Negative/positive measure includes two discrete valence classes: negative (valence $<0$ ) and positive (valence $>=0$ ) valence levels. If negative words are slower than other words, these two categories should differ. This model is the simplest discrete counterpart to the linear measure above, and was preferred by Estes and Adelman (2008a) as more complex measures tested did not account for the data better. Valenced/neutral measure treats positive and negative as a single class, compared to neutral (emotional: |valence| > 1.5; neutral: |valence| <= -1.5). If emotional words are faster than neutral words we expect to find differences between these two categories (as we would for the quadratic term of the polynomial measure).

## Design and analysis

We fit a variety of linear mixed-effects models described in more detail below, in each case testing for a partial effect of valence on lexical decision latencies, using any of the four proposed valence measures. We conducted our analyses on log-transformed RT (excluding error trials) then replicated the same analyses on untransformed RT to be sure that log-transformation did not produce anomalous patterns of results. Additionally, we fit models not only to trial-level data but also to item averages, for both $\log (\mathrm{RT})$ and untransformed RT. ${ }^{2}$

Analysis of trial level data was carried out using linear mixed-effects models (packages lme4: Bates \& Maechler, 2009; and languageR: Baayen, 2009; cf. Baayen, 2008) in the R programming environment ( R Development Core Team, 2009). Model fits included random intercepts for both subjects and items, as well as random slopes by subjects (for emotional predictors only, which are constant for each item). Analysis of item averages was carried out using ordinary least squares regression. Below we focus upon the results for trial-level analyses of $\log (R T)$ but across the board the findings are comparable for analyses of untransformed RT and/or item averages.

In all of the analyses we conduct upon valence measures, we always begin with a baseline model in which we consider the following non-emotional factors that were

[^246]controlled in all the previous studies we have mentioned: number of letters; $\log (H A L$ frequency), orthographic neighbourhood size (all from Balota et al, 2007); We also included additional non-emotional predictors controlled by Kousta et al. (2009) and which those authors argued to be essential in order to unambiguously interpret effects as emotional in nature: mean positional bigram frequency (Balota et al., 2007); ratings of concreteness, imageability and familiarity (Coltheart, 1981) and age of acquisition ratings (Stadthagen-Gonzalez \& Davis, 2006). As a result, our tests of emotional variables provide results that can be unambiguously attributed to emotion rather than other characteristics of words with which emotional properties may be confounded.

## The role of arousal

Some previous studies have shown that effects of valence are modulated by arousal (Estes \& Adelman, 2008b; Larsen et al., 2008, but see Kousta et al. 2009). Using a similar modelling approach as above, we test the role of arousal in two ways. First, we treat arousal as a categorical measure (high arousal words vs. low arousal words), testing valence $\times$ arousal interactions for any of the valence measures described previously which turn out to be significant predictors of lexical decision RT. If arousal modulates the effect of valence we should see such an interaction. Second, we treat arousal as a control variable, testing in a different set of models whether unique effects of valence can be observed after variation related to arousal is taken into account. This is particularly important for models distinguishing valenced from neutral words (i.e. quadradic term of the polynomial measure, and valenced/neutral measure) as valenced words also exhibit a strong tendency to be more arousing as well (Bradley \& Lang, 2000).

## Emotion words vs. emotionally valenced words

One essential factor that has been neglected so far in large-scale studies of emotion in lexical processing is whether any valence effect is being driven by a specific, limited set of words: those referring explicitly to emotion (e.g. love, shame, joy, hate in contrast to valenced words not directly referring to emotions, e.g. prison, cake, justice, cheat). For example, Altarriba and Bauer (2004) argue that emotion words are sufficiently different to other types of words that we ought to consider words as falling into three categories: concrete, abstract and emotion words. Moreover, it has been argued that emotion words may be embodied not only internally (via emotional experience, as argued by Kousta et al., 2011) but also due to body states associated with emotional experience (such as facial expression, posture etc., Moseley, et al., 2012). Such words tend to be prevalent in our vocabulary and even a cursory inspection of valence norms reveal many such items among the set. If these words alone are responsible for emotion effects, one cannot conclude that valence is relevant to lexical processing in general, as it may play a role only in the specific, tightly constrained domain of emotion words.

