer. Irish et al. (2012) demonstrated that semantic dementia patients were less accurate than controls for 'knowing (semantic)' nonpersonal events over the past/future 10 years. Thus, we damaged this layer in simulation of the patients' behaviour.

A recognition trial was occasionally inserted during training, in which the network was trained for judging whether the presented event pattern had been experienced before or not. The single unit in the recognition layer served to represent the network's recognition judgment. Specifically, the input layer was hard-clamped to the value of an event representation, and then the network was trained to activate this recognition unit (1.0) if the presented event representation had appeared ('old') before, as part of the main task. In contrast, the recognition unit should be turned off (0.0) if the presented episode representation had never appeared before ('new').

## Sequence Structure of the Training Set

Sequence Structure of Context Information The sequence in the main trial was semi-random. Table 1 shows the structure of the sequence. First, as the left half of Table 1 shows, the context information (i.e., first 6-bit of the 18-bit input vector) was kept constant for several successive events in order to mimic the real world, where we experience successive events in the same context then move to another one. By presenting the first 6-bit information in this way, we can more safely argue that this 6-bit information represents
the context information of an event. Thus, the predictability of the next context information was $100 \%$ in most trials unless it was the boundary of a context-block. After several events, the context information changed into another context semi-randomly (33\%-50\% predictability).

Sequence Structure of Agent/Action/Object/Instrument Information The sequence of the remaining 12-bit information of an event was also semi random. There were 81 possible input patterns, formed by crossing 3 (Agent) by 3 (Action) by 3 (Object) by 3 (Instrument). When the context information was not considered, the predictability of the next event (i.e., next agent/action/object/instrument information) varied from $4 \%$ to $45 \%$ depending on a trial. When the context was considered together, the predictability increased such that it varied from $33 \%$ to $100 \%$ depending on a trial. We implemented the constraint from context information to mimic the real world. For example, it is more difficult to predict what will happen if we see a ball bouncing at a restaurant, but it is less difficult to predict at a park.

Recognition Trials After every nine trials for event prediction (and simultaneous computation of meaning), six trials were inserted to train the model for event recognition. The network received a 18-bit input pattern, and was required to judge whether or not this pattern had been presented before as part of the main task by activating/deactivating the recognition unit. In order not to bias the network's response, 'old' and 'new' trials were evenly distributed (3 trials, each) within each recognition block. The 'old' events were randomly sampled from the main training trials that the network had experienced during event prediction. The 'new' event-set was created in the following steps. First, when we had created the sequence of the main trials, we had ensured that not all the 81 possible input patterns (formed by combining agent, object, action, \& instrument) appeared in every one of the 6 possible contexts. Specifically, in each context, 20-27 possible combination of agent/object/action/instrument information had been randomly sampled and removed from the training set such that these patterns never appeared in that particular context during the main task. These pre-removed patterns served as 'new' events. To be clear, it was possible that these patterns appeared in another context. For example, the network might have received the 18 -bit vector of $[100000,100$, $100,100,100$ (comma denotes the boundary of layers)] but not received that of [010000,100,100,100,10 0 ]. Then, the network would have to activate the recognition unit when presented with the former pattern but would have to deactivate the same unit in the case of the latter. Thus, the network was trained for recognition of a particular event involving a particular context/agent/object/action/instrument. We also ensured that not all the possible 'old' trials and 'new' trials were presented during training, such that we were able to probe the generalization performance of the network to the untrained 'old'/'new' patterns.

Figure 2: Learning curves for event prediction, recognition of trained-items, and recognition of untrained-items.

## Training Parameters

In each trial, 18 units in the input layer were hard-clamped to their input values, and the network was allowed to cycle 10 times. In each time step, the activation spread to the next layer gradually being scaled by the values of the interconnecting weights, and the network settled into the steady state (called as an attractor). After 10 cycles of updates, the discrepancy between the output activation patterns (output event layer and semantic layer) generated by the network and the correct target pattern was calculated, and the connection strength was adjusted to reduce the discrepancy. In recognition trials, only the discrepancy in the recognition unit was considered. A learning rate of 0.01 was set at the beginning of the training. Then, every 10 epochs of training, the learning rate was gradually reduced by 0.001 . A decay parameter was set to 0.0000001 at the beginning and gradually reduced by 0.00000001 as the learning rate was reduced. When we evaluated the network's performances during/after training, we used a strict criterion such that the output was scored correct if the discrepancy was within 0.5 in every unit of the target layer after the $10^{\text {th }}$ cycle (i.e., the activation is less/more than 0.5 if the target is $0.0 / 1,0$. for each unit respectively).

## Results

## Trained Tasks

Figure 2 shows the learning curves for the event prediction task and the recognition task averaged across 10 independent simulations (initiated with different random seeds). The network successfully learned to predict the next event, thus acquiring the statistical structure which existed in the event sequence as well as recognizing the presented event pattern, which was generalized to untrained items. Accuracy for computing the meaning of an event quickly reached $100 \%$ after the training was initiated.

## Episodic Future Thinking

As explained in the introduction, the current model focused to capture at least the ability to compute cue-specific events successively following its own previous event prediction, a core characteristic of episodic future thinking. Thus, we first presented cues (e.g., Context = home, Agent = john, Action $=$ cut, Object $=$ cake, Instrument $=$ knife $)$. Then, once the network generated an output (i.e., prediction of next event), we presented this output vector pattern as the input of the next event, and the network generated the next output (prediction of the next event following its own prediction, see Botvinick \& Plaut, 2004, for the same approach in action learning). This cycle was reiterated 1000 times, and the generated 1000 -event sequence was regarded as an approximation of the network's episodic future thinking. As a result, the network successfully kept the presented context information (Context 1) constant for the first 829 events (average of 10 simulations), but lost this context information after this point.

## Simulation of Semantic Dementia

Following past simulations on semantic cognition, we simulated the episodic future thinking of patients with semantic dementia by removing some of the links between the semantic layer and the hidden layer (e.g., Woollams et al., 2009). Figure 3 shows how long (how many successive events) the network maintained the cued-context information as a function of disease severity (in terms of the proportion of links removed). This 'lesioning' simulation was reiterated 50 times with different links being sampled and removed, and the outcomes were averaged in order to avoid an idiosyncratic result. We found that, as the damage became more severe, the network was increasingly unable to maintain the event sequence of the cued-context (NB., The intact model kept the context for 829 events). Thus, future thinking deviated into another context/topic. Moreover, the proportion of the links removed was negatively correlated with the number of event predictions that maintained the cued-context $[r(17)=.-75, p<.01]$, suggesting that semantics had a causal role in generating a coherent episode in future thinking. Importantly, event recognition accuracy was intact (more than 95\% accurate) after this lesioning. All of these are consistent with the data from semantic dementia patients (Irish et al., 2012).

## Discussion

The current model successfully acquired the statistical structure within the training set, and used this knowledge to generate a context-coherent sequence of events triggered by cues (episodic future thinking). Moreover, when the computation of semantic knowledge was impaired, the model could not generate a context-coherent event sequence, yet preserved its recognition ability of event patterns. Importantly, the number of the events generated in a specific context was negatively correlated with the severity of damage, suggesting the causal role of semantics in episodic

Figure 3: Numbers of successive events in which the network maintained the cued-context information as a function of disease severity.
future thinking (Irish et al., 2012). This is consistent with the idea that the semantic system provides the framework of the event (D'Argembeau \& Mathy, 2011).
How does the semantic system affect the maintenance of context-coherent event sequences? This can be explained in terms of one of the general principles of PDP models. During training, a PDP network finds a unique attractor state (= unique abstract pattern in the hidden layer) associated with each of the input patterns. Once an input value is fed into the model, the activation gradually spreads, and the internal activity of the hidden layer gradually settles onto this unique status, as if it is falling into its unique attractor basin. They are unique, but similar inputs are associated with similar attractor basins. In the current model, the input patterns that share the same context information will fall into similar/neighbouring attractors, thus producing the same context output information to keep a context-coherent episode. However, if the internal representation of the model changes due to an impaired computation at some part of the model, then the network may settle into a wrong attractor basin, generating a wrong output. The diagnostic analysis suggests that this is certainly the case in our model. Specifically, we presented six events in different contexts to the network, and the activation pattern in the hidden layer on which the network settled was measured with/without semantics. Figure 4 shows the similarity structure of these patterns found by a multi-dimensional scaling analysis. With the intact semantic information (filled-markers), the network settles onto the context-specific attractor basins such that the network does not confuse one context with another. However, when the semantic system was damaged (openmarkers), the network's internal status drifted away from its correct attractor, thus generating a different/wrong context representation (e.g., The open-circle is closer to the filleddiamond rather than filled-circle). In other words, semantic representations contribute to "binding" a time-varying event

Figure 4: The similarity structure in the activation patterns of the hidden layer as a function of the input context information and of with/without semantics.
sequence such that it forms a context-coherent episode. One might describe this as a framework within which episodic details are integrated (D'Argembeau \& Mathy, 2011). Interestingly, Schapiro et al. (2013) has recently demonstrated that temporally-close stimuli that form one coherent event are similarly represented (in terms of voxelbased neural patterns) in the inferior/superior anterior temporal lobe and inferior frontal gyrus, both of which are the damaged areas in semantic dementia patients. Damage in this area might disrupt in computation of such similar neural patterns, and bound stimuli might fall apart.
Then, the question is why collapsed semantic knowledge has little effect on episodic recognition accuracy, as was demonstrate in this model as well as in patients with semantic dementia (Irish et al., 2008). This is because recognition of a particular event is both context-specific and agent/action/object/instrument-specific. In other words, it is crucial not to confuse a new event with an old one, even if part of the information contained in that new event is semantically familiar (e.g., you have ever used that instrument before and/or have seen the same action conducted by the same agent, yet in a different context). Therefore, it is possible that event recognition is not influenced by degradation of semantic knowledge (or at least not detected with a standard test).
Admittedly, the ability to generate context-specific event predictions could be simulated if the modules representing schemas or scripts were explicitly built-in by a modeller a priori. However, the model implemented symbolic system must have assumptions about schematic knowledge preliminarily (further discussions, Botvinick \& Plaut, 2004). The present sequential model did not have that symbolic system and developed by learning the statistical structure in the event sequence. This implies that learning sequential structure enables the model to compute schema-like representation (Botvinick \& Plaut, 2004), and can capture the behaviour of semantic dementia patients..
In summary, we have clarified the mechanism by which semantics contribute to episodic future thinking. The sequence prediction model (Elman, 1990) is a useful computational framework that can be extended to an event sequence triggered by a cue such that it successfully
captures the phenomenological and neuropsychological features of episodic future thinking. Certainly, this model does not capture the whole aspects of episodic future thinking, and in this sense, this is a proto-episodic future thinking model. In future work, implementation of essential factors for episodic future thinking is required such as the concepts of "self" or "temporal distance".

#### Abstract

Creative reasoning in ill-defined problem spaces operates differently from classical reasoning in well-defined spaces. To systematically compare the two in an identical knowledge domain, we applied a classical intelligence test: the Standard Progressive Matrices (SPM), in combination with two tests of creativity: the Test for Creative Thinking - Drawing Production (TCT-DP) and the newly developed Creative Reasoning Task (CRT), in which participants are asked to create an SPM-like item, to two age groups ( $N_{l}=511,4-12 \mathrm{y}$ old; $N_{2}=205,6-10 \mathrm{y}$ old). For SPM and CRT the knowledge domain consists of relationships amongst geometrical components in $3 \times 3$ matrices. We developed a typology for scoring the number and complexity of the relationships used in these matrices. For the SPM, we scored frequencies of relationships solved and for CRT those created, and interpreted the scores in terms of differences and similarities between classical and creative reasoning in cognitive development.

Keywords: Cognitive development; intelligence; reasoning; creativity; creative cognition; creative reasoning.

## Classical and Creative Reasoning

In creativity, both convergent and divergent thinking are needed, in order to arrive at a quality formulation (Jaarsveld \& van Leeuwen, 2005). Creative processes often consist of iteratively generating, testing, and selecting intermediate productions, ultimately leading to an integral result. We interpreted this process in terms of the integration of convergent and divergent operations characteristic of creative reasoning (Jaarsveld et al., 2010). Here we will consider the integration of convergent and divergent operations against the alternative possibility that both are used as independent, quasi-additive resources.

Convergent operations are typically associated with classical reasoning. A consequence is that classical and creative reasoning share processing components. Therefore,
if convergent and divergent operations constitute independent resources, test results between classical and creative reasoning will be correlated. Longstanding investigations of intelligence and creativity test scores suggested only a moderate relationship (Wallach \& Kogan, 1965; Kim, 2005; Silvia, 2008). The strength of the relation, however, may be a matter of differences between the knowledge domains of both tests that are unrelated to the differences between reasoning types per se. To illustrate this issue, here we compared a classical intelligence test, the Standard Progressive Matrices (SPM; Raven, 1938/1998), with two creativity tests, one of which, the Creative Reasoning Task (CRT; Jaarsveld et al., 2010; Jaarsveld, Lachmann, \& van Leeuwen, 2012), shares the domain of knowledge with the SPM and the other, the Test for Creative Thinking - Drawing Production (TCT-DP; Urban \& Jellen, 1995) does not (Jaarsveld et al., 2010; 2012).

## Knowledge Domain

In general, classical and creative reasoning tests tend to operate in different knowledge domains. For instance, the SPM, which is considered to measure convergent thinking, operates in the domain of relations among geometrical components contained in a matrix (Figure 1). By contrast, the TCT-DP, which is considered to measure divergent production, operates in the domain of figural associations. Smilansky (1984) introduced a paradigm which we named the Single Knowledge Domain Paradigm. Smilansky asked participants first to solve the SPM and next to create an SPM-like item in a task which we named the Creative Reasoning Task (CRT). Hence, between SPM and CRT cognition operates on the same knowledge domain (Figure 1). Solving a classical reasoning task does not always mean the problem is understood: often a correct solution is accompanied by an incorrect line of verbal reasoning or is obtained without any conceptual understanding (Chi \& VanLehn, 1991; Karmiloff-Smith, 1992; Pine \& Messer, 1999). Such distortions are less likely with ill-defined problems.

Figure 1: An item of the solving test (SPM) and the empty response form of the Creative Reasoning Task (CRT).

## Problem Space

In the literature, classical and creative reasoning are both understood as processes operating in abstract problem spaces (Hayes \& Flowers, 1986; Simon, 1973; Kulkarni \& Simon, 1988; Runco, 2007). A problem space contains all possible states that are accessible from the initial state through iterative application of transition rules, including the ones that bring the problem solver from the initial state to the final solution. Problem spaces in classical reasoning are well-defined; like in a game of chess, no reinterpretation of rules is possible. Problem spaces in creative reasoning are ill-defined, and may allow re-interpretation of rules during the problem solving process. For instance, in rearranging your room you uncover implicit requirements that introduce a set of new transformations and/or eliminate existing ones (Barsalou, 1992) or, when conflicting constraints arise, you introduce new trade-offs (Yamamoto, Nakakoji, \& Takada, 2000).

In our first study we compared reasoning performances in well and ill defined problem spaces, those of the SPM and CRT, respectively (Jaarsveld et al., 2010). For analyzing the performance on both tasks, we developed a scoring method based on a typology of the number and complexity of the relationships in evidence in the $3 \times 3$ matrices that feature in these tests. In a second study (Jaarsveld et al., 2012) we developed for the CRT two sub-scores: Relations, which reflects convergent production in ill defined problem spaces, and Components and Specifications, which reflects divergent production. We compared across grade levels, firstly, the CRT sub-scores of Relations with scores of the SPM and the CRT sub-scores of Components and Specifications with scores on the TCT-DP. Secondly, we analyzed the complexity in matrices solved in the SPM with created in the CRT. This analysis would allow us to observe whether more advanced pupils have a higher developed ability to process complex information (Halford, 1993).

## Method

Participants Children of the first study were from Nursery and Elementary Schools ranging from four to twelve years old ( $N_{l}=511$ ), $52 \%$ girls Mean age per grade in years: Younger Nursery school children ( $M=4.64, N=33$ ), Older Nursery school children ( $M=5.68, N=31$ ), Elementary school Grade 1 ( $M=6.73, N=41$ ), Grade $2(M=7.79, N=$
42), Grade 3 ( $M=8.81, N=59$ ), Grade $4(M=9.80, N=$ 132), Grade $5(M=10.87, N=91)$, Grade $6(M=11.91, N=$ 82). In the second study we only had children from Elementary School ranging from six to ten years old ( $N_{2}=$ 205), $50 \%$ girls. Mean age per grade in years: Grade 1 ( $M=$ $7.06, N=51$ ), Grade $2(M=8.16, N=43)$, Grade 3 ( $M=$ 9.07, $N=51$ ), Grade 4 ( $M=10.05, N=60$ ). Age limits within grades for both studies were not absolute, but the average age increased with 1 year per grade.

Material The SPM is contained in a booklet, which displays one incomplete matrix per page, together with a multiple choice of completion alternatives. Participants had to infer relations between given components and choose the completing figure from among the alternatives given below the matrix (Figure 1). A separate answering sheet is offered, on which individuals mark the number of the alternative they consider to be the proper completion. The CRT asks participants to create an SPM-like item. The instruction was to make the item as difficult as you possibly can such that it will be a hard puzzle for others to solve. On an empty form reflecting the format of the SPM items (Figure 1) participants had to create components and relations, and to draw the completing figure in one of the cells in the lower part of the response form. The TCT-DP asks participants to complete a drawing on a form containing five simple components within a frame and a sixth one outside the frame. The instruction conveyed that one could do nothing wrong and draw as one liked.

Design and procedure Children first performed the solving test (50 minutes). Nursery School children and those up to Grade 3 performed the Coloured Progressive Matrices test (CPM; Raven, 1956/1976) which is designed to assess the cognitive abilities of young children. Older children performed on the SPM. Consecutively, in both studies all were asked to create a matrix in the CRT ( 15 minutes). Finally, the children of the $2^{\text {nd }}$ Study performed the Test of Creative Thinking (10 min). Nursery school children performed the tasks individually; group testing was applied for the classes of the Elementary School.

Analysis The scores of the CPM and SPM equaled the number of items solved correctly. Scores of the CPM were converted to SPM scores according to the scale provided by Raven, Raven, and Court (1998), in order to enable direct comparisons between grade levels. The score of the TCTDP was a summation of grade points (range 0-6) for each of the 14 sub-scores: Continuation, Completion, Connections Made with a Line, Connections Made to Produce a Theme, Figure-based Boundary Transgression, Figure-independent Boundary Transgression, Perspective, Humor and Affectivity, Unconventionality-a: any manipulation of the material; Unconventionality- $b$ : any surrealistic, fictitious and/or abstract elements or drawings; Unconventionality-c: any usage of symbols or signs; Unconventionality-d: unconventional use of given fragments; Speed: drawings
that are made within a certain time limit and show a score above a certain value score extra points. The score of the CRT consisted of the sub-scores Relations and Components and Specifications. Relations scores the logical complexity of relations in complete and incomplete matrices. Relations are typically transformations from one component of the matrix to another. We identified a total of twelve relations. Three for the CPM: Four Identical Components; Continuous Pattern; and Symmetry. One for the SPM: Indication of Mathematical Operation. Three for the CRT: Idiosyncratic and Semantic Coherence; Indication of Form, Texture, Amount or Orientation; and Groups of Three Components. An additional five for the SPM were taken and partly modified from Carpenter, Just, and Shell (1990): Change; Increase and Decrease; Combination; Succession; and Disappear and Remain. We analyzed the matrices of CPM, SPM, and CRT for the relations they contained. Scoring of a relation created in the CRT is done in several steps. First, we listed the relations that apply to the item and for each relation marked the components it covered. Next, for each relation we assigned an index value $i=1,2, \ldots$ to all first appearances of the marked components, starting from the top-left cell of the item, proceeding from left to right through each row from top to bottom. Third, passing through the matrix in the same order as previous, we accumulate a score, in which the first encounter of a component is scored with a value identical to its index; each next time we encounter a component again, we assign the same score as previously, incremented with 1 when it occurs in a row different from where it has previously been encountered, and with another 1 when it occurs in a column in which it has not previously been encountered. The resulting score is the sum total of all values assigned to components of the matrix. The sub-score Components scores the number of different components and the subscore Specifications scores the occurrence of different pictorial specifications (textures and line styles) and transformational specifications (size, orientation, number, and location). These specifications were scored when they did not express a relation. The categories Non Figurative and Figurative indicated matrices which featured components of a geometrical and a figurative character, respectively.

## Results

First, we present results of interrater reliability of the CRT for type and complexity of relations. Next, we present the correlations between test scores reflecting three types of cognitive processes; one which mainly features convergent thinking (CPM and SPM), one which mainly features divergent thinking (TCT-DP), and one in which both types of thinking play a role (CRT). Thirdly, we present to what extent Relations in the items created in the CRT reflected those featured and solved in the CPM and SPM. Finally, we present results of the increasing complexity of matrices created, according to number of relations applied within the matrix.

Interrater reliability Subsets of items of the CRT were scored independently by different raters and interrater reliability was calculated with Cohen's Kappa, $K$, for type of relations and with Pearson correlations, $r$, for the CRT sub-scores. Results ranged from $K=.93$ in the first study ( $n$ = 95), to $K=.94$ in the second study ( $n=69$ ), and from $r=$ .99, $p<.01$ for sub-score Relations, to $r=.91, p<.01$ (both 2-tailed) for sub-score Components and Specifications.

Test Scores Results of test scores between SPM and CRT over all grade levels did not show a significant correlation. They did show a correlation in some grade levels; in the first study in Grades 3 and 6, and in the second study in Grade 1. In the second study, as expected, the CRT sub-score Relations, which according to our theory represents convergent thinking, showed a correlation with the SPM ( $r$ $=.192, p<.01$; partial correlation corrected for TCT-DP: $r$ $=.213, p<.01$ ). The CRT sub-score Components and Specifications, which according to our theory represents divergent thinking, showed a correlation with the TCT-DP ( $r=.147, p<.05$; partial correlation corrected for SPM: .153, $p<.05$ ). Furthermore, scores of SPM and TCT-DP showed a correlation, $r=.225, p<.05$, but, as expected from the assumption that in the CRT the sub-scores represent different thinking abilities, no correlation was found between the CRT sub-scores Relations and Components and Specifications, $r=.016, p=.823$.
Moreover, as expected, there were no correlations between Relations and TCT-DP, and between Components and Specifications and SPM. The latter results hold also for partial correlation analyses. From this we may infer that convergent and divergent thinking play a role in the Creative Reasoning Task and that both can be scored on one end product.

Relations Featured, Solved, and Created in the CPM Condition Frequencies of relations solved and created showed that Young Nursery School children (age in years $M$ $=4.64)$ solved three of the four relations presented but generated a different relation, Relation 1, Idiosyncratic Coherence. Older Nursery School children (age in years $M$ $=5.68$ ) preferred an additional relation, Relation 3, Continuous Pattern. This focus shifts at Grade 1 (age in years $M=6.73$ ) to Relation 2, Four Identical Components and at Grade 2 and 3 (age in years $M=7.79$ and $M=8.81$, respectively) to Continuous Pattern. The dominance of Idiosyncratic Coherence, shows that creative reasoning in the youngest children is dominated by rules that are not deducible logically and clearly arise from an individual interpretation.

Relations Featured, Solved, and Created in the SPM Condition Relation 3, Continuous Pattern is the most frequently created relation by children of the higher grades (Grade 4, age in years $M=9.80$ to Grade $6, M=11.91$ ). Deleting a piece in an overall pattern, whether figurative or non figurative, may be the first abstract relation that plays a
role in generative problem solving. The results of the chisquare tests for independence over the frequencies of relations solved and created in both conditions were significant, p-values smaller than .05 to .001 . In the second study we observed identical results.

Components Results of chi-square tests of Components and Specifications in CPM and SPM condition followed those for Relations. Figurative components were generated by children in both studies although the solving test does not feature these types of components. In the first study the percentage of children who applied figurative components decreased significantly with grade level, $r_{s}=-.671, n=8, p$ <.05, one tailed ( $r_{s}$ Spearman Rank correlation).

Relations in the SPM and created in the CRT as a function of school grade Second study: we observed that only one relation, Combination, showed an increase with grade in both SPM and CRT. Other relations showed either, a decrease in SPM in combination with an increase in CRT, for instance Pattern Completion; an increase in SPM was observed for the relations Change and Succession; a decrease in SPM was observed for the relation Increase and Decrease; a decrease in CRT was observed for the relations Idiosyncratic Coherence, Four Identical Components, and Symmetry. (Spearman Rank correlations of frequencies over grade, $p<.05$ ). For both studies we concluded that SPM and CRT did not show the same trends with grade in the frequency of occurrence of different relations.

Number of Relations Applied per Item Complexity in the SPM matrices as measured by number of relations increased over the series of SPM items, $r_{s}=.900, n=5, p<.05$. We found a corresponding increase in complexity over grade levels in matrices created in the CRT in the first study, $r_{s}=$ $.964, n=8, p<.01$. Components increasingly show variety in number, in size and orientation. In the second study increases in complexity failed to reach significance due to lack of power, $r_{s}=.258, n=4, p=.371$.

## Conclusions and Discussion

We compared across grade levels the performance on the Creative Reasoning Task (CRT), with that on the Progressive Matrices test (CPM and SPM), and the Test of Creative Thinking-Drawing Production (TCT-DP). We used the CRT to measure convergent and divergent thinking, which we consider to play an integrated role in ill defined problem spaces. CRT and SPM operated on the same problem domain; nevertheless, operations used in both tasks differed as a function of the differences in problem spaces. Whereas the SPM uses convergent operations, both divergent and convergent operations are needed for the CRT. The absence of correlations across school grades, therefore, implies that in creative processes as tested by the CRT, convergent and divergent operations do not occur as additive process components, but play an integrated role throughout the process (Jaarsveld \& van Leeuwen, 2005.

Correspondence In addition to contrasts between the tests, similarities were observed in development. Across school grades, we observed increasing complexity in problem solving and problem creation. In the SPM we observed an increase over series of items combining several rules. In the CRT there is a parallel increase in the number of relations applied per item created. Children in more advanced grades also used more components, with an increasingly rich variety of specifications.

Differences Although relations applied in the creating task often featured in the solving task, almost within all grades performance on both tasks was uncorrelated; in the CRT grades were characterized by a preference for specific types of relations. Another difference between both tasks was the absence of concordant increases or decreases over age levels in the application of certain types of relations. Combination was the only one of 12 relations that showed an increase in both tasks. Finally, in creating, figurative components were more persistently preferred, despite the non figurative character of CPM and SPM items. Participants preferred to introduce rules and other elements from their individual episodic/semantic knowledge domains, as opposed to what they encountered in the problem solving task. This difference cannot be understood as a discrepancy in knowledge domain. Creative problem solving, therefore, does not depend entirely upon classical problem solving skills.