To address this issue, we used Wordnet-Affect (Strapparava \& Valitutti, 2004) to identify emotion words. Wordnet-Affect classifies words according to their organisation in Wordnet. Any word with an emotional sense is considered "emotional", thus this is a conservative classification. We hand-classified a few additional words as potentially emotional (e.g. courage, craven, stern) with 193 of the 1313 words classified as emotion words. To test whether emotion words alone are responsible for valence effects we fit models as above, testing the interaction between valence and emotion-word classification. If emotion words drive the effects observed we should see an interaction such that the valence effects are restricted to emotion words (or at least differ between emotion and nonemotion words).

## Results

## Fitting baseline models

It is no surprise that many of the non-emotional variables were significant predictors of lexical decision latencies, consistent with a wealth of previous studies. For the purposes of the present study we simply note here that higher-order polynomial transformations offered significant improvement in performance over linear-alone components for several of the predictors. Moreover, although some factors were not significant predictors in the baseline model (i.e., concreteness, imageability and summed positional bigram frequency) we retained them as (linear) predictors ${ }^{3}$ along with the following predictors that were significant in the (reduced) baseline model: 3-order polynomial transformations: (log frequency, number of letters, number of orthographic neighbours, familiarity); linear terms (age of acquisition) (see Figure 1).

Figure 1: Predictors in the baseline model (logRT; triallevel data). Dashed lines depict 95\% highest posterior density CI (parameter estimates). Similar patterns were observed for item-level analyses and untransformed RT.

[^247]
## Measures of emotional valence

We tested the effects of valence by adding each of the valence measures described above to the best-fit baseline model above, thus always allowing us to evaluate the partial effect of valence only after non-emotional variables were taken into account. We also added that same valence term in each model as a random slope by subjects (in analysis of trial-level data).

Table 1: Partial effects of the different valence measures (logRT, trial-level), taking non-emotional variables into account. The same patterns were observed for item-level analyses and for untransformed RT

| Valence measure | Estimate (Std err.) | $t$ statistic |
| :--- | ---: | :--- |
| Linear | $.00066(.00161)$ | 0.57 |
| Polynomial $^{4}$ |  |  |
| $\quad$ (linear term) | $.00052(.00116)$ | 0.45 |
| $\quad$ (quadratic) | $-.00158(.00076)$ | -2.07 |
| Negative/positive | $.00166(.00286)$ | 0.58 |
| Valenced/neutral | $-0.0067(.00357)$ | -1.87 |

| Linear | Quadratic | Positive- | Valenced- |
| :---: | :---: | :---: | :---: |
| (continuous) | (continuous) | Negative | Neutral |

Figure 2: Graphical depiction of parameter estimates of the different valence measures reported in Table 1. In all cases a value of 0 indicates no effect. For continuous measures, the values plotted reflect the slope (linear measure) or quadratic coefficient (polynomial measure). For categorical measures they represent the estimate of the difference between the two conditions (logRT). Horizontal
line $=$ mean parameter estimate. Box depicts 50\% confidence interval of the parameter estimate; whiskers depict 95\% confidence interval.

Only those measures in which valenced words differ from

[^248]neutral words (quadratic term of polynomial continuous measure, and valenced/neutral measure) were reliable predictors of lexical decision RT. Instead, the linear continuous measure did not predict RT once confounding factors were taken into account, and the same was true for the negative/positive measure. To assess whether the continuous (quadratic) measure offers sufficient additional explanatory power beyond the simplest categorical measure contrasting valenced to neutral words, we fit one additional set of models, in which we entered 2-order polynomial valence along with the categorical measure, and we compared the models using likelihood ratio tests. There was no significant improvement gained by adding this additional term (log likelihood ratio for valenced/neutral model = 7629.1; log likelihood ratio for combined model $=7630.0$; $\chi^{2}(5)=1.7972, p=.876$ with comparable results for itemlevel analyses and analyses of untransformed RTs.

At this stage the data suggest that the effect of valence is best described as a simple, categorical contrast between words with emotional associations and those without. Thus, when non-emotional variables are taken into account, we see that a categorical measure of valence, regardless of polarity, is sufficient to account for emotional effects in word processing.

## The role of arousal

Here we focus upon those valence measures which were reliable predictors in the previous section (i.e., 2-order Polynomial and Valenced/Neutral), assessing whether they can be accounted for, or modulated, by arousal.

First, we tested the interaction between arousal and each of the two valence measures (continuous and categorical). For these analyses we discretized arousal, using a median split to characterise words as low or high arousal (contrast coded). For trial-level analyses we included both main effects and the interaction as random slopes by subjects. We found that the main effect of valence persisted, with no effect of arousal category and no interaction between the two. For $\log$ RT and trial level analysis: quadratic coefficient estimate $=-.00338(\mathrm{SE}=.00110), t=-3.067$, arousal main effect and interaction $|t|<1.2$; categorical coefficient estimate $=-.0135(\mathrm{SE}=.0050), t=-2.725$, arousal main effect and interaction $|t|<1$ (with item level analyses and analyses of untransformed RTs showing the same pattern).

Next, we instead considered arousal as a continuous measure of arousal into the models, testing whether a partial effect of a valence measure could still be seen after arousal was taken into account. For trial-level analysis this meant including random slopes by subject for arousal as well. We started by adding arousal to the baseline model described above. When arousal was the only emotional variable included, its effects were significant (estimate of the slope $=$ -. 0050 ( $\mathrm{SE}=-.0020, t=-2.518$ ): more arousing words elicited faster responses. We then added a valence measure to this baseline+arousal model. For both the polynomial and the categorical valence measure, effects persisted once
arousal was taken into account. For log RT and trial level analysis: quadratic coefficient estimate $=-.00261$ ( $\mathrm{SE}=$ .00144), $t=-2.627$; categorical coefficient estimate $=-.0112$ (SE = .0046), $t=-2.410$ ), with the partial effect of arousal not reaching significance in either case ( $|t|<1$ ), a finding replicated in item-level analyses and analyses of untransformed RTs. These effects of emotion can thus be attributed to valence rather than arousal.

## Emotion words vs. emotionally valenced words

As in the second set of analyses considering the role of arousal, we tested whether the effects of valence described above were different for emotion words and those not referring to emotional states (using Wordnet-Affect, Strapparava \& Valitutti, 2004), by testing for statistical interactions.

Just like our analyses involving arousal, the main effect of valence was unchanged, with no effect of Wordnet-Affect category and no interaction. For log RT and trial level analysis: quadratic coefficient estimate $=-.00197$ ( $\mathrm{SE}=$ .00085), $t=-2.31$, Wordnet-Affect category main effect and interaction $|t|<1$; categorical coefficient estimate $=-.00969$ (SE = .00419), $t=-2.31$, Wordnet-Affect category main effect and interaction $|t|<1.02$ (again with item level analyses and analyses of untransformed RTs showing the same pattern).

## Discussion

Our analyses show a reliable, consistent and rather simple pattern of emotion effects in lexical processing. Once potentially confounding variables are taken into account, lexical decisions to emotionally valenced words are recognised faster than those to neutral words. This finding differs from some previous studies (Estes \& Adelman, 2008a,b; Larsen et al., 2008): those investigating ELP data, using a more limited set of words (from ANEW, Bradley \& Lang, 1999) and crucially, for which some important control variables are unavailable. Those studies also conducted analysis over item averages only, allowing the possibility that valence effects observed there may have been magnified or distorted as a consequence of treating these values as point estimates rather than varying by subjects. Our results also differ from those reported by Kousta et al. (2009) although consistent with their overall conclusions. There appears to be no benefit in considering valence as a continuous measure: the 2-order polynomial valence model is no better than the simplest categorical model (valenced vs neutral). In fact when we reanalyze their data set, there too we find that a categorical measure contrasting valenced to neutral words is comparable to the continuous measure they favoured.