Cognitive Development Perspectives Even though the material of the SPM is non figurative, relations created in the CRT tend to be expressed in figurative mode. SingerFreeman and Goswami (2001) observed that three to four year old children understand proportional equivalence, even when the materials (pizza and chocolates) to be matched are not isomorphic. Young children, therefore, do not solve analogy problems on the basis of relational similarities but on the basis of associations (Piaget, Montangero, \& Billeter, 1977). Young children in solving CPM items have the opportunity to learn that matrix components belong together according to certain relationships. They proceeded in the CRT to arrange components according to different, selfdefined relationships.
Whereas children were able to solve most relationships, per grade one type of relation was predominantly applied in the CRT. Zelazo, Frye, and Rapus (1996) observed that knowing a rule in the card sorting task does not imply that it will be used correctly after a new sorting rule has been introduced. These authors observed a change in the ability to switch to a new rule between the age of three and five years old and explained this among others, in terms of the implicitness of rule representation. It could be that representations formed in a well-defined problem space are not understood at a sufficiently explicit level to be carried over to an ill-defined space.
The observed shifts with grade level in rules preferably applied in the CRT seem to correspond to Piaget's
developmental stages. According to Piaget, children between the ages of four and seven years old are in the intuitive thought phase, which is a sub-phase of the preoperational phase. In this phase children develop Conservation (the awareness that altering the state of a substance, does not change it's properties) and Centration (the focusing on one characteristic). In our study these children applied relationships of the types: Idiosyncratic Coherence and Four Identical Components. These are relationships that mostly feature one characteristic.
Piaget considered children between seven and eleven years old to be in the concrete operational phase. In this phase children's ability to think abstractly develops and they learn to understand the concept of reversibility. In our study these children predominantly applied variations of the relationship Continuous Pattern, a relationship which does not require abstract thinking. Deleting a piece from an overall pattern, as application of this rule requires, might be the first abstract operation in this phase.
Although creative productions, therefore, seem to follow Piagetian stages, two observations need to be made: First, despite these overall restrictions, children applied more complex relationships in small frequencies, in the CRT. Second, the contrast between rules used in solving SPM items and those applied in the CRT is not a matter of decalage. Piagetian stages are in evidence in the CRT, but not in the SPM. They are not reflected in classical problem solving but in creative reasoning, which characteristically requires the integration of divergent and convergent reasoning.

Limitations of the CRT The CRT is still in an early stage of development. In its current form, there are several issues that restrict its practical utility. Before the CRT can be administered the SPM has to be completed. This task serves, amongst other things, to make participants acquainted with the particular structure of the matrices problems. Without this phase we would have needed extensive instructions, which renders the task more algorithmic and, therefore, might decrease creative production (Amabile, 1987). To have a solving task precede a generation task is consistent with the general observation that nothing is invented from scratch; creativity implies using old elements in new contexts and seeing relations that no one saw before (Barron, 1981; Boden, 1990; Indurkhya, 1992; Torrance, 1987). Familiarity with the relevant domain and experience with a variety of methods are a prerequisite for generating solutions (Voss \& Post, 1988). For the current study, SPM data were needed anyway. If one is interested only in CRT performance, however, future developments of the test should include a certain number of matrices, specifically constructed to contain the same relations that feature in the SPM. These new matrices, then, are expected to provide participants with an identical solving experience as in the SPM. Moreover, the current CRT asks participants to generate one item only. This was done in order to tap individual abilities at the moment where they had reached
the maximum level of apprehension according to SPM. However, children may not achieve to their maximum abilities in this single item. For this reason, we are currently investigating the effect of including multiple CRT items in the task.

With the Creative Reasoning Task, we were able to answer the question whether individuals who have just solved SPM items in which certain transformations featured, apply these same transformations when they design a new matrix. We found that relations featuring in the solving task differed from those applied in the problem creating task. It was concluded that creative reasoning, as measured by the CRT, does not reflect SPM solving ability, and that both cognitive abilities develop rather independently from each other from Kindergarten to Secondary school.

#### Abstract

We develop and implement a new approach to utilizing color information for object and scene recognition that is inspired by the characteristics of color- and object-selective neurons in the high-level inferotemporal cortex of the primate visual system. In our hierarchical model, we introduce a new dictionary of features representing visual information as quantized color blobs that preserve coarse, relative spatial information. We run this model on several datasets such as Caltech101, Outdoor Scenes and Underwater Images. The combination of our color features with (grayscale) shape features leads to significant increases in performance over shape or color features alone. Using our model, performance is significantly higher than using color naively, i.e. concatenating the channels of various color spaces. This indicates that usage of color information per se is not enough to produce good performance, and that it is specifically our biologically-inspired approach to color that results in significant improvement.

Keywords: Visual recognition; Color; HMAX; Biologically inspired; Visual cortex; Image classification

## Introduction

Many models are inspired by the hierarchical organization of the visual cortex, such as Fukushima (1980) and Riesenhuber and Poggio (1999). Most of these models focus on grayscale information and ignore color information. While the broad use of color information in the primate visual system is well-known, the details are still under active investigation (Conway et al., 2010). Nonetheless, in this paper, we attempt to utilize what is currently known about the use of color to enhance object and scene recognition by computer algorithms. In this paper we utilize the HMAX model (Riesenhuber \& Poggio, 1999), but this approach can be extended to other computational models.

In our experiments, we use the HMAX model (Riesenhuber \& Poggio, 1999) in concatenation with our color model in order to evaluate the use of both shape and color. HMAX is a biologically-inspired model which focuses on the shape processing capabilities of the ventral visual pathway, and has been used to perform classification tasks (Serre, Wolf, Bileschi, Riesenhuber, \& Poggio, 2007).

We focus on extending the model by modelling the highlevel usage of color by incorporating insights from cognitive psychology and neuroscience. The broad intuitive inspiration for our model follows from the fact that colors are recognized categorically just as object classes are, even though color
discrimination and matching is continuous (Palmer, 1999). Interestingly, people of different races (Boynton \& Olson, 1987), as well as chimpanzees (Matuzawa, 1985), organize colors into the same basic color categories, such as red, blue, yellow, green.

More importantly for object and scene recognition, the categorical recognition of color suggests that, if color information is incorporated into object and scene classification, then fine-grained color information (e.g. precisely specified hue) may not be necessary. For example, a beach scene might be recognized from the blue (sky and sea) and brown (sand) regions. It may not be important exactly how blue the sky/sea or how brown the sand grains are. In fact, it may be important to disregard such details in order to perform classification that is tolerant to variations in lighting, and so on.

In addition, the coarse relative spatial position of such color regions may be important. A blue region above a yellowbrown region might suggest a beach scene. If the relative positions are reversed, then the image is probably not a beach scene (or might be an upside-down one). Not only is the detailed spatial information unnecessary, it may be crucial to discard it and only retain coarse spatial information, since the exact spatial relations will depend on factors such as the precise shape of the beach and the camera angle.

Overall, our model can be loosely described as performing object and scene classification by reducing a given image to a "coarse arrangement of categorical color blobs", similar to the idea of spatial aggregation of visual keywords (Lim, 1999), but with realization on the HMAX model. This is different from approaches that utilize color information in a low-level fashion, although the two types of approaches are not mutually exclusive. Crucially, our biologically-inspired approach outperforms the naive use of color, where an image is decomposed into separate color channels that are processed independently until the final classifier stage.

## Related Work

First, we go beyond the intuitive motivation for our approach and review the biological evidence that the primate visual system utilizes color information in a manner that is broadly consistent with our model. Specifically, we review studies of color processing in the high-level visual area of the primate
brain known as infero-temporal cortex (IT), which is commonly associated with invariant object recognition.

In the broadest terms, IT is known to play an important role in color discrimination. A majority of IT neurons are color-selective (Desimone, Schein, Moran, \& Ungerleider, 1985) and two independent studies estimated this proportion to be roughly $70 \%$ (Komatsu, Ideura, Kaji, \& Yamane, 1992; Edwards, Xiao, Keysers, Földiák, \& Perrett, 2003). Contrary to the theory that color processing occurs after more rapid luminance-only processing, no evidence was found that colored images evoke responses that are delayed relative to achromatic images (Edwards et al., 2003). More direct evidence for the role of IT comes from findings that color discrimination is severely disrupted by lesions (Heywood, Shields, \& Cowey, 1988) or cooling (Horel, 1994).

Color-selective neurons in IT are found in clusters, suggesting that they may form a segregated and independent processing network (Conway, Moeller, \& Tsao, 2007). As further evidence of this, one color cluster in IT received projections from a color cluster from another part of IT, suggesting that these clusters of color-processing neurons form reciprocally-connected modules within a distributed network (Banno, Ichinohe, Rockland, \& Komatsu, 2011).

IT neurons are selective for both hue and saturation (Komatsu, 1993). Different cells have different preferred hues, and as a population, the cells' preferred color spans most of the color space (Conway et al., 2007). The colors for which IT neurons are selective for tend to correspond to the basic color names (Komatsu, 1998). Komatsu (1998) proposed that IT has templates corresponding to color categories and may be involved in determining color category by finding the best match over these categories. More recently, the distribution of color-selective neurons found in IT seems to correspond to the three to four most basic colors (Stoughton \& Conway, 2008). The largest peaks align with red, green, and blue, in order of size of peak, with a smaller peak corresponding to yellow. These peaks roughly correspond to colors perceived by humans. Prior to this, neural representation of such unique hues (Hurvich, 1981) had not been found (Valberg, 2001). Note that in the low-level primary visual cortex, the axes defined by cone opponency should more accurately be denoted bluish-red/cyan and lavender/lime opponency (Stoughton \& Conway, 2008), rather than red-green and blue-yellow opponency.

Finally, the region of IT where color-selective neurons are found is coarsely retinotopic (Yasuda, Banno, \& Komatsu, 2010), meaning that spatial information is maintained in a coarse manner, rather than completely discarded or maintained with high fidelity. Overall, these studies are broadly consistent with our proposed "coarse arrangement of categorical color blobs" model of high-level color processing in the primate visual system.

In contrast, most computer vision algorithms utilize color information in a relatively low-level manner. The simplest color extension of a non-color algorithm would be to ap-
ply it independently to the $\mathrm{R}, \mathrm{G}$ and B channels, and then concatenate the features from all 3 channels just before the final classifier stage. Most algorithms are variants of this basic idea, either using some other color space, or fusing the channels before the classifier stage (usually at the dictionary or keyword learning stage). For example, SIFT features can be computed separately for each channel in HSV color space (Bosch, Zisserman, \& Muñoz, 2008), while Brown and Susstrunk (2011) do this for RGB space, along with an NIR (near infra-red) channel. Besides SIFT features, other algorithms use (non-orientation based) histograms in the HSV (Tang, Miller, Singh, \& Abbeel, 2012), Gaussian opponent color (Burghouts \& Geusebroek, 2009), normalized RGB or opponent color spaces (Gevers \& Stokman, 2004). What these algorithms have in common is that in terms of the biology of color vision, they correspond to at most the level of color-opponent cells in the primary visual cortex, the lowest level in the hierarchically-organized visual cortex.

## CQ-HMAX

In this section, we describe our new biologically-inspired model, CQ-HMAX (Color Quantization Hierarchical Max), which uses color information in a hierarchical organization of simple and complex cells. HMAX is a hierarchical model which uses Gabor filters to find simple and complex shapes in the images. Our model has a similar hierarchical structure. However, we use color quantization cores and not Gabor filters, hence our model encodes color information. When combined with HMAX, the overall model includes both color and shape information.

Our color model has a hierarchical structure of simple and complex cells, as can be seen in Fig. 1. We first introduce the model briefly, followed by a more detailed description of each layer. An image pyramid is created in YIQ color space. The $Y$ channel represents luminance information, while the $I$ and $Q$ channels represent chrominance information. The pyramid has 10 scales, with each neighboring scale different by a ratio of $1 /\left(2^{1 / 4}\right)$. In order to evaluate the use of color information in our model, we determined that the YIQ color space produced the best results in comparison with HSV and RGB color spaces. A set of representative values from each color channel is selected as color cores and used to find the best matching unit to each individual pixel value in the pyramid. The $S 1$ layer is created on 10 scales indicating the index of the best matching YIQ core to each pixel in the image pyramids. At the $C 1$ layer, a local max pooling is computed over $\pm 10 \%$ spatial neighborhoods of approximately $6 \times 6$ on $\pm 1$ neighbor scales to find the most frequent color core in each neighborhood. A dictionary of features is sampled randomly from the $C 1$ layer of images. The distance of each dictionary feature to all patches in a neighborhood of that dictionary feature is calculated to create the $S 2$ layer and the best response to each dictionary feature in each image is chosen as the $C 2$ layer to be fed to the SVM layer for classification. We describe each layer in more detail below.

Figure 1: The CQ-HMAX model and the processing of an example beach image.

## $S 1$ Layer and Quantization Cores

The input images are first converted into YIQ color space and a pyramid of 10 scales with a ratio of $2^{1 / 4}$ is created, with the first scale having the shorter side set to 140 pixels, maintaining the aspect ratio of the original image. This image pyramid is then used as the input to the $S 1$ layer. A series of YIQ quantized "color cores" over YIQ channels are created to be used as filters for this layer. We experimented with different numbers of quantization values per color channel, and chose 5 per channel as the optimal number (which results in $5 \times 5 \times 5=125$ cores). In order to choose the optimal cores, 500 images were randomly selected and the color range of these images in YIQ color space was calculated after normalization to the range $[0,1]$. The values of YIQ channel are mostly in the range $[0,1],[0.4,0.7]$ and $[0.4,0.6]$ respectively. These ranges were selected and divided into 5 bins. The quantized values of $Y, I$ and $Q$ after normalization to $[0,1]$ were therefore chosen as follows: $Y=(0,0.25,0.5,0.75,1)$,
$I=(0.4,0.47,0.55,0.63,0.7), Q=(0.4,0.47,0.5,0.53,0.6)$. Using these values results in better classification performance than using the full range $[0,1]$ in each YIQ channel. The outputs at the $S 1$ layer are the index values (i.e. $1,2, \ldots, 125$ ) of the best-matching color core for each element in the image pyramid.

## C1 Layer

The $C 1$ layer provides local invariance to position and scale as it pools nearby $S 1$ units, and as a result, subsamples $S 1$ to reduce the number of units. The $S 1$ pyramid is convolved with a $3 D$ max filter to set the $C 1$ layer size of the bottom of the pyramid to $25 \times 25$ and the highest layer of the pyramid to $5 \times 5$ accordingly. The max is calculated over $\pm 10 \%$ spatial neighborhood on $\pm 1$ neighbor scales in the middle of the pyramid and -2 on the highest level and +2 on the lowest layer of the pyramid (hence it is called a $3 D$ max, as it takes the max over $2 D$ spatial distribution and over $\pm 1$ scale).

This layer provides a model for $V 1$ complex cells. Fig. 1 also shows an example image of $S 1$ and $C 1$ layer. $S 1$ and $C 1$ layers have a distribution of quantization cores from coarse to fine. The higher layers of the $S 1$ pyramid are taken from smaller scales of the images in the input pyramid and respectively the higher levels of $C 1$ layer are computed by taking a $3 D$ max over higher levels of $S 1$ layer. As can be seen in Fig. 1, the higher levels of the pyramid in the $S 1$ and $C 1$ layers represent less detailed information from the image. All levels in the $C 1$ intermediate layer are used for sampling a dictionary of features.

## Dictionary of Features and Distance Table

Once the $C 1$ layer is created, sampling is performed by centering patches of size $4 \times 4$ at random positions and scales using a normalized random number generator function. A distance table is created to store the actual weighted Euclidean distances of the indices from YIQ quantization cores. Since the values of the $Y$ channel are normally distributed between $[0,1]$, but the values of $I$ and $Q$ channels fall in the approximate range of $[-0.6,+0.6]$ and $[-0.5,+0.5]$ respectively, and as in most of the images the actual values of these two latter channels fall between $[-0.1,+0.2]$ and $[-0.1,+0.1]$ (before normalization to $[0,1]$ ) we weighed the distances to have an equal effect in the distance calculation. The distance table weights are calculated as:

$$
\text { DistanceTable }(i, j)=\sqrt{D(1)+\gamma D(2)+\beta D(3)}
$$

$$
\begin{equation*}
\text { Where } D(k)=(Y \operatorname{IQCore}(i, k)-Y \operatorname{IQCore}(j, k))^{2} \tag{1}
\end{equation*}
$$

with $\gamma=3.3$ and $\beta=5$. In Jalali, Lim, Ong, and Tham (2010) and Jalali, Lim, Tham, and Ong (2012) various clustering methods in the creation of the dictionary of features were implemented and it is shown that by use of random sampling in HMAX model, relatively good results can be achieved with a lower computational cost in comparison with clustering of features.

## $S 2$ Layer

Once the dictionary of features and the distance table are created, each entry in the dictionary of features is used as a filter to be convolved on $C 1$ patches of size $4 \times 4$ on the neighbor scales of the dictionary feature in the pyramid. The responses $V(d, p)$ of each dictionary feature, $d$ to all of the neighbor patches of the same size in $\pm 1$ scale and $\pm 10 \%$ in position, $p$ are calculated using a Euclidean distance equation as:

$$
\begin{equation*}
V(d, p)=\exp \left(-\frac{\|d-p\|^{2}}{2 \sigma^{2} \alpha}\right) \tag{2}
\end{equation*}
$$

where $d$ is a feature in the dictionary and $p$ is a patch in the image $C 1$ pyramid. $\sigma$ and $\alpha$ are set to 0.5 and 1 respectively as in Mutch, Knoblich, and Poggio (2010).

## $C 2$ Layer

Once the $S 2$ layer is generated, the maximum values for each patch in the dictionary are taken as the $C 2$ output. This layer
outputs a vector of the same size as the dictionary of features. We chose different sizes for the dictionary of features and in most cases a dictionary of size 10000 was chosen which results in slightly better performances than smaller sizes of about 1000 dimensions.

## Classification Layer

The $C 2$ vectors are classified using a multi-class one-versusrest linear kernel support vector machine. The algorithm used to train the classifier is weighted regularized least-squares after the data is sphered and the mean and variance of each dimension are normalized to zero and one respectively as in Mutch and Lowe (2008).

## Use of HMAX for Encoding Shape Information

For shape information, we used the HMAX model implementation of Mutch and Lowe (2008). In HMAX, the maximum response of the $S 2$ layer is chosen as the $C 2$ layer to be fed to the classifier. An $N$-dimensional vector is calculated as the output of the $C 2$ layer, where each element is the maximum response (everywhere in the image in Serre, Oliva, and Poggio (2007) and in a spatial neighborhood of each dictionary feature in Mutch and Lowe (2008)) over image patches for each dictionary feature where $N$ is the number of features in the dictionary.

Let $V_{i}^{j}$ be the response of the image patch $p_{i}$ to the dictionary feature $d_{j}$ calculated using Eq. 2. The response of the $C 2$ layer is calculated as:

$$
\begin{array}{r}
C 2(j)=\max \left(V_{i}^{j}\right) \text { for } \forall i \in M \\
\text { for } j=1, \ldots, N \tag{3}
\end{array}
$$

where $M$ is the number of valid patches in each image and $N$ is the size of the dictionary of features. This is consistent with the recent HMAX models (Mutch \& Lowe, 2008; Serre, Oliva, \& Poggio, 2007; Jalali et al., 2010; Theriault, Thome, \& Cord, 2011).

## Experimental Results

First we examine the naive use of color by computing various color spaces (RGB, HSV, YIQ) on the Caltech101 dataset (Fei-Fei, Fergus, \& Perona, 2004) and compare the results with grayscale images. The Caltech 101 dataset, includes 101 classes of objects plus a background category. Each class contains between 31 to 800 color images of different sizes. The size of each image is approximately $300 \times 200$ pixels on average. We used 30 randomly chosen images for training from each class and the rest of the images were used in the test phase. We first divide the images into three channels and feed them to the unmodified HMAX (Mutch \& Lowe, 2008) directly and evaluate the classification performance.

As can be seen in Table 1, the use of three different channels and concatenating the $C 2$ vectors of all channels to the SVM provides only marginal improvement. Since the YIQ color space gives the best overall results, we use this color space in our color model. In the rest of this section, we

| Color Component | Caltech101 | Scenes |
| :--- | :--- | :--- |
| Y channel (i.e. gray scale) | 54.65 | 71.48 |
| I channel | 35.20 | 54.62 |
| Q channel | 26.86 | 50.75 |
| YIQ channels concatenated | 55.06 | 72.66 |
| RGB channels concatenated | 26.53 | 73.81 |
| HSV channels concatenated | 31.32 | 73.69 |

Table 1: Results (percentage accuracy) for the naive use of various color channels and color spaces.
evaluated our model on three datasets: Caltech101, Outdoor Scenes and Underwater Images.

## Caltech101 Dataset

The results of using CQ-HMAX on Caltech 101 are shown in Table 2. All experiments are performed 8 times on random splits of training and test sets and the average performance is reported. As can be seen, the use of our color model in this dataset does not outperform HMAX. However, when the $C 2$ features of the color model are concatenated with $C 2$ features of HMAX, the classification results are improved by more than $6 \%$ over HMAX alone. HMAX is a computationally expensive model as Gabor filter responses over different orientations in $S 1$ layer are calculated. However, CQ-HMAX is relatively faster than HMAX as it performs a quantization with 125 cores in the $S 1$ layer instead of Gabor filters.

| Model | Caltech101 | Scenes | UWI |
| :--- | :--- | :--- | :--- |
| HMAX (i.e. shape) | 54.65 | 71.48 | 92.93 |
| CQ-HMAX (i.e. color) | 38.11 | 69.21 | 94.03 |
| CQ-HMAX + HMAX | $\mathbf{6 1 . 0 9}$ | $\mathbf{7 8 . 9 7}$ | $\mathbf{9 6 . 2 3}$ |

Table 2: Results (percentage accuracy) on the Caltech101, Outdoor Scenes and Underwater Images (UWI) datasets.

## Outdoor Scenes Dataset

This dataset contains 8 outdoor scene categories: coast, mountain, forest, open country, street, inside city, tall buildings and highways (Oliva \& Torralba, 2001). There are 2600 color images of size $256 \times 256$ pixels. We used 100 random images per category for training and the rest ( 236 on average) for testing. As can be seen in Table 2, the combination of shape and color significantly improves performance.

## Underwater Images Dataset

We also evaluated CQ-HMAX on the Underwater Images dataset (Jalali, Tan, Lim, Tham, Ong, Seekings, \& Taylor, 2013). This dataset is made of 1664 images of around 740 x 420 pixels from 13 different categories. We used 30 randomly selected images per category for training and the rest for testing. These underwater images contain small objects of various shapes and color against a varied seabed background. The main challenge with these images is in light absorption by the water, and the existence of particles that limit visibility and result in scattering and reflection of light. In this experiment, we created a set of images using both grayscale and color cameras and compared the performance of CQ-HMAX
on color images and HMAX on grayscale images. As seen in Table 2, the classification accuracy increases when color and shape information are combined.

## Conclusions

In this paper, we introduced a new biologically-inspired approach to image classification which uses color in a manner consistent with high-level visual cortex processing by incorporating insights from cognitive psychology and neuroscience. We ran this model on several datasets such as Caltech101, Outdoor Scenes and Underwater Images. The combination of our color features with (grayscale) shape features led to significant increases in performance over shape or color features alone. Using our model, performance is significantly higher than using color naively, i.e. concatenating the channels of various color spaces.

Currently, our model quantizes the YIQ color space into cubed-shaped "color cores" at the $S 1$ layer. Following the work of Shahbaz Khan et al. (2012) and Van De Weijer and Schmid (2006), learning the color values that correspond to semantic color names such as "orange", "brown", could also further improve performance. Alternatively, color cores can be learnt through unsupervised clustering, in which more frequent colors in each dataset are chosen as color cores.

Our model emulates color processing in the high-level IT cortex. Interestingly, the combination of our features with those of Zhang, Barhomi, and Serre (2012) - a biologicallyinspired model that emulates the lower-level cortex - results in classification performance as good (or better) than the state-of-the-art on several benchmark datasets (Jalali, Tan, Lim, Tham, \& Ong, 2013).

#### Abstract

We introduce a method for encoding co-occurrence of features in the HMAX model of visual recognition, and conduct a series of experiments to investigate the contribution of co-occurrence towards better recognition performance. We show that classification accuracy is increased by adding a higher-order layer to the HMAX processing hierarchy, whereby co-occurrence of features is encoded as a new dictionary of features. We show that concatenation of mean pooling, max pooling and co-occurrence information results in better classification results on three datasets (Caltech101, a subset of Caltech256, and TMSI Underwater Images). Overall, we show that incorporating co-occurrence statistics into a biologically-inspired model of visual recognition provides a boost in classification performance above that produced by incorporating occurrence statistics alone.

Keywords: computer vision; HMAX; biologically inspired; co-occurrence statistics; visual cortex; image classification.

## Introduction

Certain categories of visual stimuli can be characterized by the co-occurrence of multiple features. For example, images of cars frequently contain wheels, doors and windows. These co-occurring features do not occur in rigid configurations. Even for a rigid object, 3D rotations can result in inter-feature distances changing when projected as 2D images. However, co-occurring features are generally found close to each other. Using faces as an example, the exact distances between facial features (e.g. eyes, nose, mouth) vary from person to person, but these features are always relatively near to each other.

Can this particular property be exploited to achieve better visual recognition performance? This question cannot be cleanly answered through behavioral experiments unless brain cells encoding co-occurrence can somehow be "turned off"; computational modeling may be a better approach. In this paper, as a proof-of-concept, we modify the biologicallyinspired HMAX model of visual recognition (Riesenhuber \& Poggio, 1999) to encode co-occurrence statistics that are learnt from a training set of images, and we show that recognition performance does indeed improve.

## Background

There is evidence for Max spatial pooling (finding the maximum among a set of inputs from a local spatial region) occurring at multiple levels in the visual system in the primary
visual cortex of cats (Finn \& Ferster, 2007; Lampl, Ferster, Poggio, \& Riesenhuber, 2004), as well as in the higher visual areas of monkeys, such as areas V4 (Gawne \& Martin, 2002) and IT (Sato, 1989). Importantly, however, each of these studies also showed evidence for "Average" pooling occurring, which can be interpreted as encoding the mean occurrence frequency of features.

Beyond just being tuned to the statistics of feature occurrences, there is strong evidence that the primate visual system is also tuned to co-occurrence statistics. This refers to either the joint or conditional probabilities of two (or more) features occurring together within images belonging to a certain object category or across categories. Since a "feature" is not always a precisely defined concept, how can the cooccurrence of two features be distinguished from the occurrence of a single feature that happens to be comprised of two simpler features? To make this distinction unambiguous, experiments were designed such that the elementary features are visually distinct, due to explicit segmentation, due to spatial separation, or from the task context. We term such features, which are the result of sensitivity to co-occurrence, as "cooccurrence features".

In some sense, mid-level features themselves can be considered as co-occurrence features, with their elementary features being simple orientation-sensitive filters (corresponding to orientation-sensitive neurons in the primary visual cortex). Since lines, curves and contours are ubiquitous in images, the presence of a short line segment of a certain orientation strongly predicts that the orientation of a neighboring line segment will be similar. This is particularly so if the relative position of that neighboring line segment is such that the two line segments have the possibility of being collinear.

Our focus here is on high-level features whose elementary features are more complex than simple oriented filters. These high-level features approach the level of semantic object parts or possibly even objects themselves. In the rest of this section, we will review the experimental evidence that the primate visual system develops sensitivity to such high-level co-occurrence features.

In the field known as visual statistical learning (VSL), it has clearly been shown that adult humans develop sensitivity to co-occurrence statistics in images (Fiser \& Aslin, 2001;

Aslin \& Newport, 2012). In a ground-breaking study by Fiser and Aslin (2002) it was shown that 9-month-old infants already developed sensitivity to visual co-occurrence statistics.

There is also an abundance of evidence from monkeys that their visual systems develop sensitivity to co-occurrence statistics. Miyashita (1988) and Sakai and Miyashita (1991), monkeys were trained to recognize pairs of stimuli, in a paradigm known as paired-associate learning. Neurons were found that were sensitive to such trained stimulus pairs, but not other stimulus pairs. The pairings were arbitrary, making the likelihood that such neurons had already possessed such sensitivity vanishingly small. More recently, Hirabayashi and Miyashita (2005) found that populations of IT neurons are sensitive to feature configuration within objects.

Direct evidence for sensitivity to co-occurrence (over and above sensitivity to occurrence) was found by Baker, Behrmann, and Olson (2002). Monkeys were trained to discriminate between objects that were each composed of two distinct parts linked by a line, forming "baton" objects. Compared to untrained objects, selectivity for trained objects was enhanced. This was for both the individual parts, as well as the combined "baton" objects. Crucially, selectivity for the two parts together (i.e. the whole object) was greater than the combined (summed) selectivity for each individual part.