We also found this categorical effect of valence to be general in nature: it is not modulated by arousal, and it is not driven by words specifically referring to emotional experience. This finding resonates with recent neuroimaging evidence using a highly controlled set of words, in which activation in rostral anterior cingulate cortex (an area
associated with emotion processing) is modulated by valence (regardless of whether it is positive or negative) and not by arousal (Vigliocco et al., 2013).

Why would emotional content, regardless of polarity, facilitate lexical processing? Under general motivational accounts of processing (Lang, Bradley \& Cuthbert, 1997) both negatively and positively valenced items are relevant to survival and wellbeing albeit for different reasons. Crucial in this regard is the involvement of emotion processing systems even for lexical stimuli which do not exhibit obvious low-level visual characteristics argued to be evolutionarily linked to positive or negative emotions (vs. emotional expressions or visual properties of dangerous entities). In a recent proposal, the involvement of emotional systems has been argued to provide a means for grounding abstract concepts in internal experience, just like concrete concepts are accepted to be grounded in sensory-motor experience (Kousta, Vigliocco, Vinson, Andrews \& Del Campo, 2011; Vigliocco, Meteyard, Andrews \& Kousta, 2009). Under this view, emotional content of words would facilitate their processing, in a manner akin to the way in which sensory experience (operationalised as imageability or concreteness; Kousta et al. 2011) facilitates processing.

# Does the Influence of Stress on Financial Risk Taking Depend on the Riskiness of the Decision? 

Bettina von Helversen (bettina.vonhelversen@unibas.ch)<br>University of Basel, Department of Psychology, Missionsstrasse 62a<br>4055 Basel, Switzerland<br>Jörg Rieskamp (joerg.rieskamp@unibas.ch)<br>University of Basel, Department of Psychology, Missionsstrasse 62a<br>4055 Basel, Switzerland

#### Abstract

Many decisions under risk and uncertainty are made under physical or emotional stress. Recent research suggests that stress influences decisions between risky options, but that the direction of the influence depends on the characteristics of the gambles. For instance, stress increases risk taking for loss gambles, but decreases risk taking for gain gambles. In the current project we investigate: (1) whether the riskiness of gambles influences the direction of the stress effect and (2) whether changes in risk taking can be linked to changes in attention. Participants who gave relatively more attention to gains than to losses, as indicated by eyetracking data, were more risk seeking than participants who gave less attention to gains. Stress did not influence participants' attention. However, stressed participants became more risk seeking when considering gambles with relatively low risk, but less risk seeking for gambles with relatively high risk.

Keywords: risk; decision making; stress; cortisol; variance

## Introduction

Every day we make decisions involving risk and uncertainty ranging from buying a gamble ticket to investing in stocks, gold, or real estate. Many of these decisions are not made in cold blood, but under physical or emotional stress. How stress and stress-related release of hormones such as cortisol influence risk preferences, however, is far from clear. Research has found that men, but not women, tend to become more risk seeking under stress (Lighthall, Mather, \& Gorlick, 2009; Preston, Buchanan, Stansfield, \& Bechara, 2007; Starcke, Wolf, Markowitch, \& Brand, 2008). Similarly, studies on financial risk taking have found divergent results. For instance, offering participants choices between risky and relatively safe options, Porcelli and Delgado (2009) found that participants became more risk seeking under stress when choosing between options involving losses, but less risk seeking when choosing between options involving gains. In a similar vein, Carr and Steele (2010) found that stereotype threat reduced risk taking in women. Von Dawans, Fischbacher, Kirschbaum, Fehr, \& Heinrichs (2012), however, found no influence of stress on decisions between gambles involving gains and losses.

Porcelli and Delgado (2009) argue that stress enhances decision biases such as the reflection effect (i.e., people are more risk seeking in the loss domain than in the gain domain, Kahneman \& Tversky, 1979). In the current research we follow up on this result, suggesting that stress enhances preexisting preferences for risk. That is, in decision situations in which people usually are risk seeking, they should become even more risk seeking under stress, whereas in decision situations in which people behave risk averse, they should become even more risk averse. We test these hypotheses in a financial risktaking task.

As a second goal we aimed to examine the mechanism underlying changes in risky decision making under stress. One mechanism by which stress could enhance preexisting preferences is by narrowing the focus of attention to the piece of information that is considered as most important. In line with this idea stress has been shown to reduce cognitive resources and narrow the focus of attention as well as the amount of information that can be processed (Friedman \& Förster, 2010; Kelly, Ashleigh, \& Beversdorf, 2007; Wichary \& Rieskamp, 2011). Thus, stress could influence risky decision making by changing the amount of attention given to the attributes of the choice options such as the possible outcomes (gains or losses) and the probability of the outcome (Ben Zur \& Breznitz, 1981).

## Variability in Outcomes as a Measure of Risk

The vast majority of research on financial risk taking involves the choice between gambles; that is, options with various outcomes that occur with a specific probability and that differ in valence (e.g., gains or losses). The risk of a gamble is commonly defined by the variability of the outcomes, with higher variability implying higher risk. For instance, finance models such as the capital-assespricing model equate risk with outcome variance (Sharpe, 1964). However, other variability measures such as the coefficient of variation, a measure based on the relative variance of a gamble, have been proposed to measure risk (Weber, Shafir, \& Blais, 2004). In sum, if stress amplifies people's risk preferences by narrowing their attention to the subjectively important aspect of the decision situation,
then stress should lead to more risk-taking behavior for gambles with little outcome variability and to less risk taking for gambles with high outcome variability.

## Attention in Risky Decision Making

The attention given to positive and negative attributes is an important predictor of decisions under risk. For instance, Ben Zur and Breznitz (1981) found that how often people looked at information about how much they could win or lose was related to their choices. This suggests that if stress narrows attention to the information the participant considers most important, increase in risky choices could be related to more attention being given to gains than to losses, whereas choice of safe options may be related to increased attention to losses over gains.

A non-intrusive way of measuring the relative attention given to gains or losses is by recording eye movements. In general, visual attention is strongly coupled to eye movements (e.g., Hoffman, 1998) and has been successfully used to understand the processes underlying decision making (Glaholt \& Reingold, 2011). In particular, two measures of eye movement have been successfully used to predict decisions. First, the time spent looking at an option is positively related to choosing this option (Glaholt, Wu, \& Reingold, 2009). Similarly, the time spent looking at specific pieces of information has been linked to the importance assigned to it (Rehder \& Hoffman, 2005). Secondly, choices are often reflected by gaze cascade effects; that is, over time attention wanders to the preferred option (Glaholt \& Reingold, 2011; Fiedler \& Glöckner, 2012). In particular, the last focus is related to choice; that is, the option fixated last before making a decision is chosen more frequently than other options (Krajbich, Armel, \& Rangel, 2010). Thus in the current study, we considered the time that gains and losses were looked at as well as the last information that was fixated before making a decision.

## The Study

We investigated the influence of stress on risk taking with a financial decision-making task consisting of 40 decisions between two gambles that contained positive and negative outcomes. Mixed gambles present an interesting problem, because increased risk taking with cortisol has been shown in particular when high gains and high losses were at stake (Putman, Antypa, Crysovergi, \& van der Does, 2010). Within the 40 gambles we varied the variability in the outcomes.