Under what conditions does sensitivity to co-occurrence develop? In human adults, this is an implicit process that develops without awareness of the co-occurrence statistics, using a "cover task" or even through mere exposure (TurkBrowne, Jungé, \& Scholl, 2005; Turk-Browne, Scholl, Chun, \& Johnson, 2009; Aslin \& Newport, 2012). This is also true for human infants (Fiser \& Aslin, 2002; Aslin \& Newport, 2012). In monkeys, most work has been done using active task learning. This is so that the neural selectivity for trained objects can be compared to the control set of untrained objects. Since neural selectivity is enhanced for features that are diagnostic for active task learning (Sigala \& Logothetis, 2002), passive viewing may not be sufficient to produce selectivity that is large enough to be statistically significant when measured from electrode recordings.

How has sensitivity to co-occurrence been measured experimentally? The methods have generally been constrained by the nature of the subjects. Adult human subjects have generally been tested behaviorally, i.e. through their explicit responses (usually simple 'yes/no' tests). More recently, fMRI has been shown to be able to detect co-occurrence sensitivity (Turk-Browne et al., 2009). In human infants, due to their inability to understand or respond explicitly to verbal instruction, experiments have been constrained to using tests for novelty detection that are ubiquitous for infants. In monkeys, due to the ability to conduct invasive experiments that are not possible with humans, scientists have conducted electrophysiological experiments (i.e. using electrodes to record the responses of individual neurons). Such experiments allow for a detailed, "close-up" analysis of the effects of cooccurrence at the level of individual neurons e.g. Baker et al.
(2002); Sakai and Miyashita (1991). However, there are limitations, such as the presence of noise, limited recording time, and the ability to record from at most a few hundred neurons.

Beyond just "being sensitive" to co-occurrence statistics, what are the characteristics of such sensitivity? It is specific to spatial configuration, such as the relative position of the elementary features (Hirabayashi \& Miyashita, 2005). In addition, this sensitivity is reflected not in strength of neural responses per se, but rather in the selectivity for co-occurring features relative to non-co-occurring features (Baker et al., 2002).

One special case of sensitivity to co-occurrence of features is that of faces. The elementary features are semantic face parts such as the eyes, nose and mouth. It is very well-established that humans and monkeys are sensitive to the combination and relative configuration of face parts. Specifically, any change to the normal configuration of the face leads to reduced neural responses and poorer recognition accuracy. One manifestation of this is the Face Inversion Effect (FIE), whereby inverted faces are much more poorly recognized than upright faces (Yin, 1969). Faces with the parts in scrambled configurations are also poorly recognized. Furthermore, the sensitivity to co-occurrence seems to be unavoidable. In what is known as the Composite Face Effect, people are sensitive to the bottom halves of faces, even when they are explicitly instructed to ignore them during a discrimination task (Young, Hellawell, \& Hay, 1987).

Generally, such sensitivity requires normal visual experience during infancy in order to develop (Le Grand, Mondloch, Maurer, \& Brent, 2004). It also develops quickly, reaching adults levels (at least qualitatively) by age 4 (Heering, Houthuys, \& Rossion, 2007); this is consistent with the notion that passive exposure is sufficient for co-occurrence sensitivity to develop (see above). Evidence for sensitivity to co-occurrence for face parts has also been found at the level of single neurons. Freiwald, Tsao, and Livingstone (2009) found that in one of the brain regions that respond selectivity to faces, neurons on average responded to combinations of two to three face parts, rather than individual parts. Cooccurrences have been studied in a series of experiments such as Edelman, Yang, Hiles, and Intrator (2002).

Use of co-occurrences of features for creating more complex features in Fidler, Boben, and Leonardis (2008) shows an improvement in classification accuracy, and bag-of-features approaches show improvements in classification results using frequency of patches in the images in (Fei-Fei \& Perona, 2005). Co-occurrence information can be used to find partpart and part-whole relations of features of different receptive field sizes. If a feature is occurring too often in a class (and not likewise in other classes), it is more likely to be a discriminant feature in that class and if two features are cooccurring in a class often in a neighborhood, they may be part of a more complex feature and can have a part-part relationship and they might be more related to the object rather than the background (unless the background is also repetitive, e.g.
sky in airplane images). Also, if there exist features of different sizes and they co-occur in the same position on different scales they are likely to have a part-whole relationship.

## HMAX Model

The HMAX model (Riesenhuber \& Poggio, 1999) simulates the feed-forward path of the visual cortex. This model is used to find a good trade-off between invariance and selectivity. $S 1$ cells provide selectivity by responding to oriented filters and $C 1$ cells provide invariance by pooling over neighboring scales and positions. We use the HMAX model presented in Mutch and Lowe (2008) in the first three layers (S1, C1 and $S 2$ ). Here we have a brief review on this model and show our modifications to it.

In this implementation, an image is fed into the structure and 10 different scales of the image are created as inputs to $S 1$ layer. Gabor filters in 12 orientations are created as $S 1$ layer filters:

$$
\begin{equation*}
G(x, y)=\exp \left(-\frac{\left(X^{2}+\gamma^{2} Y^{2}\right)}{2 \sigma^{2}}\right) \cos \left(\frac{2 \pi}{\lambda} X\right) \tag{1}
\end{equation*}
$$

where $X=x \cos \theta-y \sin \theta$ and $Y=x \sin \theta+y \cos \theta$. The values of $x$ and $y$ vary between -5 and 5 , and $\theta$ varies between 0 and $\pi$. The parameters $\gamma$ (aspect ratio), $\sigma$ (effective width), and $\lambda$ (wavelength) are all taken from Serre, Wolf, and Poggio (2005) and are set to $0.3,4.5$, and 5.6 respectively.

A fixed size of Gabor filters is implemented on different scales of the images where the smaller edge of the biggest image is set to 140 pixels while maintaining the aspect ratio (the image pyramid of 10 scales created each layer by a factor of $2^{1 / 4}$ smaller than the last using bicubic interpolation). The response of a patch of pixels $X$ to a particular $S 1$ filter $G$ is given by:

$$
\begin{equation*}
R(x, y)=\left|\frac{\sum X_{i} G_{i}}{\sqrt{\sum X_{i}^{2}}}\right| \tag{2}
\end{equation*}
$$

These outputs are sent to the $C 1$ layer, which performs a local $3 D$ max operation on both scale $( \pm 1)$ and position $(3 \times 3$ neighborhood) of the filter responses. The output of this layer is a pyramid consisted of between 500-2000 different patches of size $4 \times 4,8 \times 8,12 \times 12$ and $16 \times 16$ in 8 scales depending on the size of the input image. In this level one or two samples are randomly sampled from each training image (from random scales and positions) and a dictionary of features of size 4096 is created. This dictionary is then made sparse by selecting the highest response from each orientation and setting the rest to 0 .

The response of a patch of $C 1$ units $X$ to a particular $S 2$ feature/prototype $P$ (a dictionary feature), of size $n \times n$, is given by a Gaussian radial basis function:

$$
\begin{equation*}
R(X, P)=\exp \left(-\frac{\|X-P\|^{2}}{\sigma^{2}}\right) \tag{3}
\end{equation*}
$$

Figure 1: In HMAX, the max on the columns is taken as the response for creating $C 2$ output vector. In contrast, histogram approaches based on SIFT methods use the frequency of feature occurrence, i.e. the normalized sum of the max values on the rows.

The values of $R$ are stored as $S 2$ layer. The distance of each sample from each training image with each entry on the dictionary is calculated and a local max is taken in $C 2$ layer in $\pm 1$ scale and $\pm 10 \%$ spatial neighborhood (despite a global max in Serre et al. (Serre et al., 2005)). These $C 2$ features are sent to the SVM for training. For testing images the same hierarchical procedure is repeated. In (Mutch \& Lowe, 2008) sparse prototypes are calculated and the maximum response from all directions for each window is taken and SVM normals method (Mladenić, Brank, Grobelnik, \& Milic-Frayling, 2004) is used to select the features with higher weights. In this approach, SVM is run a few times, and each time features with lower weights are dropped. In this HMAX implementation, once $S 2$ features are calculated, the $C 2$ layer is calculated as:

$$
\begin{array}{r}
C 2(n)=\max \left(V_{k}^{n}\right) \text { for } \forall k \in M \\
\text { for } n=1, \ldots, N \tag{4}
\end{array}
$$

As can be seen in Figure 1 in conventional HMAX approaches, the max on the columns is taken as the value for $C 2$ either in a local neighborhood of each feature or globally. Since taking the max in a local neighborhood (in $\pm 1$ scale and $\pm 10 \%$ spatial neighborhood) is shown to improve the performance by about 5\% in Caltech101 dataset in Mutch and Lowe (2008), in our experiments we also use a local neighborhood for calculating the responses. We also eliminate the local inhibition in $S 2$ level proposed in Mutch and Lowe (2008) as it increased the performance. Once a feature belongs to the first or last scale in the pyramid, we extend the neighborhood to two neighboring scales. Same method is used for features which fall in the borders of each scale, and $+20 \%$ or $-20 \%$ of their neighborhood is used for comparisons.

If we take the sum of the values on rows in Figure 1 and normalize them, these are "HMean" features, which are also biologically-inspired, and significantly improve classification results when concatenated with HMAX features (Jalali, Lim,

Tham, \& Ong, 2012). HMean is equivalent to the feature occurrence frequency in "bag-of-features" methods.

## Encoding Co-occurrence of Features

For each class, we first find the value and index of the mostfrequently occurring features (MOF). The next step is to encode the co-occurrence of these features as can be seen in Figure 1. For every class, we calculate the co-occurrence of the most frequent features and store it as a $S 3$ dictionary feature. Hence a new dictionary of features is added to the model which is composed of \#MOF $\times$ \#MOF entries for each class, where \#MOF was set as 20. In this dictionary of features, the value of each dictionary feature is calculated as:

$$
\begin{equation*}
C 3(i, j)=C 2(i) C 2(j) \exp \left(-\frac{\left\|S_{i}-S_{j}\right\|^{2}}{\sigma^{2}}\right) \tag{5}
\end{equation*}
$$

where $S_{n}$ represents the spatial position of the $C 2$ feature and $\sigma=0.5$.

This dictionary encodes the value of co-occurrence of every pair of features selected for each class. Hence we will have $N N$ dictionaries where $N N$ stands for the number of categories in the classification task. These dictionaries are concatenated to create the $C 2$ dictionary of features. In the training and test phases, the respective feature to each dictionary feature is found (the most similar feature in every image) and the similarity of the values in dictionary of features are calculated for every image. This results in a \#MOF $\times$ \#MOF $\times$ NN feature as the $C 3$ feature and it is concatenated to $C 2$ feature vector and sent to the classifier for classification. The extended model for encoding the co-occurrence of features is shown in Figure 2.

## Experimental Results

We evaluated our co-occurrence model on the Caltech101 dataset (Fei-Fei, Fergus, \& Perona, 2004). The model was trained on 30 images per category (standard for this dataset; see Mutch and Lowe (2008)), and tested on all the other images. We also used the Caltech 256 dataset (Griffin, Holub, \& Perona, 2007), because it allows for more images per category than Caltech101. In particular, we considered only the 14 (out of 256) categories which had 200 or more images. We trained the model on 150 images (so that there would be at least 50 images for testing), and tested on the rest. We also examined classification accuracy as a function of number of training images for Caltech256. This was motivated by the concern that co-occurrence features could require more data for reliable co-occurrence statistics to be extracted, before the advantage of co-occurrence could be properly manifested.

We also evaluated the performance of our model on a new dataset consisting of images of underwater targets. The main challenge with underwater images is the existence of particles that limit the visibility in unclear waters and results in scattering, reflection and absorption of light, and the differential absorption of light of different wavelengths by water itself. This dataset consists of 1664 images (roughly $740 \times 420$ pixels in

Figure 2: Diagram of model processing hierarchy.
size) from 13 categories. Example images from this dataset are shown in Figure 3. We used 30 images per category for training, and the rest for testing.

Results are shown in Table 1. For all images, only intensity (luminance) information was used. All results were derived using 8 random train/test splits. For all three datasets, the combination of HMAX and co-occurrence features gave better results (classification accuracy) than either type of feature alone (Caltech101: $59.3 \%$ vs. $54.7 \%$ vs. $57.7 \%$; Caltech 256 : $64.4 \%$ vs. $60.2 \%$ vs. $48.6 \%$; Underwater Images: $98.7 \%$ vs. $92.9 \%$ vs. $92.2 \%$ ). Since co-occurrence features were derived from the co-occurrence of HMean features, we also compared which of these two feature types (co-occurrence vs. HMean) gave better results when combined with HMAX. Again, for all three datasets, combining co-occurrence features with HMAX produced better results than combining HMean with HMAX (Caltech101: $59.3 \%$ vs. $58.9 \%$; Caltech256: $64.4 \%$ vs. $61.3 \%$; Underwater Images: $98.7 \%$ vs. $98.3 \%$ ). Furthermore, for all datasets, the combination of all three feature types was better than just HMAX and HMean together (Caltech101: $60.1 \%$ vs. $58.9 \%$; Caltech 256 : $64.1 \%$ vs. $61.3 \%$; Underwater Images: $99.0 \%$ vs. $98.3 \%$ ).

We also examined the effect of disregarding spatial distance (i.e. the exponential in Eq. 5). As seen in Table 1, for all datasets, results were better when spatial distance was taken into account (Caltech101: 57.7\% vs. 55.1\%; Caltech256: $48.6 \%$ vs. $44.2 \%$; Underwater Images: $92.2 \%$ vs. $83.3 \%$ ).

Figure 3: Examples from TMSI Underwater Images dataset.

Table 1: Classification performance on the Caltech101, Caltech256 (subset - see text for details), and TMSI Underwater Images datasets.

| Method | Caltech101 | Caltech256 <br> (subset) | Underwater <br> Images |
| :--- | :--- | :--- | :--- |
| HMAX | 54.7 | 60.2 | 92.9 |
| Co-occurrence <br> (no distance) | 55.1 | 44.2 | 83.3 |
| Co-occurrence | 57.7 | 48.6 | 92.2 |
| HMAX + <br> Co-occurrence | 59.3 | 64.4 | 98.7 |
| HMAX + HMean | 58.9 | 61.3 | 98.3 |
| HMAX + HMean <br> + Co-occurrence | 60.1 | 64.1 | 99.0 |

In order to evaluate the effect of number of training images for the creation of co-occurrence features, we trained the model with varying numbers of training images per category. As shown in Figure 4, the performance boost when adding co-occurrence features was greatest when using 150 training images. However, for fewer than 150 training images, the boost from adding co-occurrence features is unreliable. Nonetheless, looking at just HMAX alone, performance seems to asymptote at 150 training images, but for the combination of HMAX and co-occurrence features, performance seems to increase roughly linearly with the number of training images. While empirically, co-occurrence may help performance in all datasets, similar analyses (i.e. performance boost as a function of number of training images) for the other 2 datasets may not be meaningful, since the maximum number of training images is only 30 per category.

Figure 4: Classification accuracy on Caltech256 as a function of number of training images.

## Discussion

In this paper, we showed that combining co-occurrence features with regular HMAX features leads to better classification performance than using either feature type alone. Furthermore, adding co-occurrence features to HMAX increases performance more than adding occurrence features. The three types of features encode different information, and therefore the combination of all three feature types gave the best overall performance. For co-occurrence, the spatial distance between the two co-occurring features also contributes to better performance. In this work, we focused solely on HMAX. However, in future work, our co-occurrence method can be applied to other vision algorithms.

In preliminary experiments not reported here, we experimented with creating co-occurrence features from HMAX features (rather than HMean features, as done in this paper). However, this resulted in either a drop in performance or no change. This will be investigated further in future work.

Fig. 4 suggests that the performance boost from using cooccurrence may be limited by the number of training images. More detailed investigation is limited by the relatively small number of images per category in these datasets. Further investigation may require utilizing or creating larger datasets.

Another prospect for further improvement is to encode cooccurrence of more than two features. However, besides possibly requiring even more training data than two-feature co-occurrence, there may be diminishing returns for such "higher-order" co-occurrences. This is because relatively fewer classes will have the underlying visual structure that will benefit from encoding such co-occurrences.

In this paper, the choice of features for encoding cooccurrence was based on their frequency. Choosing discriminative (rather than frequent) features for co-occurrence encoding may be a more direct approach to maximizing classification performance. To choose discriminative features, one approach is to train the SVM several times and remove fea-
tures with low weights, as in Mutch and Lowe (2008), or to simply use features with mean response values that differ the most between different classes.

# The Assumption of Class-Conditional Independence in Category Learning 

Jana Jarecki (jarecki@mpib-berlin.mpg.de)*<br>Björn Meder (meder@mpib-berlin.mpg.de)*<br>Jonathan D. Nelson (nelson@mpib-berlin.mpg.de)*<br>*Center for Adaptive Cognition and Behavior (ABC), Max Planck Institute for Human Development, Lentzeallee 94 14195 Berlin, Germany

#### Abstract

This paper investigates the role of the assumption of classconditional independence of object features in human classification learning. This assumption holds that object feature values are statistically independent of each other, given knowledge of the object's true category. Treating features as classconditionally independent can in many situations substantially facilitate learning and categorization even if the assumption is not perfectly true. Using optimal experimental design principles, we designed a task to test whether people have this default assumption when learning to categorize. Results provide some supporting evidence, although the data are mixed. What is clear is that classification behavior adapts to the structure of the environment: a category structure that is unlearnable under the assumption of class-conditional independence is learned by all participants.

Keywords: Multiple-cue classification learning; classconditional independence; naïve Bayes; causal Markov condition

## Introduction

Categorization is fundamental for cognition. Grouping together objects or events helps us to efficiently encode environmental patterns, make inferences about unobserved properties of novel instances, and make decisions. Without categorization we could not see the woods for the trees.

Despite the ease with which we form categories and use them to make inferences or judgments, from a computational perspective categorization is a challenging problem. For instance, different diseases can cause similar symptoms, entailing that diagnostic inferences are often only probabilistic. Patients may have new symptom combinations and still require a diagnosis. Depending on the specific assumptions the physician makes about the relationship between the diseases and symptoms, a physician could justifiably make very different inferences about the diseases.

In the present paper, we investigate the role of the possible assumption of class-conditional independence of features in category learning. Class-conditional independence holds if the features of the category members are statistically independent given the true class. This assumption can facilitate classification and learning of category structures. The concept of class-conditional independence underlies the naïve Bayes classifier in machine learning (Domingos \& Pazzani, 1997), and is also a key assumption in some psychological classification models (e.g., Fried \& Holyoak, 1984; Anderson, 1991). It is related to ideas of channel separability in sensory perception (Movellan \& McClelland, 2001). Similar ideas are found
in Reichenbach's (1956) common-cause principle in the philosophy of science and in causal modeling (Spirtes, Glymour, \& Scheines, 1993; Pearl, 2000).

Both the philosophical and psychological literature make claims about the normative bases of the assumption of class-conditional-independence of features. Our focus here is not on the general normativity or nonnormativity of that assumption, but on whether the assumption of class-conditional independence may (perhaps tacitly) underlie people's inferences in learning and multiple-cue categorization tasks. We think of this assumption as one of many possible default (heuristic or meta-heuristic) assumptions that, if close enough to an environment's actual structure, may facilitate learning and inferences.

## The Psychology of Conditional Independence

Some psychological models of categorization incorporate assumptions of class-conditional independence, such as the category density model (Fried \& Holyoak, 1984) or Anderson's (1991) rational model of categorization. Both models treat features of instances as class-conditionally independent to make inferences about category membership or unobserved item properties.

Other research has focused more directly on the role of conditional independence assumptions in human reasoning. For instance, a key assumption in many formal causal modeling approaches (e.g., Pearl, 2000; Spirtes et al., 1993) is the so-called causal Markov condition, which assumes that a variable in a causal network is independent of all other variables (except for its causal descendants), conditional on its direct causes. As this assumption facilitates probabilistic inferences across complex causal networks it was suggested that people's causal inferences could also comply with this conditional independence assumption.

Von Sydow, Meder, and Hagmayer (2009) investigated reasoning about causal chains and found that subjects' inferences indicated a use of conditional independence assumptions, even if the learning data suggested otherwise. ${ }^{1}$ Other research, however, found violations of the causal Markov condition (Rehder \& Burnett, 2005). Asked to infer the prob-

[^303]ability for one effect when knowing the common cause of several effects, people's judgments were influenced by the status of the other effects rather than treating all effects as independent of each other given the cause. One explanation for this "nonindependence effect" (Rehder \& Burnett, 2005) is that it might be due to subjective explanations that disable all causal links between the cause and effects at once (Walsh \& Sloman, 2007). Other researchers have argued that these Markov violations do not indicate flawed human reasoning, but reflect the use of abstract causal knowledge that is sensitive to contextual information (Mayrhofer, Hagmayer, \& Waldmann, 2010).

## Research Questions

Should the assumption of class-conditional feature independence be used in classification learning? Do people use that assumption to guide learning about the structure of a novel environment? We extend previous research fourfold: (1) We use optimal experimental design principles (Myung \& Pitt, 2009; Nelson, 2005) to explicitly address the assumption in classification, (2) we are interested in categorization learning as opposed to causal reasoning, (3) we investigate how people's experience with a new environment shapes their classification behavior, whereas many previous studies have measured explicit numerical probability judgments. (4) We use an experience-based research paradigm, whereas previous studies used numerical (Rehder \& Burnett, 2005) or verbal (Mayrhofer et al., 2010) formats. Personal experience of events has been shown to result in different behavior and learning than word- or number-based presentation of probabilities (Hertwig, Barron, Weber, \& Erev, 2004; Nelson, McKenzie, Cottrell, \& Sejnowski, 2010). Before describing the task we designed, let us turn to the normative question of class-conditional independence in classification.

## Class-Conditional Independence in Classification

Categorization entails assigning an object to a class. Let $F$ denote an object consisting of a vector of feature values $\boldsymbol{f}$, and let $C$ denote a random variable whose values are the possible classes $c_{1}, \ldots, c_{n}$. The posterior probability of the class given the observed feature values, $P$ (class $\mid$ features), can be inferred using Bayes' rule:

$$
\begin{equation*}
P(C=c \mid F=\boldsymbol{f})=\frac{P(F=\boldsymbol{f} \mid C=c) P(C=c)}{P(F=\boldsymbol{f})} \tag{1}
\end{equation*}
$$

where $P(F=f \mid C=c)$ denotes the likelihood of feature value vector $\boldsymbol{f}$ given class $c, P(C=c)$ is the prior probability of the class, and $P(F=\boldsymbol{f})$ is the occurrence probability of the feature configuration. An important question is how we estimate the relevant probabilities to infer the posterior probability. Estimating the classes' prior probabilities, $P(C=c)$, from the data is relatively straightforward. However, estimating the likelihood of the features given the class, $P(F=f \mid C=c)$, is more complicated, as the number of probabilities grows exponentially with the number of features (the curse of di-
mensionality). One way to sidestep the problem is to assume that features are class-conditionally independent.

## Class-Conditional Independence

If class-conditional independence holds the individual features within a class are statistically independent (e.g., Domingos \& Pazzani, 1997). This means that the probability of a feature configuration given a class can be factorized such that:

$$
\begin{equation*}
P(F=\boldsymbol{f} \mid C=c)=\prod_{j=1}^{J} P\left(F_{j}=\boldsymbol{f}_{j} \mid C=c\right) \tag{2}
\end{equation*}
$$

where $P(F=f \mid C=c)$ denotes the likelihood of the feature configuration given the class, $P\left(F_{j}=f_{j} \mid C=c\right)$ is the marginal likelihood of the $j^{\text {th }}$ feature value given the class, and $j=1, \ldots, J$ indexes the different features. Thus, according to the assumption of class-conditional independence, the likelihood of each feature value combination can be estimated from the likelihoods of the individual feature values.
Advantages The key advantage of assuming that features are class-conditionally independent is that it reduces the curse of dimensionality. For example, for 10 binary features there are $2^{10}$ possible feature configurations. That means, we have to estimate 1024 likelihoods of feature configurations for each class. Assuming class-conditional independence reduces the number of required likelihoods from 1024 to 8.

Another benefit is that class-conditional independence allows inferences about new feature configurations. Even if a particular combination of feature values has not been observed yet, assuming class-conditional independence allows inference of the likelihood of the feature configuration from the marginal likelihoods of the individual feature values, thereby enabling computing the posterior class probabilities.

Robustness While class-conditional independence may rarely exactly hold in real-world environments, violations of this assumption do not necessarily impair performance. For instance, a widely used classifier in machine learning is the naïve Bayes model, which treats features as classconditionally independent and computes the posterior class probabilities accordingly. Both simulation studies and analytic results demonstrate the robustness of this model under a variety of conditions (Domingos \& Pazzani, 1997). For instance, if the optimality criterion is classification accuracy (error minimization, i.e., a zero-one loss function), then even if the derived posterior probabilities do not exactly correspond to the true posterior, as long as the correct category receives the highest posterior probability, classification error will be minimized.

Summary Treating features as class-conditionally independent in a classification task can be helpful, as it simplifies the problem of parameter estimation and violations of classconditional independence do not necessarily entail a loss in classification accuracy. On the other hand, assuming classconditional independence also puts constraints on the types
of classification problems that can be solved. For instance, treating features as class-conditionally independent can make it impossible to solve certain classification problems, such as nonlinearly-separable category structures (Domingos \& Pazzani, 1997).

From a psychological perspective, however, presuming class-conditional independence might be a plausible default assumption in category learning. If features are (approximately) class-conditionally independent, this facilitates learning and inference substantially. We designed an experiment to investigate whether people initially presume class-conditional independence, and if people change their beliefs and classification behavior when class-conditional independence does not hold in the environment.

## Experiment

Our goal was to examine whether people use classconditional independence as a default assumption in category learning when the true environmental probabilities are not known yet, that is, early in learning. In order to test this question, we designed a learning environment in which classification decisions would be strongly different if the learner presumes class-conditional feature independence, rather than basing classification decisions solely on the previous instances with the exact same configuration of feature values.

## Method

Participants Thirty subjects ( $M_{\text {age }}=23, S D=3.3$ years, $70 \%$ females) participated in a computer-based experiment in exchange for 12 Euro.
Task Participants' task was to learn classify objects with three binary features into one out of two categories. As stimuli we used simulated biological "plankton" specimens differing in three binary features ("eye", "tail", and "claw", shown in the left image in Figure 1). The classes were labelled as "Species A" vs. "Species B". The assignment of the actual physical features and their values to the underlying probabilities, as well as the class labels, were randomized across participants.
Procedure We used a trial-by-trial supervised multiplecue probabilistic category learning paradigm (e.g., Knowlton, Squire, \& Gluck, 1994; Meder \& Nelson, 2012; Nelson et al., 2010; Rehder \& Hoffman, 2005). After introducing the task and familiarizing subjects with the three features, on each trial a plankton exemplar with a specific feature value combination was randomly drawn according to the true environmental probabilities (see below) and displayed on the screen. After participants made a classification decision, feedback on the true class was given and the next trial started. Learning continued until criterion performance was achieved. Criterion performance was defined as both (1) an overall classification accuracy of $98 \%$ over the last 100 trials, and (2) accurate classification of the last five instances of every individual configuration of features.