## Method

Participants. 70 participants ( 40 in the stress condition and 30 in the no stress condition, $M_{\text {Age }}=24.4, S D_{\text {Age }}=$ 5.3) were recruited at the University of Basel. We expected that for a substantial number (approximately one third) of the participants the cold pressor task would not result in an increase in cortisol. Therefore we collected more participants in the stress condition, to ensure a
sufficient sample size in the stress condition. 48 were females. Participants received a participation fee of 20 CHF per hour (approx. 22 US-\$). Additionally one of the participant's decisions was randomly chosen and the preferred gamble was played. Participants received/paid $10 \%$ of the gamble's outcome. One participant was excluded from the analysis because he always chose the reference gamble. Overall, testing took 1 h and 30 min .

Financial Decision-Making Task. The financial decision-making task consisted of 40 decisions between two gambles. In each trial participants chose between a reference gamble (Gamble A), in which participants could win 15 Swiss Francs (CHF) or lose 5 CHF with a probability of $.5(\mathrm{EV}=5 \mathrm{CHF})$, and a target gamble (gamble B). The reference gamble was the same in each decision, but there were 40 different target gambles structured in two sets: (1) high outcome gambles (e.g., win/lose 60 with a probability of .5 ) and (2) low outcome gambles (e.g., win/lose 30 with a probability of .5). For each gamble type (high or low outcome) we created sets of gambles by varying the expected value of the target gamble from -5 to $15 / 30$ in steps of 5 . The expected value was varied by changing either (1) the amount that could be won, (2) the amount that could be lost, or (3) the probability with which each outcome could occur (see Table 1 for an overview).

Table 1: Overview of the target gambles

| No | $p($ win $)$ | Gain | $p($ loss $)$ | Loss | EV | Set |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| 1 | .50 | 60 | .50 | -70 | -5 | high |
| 2 | .50 | 60 | .50 | -60 | 0 | high |
| 3 | .50 | 60 | .50 | -50 | 5 | high |

Note: $p($ win $)=$ probability of receiving the positive outcome (Gain); $p$ (loss) = probability of receiving the negative outcome (Loss). EV = gamble's expected value.

The order in which the target gambles were presented was randomized. For half of the participants gains appeared on the left side and for the other half on the right side. Reference and target gambles were presented sequentially to allow better measures of the relative attention given to each attribute (win, loss, probability) of each gamble (see Figure 1 for a screenshot). Each trial started with a fixation cross $(100 \mathrm{~ms})$. Then the reference gamble was presented until participants pressed the return key. The target gamble appeared until participants made a choice by pressing " 1 " for the reference gamble or " 2 " for the target gamble. The task was implemented in Presentation.

Figure 1. Screenshot of a target gamble.
Stress Manipulation. In the stress condition, we induced stress with the cold pressor task (CPT; Lovallo, 1975). The CPT is a standard method to induce a stress response and has been shown to reliably increase subjective stress and cortisol levels (McRae et al., 2006). In the CPT participants immersed their right hand in ice water $\left(0^{\circ}-4^{\circ} \mathrm{C}, M=1.86^{\circ} \mathrm{C}, S D=0.67\right)$ for as long as possible, up to 3 minutes. In the no stress condition participants immersed their hand in warm water ( $37^{\circ}-$ $40^{\circ} \mathrm{C}, M=38.98^{\circ} \mathrm{C}, S D=0.81$ ).

Measurement of Mood, Arousal, and Stress. We measured mood and arousal with the Self Assessment Mannequins (SAM; Hodes, Cook, \& Lang, 1985). To measure the physiological stress response we took saliva samples collected using Salivettes (Sarstedt, Nuembrecht, Germany) to determine cortisol levels. Saliva samples
were analyzed at the laboratory of the Technical University Dresden. Salivary free cortisol levels were determined using a chemoluminescence immunoassay (IBL, Hamburg, Germany) with intra- and interassay precision of $2.5 \%$ and $4.7 \%$, respectively.

Procedure. After participants arrived we determined whether they met the inclusion criteria for the study and gave them approximately 8 fl . oz. of water to drink. Then, we took the first saliva sample and measured mood and arousal (T1). Following the measurements, participants immediately proceeded with the first session of the financial decision-making task. After that participants gave the second saliva sample and again completed the mood and arousal measures (T2). Next, participants proceeded with the stress manipulation. 15 min after the stress manipulation, so that cortisol levels had time to rise, we took the third saliva sample and measured mood and arousal (T3). Immediately afterwards, participants performed the financial decision-making task again (Session 2). After that we again measured mood and arousal and took the fourth saliva sample (T4). Figure 2 provides a schematic overview of the experimental design.

Figure 2. Overview of the experimental design. The abbreviations are explained in the text.

Eye Movements. We recorded participants’ eye movements while they solved the financial decisionmaking task by using a remote eye-tracking device (SensoMotorics Instruments LLC), using the iViewX software and a remote binocular sampling rate of 120 Hz . The stimulus material was presented on a screen with a resolution of $1680 \times 1050$ pixels and a refresh rate of 60 Hz . The eye tracker was calibrated before the decisionmaking task and calibration was checked and if necessary repeated after each decision (20 pixel tolerance). Further analysis was done in Matlab. Fixations were identified using a 20 pixel tolerance (i.e., added max-min deviation for $x$ - and $y$-coordinates) and a minimum fixation time threshold of 50 ms (see Fiedler \& Glöckner, 2012 for a similar procedure).

We defined areas of interest (AOI) as circles with a radius of 120 pixels around each piece of information;
that, is the potential loss and gain, and the probability with which a loss or gain would occur (see Figure 1).

## Results

Mood, Arousal, and Stress Response. First we analyzed whether the stress manipulation influenced participants' mood, arousal, and cortisol levels (for means and $S D$ see Table 2).

Table 2: Descriptive statistics (Means and SDs) for mood, arousal, and cortisol by stress condition

| Measure | T 1 | T 2 | T 3 | T 4 |
| :--- | :---: | :---: | :---: | :---: |
|  | $M(S D)$ | $M(S D)$ | $M(S D)$ | $M(S D)$ |
| Stress |  |  |  |  |
| Mood | 2.85 | 3.08 | 2.95 | 3.03 |
|  | $(1.00)$ | $(1.19)$ | $(1.11)$ | $(1.10)$ |
| Arousal | 6.38 | 6.38 | 6.03 | 6.9 |
|  | $(1.29)$ | $(1.63)$ | $(1.95)$ | $(1.28)$ |
| Cortisol | 12.50 | 10.16 | 17.92 | 14.21 |
| (nmol/l) | $(10.04)$ | $(7.13)$ | $(10.86)$ | $(11.12)$ |

| No Stress |  |  |  |  |

| Mood | 3.17 | 3.07 | 3.10 | 3.03 |
|  | $(1.10)$ | $(1.16)$ | $(1.32)$ | $(1.10)$ |
| Arousal | 6.03 | 6.10 | 6.86 | 6.76 |
|  | $(1.57)$ | $(1.70)$ | $(1.62)$ | $(1.86)$ |
| Cortisol | 12.09 | 9.95 | 8.12 | 7.40 |
| (nmol/l) | $(7.50)$ | $(5.68)$ | $(3.79)$ | $(3.53)$ |

Note: $\mathrm{N}_{\text {stress }}=40 ; \mathrm{N}_{\text {no stress }}=29$; lower numbers indicate more positive mood and higher arousal

Mixed analyses of variance (ANOVAs) on mood, arousal and cortisol with measurement time (T1-T4) as within-subject factor and stress condition as betweensubjects factor showed that arousal and cortisol levels increased in the stress group but not in the no stress group. In the no stress group cortisol and arousal decreased, suggesting that participants' initial excitement decreased during participation. This was indicated by significant interactions of measurement time and stress condition, Arousal: Greenhouse-Geisser corrected $F(3,166)=6.15, p=.01$; Cortisol: Greenhouse-Geisser corrected $F(3,90)=18.23, p<.001$. We did not find an effect of stress on mood, that is there was no interaction between measurement time and stress condition, $F(3$, 201) $=0.87, p=.46$, nor main effects of time or stress condition (all $p s>.65$ ).