Environment Using optimal experimental design (OED) principles (Myung \& Pitt, 2009; Nelson, 2005) we conducted simulations to find environmental probabilities that best differentiate between a learner that assumes class-conditional independence and a learner that makes predictions based only on previous instances of the same feature configuration. The possible environmental probabilities for our task consisted of the following parameters: (i) the base rate of Species A (determining the Species B base rate), (ii) the likelihoods of each of the eight possible feature value combinations given Species A and (iii) the corresponding values for Species B. The parameter values were obtained via optimization, using genetic algorithms to search for desirable environments which had frequent configurations of features with large absolute discrepancies between the actual posterior probability of Species A, and the posterior probability presumed based on the class-conditional independence assumption. Formally, the genetic algorithm optimized the following fitness function:

$$
\begin{equation*}
\sum_{i=1}^{I}\left[P_{\text {true }}\left(C=c \mid F=f_{i}\right)-P_{\text {cci }}\left(C=c \mid F=f_{i}\right)\right]^{2} \times P\left(F=f_{i}\right)^{2} \tag{3}
\end{equation*}
$$

where $i$ indexes all possible feature value combinations and the subscripts true vs. cci indicate the posteriors calculated according to the true vs. class-conditionally independent parameters.

The obtained environment is summarized in Figure 1. The environment contains five out of eight possible feature combinations (henceforth denoted as $111,000,100,010,001$ ); the remaining three combinations $(011,101,110)$ do not occur. The figure illustrates the category base rates, the likelihoods of the feature configurations given the two classes, as well as the marginal likelihoods of the features, which provide the basis for inferring posterior probabilities according to the class-conditional independence assumption. Note that although nothing in the optimization prescribed finding a deterministic environment, in fact the posterior probabilities of Category A are one or zero, for each of the feature configurations that occurs.

In this environment, assuming class-conditional independence leads to classification decisions that systematically deviate from decisions based on the true environmental probabilities. Table 1 summarizes the feature configurations, their probability of occurrence, the posterior probabilities according to the true environmental probabilities, and the posterior probabilities derived assuming class-conditional independence. For four out of the five feature configurations, the classification decision derived assuming class-conditional independence conflicts with the actual class membership (indicated by $\neq$ in Table 1).

Consider feature configuration 111. This item always belongs to Species $A$ in the true environment. If features are treated as class-conditionally independent, it belongs to Species A with probability 0.91 . The small difference between the actual probability of 1.00 and 0.91 should not

Figure 1: Task environment. a) Stimuli and base rates of classes. b) Joint likelihoods of true environment. c) Marginal likelihoods used assuming class-conditional independence
change the learner's classification decision for this stimulus. This, however, is not true for the other items. For instance, according to the true environment, item 000 belongs to Species A with probability 1 , but assuming class-conditional independence entails that it belongs to Species B with probability 0.67 . Thus, a learner assuming class-conditional independence would believe that on average about $67 \%$ of the 000 items belong to Species B, despite experiencing that it always belongs to Species A. The same divergence holds for the other three configurations $(100,010,001)$ : whereas all of those items actually belong to category B , treating features as class-conditionally independent entails that the probability for category A is higher (0.58).

Table 1: True environment vs. assuming classconditional independence (cci).

| Features | $\begin{array}{c}P \text { (features) } \\ \text { true env }\end{array}$ | $P$ (class $\mid$ features) |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| true env |  |  |  |  |$)$

The strongest discrepancy is for the 000 configuration, which is the second-most-frequent configuration, occurring with probability .28. Note that a hypothetical learner (even with perfect memory) who assumes class-conditional independence of features, and is unable to give up this assumption, will never learn the true statistical structure of this environment, even after completing a quadrillion learning trials.

Achieving criterion performance would also be impossible if learners looked at one feature only (at 1 xx , or x 1 x , or xx 1 and ignoring the x ). Considering single features, participants should think any feature configuration belongs to Species A
with probability 0.78 . This holds for attending solely to any of the three features.

## Hypotheses

If participants make no (not even tacit) assumptions of classconditional feature independence, and learn each item separately, then items could be learned in order of their frequency of occurrence (a frequency-of-configuration hypothesis). If participants approach the task by assuming features to be class-conditionally independent, classification decisions should systematically deviate from ones derived from the true environmental probabilities, especially early in learning (a posterior-discrepancy hypothesis).

Both hypotheses predict the fewest errors for item 111, the most frequent feature configuration and the one for which the class-conditional independence posterior is closest to accurate. For the four critical items, the difference in posterior probability is the largest for item 000. The posterior-discrepancy hypothesis predicts the most errors for item 000 , and thus that the ordering of errors should be $111<100 \approx 010 \approx 001<000$. However, the frequency-ofconfiguration hypothesis predicts that the ordering of classification errors should be $111<000<100 \approx 010 \approx 001$.

Key empirical questions are therefore whether there are any systematic differences in learning rate for the individual items, whether the early learning data suggest a presumption of class-conditional independence, and if so, whether the occurrence frequency of an item or the degree to which classconditional independence fails on it determine learning.

## Results and Discussion

All participants reached criterion performance, i.e. learned the category structure (in a mean number of 391 trials, $\mathrm{SD}=155, \mathrm{Md}=348$, range 210 to 808 trials). To reach criterion performance, participants needed to classify each individual feature configuration correctly five times in a row. To investigate whether there was a difference in learning speed for the different feature configurations, we calculated the number of times each item needed to be observed before reaching this criterion (Table 2). We will first consider learning time and then error rates.

Table 2: Number of trials an item needed to be seen to correctly classify it five times in a row.

| Features |  |  | Trials |  |  |  |
| :--- | :--- | :--- | :--- | :--- | ---: | ---: | ---: |
|  |  |  | mean | $S D(S E)$ | median |  |
| 1 | 1 | 1 |  | 10.4 | $10.7(1.9)$ | 7.0 |
| 1 | 0 | 0 |  | 11.4 | $8.0(2.1)$ | 7.5 |
| 0 | 1 | 0 |  | 11.5 | $7.7(2.1)$ | 9.0 |
| 0 | 0 | 1 |  | 11.5 | $7.0(2.1)$ | 9.0 |
| 0 | 0 | 0 |  | 15.8 | $11.5(2.9)$ | 13.5 |

In our data most subjects learned item 111 before item 000 ( 22 out of 30 , binomial $p<.02$ ), which is consistent with both hypotheses. Did learning time follow
the frequency-of-configuration hypothesis, or the posteriordiscrepancy hypothesis? The posterior-discrepancy hypothesis predicts an ordering of $111<100 \approx 010 \approx 001<000$, whereas the item-frequency hypothesis's ordering prediction is $111<000<100 \approx 010 \approx 001$. The critical difference in predictions is between the learning time for items 100,010 , and 001 and item 000 . The frequency hypothesis predicts that item 000 will be learned faster, whereas the posterior discrepancy hypothesis predicts that items 100, 010, and 001 will be learned first. Here, our results strongly support the posterior discrepancy hypothesis, and contradict the item frequency hypothesis. Items 100, 010 and 001 were learned more quickly by more people than item 000 , despite item 000 's greater frequency (item 001 faster: 21 out of 30 , binomial $p<.05$; item 010 faster: 20 out of 30 , binomial $p<.1$; item 100 faster: 21 out of 30 , binomial $p<.05$ ). Moreover, there was a nonsignificant trend for items 100,010 , and 001 to take longer than item 111; consistent with the posterior discrepancy hypothesis but not the configuration frequency hypothesis.

Figure 2: Percentage incorrect classifications for the first 50 trials each item was encountered.

The error rates throughout early learning are summarized in Figure 2. This figure corroborates the analysis of the number of learning trials required for each stimulus configuration: item 000 was clearly the most difficult to learn. As this feature configuration is the one for which the difference in posterior probability is largest when assuming class-conditional independence versus using the full true environmental probabilities, this finding is consistent with the idea that people treat features as being class-conditionally independent early in learning. However, items 100, 010 and 001 were much closer to (or even indistinguishable from) item 111, consistent with the above analysis in Table 2.

## General Discussion

The present paper examined the role of the assumption of class-conditional independence of features in category learning. While different types of conditional independence assumptions play an important role in various scientific debates and computational models of cognition, little is known about their descriptive validity in the context of classification learning with multiple cues. Our goal was to empirically investigate whether people initially (early in learning) treat features as class-conditionally independent. The present results partially support the idea that people initially treat features as class-conditionally independent and make classification decisions accordingly. We think of the results as tentative because some aspects of the data are not perfectly clear.

Our focus in the present study was on participants' behavior early in learning, when evidence about the category structure and environmental probabilities is limited. This approach is similar to the studies of Smith and Minda (1998), who investigated possible transitions in categorization strategies and stimulus encoding over the course of learning.Their finding was that late in learning exemplar models (e.g., Medin \& Schaffer, 1978) accounted best for subjects' behavior, but that this was not the case early in learning (in which a prototype model seemed to better account for human performance, see below). This is also a possible explanation for the finding that despite strongly violating class-conditional independence, the environment in our experiment was clearly learnable. Participants could have initially treated features as class-conditionally independent and computed posteriors accordingly and later shifted to an exemplar-based strategy to minimize classification error.

A key methodological aspect of our study was to use optimal experimental design principles to find environments that would allows us to directly test whether people use classconditional independence as a default assumption in categorization. Interestingly, the optimizations told us that the best environment to differentiate between a learner that assumes class-conditional independence and a learner that makes predictions based only on previous instances of the same feature configuration was deterministic. The crucial aspect of this environment, however, is not that it is deterministic, but that it entails a nonlinearly separable category structure. Since the class-conditional independence model induces a linear decision bound (Domingos \& Pazzani, 1997), it could not achieve criterion performance in this particular task environment.

This, in turn, relates our study to earlier research in psychology, which investigated whether linearly separable categories are easier to learn than nonlinearly separable ones (e.g., Medin \& Schaffer, 1978; Medin \& Schwanenflugel, 1981). This research focused on two types of categorization models, exemplar- and prototype-models, both of which assume that categorization decisions are derived from similarity comparisons (either to specific exemplars stored in memory or to prototypes of categories). By contrast, we investigated category learning and human subjects' initial assump-
tions from the perspective of probabilistic inference (see also Anderson, 1991; Fried \& Holyoak, 1984), a conceptually different view. Nevertheless, there are some interesting connections between our work and these earlier (similarity-based) models. For instance, assuming class-conditional independence entails that not all information (about feature configurations and corresponding class probability) is encoded during learning, but only marginalized conditional likelihoods and category base rates. In this respect the class-conditional independence model is similar to prototype models, which encode parametric information of central tendencies (e.g., mean or mode of feature values) that form the prototype (e.g., Smith \& Minda, 1998).

Importantly, these accounts assume that information is stored separately for each feature and the to-be-classified item is compared to the prototypes separately on each feature dimension individually. Conversely, a learner who makes no assumptions about the structure of the relations between classes and features and directly tracks the true environmental probabilities is conceptually more similar to exemplar models of category learning. The difference is that prototype models, like our independence model, do not need to store each individual instance that is experienced.

In sum, the current paper adds to the debate about the role of conditional independence assumptions for computational models of cognition. The task environment identified based on optimal experimental design principles allowed us to directly examine the descriptive validity of this assumption in category learning. Here, we do find evidence consistent with its use.

## Acknowledgments

This research was supported by grants NE 1713/1 to JDN and ME 3717/2 to BM, from the Deutsche Forschungsgemeinschaft (DFG) as part of the priority program "New Frameworks of Rationality" (SPP 1516). We would like to thank Gregor Caregnato for data collection and Laura Martignon, Michael Waldmann, Ralf Mayrhofer, and the reviewers for their helpful comments. We also thank Jorge Rey and Sheila O'Connell (University of Florida, FMELe) for allowing us to base our artificial plankton stimuli on their copepod photographs.

# Similarity, causality and argumentation 

William Jiménez-Leal (w.jimenezleal@uniandes.edu.co)<br>Christian Gaviria (cgaviria@uniandes.edu.co)<br>Departamento de Psicología, Universidad de los Andes. Cra. $1 \mathrm{~N}^{\circ}$ 18A- 12, Edificio Franco, Bogotá, 111711. Colombia

#### Abstract

Similarity is a notion that is widely used both in cognitive science and in argumentation theory. These research programs have, however, developed in large part separately and in consequence rely on disparate notions of similarity. Only recently there has been a proposal for specifying how similarity actually plays a role in judging slippery slope arguments. We present here further theoretical discussion and empirical evidence in order to show how similarity can play a role in slippery slope arguments and in argumentation in general. In the experiment presented here, we manipulated the availability of causal information, and showed that people are sensitive to it when judging arguments' strength. We conclude that similarity between causal properties of the elements presented in arguments is crucial for arguments' strength assessments.

Keywords: Argumentation, similarity, causality, analogical reasoning.

## Introduction

The degree of conviction that an argument generates depends on many elements. The effectiveness of some arguments seems to depend on the perceived similarity between the elements presented in the premises and the conclusions that might follow. For example, such is the case of the argument based on precedent, where the similarity between past events and the one under discussion is such as to warrant following the same course of action as with the precedent (Walton, 2010). Similarly, some arguments fail because the relation of similarity between premises and conclusion is weak. The fallacy of false analogy (Tindale, 2007) is one example, where there is a comparison between situations based on superficial similarities that do not support the conclusion. Walton, Reed \& Macagno (2008) recognize that judgements of similarity between a class and an exemplar are key for the quality of arguments from verbal classification (from definition, vagueness, arbitrariness) (See also Macagno, 2009; Walton, 2009). The notion of similarity is thus central to explaining why people deem some arguments good or bad, and it is taken as a primitive element for explaining how people evaluate arguments.

Similarly, the typologies of arguments put forward by perspectives like the dialectical (Walton, 2010) and the pragma-dialectical (van Eemeren, Houtlosser, \& Snoeck, 2007), rely on identification of similarity. In the pragmadialectical perspective, for example, one of the three main types of arguments is the 'argumentation based on comparison" (van Eemeren, et al., 2007), where the argument and the standpoint argued for refer to different things but share a predicate. In the example "It is not at all
necessary to give James a 10 dollar allowance, because his brother always got 10 dollars a week", the similarity between James and his brother regarding the money needed, is the justification that allows one to proceed from premise to conclusion (Hitchcock \& Wagenmans, 2011). In fact, the questions proposed to identify this type of argumentation scheme presuppose the notion of similarity (e.g. "Are there enough relevant similarities in the things that are compared?")

Similarity thus plays a dual role in argumentation: not only is it proposed that similarity judgments are performed by people engaged in argumentation, but it is also suggested that argumentation schemes are to be identified by questions that imply similarity judgements. That is, similarity plays a role both in explaining what people do, and also as a tool that the argumentation scholar needs to identify arguments and evaluate its correctness.

Even though there has been vigorous research on the role of similarity in several psychological processes (Goldstone \& Son, 2005), and despite argumentation research consistently using this construct as a tool to characterise several argumentation schemes (Walton et al, 2008), little work has been done to integrate the findings of cognitive science into our understanding of how people reason with arguments. In what follows, we will briefly examine the most common notions of similarity currently in use in cognitive science and consider the only work we are aware of that explicitly makes use of this idea to explain argument strength (Corner, Hahn \& Oaksford, 2011). This will lead us to consider causality as one of the key ideas that is missing when using similarity as an explanatory principle. We will then present some empirical evidence to support our claims.

## Similarity and cognitive science

It is difficult to overstate the importance of similarity as an explanatory tool in cognitive science. From categorisation to analogy, similarity judgements are advanced to explain very diverse phenomena. Links between rules and similarity as well as the very need of appealing to similarity in explaining cognition have been widely discussed (Sloman \& Rips, 1998; Goldstone, Day \& Son, 2010). It is more or less accepted that alternative ways of conceiving similarity capture different intuitions about our use of this notion, and that all have different weaknesses and strengths.

The multiplicity of contexts in which it is possible to use the notion of similarity is consistent with the diversity of ways in which people judge that objects are alike. One can distinguish three main models to conceive similarity: geometric models, featural models and alignment based
models. ${ }^{1}$ While none of these models can possibly capture the flexibility of similarity, they offer important insights into how similarity can be possibly used in the context of argumentation.

Geometric models are based on multidimensional scaling of similarity and dissimilarity judgments provided by participants. People judge how alike two objects are, and their ratings are used to generate a set of points organised in a metric space. The similarity of two objects is an inverse function of the distance between points that represent the objects. The distances measured depend on the number of dimensions inferred (Goldstone el at., 2010). Certainly, a geometrical representation of similarity seems to be at play in the case of induction of blank properties, as proposed by the similarity-coverage model of induction (Osherson et al. 1990). Knowing that "bears require Biotin for haemoglobin synthesis" makes one more likely to believe that wolves require that substance when compared to whales. In this case, the induction is possibly supported by a similarity judgement along the dimensions of "animal with fur", and "lives in the woods".

Notice that this conception of similarity relies on the idea of objects represented by dimensions, which can be adequately captured by classification tasks. The problem with this idea is that it makes geometric models too heavily committed to the assumptions of minimality, symmetry and the triangle inequality, as pointed out by Tversky (1977). These assumptions make the model psychologically implausible for some similarity judgments (e.g. asymmetric judgments like "Korea is more similar to China than China is to Korea"). Featural models capitalise on some problems of geometric models to advance a notion of similarity based on weighted feature-matching. Here the objects are characterised as a set of features, and resemblance is established by some linear combination of shared and distinctive features, with their respective weights. Featural models have found success particularly in explaining categorisation tasks (Verguts et al, 2004). Typically, these tasks involve a learning phase where participants are presented several exemplars that belong to an artificial category (e.g. Flowers whose colour, number of petals and size can vary). Participants are then tested with new exemplars, whose characteristics may match the ones presented in the study phase.

Both geometric and featural representations of similarity have traditionally been used to analyse tasks with relatively unstructured inputs. The link between the inferred dimensions or features had traditionally been overlooked. In response to this problem, and inspired by research in analogy and metaphor, Gentner and Markman (1995) proposed the idea of having situations as the input of the comparison process, and thus starting with complex inputs. Similarity between objects is in this case derived from the

[^304]role the object fulfils in the scene. This principle guides the selection of characteristics relevant for the comparison process. Alignment-based models assume that similarity comparisons involve a mechanism of structure-mapping, called structural alignment, that seeks maximal structurally consistent matches. When maximizing these matches, there is a set of matched characteristics and two sets of differences, alignable and non-alignable. The latter are key to establishing similarity and explaining the effects of asymmetry and minimality identified by Tversky.

While these approaches to similarity have met different degrees of success in explaining phenomena like categorisation and metaphor, little has been done to specify the particular approach at play when turning to the idea of similarity in the context of explaining argumentation. Thus we now consider the extant literature about argumentation.

## Similarity in argumentation

To our knowledge, there are only two explicit proposals for using similarity as an explanatory tool in argumentation. The first one is attributed to Walton (2010, 2012), who presents an analysis showing how arguments from precedent are based on arguments from analogy and classification. The second one is attributed to Corner, Hahn and Oaksford (2011), who, in the framework of the Bayesian approach to argumentation (Hahn \& Oaksford, 2007), claim that the mechanism underlying the slippery slope arguments (SSAs) consists of a category boundary re-appraisal process, which in turn depends on the perceived similarity between an exemplar and a category. We now consider each one in turn.

In law, arguments from precedents involve applying an earlier decision to a later case deemed to be the same. Of course, the issue at stake here is when two cases can be considered the "same" in light of the precedent. By the same token, in arguments from analogy a decision is suggested because the case is similar to another one, where "how similar" is the critical question. Walton (2010) is interested in finding an objective way "to identify, analyse and evaluate arguments from analogy" (p. 217), and proposes that arguments from precedent are a special case of arguments from analogy, which in turn are cases of arguments by classification or definition. Given Walton's interest in legal reasoning, the inputs of the process are "cases", complex situations that afford comparisons at multiple levels. Comparisons are only possible if there is a "plausible story" that connects the cases being compared.

The mechanism proposed to establish similarity is an abstract structure called a "story scheme" (Bex, 2009), which is a template that contains a connected sequence of events or actions represented by variables, so that different stories can be represented as instances of it (Walton, 2012). Once the right story scheme is selected, it is possible to establish if the case argued for is an instance of the story scheme. For example, the argument that selling unhealthy food is analogous to selling a malfunctioning car, and thus the same controls should be implemented for food, is only possible in a story scheme that can encompass both food
and cars. In other words, to judge the quality of the argument, it is necessary to decide whether the coverage of the story scheme is to be extended to include the new case.

The methodology proposed by Walton is, ultimately, a combination of story schemes and the argumentation scheme from analogy. As such, it is a tool used by the argumentation analyst and it is not intended to have psychological reality. However, its use does imply a functioning cognitive system able to comprehend similarity. As such, the judgements of similarity from story schemes implicitly rely on an alignment-based approach.

The second case is the work of Corner et al. (2011), whose goal is to provide the objective basis for judging SSAs. SSAs are arguments where a proposal is put forward but its consequences are thought to be undesirable, so that if the proposal is allowed, the undesirable consequence will unavoidably follow (e.g. "if freedom of speech is refused to extremist groups, then there will be censorship to any kind of political expression") (Volokh, 2003). Corner et al. present evidence on how the strength of slippery slope arguments is related to the perceived similarity of the elements present in the premises of the argument. They propose that the mechanism underlying the judged strength of slippery slope arguments is the assessment of similarity between the exemplars presented in their premise and conclusion.

More specifically, Corner et al. claim that when assessing a SSA there is a process of category boundary re-appraisal (Corner et al., 2011), and thus the exemplar under discussion can be rightly considered within the scope of the category discussed. Consequently, people are more willing to accept arguments of this form when the similarity between the elements presented in the premises is high, and otherwise consider the argument fallacious. How good an SSA is, depends on extending the category boundaries to include the case under discussion. For example, the acceptability of the argument "If voluntary euthanasia is legalised, then in the future there will be more cases of 'medical murder" (Corner et al, 2011, p. 133), depends on being able to redraw the limits of the category 'medical murder' to include 'euthanasia'. Their claims are based on extensive findings from work on exemplars' effects on categorisation (Nosofsky, 1986).

This idea is certainly a step forward in integrating research in cognitive science and argumentation. However, the generality of Corner et al's proposal is lessened when considering the materials used in their experiments.

In their experiments $2,2 \mathrm{a}$ and 3 , they use numerically defined exemplars. They describe a situation where there is a discussion about the inclusion of a new territory in the category of places of outstanding beauty (PONB). Participants were presented with cases of areas that were either declared PONB or not, including the number of animal species in each place, as the decisive criterion. For example, they were told that location A (114 species) and location B (149 species) were not considered eligible as PONB, whereas location C (224 species) and D (259
species) were. In the testing phase, which corresponds with the SSA, a new pair of exemplars was presented in terms of two conditions: similar (194 and 179 species) and dissimilar ( 218 vs. 179 species). If the mechanism of SSA is an instance of category boundary re-appraisal, it would be expected that (1) an argument involving a comparison of items should be better evaluated when they are similar; and (2) that the results of a categorisation task would support this prediction. They did in fact find a good match between categorisation decisions and the strength of SSAs.

The similarity of the cases considered in Corner et al (2011) depends on numerical thresholds (e.g. number of species in a natural park necessary to declare it a PONB (exp. 2); number of years of imprisonment for knife/gun crime (exp. 3)), given by the fact of dealing with numerically defined categories with only one dimension. As such, their proposal suggests at least one question; namely, will the link between similarity and SSAs show up in cases where the similarity metric depends on more than one dimension (or no dimensions at all: features, stories, etc.)? The next logical step is then to examine the functioning of the hypothesized mechanism in the cases suggested.

The common theme in the work of Walton and Corner et al. is the idea of a more basic mechanism at work when dealing with arguments: Walton, at the level of the scholar of identifying and analysing argumentation schemes; Corner et al, at the cognitive level of individuals faced with arguments. We believe the latter is a particularly promising avenue of research since it relies on the accumulated knowledge of cognitive science about similarity and promotes the integration of cognitive science and argumentation theory (Hornikx \& Hahn, 2012). However, as has been acknowledged, the evidence presented by Corner et al. is limited to cases where similarity judgments operate within a dimension, suffering, in consequence, from one of the main criticisms put forward against geometric approaches to similarity, that is, overlooking the connection between the judged dimension and other aspects of the objects under consideration.

## Causality and similarity

We believe there is a complementary way of conceiving similarity in the context of argumentation that comes from the literature on causal categorisation. This literature offers a way of dealing with the dichotomy between dimensions and features, and also accounts for the fact that features are usually correlated in exemplars.

There is ample evidence of causal effects on similarity assessments in the categorisation literature (Rehder, 2003). According to the causal model of categorisation, the observed correlation between exemplars' features are understood as evidence of an underlying mechanism at work, resulting in those features (Rehder \& Burnett, 2005). Whereas Rehder (2006) considers causality and similarity as two independent sources of information, it is possible to interpret categorisation as cases that depend on similarity judgments inspired by causality. Similarity is not a fixed
notion, as noted above, and proposing that causal information determines our perception of similarity amounts to saying that features and dimensions that enter comparisons are governed by a more general principle. In fact, causal-based models can actually provide a way to solve the apparent opposition of models based in either features or dimensions. Kemp, Shafto, Berke and Tenenbaum (2008) propose a causal model that integrates both kinds of knowledge, relations between objects and relation between features. The evidence accumulated recently in favour of the causal models of categorisation and induction gives good grounds for suggesting that the similarity assessment at work in the case of argumentation depends on the perceived causal similarity, in at least some relevant cases.

This would lead one to consider causal-based similarity judgements as the mechanism underlying some argumentation schemes, which can be characterised by the inclusion of a new exemplar under the scope of the category. Some of these argument types have been suggested above: analogy, precedent, classification, definition and slippery slope. Similarly, some forms of the SSA could be considered special cases of causal similaritybased argumentation, where how slippery a slope is, depends on the causal links shared by the exemplars presented in the premises of the argument, as the evidence of their features provide. ${ }^{2}$

Here we do not commit to a particular model of causal reasoning, only to the idea underlying causal-based models of categorisation. However, our proposal has the general appeal of using the logic of weighted feature-matching, where the weights are assigned following a psychological principle, viz. causal representation. In consequence, the strength of the arguments that depend on this mechanism can be predicted by establishing what the particular causal mechanism at work is.

## The present experiment

As a first attempt to test this idea, we designed an experiment where the presence of the causal efficient feature was manipulated as well as the overall similarity (number of matched features), in the context of a slippery slope argument. This is a 3 (number of matched features) X 2 (presence/absence of a causally relevant feature), between-subjects design. We expect to see a main effect of the causally relevant feature, regardless of the overall similarity indicated by simple feature matching. In consequence, arguments based on causally matched information will be judged stronger.

[^305]
## Experiment

## Participants

132 university students ( 77 female) with ages between 18 and $34(\mathrm{~m}=21.25, \mathrm{sd}=3.36)$ took part in this study. The students came from several different undergraduate programs. Participants were randomly allocated to one of the six possible combinations, with 65 and 67 participants in the causal condition and non-causal condition, respectively, and 41,42 and 39 for each one of the groups defined by the number of matched features.

## Materials and procedure

Participants were tested in groups at the end of one of their classes. Each participant was provided with a fourpage booklet containing, in the first page, some general instructions, in the following two pages the main task, and in the last page participants were requested to provide basic demographic information.

The main task involved making judgments relative to two scenarios (drugs and fertilizers). The first part of each scenario described a situation where a government agency had to decide whether to allow the use of a new substance (drug/fertilizer). The second part of the scenario included a table comparing the features of a banned substance and the corresponding characteristics of the new substance under consideration. Each table had four items, where the number of matched characteristics $(1,2$ or 3$)$ and the presence of the key causal feature (matched or not) were manipulated. For example, table 1 shows the information presented in the fertilizer scenario, with two matched features in the noncausal condition. Polenoy is the currently banned fertilizer, and Soilex the fertilizer the government is considering whether to allow. In this case, the "high concentration of nitric acid" was the key causal feature.

Causal features were selected from ratings provided by an independent group of 20 participants who selected what characteristic they considered more important for banning/allowing fertilizers and potentially addictive substances. Agreement on the most causal feature for the fertilizer scenario was $100 \%$, and in the drugs scenario was $80 \%$.

Table 1: Information presented in a sample item

|  | POLENOY | SOILEX |
| :--- | :---: | :---: |
| Doses lower than 50kg per hectare | YES | YES |
| Highly soluble in water | YES | NO |
| Delivered with sprinklers | YES | NO |
| High concentration of nitric acid | YES | YES |

An argument was then presented claiming that the new substance should not be allowed, because allowing it would inevitably lead to removing the ban on the former substance too ("If we allow Soilex now, we are going to have to allow Polenoy. In consequence, we should not allow Soilex"). In both scenarios the arguments were uttered by fictitious characters in positions of power. Participants were asked to rate how convincing each argument was on a 10-point scale. All of the participants rated both scenarios, with the presentation order counterbalanced. Finally, participants rated how negative/positive (on a scale of 1 to 10) they
considered the consequence stated in the conclusion of each argument to be, as a measure of the perceived utility.

## Results

Results of each scenario were submitted to a 2 (presence/absence of a causally relevant feature) X 3 (number of matched items: 1, or 3) between subjects Anova. Results for each scenario are considered separately because their respective utility ratings differed (paired $t(131)=4.56$, $\mathrm{p}<0.001$ ), even though there was no significant difference between their acceptance ratings (paired $t(131)=0.6, p=.5$ )
For both items, there was a main effect of causal information. People rated the argument with the matched relevant causal feature as more convincing than the case without the matched feature ( 5.8 vs. 3.7 for the drugs scenario and 5.3 vs. 4 for the fertilizer scenario)(see table 2). The differences are statistically significant in both cases, F $(2,128)=19.95, \mathrm{p}<0.01, \eta^{2}=0.03 ; \mathrm{F}(2,128)=3.92, \mathrm{p}<0.05$, $\eta^{2}=0.18$.

Table 2: Summary of argument strength ratings by causal information and number of matched items

| Scenario | Causal Info | \# of matched features | Mean (s.d) |
| :---: | :---: | :---: | :---: |
| Drugs | Yes | 1 | 5.29 (3.15) |
|  |  | 2 | 6.14 (2.41) |
|  |  | 3 | 6.15 (3.26) |
|  |  | Total | 5.76 (2.91) |
|  | No | 1 | 3.03 (2.56) |
|  |  | 2 | 5.17 (2.71) |
|  |  | 3 | 3.40 (1.64) |
|  |  | Total | 3.69 (2.51) |
| Fertilizers | Yes | 1 | 4.91 (3.11) |
|  |  | 2 | 5.72 (2.61) |
|  |  | 3 | 5.35 (1.98) |
|  |  | Total | 5.24 (2.69) |
|  | No | 1 | 4.50 (2.87) |
|  |  | 2 | 5.76 (3.10) |
|  |  | 3 | 2.15 (1.82) |
|  |  | Total | 4.14 (2.99) |

There was also a main effect of the number of matched features $\left(F(2,126)=3.99, p<0.05, \eta^{2}=0.05 ; F(2,126)=3.58\right.$, $\mathrm{p}<0.01, \eta^{2}=0.05$, for fertilizer and drugs, respectively). The degree of persuasion that an argument exerted changed with the number of matched features for both scenarios. Post hoc tests (Tukey) revealed that the mean acceptance rating was lower when having only one matched feature (the causal characteristic), compared to two or three matches. However, there is no consistent pattern of differences across scenarios when having more than one matched feature.

Interaction was significant for the fertilizer scenario $(\mathrm{F}(2$, $128)=3.62, \mathrm{p}<0.05, \eta^{2}=0.02$ ) but not for drugs item $(\mathrm{F}=1.1)$. In the fertilizers scenario, the difference between the causal and non-causal condition was larger when having only one feature matched. Maybe in this scenario having a single feature matched was more salient.

Utility ratings were significantly higher for fertilizer than for drugs ( 4.5 vs. 37 , paired $\mathrm{t}(131)=4.56, \mathrm{p}<0.01$ ), which means people were more in agreement with fertilizer use. However, the utility ratings were not correlated with acceptance ratings in either scenario ( 0.04 and 0.002 ) and did not differ as a function of the inclusion of causal information or matched items ( F 's $<1$ for all anovas).

In short, both items were rated in the predicted direction, with the more convincing arguments being those that have a causally relevant matched feature to the sample item. However, the number of items does not have a clear effect. Increasing the number of matches is not linearly associated with higher argument acceptance ratings, but adding a matched feature does have an effect. The present experiment does not support a firm conclusion about this aspect.

## Discussion

People are sensitive to causal information in the assessment of argument strength in SSA. In the case of the scenarios used in this experiment, people recognise the causal feature (e.g. concentration of nitric acid) as the key characteristic that produces the undesirable consequence and thus determines the acceptability of the SSA. This experiment adds support to Corner et al's proposal of category reappraisal as the mechanism at work in SSA, and also sets it in the larger context of the use of causal information for categorisation. A potential problem with the interpretation of the data presented is that is not possible to discard that the other features presented were also interpreted as causal. This would explain why adding a matched feature was associated to higher acceptance ratings. Even in this case, it would still stand that matching the most causally efficient feature is related with a significant increase in the acceptability of the argument.

## Summary and conclusions

Similarity clearly plays a role in argument evaluation. Here we have presented evidence of a particular way in which this can occur. The experiment presented shows that people are sensitive to causal information when judging how similar a new exemplar is to a known class. This finding complements Corner et al's (2011) work, by further specifying the mechanism at play, beyond the case of a geometrical notion of similarity. SSAs often imply an evaluation of how "inevitable" an undesirable consequence is once the proposed action has been effected, and in that sense, causal knowledge linking the elements in the argument is especially relevant.

Taking into account research in cognitive science on similarity has several benefits. First, it makes it possible to take further steps in the integration of dissimilar perspectives in the study of argumentation (Hornikx \& Hahn, 2012). The different ways in which different evaluations of similarity can play a role in argumentation are still unexplored. Second, it can help predict cases where arguments may be considered bad or fallacious, by providing an understanding of similarity ratings of the
elements under discussion. The reverse is also true: by examining the way people assess arguments, it might be possible to examine the conceptual representation of the world, and the causal structure implied. The actual scope of the causal similarity mechanism is a matter of empirical research. For example, the perceived strength of ad hominem arguments, such as the ad hitlerum (Harris et al, 2012), where adopting policy X would lead to the adoption of other undesirable policies, might depend on the similarity of the causally relevant links that connect policy X with other undesirable policies. Third, the study of causal similarity from a cognitive perspective can potentially provide a unifying theme to the study of the argument typologies proposed in informal logic. The dialectical (Walton, 2010) and pragma dialectical (van Eemeren, Houtlosser, \& Snoeck, 2007) approaches propose typologies that, useful as they are for the study of argumentation, might conceal important unifying psychologically themes in the evaluation of arguments. One of them, as suggested in this paper, is the use of categorical causal information.

There are several other questions that can be explored using judged causal similarity as a framework. For example, it is clear that complex situations require the rapid evaluation for alignable matches and mismatches (Gentner \& Markman, 1995). Are alignable differences more important when they refer to causal characteristics? The way similarity is assessed, in the absence of specific characteristics to be matched (cf. geometrical models), will probably have a differential impact on argument strength, when compared to cases where the exemplars are fully specified by a set of characteristics. A causal-based model of categorisation offers a wealth of hypotheses to be investigated.

# Good Decisions, Good Causes: Optimality as a Constraint on Attribution of Causal Responsibility 

Samuel G. B. Johnson (samuel.johnson@yale.edu)<br>Department of Psychology, Yale University<br>2 Hillhouse Ave., New Haven, CT 06520 USA

Lance J. Rips (rips@northwestern.edu)<br>Department of Psychology, Northwestern University<br>2029 Sheridan Road, Evanston, IL 60208 USA

#### Abstract

How do we assign causal responsibility for others' decisions? The present experiments examine the possibility that an optimality constraint is used in these attributions, with agents considered less responsible for outcomes when the decisions that led to those outcomes were suboptimal. Our first two experiments investigate scenarios in which agents are choosing among multiple options, varying the efficacy of the forsaken alternatives to examine the role of optimality in attributing responsibility. Experiment 3 tests whether optimality considerations also play a role in attribution of causality more generally. Taken together, these studies indicate that optimality constraints are used in lay decision theory and in causal judgment.

Keywords: Causal attribution; decision-making; theory of mind; responsibility; lay decision theory.

## Introduction

Many of the decisions we make on a daily basis are thoroughly mediocre. This conclusion has been the joint product of the philosophical discipline of Decision Theory, which aims to characterize the decisions we ought to make given our knowledge and priorities (e.g., Jeffrey, 1965), and the psychological discipline of Judgment and Decision-Making (JDM), which aims to characterize actual decision-making behavior (e.g., Tversky \& Kahneman, 1974). JDM research has shown that normative decision theory largely fails as a descriptive theory of human decision-making, documenting a plethora of ways in which our actual decision-making does not live up to normative standards.

Less is known, however, about how people conceptualize and evaluate the decisions of others-a research question one might term lay decision theory. The present research begins to examine this question, investigating how people assign causal responsibility to agents for the outcomes of their decisions.

In these experiments, we consider situations in which an agent made a decision that led to an outcome with probability $\mathrm{P}_{\mathrm{ACT}}$ (always $50 \%$ ), but could have made an alternative decision that would have led to that outcome with probability $\mathrm{P}_{\mathrm{ALT}}$ (which was varied between $10 \%$ and $90 \%$ across conditions). For example:

Angie has a shrub, and wants the shrub's flowers to turn red. She is considering two brands of fertilizer to apply:
If she applies Formula PTY, there is a $50 \%$ chance that the flowers will turn red.
If she applies Formula NRW, there is a $10 \%$ chance that the flowers will turn red.
Angie chooses Formula PTY, and the flowers turn red. Thus, Angie's actual choice of Formula PTY led to the outcome with probability $\mathrm{P}_{\mathrm{ACT}}=50 \%$, and her alternative choice of Formula NRW led to the outcome with $\mathrm{P}_{\text {ALT }}=$ $10 \%$. Because $\mathrm{P}_{\text {ACT }}>\mathrm{P}_{\text {ALT }}$, Angie's choice was optimal. However, if Formula NRW had led to the outcome with $\mathrm{P}_{\mathrm{ALT}}=90 \%$, then $\mathrm{P}_{\mathrm{ALT}}>\mathrm{P}_{\mathrm{ACT}}$, and Angie's choice would have been suboptimal. Finally, if $\mathrm{P}_{\text {ALT }}$ had been $50 \%$, then $\mathrm{P}_{\mathrm{ACT}}=\mathrm{P}_{\mathrm{ALT}}$, and there would have been no uniquely optimal decision.

There are at least three possible predictions one could make about how judgments of Angie's responsibility for the outcome would vary as a function of the counterfactual alternatives that Angie forsook.

First, according to the Counterfactual Stability view, counterfactual alternatives are irrelevant to computing causal responsibility in situations like Angie's. This seems plausible, since $\mathrm{P}_{\mathrm{ACT}}$ is fixed across all conditions at $50 \%$, and the likelihood of goal completion does not depend on the efficacy of the alternative. Moreover, it is stipulated in the vignette that the agent achieves her goal, eliminating uncertainty about the outcome. This result would be obtained if people are permissive of suboptimal decision-making when computing causal responsibility. In actual decision-making practice, after all, computational limitations prevent us from analyzing every possible course of action, so we often settle for an option that is satisfactory even if not optimal (Simon, 1956).

Second, according to the Difference-Making view, judgments of responsibility are a linear function of the difference made by the actual choice, relative to the alternative choice. On this view, responsibility judgments would be proportional to $\left[\mathrm{P}_{\mathrm{ACT}}-\mathrm{P}_{\mathrm{ALT}}\right]$, known as $\Delta \mathrm{P}$ in the causal learning literature. On this view, one is most responsible for an outcome when the quality of the alternative options is very low, because the choice made a
large difference, while one is viewed as less responsible as the size of this gap decreases. For suboptimal choices (i.e., when $\Delta \mathrm{P}<0$ ), one's responsibility could further decrease (or be viewed as preventive) as the forsaken alternatives become increasingly efficacious and $\Delta \mathrm{P}$ becomes increasingly negative. Though prior research on causal attribution (e.g., Cheng \& Novick, 1992; Spellman, 1997) does not directly predict this result, this pattern would be most consistent with those previous findings.

Finally, according to the Optimality view, judgments of responsibility would be higher for optimal decisions than for suboptimal decisions, without consideration for how much better that decision is, compared to its alternatives. As we know humans to be satisficers and heuristic decision-makers, it may seem unlikely on the surface that we should require optimal behavior from others when assigning causal responsibility. However, theoretical considerations make this view seem less far-fetched.

Dennett (1987; see also Davidson, 1967) proposed that mental state inferences can often be accomplished by invoking a well-formedness rule called the Principle of Rationality. Just as we can solve the equation ' $X+Y=Z$ ' if given the values of two of the three variables, so can we make inferences about agents' actions, goals, and situational constraints by using the principle that agents act rationally to satisfy their goals, given situational constraints. These inputs to the rationality 'formula' can be either states of the world (when reasoning teleologically), or mental states (i.e., beliefs, desires, and intentions, when reasoning mentalistically). In either case, the Principle of Rationality produces a unique prediction for one element given the other two, just as the facts of arithmetic yield a unique solution for ' $2+Y=5$ '. Actions conforming to the Principle of Rationality are optimal, relative to the agent's goals and situational constraints.

Previous research has shown that both adults and infants often make inferences afforded by the Principle of Rationality. In a series of experiments using a violation-of-expectation paradigm, Csibra et al. (1999) presented young infants with simple visual displays of geometric figures. The infants successfully used teleological constraints to predict these figures' actions from their goals and situational constraints. More recently, Baker, Saxe, and Tenenbaum (2009) developed a computational model to capture adults' inferences about goals from a display of the agent's movements in a simple maze.

The Principle of Rationality could lead people to discount the causal efficacy of suboptimal decisionmakers in two ways. First, because actions are assumed to follow the Principle of Rationality, apparently suboptimal actions are often reinterpreted as optimal actions under different assumptions-for example, that the agent was acting under a different goal, or that the agent's beliefs were incomplete or erroneous (Baker et al., 2009; Buchsbaum et al., 2011). Although the action is optimal under such a reinterpretation, the assumptions made about the agent (such as ignorance) to rationalize the action may
undermine the agent's perceived causal role in producing the outcome. Second, Csibra et al. (1999) have suggested that conformity to the Principle of Rationality is used as a principle for determining which entities are treated as agents, that is, as subject to folk-psychological principles. A decreased belief in the decision-maker's status as an agent could lead to a decreased attribution of causation. Indeed, such reasoning may not be restricted only to human agents. Kelemen and Rosset (2009) found that even adults apply teleological principles 'promiscuously' to inanimate objects. If people use efficiency cues to classify entities as agents, they may assign greater causal responsibility for objects that fulfill their causal affordances in the most efficient manner.
If the Optimality view is correct, responsibility judgments would be higher when $\mathrm{P}_{\mathrm{ACT}}>\mathrm{P}_{\text {ALT }}$ (an optimal choice) than when $\mathrm{P}_{\mathrm{ACT}}<\mathrm{P}_{\text {ALT }}$ (a suboptimal choice). However, the size of $\left[\mathrm{P}_{\mathrm{ACT}}-\mathrm{P}_{\text {ALt }}\right]$ would not affect judgments, since optimality is a qualitative property of a choice and does not depend on the magnitude of this difference. This view does not make a specific prediction about judgments when $P_{A C T}=P_{\text {ALT }}$, because there is no uniquely optimal choice in such situations.

Three experiments distinguished among these possibilities. First, we examined whether an agent's perceived responsibility (Experiment 1A) or causal contribution (Experiment 1B) for the outcome of a decision depends on the efficacy of an alternative, forsaken option. Second, we replicated and extended these findings using situations in which agents decide among three options (Experiment 2A) or in which the base rate of the outcome is specified (Experiment 2B), ruling out an alternative interpretation of Experiment 1. Finally, we explored the possibility that optimality constraints are used in assessing causation more generally, even for inanimate causes (Experiment 3).

## Experiments 1A and 1B

In Experiment 1, we examined whether the predictions of the Counterfactual Stability, Difference-Making, or Optimality view best capture judgments about vignettes such as those presented in the introduction. Additionally, to assess the consistency of these effects across measures, we included questions both about responsibility (in Experiment 1A) and about causation (in Experiment 1B).

## Method

Participants Fifty participants ( $56 \%$ female) were recruited from Amazon Mechanical Turk to participate in Experiment 1 A , and a different group of 50 participants ( $44 \%$ female) to participate in Experiment 1B.
Materials and Procedure Participants read five vignettes similar to the text given above, with five different cover stories. In these vignettes, $\mathrm{P}_{\mathrm{ACT}}$ was fixed at $50 \%$, while $P_{\text {ALT }}$ was varied across cover stories (at $10 \%, 30 \%, 50 \%$, $70 \%$, and $90 \%$ ) using a Latin square. The corresponding values of $\Delta \mathrm{P}\left(\mathrm{P}_{\text {ACT }}-\mathrm{P}_{\text {ALT }}\right)$ are thus $40 \%, 20 \%, 0 \%$,
$-20 \%$, and $-40 \%$, respectively. Participants were asked to rate their agreement with either a responsibility statement (e.g., "Angie is responsible for the flowers turning red") in Experiment 1A, or with a causal statement ("Angie caused the flowers to turn red") in Experiment 1B, on an 11-point scale (0: 'disagree'; 5: 'neither agree nor disagree'; 10: 'agree'). Manipulation check questions were included in this and all subsequent studies to monitor comprehension of the vignettes; however, these questions are not discussed further because no participants were eliminated from the analysis for these or any subsequent experiments.

## Results

As shown in Table 1, judgments of responsibility and causation were higher when $\mathrm{P}_{\mathrm{ACT}}>\mathrm{P}_{\mathrm{ALT}}$ than when $\mathrm{P}_{\mathrm{ACT}}$ $<\mathrm{P}_{\mathrm{ALT}}$, while judgments were intermediate when $\mathrm{P}_{\mathrm{ACT}}=$ $P_{\text {ALT }}$. Yet, the magnitude of the difference between $\mathrm{P}_{\mathrm{ACT}}$ and $P_{\text {ALT }}$ had no effect on judgments beyond the direction of the difference, consistent with the Optimality view.

This pattern was confirmed with a mixed-model ANOVA on judgments, with $\mathrm{P}_{\text {ALT }}(10 \%, 30 \%, 50 \%, 70 \%$, or $90 \%$ ) as a within-subjects factor, and Experiment (responsibility question or causal question) as a betweensubjects factor. This revealed a significant main effect of $\mathrm{P}_{\mathrm{ALT}}, F(4,392)=13.97, M S E=3.34, p<.001, \eta_{\mathrm{p}}{ }^{2}=.13$, and a main effect of Experiment, $F(1,98)=10.54, M S E=$ 15.41, $p=.002, \eta_{\mathrm{p}}^{2}=.10$, with responsibility ratings higher overall than causal ratings ( $M=6.09, S D=1.67$ vs. $M=4.95, S D=1.83$ ). This main effect may have occurred because the word 'cause' triggered a deterministic causal concept at odds with the probabilistic character of the decision problem. There was no interaction between $\mathrm{P}_{\mathrm{ALT}}$ and Experiment, $F(4,392)=$ $0.87, M S E=3.34, p=.48, \eta_{\mathrm{p}}^{2}<.01$, indicating no reliable difference in the effect of $\mathrm{P}_{\mathrm{ALT}}$ between experiments.

To explore the main effect of $\mathrm{P}_{\mathrm{ALT}}$, pairwise planned comparisons were conducted on adjacent $\mathrm{P}_{\text {ALT }}$ conditions (means from the combined experiments are presented in the bottom row of Table 1). The $10 \%$ and $30 \%$ conditions did not differ, $t(99)=1.09, S E M=0.21, p=.28, d=0.11$, nor did the $70 \%$ and $90 \%$ conditions, $t(99)=-0.21$, SEM $=0.24, p=.84, d=-0.02$. However, the $50 \%$ condition differed significantly from both the $30 \%$ condition, $t(99)$ $=-3.13, S E M=0.25, p=.002, d=-0.31$, and the $70 \%$ condition, $t(99)=2.22, S E M=0.21, p=.029, d=0.22$.

Table 1: Results of Experiment 1 (SDs in parentheses).

| $\mathbf{P}_{\text {AlT }}$ | $\mathbf{1 0 \%}$ | $\mathbf{3 0 \%}$ | $\mathbf{5 0 \%}$ | $\mathbf{7 0 \%}$ | $\mathbf{9 0 \%}$ |

## Discussion

These results are most consistent with the Optimality view. Although there was an effect of $\mathrm{P}_{\text {ALT }}$ on responsibility ratings, this occurred only because judgments were dependent on the sign of $\Delta \mathrm{P}$ : Judgments were higher when $\mathrm{P}_{\mathrm{ACT}}>\mathrm{P}_{\text {ALT }}$ than when $\mathrm{P}_{\mathrm{ACT}}=\mathrm{P}_{\mathrm{ALT}}$, and higher when $\mathrm{P}_{\mathrm{ACT}}=\mathrm{P}_{\mathrm{ALT}}$ than when $\mathrm{P}_{\mathrm{ACT}}<\mathrm{P}_{\mathrm{ALT}}$, but the magnitude of $\Delta \mathrm{P}$ did not affect judgments. This finding cannot be explained by either the Counterfactual Stability view, according to which responsibility judgments would be invariant over different values of $\mathrm{P}_{\text {ALT }}$, or by the Difference-Making view, according to which responsibility judgments would be proportional to $\Delta \mathrm{P}\left(\mathrm{P}_{\mathrm{ACT}}-\mathrm{P}_{\mathrm{ALT}}\right)$. Moreover, the lack of magnitudedependence held for both attributions of responsibility and of causation, indicating that these results are not due to idiosyncratic properties of either phrasing.

Although the Counterfactual Stability and DifferenceMaking views cannot explain the results of Experiment 1, these results do not uniquely entail the Optimality view, because participants could have made these responses on the basis of whether $\Delta \mathrm{P}>0$. In more complex decision problems, it is possible for multiple options to have positive $\Delta \mathrm{P}$, yet for only one option to be uniquely optimal. Experiment 2 investigated whether people would still be sensitive to optimality in more complex scenarios.

## Experiments 2A and 2B

To examine whether the response pattern in Experiment 1 was based on optimality or simply on whether $\Delta \mathrm{P}>0$, Experiment 2 used vignettes in which agents faced three choices, of which $(A)$ had a low probability of leading to the goal, $(B)$ had a moderate probability of leading to the goal, and $(C)$ had the highest probability of leading to the goal. Thus, $C$ is the optimal choice, but both $B$ and $C$ have positive $\Delta \mathrm{P}$ relative to $A$. If judgments are based on optimality, then an agent choosing $C$ should be rated more responsible than an agent choosing $B$, since $C$ is optimal but $A$ and $B$ are not. However, if people are merely sensitive to $\Delta \mathrm{P}$ being positive, they should rate agents choosing $B$ and $C$ equally highly, since $\Delta \mathrm{P}>0$ for both.
Experiment 2 employed two different framings of the "least optimal" alternative. In Experiment 2A, all three options were described as alternative choices with varying probabilities of success. In Experiment 2B, the "least optimal" alternative was described as a base rate-the probability of the goal occurring in the absence of any action. This second phrasing makes the fact that $\Delta \mathrm{P}>0$ for both of the other alternatives more salient, providing a stronger test against the Optimality hypothesis.

## Method

Participants One hundred participants (52\% female) were recruited from Amazon Mechanical Turk to participate in Experiment 2A, and a different group of 100 participants ( $49 \%$ female) participated in Experiment 2B.

Each experiment was conducted as part of a session that included additional experiments not reported here; the order of the experiments was counterbalanced.
Materials and Procedure In Experiment 2A, participants read two vignettes from Experiment 1, modified to read:

Angie has a shrub, and wants the shrub's flowers to turn red. She is thinking about applying a fertilizer, and has three options:
If she applies Formula LPN, there is a $10 \%$ chance that the flowers will turn red.
If she applies Formula PTY, there is a $50 \%$ chance that the flowers will turn red.
If she applies Formula NRW, there is a [30/70]\% chance that the flowers will turn red.
Angie chooses Formula PTY, and the flowers turn red.
For Experiment 2B, the phrase "if she applies Formula LPN" was replaced by the phrase "if she applies nothing," to make the $10 \%$ base rate more salient. Whether Formula NRW had a $30 \%$ or $70 \%$ chance of leading to the goal ( $\mathrm{P}_{\mathrm{ALT}}$ ) was manipulated within-subjects (in the former case, the actual choice was optimal, while in the latter case, the actual choice was suboptimal), with the assignment of $\mathrm{P}_{\mathrm{ALT}}$ to vignette counterbalanced. Participants rated the agent's responsibility for the outcome on the same 11-point scale as Experiment 1A.

## Results and Discussion

As shown in Figure 1, agents were viewed as less responsible when their choice was suboptimal, whether the "least optimal" option was described as an alternative (Experiment 2A) or as a base rate (Experiment 2B). This occurred even though $\Delta \mathrm{P}$ was positive for both choices.

An ANOVA was conducted on responsibility judgments, with $\mathrm{P}_{\text {ALT }}(30 \%$ or $70 \%$ ) as a within-subjects factor and Experiment ( 2 A or 2 B ) as a between-subjects factor. There was a main effect of $\mathrm{P}_{\mathrm{ALT}}, F(1,198)=18.57$, $M S E=1.91, p<.001, \eta_{\mathrm{p}}{ }^{2}=.09$, with responsibility rated higher when $\mathrm{P}_{\mathrm{ALT}}=30 \%(M=6.83, S D=2.01)$ than when $\mathrm{P}_{\mathrm{ALT}}=70 \%(M=6.24, S D=2.14)$. Thus, responsibility ratings were higher for optimal decisions.

There was also a main effect of Experiment, $F(1,198)=$ 12.57, $M S E=6.37, p<.001, \eta_{\mathrm{p}}{ }^{2}=.06$, with judgments higher in Experiment 2B $(M=6.98, S D=1.53)$ than in Experiment 2A $(M=6.09, S D=2.01)$. This may have occurred because Experiment 2B described the least effective option as an omission rather than as an action, creating a qualitative difference among the options. However, there was no interaction between Experiment and $\mathrm{P}_{\mathrm{ALT}}, F(1,198)=0.30, M S E=1.91, p=.59, \eta_{\mathrm{p}}^{2}<.01$.

Although the Difference-Making account would make the same predictions as the Optimality account for these cases, the results of Experiment 2 show that the responses in Experiment 1 are unlikely to have been based merely on considerations of whether $\Delta \mathrm{P}>0$, since this was the case for both the optimal and the suboptimal case in Experiment 2. The Optimality view is the only account that is consistent with the results of both experiments.

Figure 1: Mean responsibility judgments (Experiment 2) and causal judgments (Experiment 3) on 11-point scales.

## Experiment 3

One potential explanation for the results of Experiments 1 and 2 is that participants were reinterpreting apparently suboptimal actions as guided by a different set of assumptions about the agent's knowledge or goals (e.g., Baker et al., 2009; Buchsbaum et al., 2011). Angie's objectively suboptimal decision to use Formula PTY may have led participants to view her as ignorant of the choice situation, or as having some other goal in mind other than making the flowers turn red, and participants may have accordingly downgraded her responsibility.

Another possibility, however, is that these results reflect principles used to designate entities as subject to our folk-psychological theorizing in the first place. Csibra et al. (1999) suggested that the Principle of Rationality is used for this purpose; indeed, efficiency may even be detected at the perceptual level (Gao \& Scholl, 2011). If individuals failing to behave optimally are not conceptualized as agents to the same extent as those behaving optimally, this could lead people to discount their role in causally producing the outcome.

If our earlier effects were obtained at least in part because optimality is used as a principle for designating agents, optimality considerations might be used more generally in causal reasoning, outside the social realm, because people may reason about efficient causes as though they were endowed with agent-like properties. This prediction, while counterintuitive, is bolstered by findings of 'promiscuous' teleological reasoning (Kelemen \& Rosset, 2009), with children and even adults under time pressure treating natural kinds as though they were artifacts endowed with purposes. Experiment 3 examined this prediction by testing whether people treat event types as more causal when they lead optimally to their effect, relative to other possible causes.

## Method

Participants One hundred participants ( $44 \%$ female) were recruited from Amazon Mechanical Turk to participate in Experiment 3. This experiment was
conducted as part of a session that included an additional experiment not reported here; the order of the experiments was counterbalanced.
Materials and Procedure Participants read two vignettes adapted from Experiment 2 B so that they no longer referred to a choice made by a human agent, but instead to the probability of an effect occurring given two different (non-human) causes:

There is a certain shrub that has flowers which sometimes turn red. There are two brands of fertilizer: Formula PTY and Formula NRW.
When nothing is applied, there is a $10 \%$ chance that the flowers turn red.
When Formula PTY is applied, there is a $50 \%$ chance that the flowers turn red.
When Formula NRW is applied, there is a [30/70]\% chance that the flowers turn red.
Each participant was then asked to what extent they agreed with the statement that "Formula PTY causes the flowers to turn red" on the same 11-point scale used in previous experiments. In both conditions, participants judged the strength of a cause with $50 \%$ efficacy (i.e., $\mathrm{P}_{\mathrm{ACT}}=50 \%$ ), while the efficacy of the other cause ( $\mathrm{P}_{\mathrm{ALT}}=$ $30 \%$ or $\mathrm{P}_{\mathrm{ALT}}=70 \%$ ) was manipulated within-subjects and counterbalanced with vignette.

## Results and Discussion

As shown in Figure 1, Formula PTY was judged more causal when it was optimal than when it was suboptimal, even though it always had a $50 \%$ chance of leading to the effect. A paired-sample $t$-test revealed that causal ratings were higher in the $\mathrm{P}_{\mathrm{ALT}}=30 \%$ condition $(M=6.58, S D=$ 1.67) than in the $\mathrm{P}_{\mathrm{ALT}}=70 \%$ condition $(M=6.00, S D=$ 1.72), $t(99)=4.50, S E M=0.13, p<.001, d=0.45$.

This result suggests that the mechanism underlying the optimality effect in lay decision theory is not specific to human agents, but can be extended 'promiscuously' to other entities, with people discounting a cause's efficacy in the face of a superior alternative cause.

One concern about this result might be potential scale or contrast effects. For example, suppose that participants implicitly judge each cause in each vignette (including the alternative cause that was not asked about), and always give the 'best' cause for each vignette the same rating. Then, a participant in the optimal condition might have assigned the better (actual) cause a rating of ' 7 ' and implicitly assigned the worse (alternative) cause a rating of ' 5 ', and in the suboptimal condition implicitly assigned the better (alternative) cause a rating of ' 7 ' and the worse (actual) cause a rating of ' 5 ', leading to our effect. Similarly, a contrast effect could have occurred if the psychological weight of $\mathrm{P}_{\mathrm{ACT}}$ differed between conditions. $\mathrm{P}_{\mathrm{ACT}}(50 \%)$ could have felt like a larger magnitude when compared to $\mathrm{P}_{\mathrm{ALT}}=30 \%$ than to $\mathrm{P}_{\mathrm{ALT}}=70 \%$, leading to higher ratings in the optimal condition.

Although these possibilities can only be ruled out definitively with future study, our within-subjects design
renders these explanations unlikely. The vignettes were read and judged consecutively, which both calls attention to the consistency of $\mathrm{P}_{\mathrm{ACT}}$ across conditions, and creates pressure to give identical responses across conditions. Nonetheless, converging evidence from other tasks will be of use in ruling out these possibilities more directly.

The present result should be distinguished from the superficially similar phenomena of discounting (e.g., Khemlani \& Oppenheimer, 2011) and cue competition (e.g., Waldmann \& Holyoak, 1992). Discounting occurs when one has a prior causal schema in which two causes (e.g., Formulas PTY and NRW) are each sufficient for an effect (the flowers turning red). If one cause (Formula NRW) is known to occur on some particular occasion, this makes the other cause (Formula PTY) less likely to be present on that occasion, because the known presence of Formula NRW "explains away" the effect and removes any reason to posit Formula PTY. Thus, the discounting phenomenon involves prior knowledge of causal types influencing subsequent inferences about causal tokens.

In the related phenomenon of cue competition, tokenlevel observational data affect subsequent formation of type-causal schemas. For example, in backward blocking, two candidate causes are first paired with the effect (i.e., Formulas PTY and NRW are both applied for several trials on which the flowers turn red), then one of the candidates alone is paired with the effect (i.e., only Formula PTY is applied for several trials on which the flowers turn red). Observing that the alternative cue (Formula PTY) produces the effect by itself reduces the belief that Formula NRW causes the effect in general.

However, the logics underlying these phenomena do not apply to our experimental situation. The input to the discounting process is type-causal schemas, and the output token-causal inferences; the input to cue competition is token-causal observations, and the output type-causal schemas. In our task, in contrast, participants made type-causal judgments from knowledge about statistical relationships at the type level. Thus, the present phenomenon is conceptually distinct.

Although Experiment 3 suggests that the optimality effect in lay decision theory occurs at least in part because conformity to the Principle of Rationality is used to designate entities as subject to folk-psychological principles, this does not preclude the possibility that some participants in Experiments 1 and 2 were additionally reinterpreting the agents' actions as optimal under a different set of assumptions. Nonetheless, Experiment 3 shows that re-interpretation cannot be a full explanation. Indeed, the effect in Experiment 3, which cannot not be explained in terms of re-interpretation, was of similar magnitude to that in Experiment 2.

## General Discussion

The present studies examined whether optimality is used as a cue for assigning causal responsibility. In Experiment 1, agents were judged more responsible for, and more
causal in, producing an outcome when their decision was the optimal choice for obtaining the outcome, but the magnitude of the difference between the efficacy of the optimal and suboptimal choices did not affect judgments. Experiment 2 showed that perceived responsibility is greater when a decision is optimal than when suboptimal, even when the suboptimal option is superior to a worst option or to the base rate of the outcome. Finally, Experiment 3 demonstrated an optimality effect in reasoning about causation for inanimate causes, suggesting that the optimality effect occurs at least in part because entities acting optimally are more likely to be designated as agents subject to our folk psychology.
Our results suggest several potentially promising avenues for future research. We are seldom confronted in real life with decisions for which we know the exact probabilities, more often entertaining a range of probabilities as potentially valid (Levi, 1985). A more ecologically valid test of our optimality hypothesis would specify realistic decision alternatives for which participants had a range of prior beliefs about the efficacy for achieving an outcome, rather than a single probability value. We chose to instead specify the probabilities so as to maximize experimental control. However, replicating the current results with more naturalistic stimuli would both enhance the generality of our findings and allow for exploration of boundary conditions.
Little appears to be known concerning folk beliefs about decision-making, what we term lay decision theory. In addition to shedding light on our theory of mind abilities, understanding the principles of lay decision theory may have practical implications for behavioral game theory, in which people must model others' behavior in order to make their own decisions. The present research addresses only a small fraction of the questions that might be asked: for example, how these beliefs are used in explaining and predicting behavior, whether (and when) people conceptualize decisions in terms of mental states or as states of the world (i.e., with mentalistic or teleological representations), how people conceptualize more complex decision problems in which multiple goals must be balanced against one another, and whether optimality constraints are applied equally to our own behavior as to the behavior of others. We are currently conducting research to probe these questions.

## Conclusion

Rationality constraints are commonplace heuristics for making inferences about human actions. The present research shows that such constraints also play a role in the evaluation of decisions, affecting how causal responsibility is assigned for an outcome.
As suboptimal decision-makers ourselves, it may appear hypocritical for us to hold others less responsible for the outcomes of their decisions when they decide suboptimally. Yet, we may have little choice-our rationality is, after all, bounded.

#### Abstract

Humans, as a cooperative species, need to coordinate in order to achieve goals that are beyond the ability of one individual. Modeling the emergence of coordination can provide ways to understand how successful joint action is established. In this paper, we investigate the problem of two agents coordinating to move an object to one agent's target location through complementary action. We formalize the problem using a decisiontheoretic framework called Decentralized Partially Observable Markov Decision Processes (Dec-POMDPs). We utilize multiagent Q-learning as a heuristic to obtain reasonable solutions to our problem and investigate how different agent architectures, which represent hypotheses about agent abilities and internal representations, affect the convergence of the learning process. Our results show, in this problem, that agents using external signals or internal representations will not only eventually perform better than those that are coordinating in physical space alone but also outperform agents that have independent knowledge of the goal. We then employ information theoretic measures to quantify the restructuring of information flow over the learning process. We find that the external environment state varies in its informativeness about agents' actions depending on the agents' architecture. Finally, we discuss how these results, and the modeling technique in general, can address questions regarding the origins of communication.

## Introduction

The moment we move from a study of individual cognition to a detailed analysis of the social realm, we have committed ourselves to the investigation of a different type of system. There is no centralized controller; this system is inherently decentralized. The questions we ask, however, may be similar. Just as we wish to study how a individual decision maker adapts its behavior in a task environment, we can investigate the ways in which multiple, possibly non-identical, decision makers reorganize their internal world and their external interactions to form a new functional system that solves a problem which cannot be addressed by one individual alone (Hutchins, 1995).

One important problem that cooperative agents face is how to coordinate their movements to arrive at a goal known only to one of the agents. This problem was addressed in Hazlehurst and Hutchins (1998), where the authors constructed an algorithm that allowed for a set of agents to converge on similar form-meaning mappings which also related to their movements within a given environment. This setup, like many modeling studies that focus on issues of hidden goals of other agents, has a strong predilection towards imita-
tive learning. Not all learning and reorganization in a multiagent system is imitative, however, and another focus of modeling should be on complementary action learning (Hutchins \& Johnson, 2009). It has been shown elsewhere that agents can learn to coordinate in complementary ways without sharing information about each other (Sen, Sekaran, Hale, et al., 1994), but this presumes an environment where there is only one destination and both agents know its identity. By combining aspects from these two studies, we can investigate scenarios in which agents must collaboratively, through complementary action, arrive at a goal location known to only one agent.

While it is typically intractable to find the optimal solution to many multi-agent coordination problems, these problems are particularly important because their inherent challenges highlight several important features of social interaction and group dynamics that need to be studied:

1. Non-stationary World: Agents are constantly adapting to the statistics of their environment, including other agents. Since other agents do not have a fixed method of interacting with the world a priori, the world is inherently nonstationary (Buşoniu, Babuška, \& Schutter, 2008).
2. Non-independent Sampling: An agent's own actions affect its incoming sensory information and this in turn affects the regularities it can extract from the world (Lungarella \& Sporns, 2005). Motor activity and sensory information obtained from the environment are interdependent; the way we move in the world shapes our understanding of it and these patterns of data have structure.
3. Distribution of Knowledge: Not all agents in the world have access to the same information or capabilities. The social realm is comprised of more than just a set of identical individual problem solvers (Hutchins, 1995).

Another prominent research direction in studying multiagent systems is determining "(h)ow to develop... problem solving protocols (information flow) that enable agents to share results and knowledge in a timely, effective manner" (Sen, 1997). It is important to understand how a group of individual agents reorganizes in functional ways that alter the flow of information; we need to understand "what information goes where and in what form" (Hutchins, 1995) and how these pathways change. This situation is complicated by the
fact that researchers in Cognitive Science hold different assumptions about the internal organization and external behavior of agents, which specifies the model elements, and this constrains the possible ways to reconfigure information flow. This situation can be rectified, however, by utilizing a common formalism for comparing and contrasting the consequences of different sets of assumptions.

In this paper, we utilize a formal framework, Decentralized Partially Observable Markov Decision Processes (DecPOMDPs), to place our problem of interest into a larger set of multi-agent coordination problems in order to investigate coordination problems when agents have access to different amounts of information (Karnowski, accepted). We then discuss how several assumptions about agent architecture map into specific changes in the problem structure, demonstrating how we can vary our hypotheses by altering the components of the Dec-POMDP. Through the use of multi-agent Qlearning, we can demonstrate the speed with which agents reorganize themselves into stable patterns of behavior that allow them to coordinate their actions and achieve a joint goal. This reorganization brings differences in performance, however, based on the assumptions made about agent capabilities. We utilize mutual information to measure the changes in statistical dependencies among streams of information and to show how agents' behaviors respond to environmental regularities. We conclude by discussing how one problem formulation may provide insights into the study of the evolution of communication and future directions in this area.

## Methods

## Decentralized Partially Observable Markov Decision Processes (Dec-POMDPs)

Dec-POMDPs (D. Bernstein, Zilberstein, \& Immerman, 2000) are a way to formalize multi-agent coordination problems. They provide a common structure that aids in the discussion of related problems and the development of solution techniques. While there exist other frameworks that tackle problems of agent coordination and problem solving (Dec-POMDP-COM, MTDP, and COM-MTDP with perfect recall), many of them have been shown to be formally equivalent (Seuken \& Zilberstein, 2008). The reason for the variety is that the frameworks emphasize different features. For instance, while Dec-POMDPs and Dec-POMDP-COMs (DecPOMDPs with communication) (Goldman, Allen, \& Zilberstein, 2007) are formally equivalent, the former tends to focus on bodily coordination in physical space and the latter with problems that also involve symbolic coordination. In addition to communication, frameworks often contain assumptions about the representational capacities of their agents, providing agents with, for example, the ability to model the goals or actions of other agents (Claus \& Boutilier, 1998). Providing a language for researchers in Cognitive Science to systematize problems in cooperative multi-agent interactions and make explicit their assumptions about individual architecture will allow for a thorough comparison of current models and
the exploration of regions between models with different assumptions.

Formally, a Dec-POMDP can be defined by a tuple $\langle\{A g\}, S,\{A\}, P,\{\Omega\}, O, R\rangle$, where $\{A g\}=\{1,2, \ldots, n\}$ is the set of agents, S is the possible states of the world, $\{A\}=$ $\left\{A_{1}\right\} \times\left\{A_{2}\right\} \times \ldots \times\left\{A_{n}\right\}$ is the set of joint actions (with $a=\left(a_{1}, a_{2}, \ldots, a_{n}\right)$ being a joint action and action $a_{i}$ is the action of agent i ), P is the transition function (with $P\left(s^{\prime} \mid s, a\right)$ being the transition to state s' given current state $s$ and joint action a), $\{\Omega\}$ is the set of possible observations, O is the matrix that defines the probability of seeing observation o given state s , and $R=R\left(s, a, s^{\prime}\right)$ is the reward for taking the joint action a in state s and transitioning to state s '. The goal of solving a Dec-POMDP is to find a joint policy $\pi=\left\{\pi_{1}, \pi_{2}, \ldots, \pi_{n}\right\}$ (where each $\pi_{i}$ is a local policy of one agent that maps an observation of a state to an action, i.e. $\pi_{i}: S \rightarrow A_{i}$ ) such that the group minimizes some cost function over time (similarly, it can maximize a reward function).

## Multi-agent Q-learning

Dec-POMDPs are a useful abstraction which allows for a common language when speaking about coordination problems. These problems, are typically difficult to solve (D. Bernstein et al., 2000), but solution algorithms are a current research trend (Spaan \& Oliehoek, 2008). Another way to address these problems is to use on-line adaptive heuristic algorithms that provide good approximate solutions, such as Q-learning (CJC, 1989), as they stochastically approximate off-line learning of optimal policies. In this paper, we use the Q-learning algorithm in a multi-agent context (Buşoniu et al., 2008). Within each agent, state-action pairs are strengthened depending on the outcome of the chosen action. For instance, if an agent transitions to state $s^{\prime}$ after performing action $a$ while in state $s$, an agent will receive a reinforcement $R$ and update the value of that state-action pair $(s, a)$ :

$$
\begin{equation*}
Q(s, a) \leftarrow(1-\alpha) Q(s, a)+\alpha\left(R+\max _{a^{\prime} \in A} Q\left(s^{\prime}, a^{\prime}\right)\right) \tag{1}
\end{equation*}
$$

Other parameters relate to the learning algorithm itself. The learning rate, $\alpha$, determines the degree to which the current state is updated given new experience, and the discount factor, $\gamma$, specifies how influential future states and actions are to the current state. In this experiment, actions were chosen in a greedy manner.

## Behavioral Info-Dynamics

Consider an isolated animal collective $X$ consisting of $n$ freely moving animals. Temporal data is collected on each animal's behavior generating a unique time series. Given a collection of sensorimotor time series data from a set of animals, we can measure statistical dependencies during different behavioral patterns. Tononi, Sporns, and Edelman (1994) (and later Tononi, Edelman, and Sporns (1998)) introduced a set of appropriately defined information-theoretic measures to capture the statistical properties of a system with $n$ components. While their methods were originally designed to study
neural systems, more recent work has adapted these measures to study sensorimotor coordination in embodied agents by collecting sensor and motor time series data (Lungarella, Pegors, Bulwinkle, \& Sporns, 2005). We utilize a Python implementation of these measures (available at https:// github.com/OpenCV-at-DCog-HCI/BID) to further extend these measures to study the behavior of a system of agents. In this paper, we focus only on the mutual information between pairs of time series. Depending on their interaction with the world, solitary agents and collections of agents exploit different statistical dependencies among streams of information. We can show these changes by measuring mutual information (Sporns, Karnowski, \& Lungarella, 2006; Di Prodi, Porr, \& Wörgötter, 2010).

Entropy defines the uncertainty inherent in a time series, or the average amount of information present. For instance, if knowing the state of the system at a given point in time will give you a lot of information about the time series as a whole, then this will contribute to a lower entropy. This could happen if that state is highly unlikely, and thus is more informative. If every state, however, is equally likely, then knowing the state at one point in time gives no information about the time series as a whole and entropy is maximal.

$$
\begin{equation*}
H(X)=-\sum_{j=1}^{n} p\left(x_{j}\right) \log \left(p\left(x_{j}\right)\right) \tag{2}
\end{equation*}
$$

Mutual information measures the dependence between two distributions (and in our case, time series). It is defined as the Kullback-Leibler distance ( $D_{K L}$ ) between the joint distribution $p\left(X_{1}, X_{2}\right)$ and the independent distribution $p\left(X_{1}\right) p\left(X_{2}\right)$. Mutual information is also defined as the sum of the entropies of the individual parts with the joint entropy subtracted out.

$$
\begin{align*}
& M I\left(X_{1}, X_{2}\right)=D_{K L}\left[p\left(X_{1}, X_{2}\right) \| p\left(X_{1}\right) p\left(X_{2}\right)\right]= \\
& H\left(X_{1}\right)+H\left(X_{2}\right)-H\left(X_{1}, X_{2}\right) \tag{3}
\end{align*}
$$

Any dependence between the two time series will increase the mutual information between them. For instance, if the state of one agent provides a lot of information about the state of another agent, this will result in higher mutual information. If the agents are completely independent, then this predictive power is lost, and mutual information will be zero.

## Problem and Experimental setup

To explore how two agents could coordinate via complementary actions to arrive at a hidden goal, we created an extension of the 'block pushing problem' (Matarić, 1996; Sen et al., 1994) where two agents are tasked to move from a start location to the goal, which is one of two possible locations, and follow as closely as possible a path P between the two. At every timestep, Agent i uses a force $\vec{F}_{i}$, where $0 \leq\left|\vec{F}_{i}\right| \leq F_{\max }$ on the block at an angle $\theta_{i}$, where $0<\theta_{i}<\pi$, which results in the block being offset by $\left|\vec{F}_{i}\right| \cos (\theta)$ in the $x$ direction and $\left|\vec{F}_{i}\right| \sin (\theta)$ in the $y$ direction. The new position of the block is calculated by vector addition of the displacement created
by the two agents. The new coordinates are then assigned to the correct discrete bin. The location of the block is used as feedback for the agents, depending on which scenario is being considered.

In our problem, $\{A g\}$ is a set of two agents, $S$ is the xcoordinate in a $20 \times 20$ grid world, the actions are a vectoraddition of individual agent actions that combine force and angle ( $0.2 \leq\left|\vec{F}_{i}\right| \leq 2.0$ ) in 0.2 increments and $15 \leq \theta_{i} \leq 165$ in 15 degree increments), $P$ is deterministic (the probabilities of moving to the next state given a joint action is 1 and the rest are zero), the set of observations is always the current x-coordinate in the grid world but more information is added depending on the scenario (for the agent with the goal, the current goal is also added to the observation), $\Omega$ is deterministic (the probabilities of an agent perceiving a particular observation given a state is 1 and the rest are zero), and the feedback depends on the scenario.

The first goal of our study was to establish a baseline. We implemented the scenario as found in (Sen et al., 1994):
0. Agent 2 also knows goal (Full Information): Both agents receive an observation of their x-coordinate and the goal. Their feedback is a function of their distance from the goal path $P$.

Even though there are two possible paths, there is only one goal for each trial, and therefore our agents acted in similar manner and replicated the results obtained by Sen et al. (1994). We then set out to construct a situation where there is a disparity in the amount of information accessible to each agent. In our 'base case', we consider the impact of removing information about the goal from Agent 2 and only allowing Agent 1 to have this knowledge. From here, our models were motivated by research agendas within Cognitive Science. Given different assumptions of agent architecture, we alter the Dec-POMDP in specific ways:

1. Agent 1 knows the goal but Agent 2 does not ('Base Case'): Agent 1 remains identical to previous results, but the observation Agent 2 receives does not contain information about the goal. The feedback for Agent 2 is a function of the distance from the closest path (i.e. when there is no information about the goal, the closest path is the best)
2. Agent 2 tracks probability of goal ('Theory of Mind'): Giving an agent the ability to represent the goal of another agent and make inferences about that goal given data is one way to conceptualize Theory of Mind. In this situation, Agent 2 begins a trial with the prior belief that either goal is the possible target. At each time step, the state of the world is a sample with which Agent 2 updates its belief of the current goal via Bayes rule. The probability of this sample is the probability that the x -coordinate is sampled from a Gaussian distribution with the x-coordinate of the goal being the mean and a standard deviation of 2.5 (Altering this distribution is future work). The probability space was discretized into 10 bins. The feedback for Agent 2 is
an weighted average (given current belief) of the feedback for both paths.
3. Agent 1 can make sounds ('Communication'): Agent 1 produces either a 0 or 1 which becomes part of the state which Agent 2 will experience on the next time step. The feedback for Agent 2 is a function of the closest path.
4. Agent 1 can make sounds and Agent 2 tracks probability of goal ('Theory of Mind' and 'Communication'): This is a combination of the previous two alterations. The feedback for Agent 2 is the weighted average of the feedback for both paths.

The feedback in each of these cases is determined by a function of the distance from the desired path, $f(\delta x)=$ $K * a^{-\delta x}$, similar to the original setup in Sen et al. (1994). This provides a high value for being on the path and an exponentially decreasing value further away from the desired path. Starting out the learning process with high values for state-action pairs and providing feedback after every trial was another feature in Sen et al. (1994) that allowed the agents to explore the available actions (alternatively, one could set the values in the beginning to be zero, but receiving feedback after just one trial would bias the agent to take the same path every trial). Also, any updates to state-action pairs could not be larger than the original high value (in our case, this was set to 100).

At the beginning of every trial, the two agents start at $(x, y)=(10,0)$ and the goal is randomly chosen from two options: $(3,20)$ or $(17,20)$. They make individual actions which combine into a joint action as outlined above. If the agents move the object outside of the $20 \times 20$ grid world, then the trial ends. Similarly, if the agents arrive at the goal state, the trials ceases. In the rare chance that agents would take more than 100 timesteps, the trial would also stop (forcing the angles to not allow agents to travel parallel to the x-axis helps alleviate this problem). An additional feature incorporated into the world dynamics was an automatic movement forward if the agents did not move forward enough on a trial. This was added to ensure agents did not remain still and allowed for better convergence.

## Results

In our experiments, agents always began with equally valuable state-action pairs and this caused their actions to be selected randomly. Over many trials, as agents adjust the values of different actions within each state, their behaviors begin to become patterned. Practices reduce the entropy of the shared environment, which leads to better policies and to a decrease in the average distance from the goal path. One would suspect, however, that performance would be best when there is complete information for both agents and that scenarios in which one agent has partial and incomplete information, the resulting joint actions would lead to poorer performance. This is not what we find, as shown in Figure 1. Having the ability to produce and utilize sounds allows agents, over time,
to perform better than those with complete information. Having the ability to represent and make inferences about the goals of another agent provides even more improvement in joint coordination.

Figure 1: The average distance of the actual path from the goal path given different agent assumptions ( $\alpha=0.01, \gamma=$ $0.9)$. Each experiment had 5000 trials and the data has been averaged over 100 experiments. Other learning rates ( $\alpha \in$ $\{0.1,0.2,0.3\}$ ) resulted in the similar patterns of performance with different rates of convergence.

We can determine how the two agents functionally reorganized themselves based on the levels of statistical dependence between different data streams. Mutual information provides a way to measure how predictable one data stream is from another. As we can see in Figure 2, both the scenario in which Agent 1 and Agent 2 have full knowledge of the goal and the 'base case', where Agent 2 does not know the goal, there is an increase in the mutual information between the x-coordinate and the angle of Agent 2 but this mutual informativeness plateaus. In the scenarios where there is Theory of Mind, Agent 2 is receiving a wealth of information about the goal through its current location but not necessarily needing to rely on any connection between its angle action choices and its location, which would have forced it to be more precise in its actions. In the scenarios with sound, there is a lot of extra structure in the shared environment that becomes highly predictive of the x-coordinate and therefore in the actions of Agent 2, including the angle. Another situation was created in which Agent 1 produced a sound but the state also included another random noise (to take away the special nature of the sound but not its ability to be manipulated). While the graph does not show the full increase of MI, other simulations showed this had the same trend as the case with communication, just over a longer period of time. This makes sense if agents were learning to utilize structure, but randomness was slowing this process down.

We did not find that the forces with which agents pushed the box had any predictive power for other data streams. When there was an increase in mutual information, it ap-

Figure 2: The mutual information between the x-coordinate and the angle of Agent 2.
peared to be due to the high predictability of angle and $x$ coordinate. As the world dynamics forced agents ahead one step if they did not apply enough force, it may have been the case that this affected the importance of force as a predictive element. This is probably not the case, however, as the agents in our model (and those in Sen et al. (1994)) only observe the x-coordinates, which would in turn dampen some of the informativeness of force in agent action choices.

## Discussion

In this paper, we have discussed the benefits of utilizing a common theoretical framework for addressing cooperative multi-agent problems in Cognitive Science and demonstrated how changes to framework elements can encapsulate various hypotheses about agent actions and internal representational capacities. We have designed a new multi-agent problem, focusing on understanding the acquisition of complementary actions in a goal-directed task where there is an information disparity. We used Q-learning, an algorithm commonly used in modeling single agent decision making, in a multi-agent setting to investigate how agent hypotheses affect the convergence of the learning process. And finally, we used mutual information to quantify how informative one data stream, the
x-coordinate, is about another data stream, the angle chosen by Agent 2 and charted the changes in this informativeness over time.

The results for this particular problem formulation provide a partial ranking of models based on performance. There are, however, a couple of caveats. First, while our simulated agents chose their actions in a greedy manner, different results might be obtained through other action selection methods, such as using a Boltzmann action selection mechanism. Second, Dec-POMDPs are typically used when there is some uncertainty in state transitions (due to modeling motor noise) or observations (due to sensory noise or partial view of the world). While this problem does not utilize this feature, future work manipulating these parameters may change the success of models with different assumptions about agent architecture.

This work highlights several of the open problems in the study of the emergence of communication, as it simultaneously investigates the origin of signaling channels, the sources of representation in signals, and the roles of social interaction in learned communication systems (Lyon, Nehaniv, \& Cangelosi, 2006).

Future work related to this particular example will strive to explore how agents could learn to discover that one information stream is informative about another, a hallmark of communication. As a starting point, for instance, we are particularly interested in the case where the agents have an ability to put structure into the shared environment through sounds. In this case, it could be that the agent with the goal is able to create noises, which allows the second agent to adjust its policy given this external structure. This in turn forces more regular behavior to which the speaking agent can then adjust. Originally, the noise was not functionally related to the current state; in the beginning, sounds just happened. As engagement proceeds, that noise ends up carrying information, and at that moment, the sounds would become a signaling channel.

This process, however, hasn't held any commitments to the content of that signaling channel. It may turn out that the speaking agent, through features of the algorithm, converges on highly rewarding action-sound pairings and the second agent only need adjust its behavior accordingly. In either case, we suspect that putting structure out into the world may create stable regularities with which agents could take advantage and eventually internalize (Vygotsky, 1978). Agent interactions themselves would be the determining factor behind the sources of representations in the signals they employ. In problems similar to ours, it is often the case that multi-agent Q-learning fails, precisely because neither agent experiences a stationary environment (Claus \& Boutilier, 1998). Placing stationary-creating behavior at the center of new algorithms is also possible future work.

Here we have shown that we can operationalize several assumptions in Cognitive Science and discover what structure and organization emerge from these hypotheses. In the present examples, however, agents are endowed with cer-
tain abilities a priori. We would really like to explore the conditions under which language-like abilities and Theory of Mind-like processes could emerge from ongoing interactions between autonomous agents. Additional future work will look at the space between these hypotheses and how various learning algorithms could take agents from a lack of abilities to a state where additional mental abilities have emerged through agent interactions.

## Acknowledgments

The authors would like to thank Chris Johnson, Ben Bergen, and Ben Cipollini for helpful discussions. Jeremy Karnowski is a Jacobs Fellow and is the recipient of a CARTA Graduate Fellowship in Anthropogeny.

# Representational Shifts Towards the Prototype in Memory for Hue 

Laura Jane Kelly (lkelly@ucmerced.edu)<br>Evan Heit (eheit@ucmerced.edu)<br>Cognitive and Information Sciences, University of California, Merced<br>5200 N. Lake Road, Merced, CA 95343 USA

#### Abstract

Representational shifts in memory have been a recent topic of interest and debate (Blanco \& Gureckis 2012; Lupyan, 2008; Richler, Gauthier \& Palmeri, 2011; Richler, Palmeri \& Gauthier, 2012). Whether there are true systematic biases in memory due to a stimulus being labeled has been proposed and contested. The fundamental proposal that representations shift toward the prototype has not previously been demonstrated. In the present experiment, participants judged colored silhouettes by color category or by preference, then were asked to remember the hue of the original silhouette among five narrowly distinct options. By using the single dimension of hue, we are able to show prototypical representational shifts in memory for colored silhouettes after a few minutes. We did not observe a difference between color labeled and preference judged silhouettes, refuting the claim that labeling is the source of prototypical representational shifts.

Keywords: Concepts and Categories; Representation; Perception; Memory; Labels; Color

## Introduction

A representational shift is a spatial metaphor for a systematic difference between the representation as measured and the original stimulus that inspired the representation. The representation is said to have shifted from the original sensory input somewhere along its cognitive path before being measured. The representational shift hypothesis (Lupyan, 2008) suggests that when explicit labels are used while perceiving an object, the encoded representation shifts from what it would be without explicit labeling to a more prototypical representation.

The original experiments (Lupyan, 2008), described in more detail below, did not directly address the main predictions of the representational shift hypothesis: the existence of a systematic shift or the direction of that shift. The analysis relied on inferring a representational shift from a pattern of non-directional forgetting. The data only directly indicated worse memory for labeled objects. The existence of a systematic shift and the direction of the potential shift is simply not shown by the data collected.

In the experiment presented here, we use color to test memory for recently presented silhouettes of animals and objects. In a paradigm similar to Lupyan (2008), the objects are labeled or not labeled followed by a surprise memory task. Instead of a yes-no recognition task, we present an array of 5 hue variations for the participants to choose among. By switching from multidimensional objects to unidimensional hue, and testing fine variations of hue
memory rather than course-grained recognition memory, we can see whether there are systematic shifts of hue memory and their direction within the dimension of hue. The pattern of false alarms is used to look for representational shifts.

Why do these representational shifts matter? We already know there are top-down influences on memory (e.g., Heit, 1997). Two particularly dramatic examples of the imperfection of memory are eyewitness testimony (Wells \& Olson, 2003) and flashbulb memories (Schmolck, Buffalo, \& Squire, 2000). Small differences between the experience of an object or color and its representation in memory may seem minor in comparison to changing the race of a shooter based on stereotypes or radically rewriting how you heard about a defining national moment over the course of a few years. However, taking into account how pervasive these small differences would be, representational shifts could have extensive effects on how meaning is build and supported. Prototypes can be conceived of as resulting from the build up of exemplars over time (Nosofsky, 1986; Palmeri \& Nosofsky, 2001). As a ramification of the representational shift hypothesis, exemplars in memory would not accurately reflect experience alone but would also have a bias related to when the example of the category was experienced. The stronger the category, the stronger the pull of the prototype, and as a result, the more new exemplars are biased towards categories as they already stand.

## The Representational Shift Hypothesis

Lupyan (2008) proposed that there would be a difference in encoding and retrieving memories of objects if the categorization was explicit rather than only implicit at the time of encoding. Previous work had shown better category learning with labels than without labels (Lupyan, Rakison \& McClelland, 2007), suggesting that there are differences in how categories with labels are activated. The difference in activation of the category could influence the encoding of exemplars of the category. Specifically, the representational shift hypothesis asserts that concurrent labels activate a more prototypical representation of the category than would the perceived exemplars activate alone. The stored encoding is hypothesized to be a mixture of the exemplar activation and the label activation; the final representation has shifted toward the prototype as a result of the interaction of perception and semantic memory.
The original work (Lupyan, 2008) used an experimental paradigm consisting of a presentation of chairs and lamps followed by a surprise recognition test including both the old objects and matched new object lures that were very
similar to the old objects. There were two conditions, category judgments and preference judgments. During the initial presentation of the objects, each object was either judged to be a chair or lamp, or was judged to be liked or disliked. The results were then analyzed in terms of both hits and false alarms. Lower hit rates for the categorically judged objects than for the preference judged objects were taken to indicate a distorted or shifted memory. High false alarm rates, on the other hand, would have been taken to indicate overall poor memory. The results showed the predicted lower hit rate without a higher false alarm rate in the category judgment condition but not in the preference judgment condition. This pattern of forgetting was taken to be evidence for the representational shift account.

## Challenges to a Representational Shift Account

Not all researchers accept the representational shift hypothesis. An alternative hypothesis to explain the low hit rates (Lupyan, 2008) is depth of processing. A depth of processing account predicts both high false alarm rates and low hit rates for the category judgment condition because only minimal exemplar specific information would be encoded for categorical judgments but more detailed information about each exemplar would be processed and encoded for preference judgments. Follow-up experiments explored this idea using additional judgment conditions of location (Richler, Gauthier \& Palmeri, 2011) and of orientation (Blanco \& Gureckis, 2012). They tested whether a preference judgment simply forces more fine-grained processing of an object than a category judgment does, leading to more detailed encodings. The location and orientation judgments were not expected to require as much processing of the actual item as preference judgments. According to the representational shift hypothesis, if labeling forces a more typical encoding than non-labeling, then a category judgment should result in the lower hit rates without a change in false alarms while preference, location and orientation judgments should all have higher false alarm rates. The labeling conditions did not uniformly create lower hit rates than non-labeling conditions. The hit rates were only lower in comparison to the preference condition supporting depth of processing.

Richler, Palmeri, and Gauthier (2012) tested the representational shift hypothesis, or labeling effect, against a paradoxical production effect (MacLeod, Gopie, Hourihan, Neary \& Ozubko, 2010) which is characterized by more distinct and accurate memory for vocally named words and objects. Explicit category responses by button push, by silent labeling, and by verbal labeling were contrasted with preference judgments using the same surprise recognition memory test paradigm as Lupyan (2008). Richler et al. found varying levels of memory strength. Verbal labeling was remembered most accurately, then preference, followed by silent naming, with button press categorization being the least strong. The pattern of forgetting along with the pattern of accurate memory was used to support the distinctiveness
of processing account which emphasizes the uniqueness of features over depth of processing

In each of these follow-up experiments, the pattern of forgetting was used to support a depth of processing account.

## But What About the Shifts?

There is now one set of experiments in favor of the representational shift hypothesis and three sets opposed. However, none of these experiments truly get at the main prediction of the representational shift hypothesis: a stimulus processed with overt categorization will undergo a shift where the encoded representation in memory will be more prototypical than the original stimulus. The literature accepts an effect that is only implied, arguing about its cognitive mechanism rather than its existence. Rather than looking at the absence of recognition and trying to infer what processes could result in poor recognition memory, we can instead look at patterns of recognition to see if the encoding has shifted and by how much which should lead more straightforwardly to possible underlying processes. One way to go about looking at the shifts is to move the categorization and subsequent shifts onto a single dimension, in this case the hue dimension, rather than trying to infer shifts in chair-versus-lamp space, with multiple unknown dimensions.

## Hue Perception and Memory

In psychological color research, it has been found that there is a near universal progression of basic color names (e.g., Berlin \& Kay, 1969) and optimized focal or prototypical shades of color within a named category (e.g., Regier \& Kay, 2009). This has led to further research looking at categorical perception where colors are labeled differently based on their relation to the focal colors and the color boundaries of their language's color categories (e.g., Kay \& Kempton, 1984). An implication of this literature is that colors are not always experienced the same even if they are objectively the same wavelength of light. A speaker of Russian will see two shades as more different from each other when they cross the boundary between the Russian light blue and dark blue basic categories than an English speaker who would categorize them both as blue (Winawer et al., 2007). Color space has a distorted topography of similarity and difference based on the categories applied to it.

As implied by the term categorical perception, it is tempting to conclude that there is always an issue of categorization at play with color perception. We routinely perceive colors to be different than they actually are as in these color perception tasks. However, in the psychophysics literature, hue is highly memorable. Hue is one of three dimensions along with lightness and saturation that are used to describe color. Under some circumstances, participants can quite accurately reproduce the hue that they have just seen (Pérez-Carpinell, Baldoví, de Fez, and Castro, 1998). These results contrast with the psychological literature

Figure 1: Example colored silhouettes. The silhouettes are representative of the two color categories: red and green, as well as the two animacy categories: living and non-living.

Focused on distortion, instead suggesting that we do not always influence the colors we see with top-down knowledge but truly record hues as they objectively are in the world.

Color is a domain where memory has proven accurate to experience and is a domain where categories affect perception. The representational shift hypothesis can be tested in a domain where memory has shown to be accurate to experience without labels. By adding labels alongside hue perception we can see if representations of the colors do indeed shift.

## Experiment

The present experiment was designed to test the predictions of the representational shift hypothesis: There is a systematic prototypical shift of memory for overtly labeled objects, and preference-judged objects are not subject to the same shift. Preference-judged objects could lack a representational shift or at the least demonstrate a less strongly prototypical shift.

## Method

Participants 39 participants were recruited through UC Merced's participant pool. All participants were monolingual or early (by age 10) bilingual English speakers. Participants had normal or corrected to normal vision. They also had normal color vision, tested using the CITY color vision test (City University, 2002) at the conclusion of the experimental session.

Stimuli 40 colored silhouettes were created in Adobe Photoshop for the study phase of the experiment. All colors

Figure 2: A representation of CIE L*C*h color space. The variations in hue are calculated in degrees on the plane of lightness and the radius of saturation. (http://nyman.netsolution.ch/IT8FujiProvia.htm)
were calculated in device independent CIE $L^{*} a^{*} b^{*}$ color space and converted to RGB device dependent color space via unique monitor profiles created by a X-rite il Display Pro color calibrator to ensure color constancy across testing stations. 20 silhouettes were living things such as a giraffe and a butterfly, and 20 silhouettes were non-living objects such as a pan and an airplane (see Figure 1). 8 main hues, 4 reds and 4 greens were selected. The colors had the lightness and saturation values of their category's focal color (Sturges \& Whitfield, 1995). Each object was randomly assigned a hue of red and a hue of green. The silhouettes were randomly assigned to 4 groups of 10 objects, 5 living and 5 non-living. The groups were then assigned a color category between subjects (i.e. Participant 1 saw groups $1 \& 2$ in their red hues and groups $3 \& 4$ in their green hues while Participant 2 saw groups $1 \& 3$ in red and groups $2 \& 4$ in green, etc.) The semi-random creation of colored silhouettes preserves color and animacy balances while counterbalancing the color/shape pairings across participants.

For the testing phase of the experiment, four variations of each of the 8 main hues were calculated in CIE L*C*h color space (Figure 2) with a distance of $4^{\circ}$ along the hue dimension from its adjacent hue. A test scale for each silhouette of two steps more typical, one step more typical, the original, one step less typical, and two steps less typical was created.

## Procedure

The experiment consisted of two main parts: a judgment phase and a memory test. Each participant encountered 80 judgment trials followed by 40 memory trials. For the judgment phase, the participants had been instructed to

## Hue Variant Chosen by Judgment Condition

Figure 4: Average percent of each hue typicality chosen by participants. $20 \%$ chosen would be expected if participants were choosing at random.
remember the silhouettes as they would show up more than once but were not explicitly told of a memory test.

Initially, participants were instructed in the two types of judgments: color (" 1 " for red or " 2 " for green) and preference (" 3 " for like or " 4 " for dislike). Tags were placed above the keys on the keyboard to remind participants of the mappings mid-task. The trials were presented in alternating judgment blocks with 10 trials per block. Each silhouette was judged twice by each participant, both within the same judgment type (e.g., if the giraffe was judged for color the first time it appeared, the giraffe would be again judged for color the second time it appeared). The silhouettes were judged in each judgment condition between participants.
Each trial consisted of a fixation cross ( 1500 ms ), the silhouette to be judged ( 300 ms ), a question mark eliciting the judgment for that block ( 700 ms ), followed by a blank screen ( 1000 ms ).

After the judgment phase, participants were then tested for hue memory. The memory trials consisted of a circular array of the 5 hue variants of a particular silhouette (Figure 3). The array had the hues in graded clockwise order with the most typical hue rotated to a random position by trial resulting in a consistent appearance of selecting from a gradient of hues but avoiding position effects that would be present in a line. Each of the 5 positions had a location label 1 through 5 that participants entered on the keyboard to make their selection. There was no time limit imposed on the memory test responses with an intertrial interval of 1500 ms .

## Results

Not all participants proved equally skilled or motivated to complete this task. The following criteria needed to be met in order to include a participant's data in the analysis: at least $80 \%$ accuracy for color judgments (4 participants did
not meet this criteria), and responded using at least 3 of the 5 memory test positions ( 6 participants did not meet this criteria). As a result, 29 participants were included in the analyses.

As can be seen in Figure 4, there was a systematic shift of responses in the hue memory test. As described above, the position of the hues was randomized, disambiguating position responses from typicality. The judged stimuli selected were both clockwise and counterclockwise to the focal color in color space disambiguated hue space direction and the direction of typicality. Only when taking into account the relative direction in hue space of the focal color does the systematic bias emerge from the data.

There are three main questions to be addressed in the data analysis to test the representational shift hypothesis: Is there a shift of memory for color judged silhouettes? Is there a shift for preference judged silhouettes? Is there a difference between the two shifts should they both be observed?

To test whether there is a shift for items in the color judgment condition, a one sample t-test with a comparison value of 3 was performed on the average typicality value of the hue chosen at memory test. Responses lower than 3 are more typical of the color category, a response of 3 is true to the original color viewed, and response values higher than 3 are atypical of the color category. The mean response typicality for color judged silhouettes is 2.70 . The mean is significantly lower than 3 , indicating that the shift is in the prototypical direction, $\mathrm{t}(28)=-3.93, \mathrm{p}<.001$. In the color judgment condition, there is an observed representational shift is the prototypical direction as predicted by the representational shift hypothesis.

To test whether there is a representational shift for items in the preference condition, another one sample t-test with a comparison value of 3 was preformed. Again the mean response typicality is less than 3 at 2.56 indicating a prototypical representational shift, $\mathrm{t}(28)=-5.82, \mathrm{p}<.001$. The
representational shift hypothesis does not explicitly reject such a shift, but it does predict that the shift due to labeling should be stronger.

Finally, the mean is significantly greater for the color condition (2.70) than the preference condition (2.59), paired $\mathrm{t}(28)=2.05, \mathrm{p}<05$. The direction of the difference is actually the opposite of the prediction made by the representational shift hypothesis. There is more of a prototypical shift for preference-judged stimuli than color judged stimuli. Even if the two conditions being statistically different were a matter of chance, it is quite unlikely that they are truly different in the opposite direction.

## Discussion

As designed, this paradigm allows us to directly view representational shifts within hue color space. Participants were exposed to colored silhouettes then tested on 5 variations of the original silhouette. Participants on average chose hues that were slightly more prototypical of the basic color category than the hue that they had originally seen. This is the prototypical representational shift predicted by the representational shift hypothesis. However, the type of judgment made on the silhouette did not make a difference in whether a prototypical representational shift occurred. In contrast to the predictions of the representational shift account, participants chose a more prototypical hue in even larger proportions when they had made preference judgments about a silhouette rather than labeling the color category.

## Depth of Processing

In previous experiments there have been measurable differences between conditions (Blanco \& Gureckis, 2012; Lupyan, 2008; Richler et al. 2011, 2012) that were interpreted as superior memory for preference-judged items. The restriction to a single dimension for variation limited the ways in which preference-judged items could be uniquely encoded into memory to benefit recognition. For the dimension tested, the depth of processing predictions could have been turned around with color being more deeply processed with category judgments than with preference judgments. While making preference judgments, participants were not limited to opining on the color. It is plausible that they paid more attention to whether they liked giraffes and pans than the particular hue. Thus, a depth of processing account of the present results appears most plausible.

## Implications of Representational Shifts

Earlier we discussed a potential implication of representational shifts: a pervasive influence of past experience and existing categories on new representations. These representations then become part of the categories that proceed to influence representational shifts in future experiences. Rather than categories being an accumulation of raw experience, these distortions in how new exemplars
are encoded support existing category structures and discourage new categorization schemes from developing in well-categorized domains. As categorization schemes mature, the representational shifts would cascade, potentially reaching the extreme of the characteristically discrete looking categorical perception effect (Harnad, 1987; but see Huette \& McMurray, 2010). These implications hold for the representational shift effect regardless of the mechanism behind the shifts.

## Online Influence of Categories

Categories, regardless of overt labeling, affect memory. In the context of this experiment, hue memory was not as accurate as it has been reported in other research (e.g., Pérez-Carpinell et al., 1998). Given that categorization of objects is fairly automatic (Grill-Spector \& Kanwisher, 2005), having category judgments in the course of the experiment could have created a 'category-relevant' context where regardless of explicit categorization responses, categories were activated for all stimuli. The implication is that categories alter memory formation online rather than being a permanent perceptual bias consistent with recent research (e.g. Landau, Dessalegn, \& Goldberg, 2010). A non-category relevant context with added overt labels is a possible scenario where labeling may have an effect on representational shifts.

## Time Course

Our previous research (Kelly \& Heit, 2012) has shown that atypical representational shifts-shifts away from the prototype - are found with immediate (half second and five second delay) recognition tests. At some point between five seconds and a few minutes representations go from being distorted atypically to being distorted typically. Representations are not veridical to the stimulus initially or subsequently.
It's possible that these shifts are symptomatic of competing needs of working memory and long term memory. Working memory could privilege differentiating information in case details are important in the moment. Detailed information that will go unused would deplete resources unnecessarily when being encoded into long term memory, making relying on the category general information to supply a complete representation upon recall more advantageous. Variables that change depth of processing could be indicative of how likely specific differentiating information is to be needed in the future. These explanations for the mobility of representational shifts are purely speculative and need to be researched further.

## Push or Pull?

Lupyan (2008) hypothesized the mechanism of blended representations between exemplar and category prototype as the cause of prototypical representational shifts. Another proposed mechanism to account for this bias is boundary truncation (Huttenlocher, Hedges, Lourenco, Crawford, \&

Corrigan, 2007). Rather than having a pull toward the prototype via prototype activation, there is a push toward the prototype by disregarding extreme information. The shift into the category would be consistent with both theories and needs to be explored further.

## Conclusion

Representational shifts exist in memory for hue. There are prototypical shifts in memory for colored silhouettes encountered minutes before test. These shifts can be seen and measured on a unidimensional testing ground. Conceptual space has long been known to be contorted in color (Kay \& Kempton, 1984) and beyond (Goldstone, 1992). Our results support the idea that the creation and maintenance of these contortions could be due to representational movement.

#### Abstract

Foraging is a search process common to mobile organisms, and foraging paths commonly exhibit statistical patterns akin to Lévy walks. There may be common factors and benefits underlying these patterns, but investigations are hindered by difficulty in assessing and manipulating search environments and task conditions. In the present study, a simple foraging game was developed to isolate and manipulate two factors hypothesized to make Lévy walks adaptive search strategies-sparsity, and spatial clustering of targets in the search environment. Players navigated a fuel-limited ship over a 2D grid to find as many targets as possible, rendered as asteroids in outer space. Over 1800 participants were recruited to play using Amazon's Mechanical Turk, in order to widely sample the parameter space defined by degrees of target sparsity and clustering. Observed search paths resembled Lévy walks with memory, and those of high performers were found to vary adaptively with clustering, but not sparsity. Results indicate that Lévy-like walks can emerge from search strategies and algorithms adapted to environments with clustered resources.

Keywords: Foraging; Lévy walks; crowdsourcing; adaptive search.

## Introduction

Perhaps the most ancient kind of search function in biological organisms, in terms of evolutionary history, is foraging-moving about one's environment in search of resources like food, locales like shelter, or other organisms like mates. Studies of animal foraging have found that foraging paths tend to resemble Lévy walks (Viswanathan et al., 1996). Paths are clustered such that most path segments are relatively short, but they are interspersed with longer segments, occasionally much longer. Paths resemble Lévy walks in that distributions of path lengths follow an inverse power law, $\mathrm{P}(l) \sim 1 / l^{\alpha}$, where $\alpha \sim 2$. Lévy-like paths are observed for foragers from bacteria (Berg, 1993) to humans (Rhee, Shin, Hong, Lee, \& Kim, 2011).

Lévy foraging paths can be modeled simply as random walks with path lengths sampled from a power law, although path directions may be correlated over time (Viswanathan et al., 2001), and mechanisms of navigation
are left unspecified. Despite their simplicity, Lévy walks have proven influential because they suggest that search benefits are conferred by power law path lengths, at least under certain foraging conditions (Viswanathan \& Buldyrev, 1999). In particular, when $\alpha \sim 2$ and targets are sparsely and randomly distributed, Lévy walks maximize the rate of finding targets compared with Gaussiandistributed random walks.

The potential benefits of Lévy walks recently have led cognitive scientists to investigate whether they occur in perceptual, memory, and decision-making search tasks. First were Rhodes and Turvey (2007), who investigated Lévy walks in a classic category recall paradigm (Bousfield \& Sedgewick, 1944). Participants recalled as many animals as they could from long-term memory, for twenty minutes. Inter-response intervals were used as indirect measures of memory "path lengths", and they were found to be best fit by inverse power law functions with exponents near two. Then, Rhodes, Kello, and Kerster (2011) found that saccade lengths in visual foraging tasks also followed a heavy-tailed distribution resembling efficient Lévy walks, although the lognormal function provided the best fit to data. A lognormal can be viewed as a constrained power law (Stephen \& Mirman, 2010), which should be expected when search is constrained to a relatively small space (a computer monitor). Most recently, Radicchi and Baronchelli (2012) found search intervals to be Lévy-like when buyers searched the bid space in online auctions, and observed exponents were shown to maximize economic gains.

These and other similar studies raise the question of what mechanisms and factors give rise to Lévy-like search paths across so many different species and foraging conditions. Theoretical analyses suggest that sparsity of targets is a factor, but it is prohibitively difficult to test this hypothesis in natural foraging conditions, including visual and memory foraging of natural scenes and categories. Also, most theoretical analyses have assumed randomly distributed targets (Viswanathan \& Buldyrev, 1999), but food and other resources may instead tend to be clustered in nature, as is the case with plankton distributions, for instance (Mackas \& Boyd, 1979). In terms of mechanism, Lévy-like foraging
may be intrinsic to both biological and cognitive search functions, in which case Lévy walks would occur regardless of search conditions. Alternatively, Lévy walks may emerge as a result of interactions between search processes and their environments. These interactions may unfold over the course of minutes and even faster timescales.

In the present experiment, we examined the roles of sparsity and clustering in a web-based video game designed to mimic canonical foraging. We used a video game because it allowed us to know and manipulate search conditions. We made the game web-based to collect data from large numbers of participants on Amazon's Mechanical Turk. Recent studies show that Turk yields data comparable to university participant pools (Germine et al., 2012; Snow, O’Connor, Jurafsky, \& Ng, 2008), and we confirmed this in a pilot study run through the UC Merced participant pool (not reported). Turk allowed us to robustly sample the parameter space created by factorial manipulation of sparsity and clustering. Turk also allowed us to collect enough data to compare players who find greater versus fewer numbers of targets, i.e. high versus low performers.

Comparisons of high versus low scorers are critical because they test whether adaptive search is associated with closer-to-optimal (i.e. higher scoring) performance. That is, do high performers adapt their search strategies, as measured by path length distributions, to changes in sparsity and clustering? Do high scoring foraging paths more closely resemble Lévy flights with the theoretically optimal exponent of two? Addressing these questions will provide evidence on 1) whether Lévy-like foraging paths can emerge from searcher-environment interactions on timescales no longer than minutes, and 2) whether adapting paths to sparsity or clustering is associated with better performance.

## Methods

The foraging game was framed as a task of exploring outer space to find resources on asteroids (see Figure 1, and http://cogmech.ucmerced.edu/downloads.html to play). Participants used a mouse (or functionally equivalent device) to move a spaceship over a $1280 \times 1024$ grid of space. Movement was controlled at two scales, zoomed in and zoomed out. When zoomed out, the entire space was visible at once, and participants clicked on a location to "fly" the ship to that spot (shown by animation). Participants pressed the space bar to zoom in 15X at a given location, at which point they again could navigate the ship via point-and-click. Hubble images were used as background to help engage players by giving the sense of outer space, and to provide environmental cues that are, in general, ubiquitous to natural search conditions. These cues may encourage use of memory in navigation (e.g. Vinson, 1999), which shall be discussed later.

Asteroids were visible only when zoomed in, and resources were harvested by moving to them such that collision occurred between the asteroid and ship graphics. A set amount of fuel was provided for each play of the game,
and fuel usage (shown by a fuel bar) was a linear function of distance traveled, plus a small constant for each zoom in/out. The amount of fuel provided was determined based on pilot work to allow for about 5 minutes per play, and to enable players to find some but not all asteroids. Each successful harvest was indicated by sight and sound, and asteroids could only be harvested once (the un/harvested status of asteroids was not displayed). Each harvest added one point to the score (no fuel was added), and play continued until all fuel was expended.

Figure 1: Example game space shown zoomed out (above), along with the corresponding zoomed in view (below).
Current score is shown in upper left corner, and fuel bar with remaining fuel in red is shown in upper right corner.

The game was designed to mimic foraging as exemplified by aquatic birds hunting for fish, or the eyes scanning a scene to gather visual information. Relatively short movements are made during resource acquisition (while in the water and close to the surface, or during fixations), interspersed with longer-scale movements when no resources are acquired (while flying high above the water, or during saccades when visual information uptake is attenuated; Ross, Morrone, Goldberg, \& Burr, 2001). Foraging costs in natural searches (e.g. risk and energy expenditure) were lumped into the fuel cost of travel, although time costs were also a factor, given the natural tendency to minimize time spent foraging. The game was coded in Flash so it could be distributed via the web, with game data collected on a local server. We
used Amazon’s Mechanical Turk to find people willing to play the game twice (plus a 1 minute practice session to learn) for 75 cents in compensation. Pilot work indicated that the availability and quality of Turk workers fell off precipitously for tasks lasting more than 10-15 minutes. A step-by-step demo, along with instructions in English, was presented at the beginning of play, and each play was set to last about 5 minutes (assuming no breaks). Two plays were required for each paid work session.

Figure 2: Example of 150 asteroids clustered at 0.05, 0.15, 0.25 , and 0.5 , left to right, top to bottom.

The number of asteroids per play was set at four different levels: 25, 50, 100, and 150. Pilot work indicated that 25 asteroids meant that players occasionally found only a few of them (or even none), and 150 meant that players found asteroids nearly every time the zoomed in. Clustering of asteroids was manipulated at four different levels of a probabilistic parameter: $0.05,0.15,0.25$, and 0.5 . This parameter controlled the probability of dividing asteroids evenly (0.5) or entirely to one side (0.0) in an algorithm that divided a given set of asteroids recursively into alternating horizontal and vertical splits of a given 2D space. Asteroids were placed when only one remained in a given recursively split section of the space (placed at random in the section), and/or when the space could be split no further (see Figure 2 for example asteroid distributions, and Figure 3 for pseudocode). This algorithm created clusters whose sizes followed a nested scaling relation to varying degrees, consistent with findings of scaling law clustering of natural resources (Humphries et al., 2010; Mackas \& Boyd, 1979). The algorithm also created asteroid distributions that were independent of Hubble image backgrounds, and participants were informed of this independence during the demo/ instruction period.

The full $4 \times 4$ factorial of sparsity and clustering levels was tested. Each participant played twice in only one of the 16 possible conditions, chosen at random at the start of each Turk session. The demo and instructions included an
example asteroid distribution for the condition the participant was in, to help them formulate an informed foraging strategy. Players were also encouraged to achieve the best score possible by maintaining a high score board, and allowing high scorers to enter their initials for display to other players.

Note that a smaller parameter leads to increased clustering.

## Results

A total of 1,825 game sessions were administered on Turk. Participants who did not produce more than 80 zoomin actions per play were excluded from analysis (603 participants). Pilot work indicated that participants who simply expended fuel to complete the task, rather than endeavored to find asteroids, were revealed by low numbers of zoom-in actions. Of the remaining 1,222 participants, 393 played in two or more Turk sessions. Analyses with and without these repeats indicated no qualitative change in results, so both were included in the reported results. Analyses combine zoomed in and zoomed out path lengths.

Visual inspection of zoomed out flight paths revealed directional movements that ranged in their temporal correlations, which express a very simple memory (i.e. effect of history) in search paths. Two example paths at the two ends of this range are shown in Figure 4. Paths that consisted of highly regular directional movements were seen as "sweep" strategies designed to systematically cover the space in left-right, top-down, spiral, and other search patterns. Other paths consisted of apparently haphazard directional movements, akin to random walks. In the middle were mixtures of the two, plus directional movements that followed irregular contours of Hubble images (despite instructions that distributions were independent of images).

To minimize effects of practice and learning, only the second of two plays per Turk session was analyzed. Performance was measured as the proportion of available targets found, and plays were divided into three categories of performance, for each of the 16 game conditions: Top 20, middle 20, and bottom 20 scores. More than 60 Turk
sessions were randomly assigned to each game condition, so any additional plays were excluded from reported analyses. The constant of 20 plays per cell simplified statistical analyses, and excluding intermediate performances helped to further distinguish our three categories.

Figure 4: Two example flight paths of more versus less directionally correlated movements (top versus bottom). Red and green lines indicate zoomed out and zoomed in movements, respectively. Blue dots indicate clicked locations, and yellow dots indicate points of harvest. White boxes indicate areas of zoom in.

All results are graphed and analyzed as a function of sparsity, clustering, and performance category. A three-way analysis of variance was conducted for each dependent measure, but we report only main effects and two-way interactions relevant to our research questions and hypotheses. First, we examined score as function of sparsity, clustering, and performance levels (Figure 5). The main effect of performance category is itself based on score, and is so large throughout our analyses that reporting its reliability was unnecessary.

As for the other two main effects, sparsity was not reliable, $\mathrm{F}(3,18)=2.1, \mathrm{p}>0.1$, but clustering was, $\mathrm{F}(3,18)=$ 38.42, $\mathrm{p}<.05$. The interaction of performance level with sparsity was also not reliable, $F(6,18)=0.84, \mathrm{p}>0.5$, but it did interact with clustering, $\mathrm{F}(6,18)=55.41, \mathrm{p}<.05$. Visual inspection shows that scores improved with clustering for high performers, but the opposite effect occurred for low
performers. These results show that foragers adapted to clustering but not sparsity, and low performers appeared to adapt counterproductive strategies in terms of score. Thus we have initial evidence that high performers took advantage of the spatial correlations in clustering, suggesting that foraging paths adapted based on interactions between search processes and game conditions.

Figure 5: Proportional score as a function of sparsity, clustering, and performance category.

However, one might argue for an alternate interpretation of the data. It may be that each forager chooses a strategy a priori without regard to conditions, and effects of clustering merely show that strategies matter more for greater clustering. We tested this possibility by examining the change in score from first to second play. We found that score increased over time for high performers ( $+19 \%$ ), but decreased for low performers ( $-14 \%$ ), $t(638)=17.7, \mathrm{p}<.01$. This difference suggests that strategies changed over the course of play, for better or worse, indicating that strategies were indicative of interactions between search processes and game conditions.

Figure 6: Path Length as a function of sparsity, clustering, and performance category.

Next we examine mean path length, shown in Figure 6. High performers had shorter path lengths overall, reflecting the fact that shorter path lengths allowed for greater coverage of the space by reducing zoom costs. This main
effect would be expected to diminish, and possibly even reverse, if fuel costs were greater per zoom.

There were no main effects of sparsity on mean path length, $\mathrm{F}(3,18)=2.19, \mathrm{p}>.1$, or clustering, $\mathrm{F}(3,18)=1.7$, p $>$.2. Once again, the interaction of performance category with sparsity was not reliable, $\mathrm{F}(6,18)=1.66, \mathrm{p}>.15$, but it was with clustering, $\mathrm{F}(6,18)=4.61, \mathrm{p}>.05$. Visual inspection shows that path lengths for high performers increased with clustering, whereas they decreased for low performers. The increase for high performers presumably reflects the increased need for larger jumps as clusters became sparser. Again, low performers appeared to adjust strategies as well, but in counterproductive ways.

Next we examine whether foraging paths resembled Lévy walks, in the sense that path length distributions were power law distributed with estimated exponents near two. We used multi-model inference (Symonds \& Moussalli, 2010) to test which of four different functions provided the best fit to the distribution of path lengths for each participant (mean of 217 path segments per participant): Normal, exponential, lognormal, and Pareto. Only the latter two are heavy-tailed and Lévy-like, and the method uses Akaike's information criterion (AIC) to find the function with the shortest information-theoretic distance to the data.

The lognormal function provided the best fit for $68 \%$ of the participants, with the remaining trials roughly evenly split between normal and exponential fits (Pareto never provided the best fit). As mentioned earlier, the lognormal is akin to a constrained power law, and the foraging game constrained movements in terms of a limited amount of space. An example distribution from one participant is plotted in Figure 7 in logarithmic coordinates, which is representative of the majority of participants. The constrained, normal-like portion of the distribution is seen as a slight hump on the left side, and the power law-like tail is seen as a negatively sloped line on the right.

Figure 7: An representative path length distribution for one participant, plotted in logarithmic coordinates

We further examined the tails of path length distributions in two ways. First, the fitted lognormal functions have $\mu$ and $\sigma$ parameters, where the latter roughly corresponds with the heaviness of the tail. Heavier tails indicate more Lévy-like distributions. Best-fitting $\sigma$ 's are shown in Figure 8 for all
participants, including those whose data were better fit by normal or exponential distributions.

The overall pattern of results was similar to those reported earlier. There was no main effect of sparsity, $\mathrm{F}(3,18)=1.17$, $p>.35$, but clustering was again reliable, $\mathrm{F}(3,18)=10.52$, p $<.05$. Visual inspection reveals the possibility of an effect in the high/mid performers which was supported by a reliable interaction of performance category with clustering, $F(6,18)=12.29, p<.05$. Once again, there was no reliable interaction with sparsity, $\mathrm{F}(6,18)=1.77, \mathrm{p}>.15$. Visual inspection shows that the tails of path length distributions were heavier overall for low performers, but they became heavier with greater clustering only for high performers.

To gauge whether distributions were becoming more similar to the theoretical power law exponent of two, we fit regression lines (see Figure 7) to the right half of distributions in logarithmic coordinates, and results are shown in Figure 9. None of the main effects (excluding performance category) or interactions were reliable, but slopes were generally in the neighborhood of the theoretical optimum of -2 (negative of the optimal exponent). Moreover, slopes for high performers were closest in their approach towards -2 with greater clustering.

Figure 8: Lognormal $\sigma$ as a function of sparsity, clustering, and performance category.

To summarize, search paths generally resembled efficient Lévy walks as predicted, at least to some degree. The majority of path length distributions were heavy-tailed, and tails resembled truncated power laws with exponents near two. Distributions most closely resembled Lévy walks for high performers in the most clustered resource conditions. Foraging paths were not like random walks, in that path directions were never drawn purely at random. Instead, path directions tended to be correlated over time. This tendency can be quantified simply by computing the proportion of times that next steps went in the same direction, within some threshold. Angular changes were between 0 and 180 degrees (collapsing left versus right turns) and divided evenly into 45 bins. The proportion of movements falling into the smallest angular bin was $25 \%$, about ten times greater than chance. Thus foraging paths had memory in that the direction of each step was sensitive to previous steps.

Figure 9: Regression slopes as a function of sparsity, clustering, and performance category.

## Discussion

In the present study, analyses of data from a web-based foraging game showed that Lévy-like search paths emerge from search processes that change depending on the clustering of resources. This was true for both high and low performers, although only high performers changed their search processes adaptively. The lack of a sparsity effect was conspicuous because prior theoretical analyses suggest that the benefits of Lévy-like search paths are most prevalent when items are rare to be found. However, prior analyses focused on random Lévy walks, whereas observed foraging paths clearly had memory. Memory sometimes manifested as "sweep" searches, but more generally, directions of next steps depended on previous steps.

Our results suggest that the prevalence of Lévy-like walks in both animal and cognitive searches can be better modeled by processes with memory that attend to target and task conditions, as opposed to random walk processes. The observed effects of clustering indicate that search processes take advantage of spatial correlations in resource distributions when they exist and are known or learned. A simple approach to modeling an effect of spatial correlations is for search processes to follow a gradient of resource density. These and related modeling ideas (e.g. Ferreira, Raposo, Viswanathan, \& da Luz, 2012) are potentially interesting topics for future research.

#### Abstract

We propose a modular neural-network structure for implementing the Bayesian framework for learning and inference. Our design has three main components, two for computing the priors and likelihoods based on observations and one for applying Bayes' rule. Through comprehensive simulations we show that our proposed model succeeds in implementing Bayesian learning and inference. We also provide a novel explanation of base-rate neglect, the most well-documented deviation from Bayes' rule, by modelling it as a weight decay mechanism which increases entropy. Keywords: Neural-network; Bayes’ rule; Bayesian learning and inference; base-rate neglect; weight decay; entropy

## Introduction

Bayesian models are becoming prominent across a wide range of problems in cognitive science including inductive learning (Tenenbaum, Kemp, \& Shafto, 2006), language acquisition (Chater \& Manning, 2006), and vision (Yuille \& Kersten, 2006). While these Bayesian ideas provide computation level models, it is beneficial, and sometimes necessary, to appeal to some implementation-level (biological) models to explain human behaviour. Connectionist approaches provide a neural-based model of cognitive processes.

There is growing evidence in neuroscience supporting the relevance of Bayesian models on a neural level (Doya, Ishii, Pouget, \& Rao, 2007). Many perceptual and sensorimotor tasks that are learned and performed by the central nervous system can be described in a Bayesian framework (Konrad \& Wolpert, 2004). Neural computations, as simple as summing up the firing rates, can be seen as analogous to a Bayesian inference process, with population activity patterns encoding posterior distributions (Pouget, Dayan, \& Zemel, 2003).

In theoretical terms, connectionist models show promising prospects in implementing computational-level Bayesian ideas. Under certain assumptions, and inspired by the nature of neural activation functions, neural units can compute posterior probability values (McClelland, 1998). So-called Boltzmann machines, a type of stochastic recurrent neural network, were also suggested to implement Bayesian learning (Ackley, Hinton, \& Sejnowski, 1985). Later work introduced generative networks called restrictive Boltzmann machines that can make bidirectional inferences based on what they learned (Hinton \& Osindero, 2006).

All these connections between Bayesian and neuralnetwork models motivate further exploration of the relation between the two. In this paper, we propose a complete, modular neural-network structure implementing Bayesian learn-
ing and inference in a general form. We do this by using three main modules, two responsible for computing priors and likelihoods based on observations, and one responsible for applying Bayes rule and computing the posteriors. We show that our model is able to successfully implement Bayesian learning and inference and replicate analytical results with high precision in a brain-like fashion which could later be used to gain intuition into how brains implement Bayesian reasoning. Our work also provides a framework to study the deviations from optimal Bayesian reasoning which result from base-rate neglect (Kahneman \& Tversky, 1996; Eddy, 1982).

Our work is novel in its precise and complete implementation of a Bayesian framework in a modular, brain-like fashion. The proposed network takes observations as inputs and computes the posterior probabilities (i.e., updated beliefs). Moreover, using a fast, constructive learning algorithm (sibling-descendent cascade-correlation) for the network provides the advantage of a self-organizing learning and inference method which is similar to humans' developmental, autonomous inference and learning (Shultz \& Fahlman, 2010). Another novelty of this work is the modelling of base-rate neglect as a weight decay mechanism.

The idea of neural implementation of Bayesian phenomena was suggested before. Shi and Griffiths (2009) introduced a scheme for implementing importance sampling with radial basis function (RBF) networks. They assume that the unit activation functions are of radial basis type. Hence, in their model, a single RBF neuron measures likelihood, resulting in a straightforward implementation of importance sampling. Also, Griffiths et al. (2012) used a linear network to approximate the generalization performance of a probabilistic model. Their linear networks produce different solutions from Bayes on structures other than those based on Wishart priors. Our work differs in two major ways. First, we assume that the characteristics of the likelihood/priors and the network's structure are unknown a priori and learn them for a wide range of likelihood and prior distributions through a constructive training phase. Also, these functions are learned precisely (i.e., no approximation) using a population of neurons with simple though realistic activation functions (sigmoid) rather than linear or complex ones (RBF).

## The Basics of Bayesian Learning and Inference

The Bayesian framework addresses the problem of updating beliefs and making inferences based on observed data. As-
sume that we have a set of mutually exclusive and exhaustive hypotheses, $\mathcal{H}=\left\{h_{1}, \ldots, h_{N}\right\}$, and want to infer which of these hypotheses best explains observed data. In this setting, we denote the degree of belief in different hypotheses by probabilities. Bayesian inference is based on a simple formula known as Bayes' rule. This rule specifies how posterior probabilities (of a hypothesis being true given the observed data) can be computed using the product of data likelihood and prior probabilities:

$$
\begin{equation*}
P\left(h_{i} \mid d\right)=\frac{P\left(d \mid h_{i}\right) P\left(h_{i}\right)}{P(d)}=\frac{P\left(d \mid h_{i}\right) P\left(h_{i}\right)}{\sum_{i=1}^{N} P\left(d \mid h_{i}\right) P\left(h_{i}\right)} . \tag{1}
\end{equation*}
$$

Priors, $P\left(h_{i}\right)$, represent how much we believe in a hypothesis before observing data. Likelihoods, $P\left(d \mid h_{i}\right)$, denote the probability with which we would expect to observe these data if a hypothesis were true. The denominator, known as marginal probability of data, is a normalizing sum which ensures that the posteriors for all hypotheses sum to one.

The Bayesian framework is generative. This means that observed data are generated by an underlying mechanism or hypothesis. Then, the role of inference is to evaluate different hypotheses and choose the one which is the most likely mechanism responsible for generating the data (i.e., the one with the highest posterior probability). These generative processes can be specified by probabilistic models. Here, we describe likelihoods and priors respectively with probability distributions and mass functions as their generative mechanisms.

## Proposed Connectionist Model

We construct a modular neural network implementing Bayesian learning and inference. The algorithm we use to build our artificial neural modules is a variant of the cascadecorrelation (CC) method called sibling-descendant cascadecorrelation (SDCC) which is a constructive method for learning multi-layer artificial neural networks (Baluja \& Fahlman, 1994). CC offers two major advantages over standard backpropagation (BP) methods. First, it constructs the network in an autonomous fashion (i.e., a user does not have to design the topology of the network). Second, its greedy learning mechanism can be orders of magnitude faster than the standard BP algorithm. In addition to these, SDCC has another important benefit; due to its design, it can often reduce the depth of the network drastically (Baluja \& Fahlman, 1994).

We build our model in a modular fashion. Module 1 (shown in Fig. 1) implements Bayes' rule. For this module, we assume that there are two hypotheses to compare; extending it for any finite number of hypotheses is straightforward. There are three inputs (the prior and the two likelihoods) and one output (the posterior), and the module learns and implement (1). We run this module once for each hypothesis.

When data are observed in consecutive rounds, posteriors at one round are taken as priors for the next round; this is how the beliefs are updated in light of new observed data (rational inductive inference). Therefore, by connecting the output of module $1, P\left(h_{1} \mid d\right)$, to the input corresponding to the prior, $P\left(h_{1}\right)$, we can model this aspect of human cognition.

Figure 1: Module 1 computes the posterior based on the likelihoods and prior and according to Bayes' rule.

Module 1 assumes that the values of prior and likelihood probabilities are given and then applies Bayes' rule using them as input. Module 2 (shown in Fig. 2) is responsible for computing the likelihoods. It takes observation(s) as input(s). Due to the generative nature of the Bayesian framework, we describe likelihoods as probability distributions. The role of module 2 is to learn these distributions as the underlying mechanisms generating data. However, this should be done without any implicit or explicit knowledge about the specifications of the distribution and solely based on the observed training data.

Figure 2: Module 2 computes the likelihoods based on the observed data.

We denote the generative process (probability distribution) as a function of the observed data and hypothesis, $f(d, h)$. For example, if the likelihood distribution for hypothesis $h$ is a Gaussian with average $h$ and standard deviation 1, then:

$$
\begin{equation*}
f(d, h)=\frac{1}{2 \pi} e^{\frac{(d-h)^{2}}{2}} \tag{2}
\end{equation*}
$$

Finally, module 3 (shown in Fig. 3) computes the hypotheses' priors by learning their generative discrete distribution function. Note that the input to this module can be chosen from a finite number of possible hypotheses, $\mathcal{H}=$ $\left\{h_{1}, \ldots, h_{N}\right\}$, and hence the generative distribution is discrete. It takes the hypotheses as input and gives their prior probability as output. We represent the generative mechanism of priors as a probability mass function denoted by $g(h)$. For instance, this function can be of the following form:

$$
\begin{equation*}
g(h)=\alpha \cdot e^{\frac{h^{2}}{2}} \tag{3}
\end{equation*}
$$

where $\alpha$ is chosen so that the sum of priors equals 1 .

Figure 3: Module 3 computes the prior probabilities.

If we have $N$ hypotheses, to run a complete Bayesian learning and inference, we learn modules 1 and 3 one time and use them $N$ times (for respectively computing the posterior and prior of each hypothesis). However, since the likelihood distributions might be different for different hypotheses, we learn $N$ different units of module 2 and use each of them once.

## Simulation Results

## Setup

We test each module individually. Using SDCC, we first train each module by presenting input(s)-output pairs as training patterns. Then, we test the generalization ability of the learned module by utilizing a set of input(s)-output testing patterns. The accuracy of the module's outputs is examined by comparing them with the correct outputs presented in the testing set. In all our modules, the hidden units have sigmoid activation functions and the output units have linear activation functions.

## Module 1

Module 1 takes the two likelihoods, $P\left(d \mid h_{1}\right)$ and $P\left(d \mid h_{2}\right)$, and the prior, $P\left(h_{1}\right)$ as inputs and gives the posterior, $P\left(h_{1} \mid d\right)$, as the output. The training set is all the triplets starting from ( $0.1,0.1,0.1$ ) and going up to $(0.9,0.9,0.9)$ with steps of size 0.1 paired with appropriate output derived from (1). The testing set is all the triplets starting from $(0.05,0.05,0.05)$ and going up to $(0.95,0.95,0.95)$ with steps of size 0.1 paired with correct outputs. Thus, we have 1000 training and 1000 testing points and these two sets have no overlap.

Because of the random nature of SDCC, we get a different network with different structure every time we run the algorithm on the training set. Across 50 learned networks for module 1, on average, each network had 13.2 hidden units and 3.4 hidden layers, and the training took 970 epochs.

We compare the outputs of module 1 with the actual results of Bayes' rule by plotting them against each other in a scatter plot. In order to check the generalization accuracy of the built network we use the testing set data (which are not used in training the network) in our analysis. The results in Fig. 4 show that there is a high correlation between the outputs of the network and the true values. Also the slope and $y$-intercept of the fitted line are respectively near 1 and 0 . In sum, the learned module 1 produces highly precise outputs and we can conclude that it implements the Bayes' rule successfully.

## Module 2

Module 2 computes the likelihood given the observed data. This module learns the distribution generating data solely based on the training set presented to it during the training phase. It has no prior information about the form or characteristics of this distribution. Different hypotheses can have different likelihood distributions, hence we run one module 2 for each hypothesis. Through several experiments, we show that module 2 can learn a variety of likelihood distributions.

Figure 4: Outputs of module 1 plotted against true values.

We start with the Gaussian distribution. In this case, the likelihood is given as in equation (2). The observed data, $d$, is the input and its likelihood is the output. Given the hypothesis $h$, we have a Gaussian likelihood with mean $h$, and standard deviation 1. For example, $h$ could be 0 or 1 in the case where we have two hypotheses. Each of these distributions can be learned using SDCC. We define our training set to be the collection of equidistant points from -5 to 5 with steps of size 0.01 and the testing set to be equidistant points from -4.975 to 4.975 , with the same step size, all paired with appropriate outputs derived from (2). Across 50 learned networks, on average, module 2 had 1.8 hidden layers and 8.2 hidden units.

To check the accuracy of the module's outputs, we plot them against the actual Gaussian values in a scatter plot shown in Fig. 5. The high correlation and the equation of the fitted line show that this module succeeds in learning the Gaussian distribution. To further assess the performance of module 2, we plot the probability distribution function generated by it alongside the actual Gaussian distribution in Fig. 6a. We observe that the two curves are very close.

Figure 5: Outputs of module 2 plotted against true values of a Normal distribution. For the Normal, there are two $x$ values for every y value; hence, there are two lines of dots.

Figure 6: Outputs of module 2 compared with the actual values for three sample distributions.

The replication of the original likelihood distribution by our model is of special importance, because it is done without any explicit or implicit information about the actual distribution. The only information available to the learner is the probability values of the points in the training set. Based on that and by generalization, module 2 learns the actual distribution which generates the data. This capacity is not limited only to the Gaussian distribution. In our simulations, we observe that a wide range of distribution functions can be learned by this module. In Fig. 6, we show that for a couple of sample probability distributions module 2 produces results very close to the actual distribution functions.

## Module 3

Module 3 computes hypotheses' priors. Although their inputs and outputs are of different nature, modules 2 and 3 are functionally the same. They both compute the output based on a probability distribution over the input. Therefore, like module 2 , module 3 is capable of learning the underlying structure of its inputs - the possible hypotheses. The only difference between modules 2 and 3 is that the likelihood distributions (in module 2) are continuous while prior distributions (in module 3) are discrete. We analyse module 3 in more detail while discussing base-rate neglect in the next section.

## Base-rate Neglect as Weight Decay

In contemporary cognitive science, rationality in learning and inference is frequently defined and measured in terms of conformity to Bayes' rule. However, this appears to conflict with the Nobel-prize-winning work showing that people are somewhat poor Bayesians due to biases such as base-rate neglect, representativeness heuristic, and confusing the direction of conditional probabilities (Kahneman \& Tversky, 1996). Even experienced medical professionals deviate from optimal Bayesian inference and make major errors in their probabilistic reasoning (Eddy, 1982). More recently, Prime and Shultz showed that base rates (i.e., priors) are not entirely ignored but just de-emphasized (Prime \& Shultz, 2011).

We first show how base-rate neglect can be interpreted in the Bayesian framework. Then, as an important contribution
of this work, we show that this neglect can be modelled as weight decay in our proposed neural network. This explanation is particularly of interest because it is neurologically plausible and in accordance with theories explaining memory loss and decline in some other cognitive functions as a result of synaptic decay over time (Hardt, Nader, \& Nadel, in press).

Base-rate neglect is an error in computing the posterior probability of a hypothesis without taking full account of the priors. In the Bayesian framework, in the extreme case of entirely ignoring the priors, Bayes' rule in (1) becomes:

$$
\begin{equation*}
P\left(h_{i} \mid d\right)=\frac{P\left(d \mid h_{i}\right)}{\sum_{i=1}^{N} P\left(d \mid h_{i}\right)} \tag{4}
\end{equation*}
$$

Looking at this equation from a different perspective, we can assume that in the original Bayes' rule, all the hypotheses had equal priors and these priors were cancelled out to give equation (4). Therefore, in the Bayesian framework, base-rate neglect is translated into assuming equal priors (i.e., equiprobable hypotheses). This means that the more the original priors (base rates) are averaged out and approach the uniform distribution, the more they are neglected in Bayesian inference. We can explain this more abstractly by using the notion of entropy defined in information theory as a measure of uncertainty. Given a discrete random variable $X=\left\{h_{1}, \ldots, h_{N}\right\}$ with probability mass function $P(\cdot)$, its entropy is defined as:

$$
\begin{equation*}
H(X)=-\sum_{i=1}^{N} P\left(h_{i}\right) \log _{2} P\left(h_{i}\right) \tag{5}
\end{equation*}
$$

Entropy quantifies the expected value of information contained in a distribution. It is easy to show that a uniform distribution has the maximum entropy (equal to $\log _{2} N$ ) among all discrete distributions over the set $\left\{h_{1}, \ldots, h_{N}\right\}$. In sum, we can conclude that in the Bayesian framework, base-rate neglect is equivalent to ignoring the priors in the form of averaging them out to get a uniform distribution, or equivalently, increasing their entropy.

We show that weight decay in our proposed neural network produces the same results as just described, namely approaching a uniform distribution and increasing entropy. We then conclude that we can model base-rate neglect in the Bayesian framework by a weight decay mechanism in our brain-like

(a) The priors' initially Gaussian distribution approaches uniform as time passes and weights decay more (decay rate $=0.2$ ).

(b) The entropy of prior distributions increases as time passes and weights decay more.

Figure 7: Effects of connection weight decay.
network implementing the posterior inference. We take priors as the states of a learning and inference system. As weights decay, the system moves towards more stable states and thus the entropy increases. In special cases, some priors are updated so often that the effects of decay are overcome and these priors stay strong. On the other hand, likelihoods are new evidence and thus, they are not subject to much decay.