The Influence of Stress on Decisions under Risk. We measured risk taking as the proportion of trials in which the risky option (i.e., the target gamble) was chosen. On average participants chose the risky option in $44 \%$ of the choices in the first session and in $46 \%$ in the second session, indicating that participants were rather risk averse (a risk neutral decision maker who always chose the
option with the higher expected value should have chosen the target gamble in $67.5 \%$ of the trials). In a first step we analyzed whether stress influenced the proportion of risky choices with a mixed ANOVA with session (before/after the stress induction) as within-subject factor and stress condition as between-subjects factor. We did not find a main effect of session $(F(1,67)=0.89, p=.35)$ or stress $(F(1,67)=0.43, p=.51)$, nor an interaction between them $(F(1,67)=0.10, p=.75$; for means and $S D$ see Table 3).

In the next step we tested whether the difference in outcomes of the gambles influenced how stress affected risky decision making. We focused on the choices where target gambles offered a higher expected value than the reference gamble (i.e., $E V>10$ ), to account for participants' overall risk aversion. A mixed ANOVA with session and gamble type as within-subject factors and stress condition as between-subjects factor showed that participants chose the target gamble more frequently for the low outcome gambles than the high outcome gambles, $F(1,67)=70.96, p<.001$. Additionally we found a threeway interaction between stress condition, session and gamble type, $F(1,67)=5.87, p=.02$. As illustrated in Figure 3, repeated measurement ANOVAs for stressed and not stressed participants separately showed an interaction between time and gamble type for participants in the stress condition, $F(1,39)=7.53, p=.01$, but not in the no stress condition, $F(1,28)=0.76, p=.39$. This suggests that in the second session compared to the first session participants in the stress condition-but not participants in the no stress condition-took more risks with low outcome gambles, but less risk with high outcome gambles.

Figure 3. Proportion of risky choices for gambles with high and low outcomes in the stress and no stress group

Because previous literature has shown that men and women react differently to stress (e.g., Lighthall et al., 2009), we ran additional analyses including gender as a further between-subjects factor. We found a main effect
of gender in that women chose the risky option less frequently than men ( $M_{\text {men }}=.79, S E=.05, M_{\text {women }}=.63$, $S E=.03, F(1,65)=7.15, p=.01)$. However, gender did not interact with the gamble type, nor affect the results of stress on high and low outcome gambles.

Table 3: Descriptive statistics for risky decision making and measures of eye movement by stress condition

| Measure | Stress |  | No stress |  |
| :--- | :---: | :---: | :---: | :---: |
|  | $M$ | $S D$ | $M$ | $S D$ |
| Risky Choices (Session 1) | 0.43 | 0.17 | 0.46 | 0.19 |
| Risky Choices (Session 2) | 0.45 | 0.18 | 0.47 | 0.22 |
| FixationGainLoss (High 1) | 0.08 | 0.09 | 0.08 | 0.10 |
| FixationGainLoss (High 2) | 0.07 | 0.11 | 0.08 | 0.10 |
| LastGainLoss (High 1) | 0.20 | 0.27 | 0.19 | 0.31 |
| LastGainLoss (High 2) | 0.19 | 0.37 | 0.18 | 0.30 |
| FixationGainLoss (ow 1) | 0.08 | 0.10 | 0.08 | 0.11 |
| FixationGainLoss (Low 2) | 0.06 | 0.11 | 0.08 | 0.11 |
| LastGainLoss (Low 1) | 0.17 | 0.36 | 0.25 | 0.26 |
| LastGainLoss (Low 2) | 0.15 | 0.38 | 0.27 | 0.31 |

Eye Movements. Can the influence of stress on risktaking be explained by the relative attention given to gains and losses? To answer this question, we considered two measures of eye movements: (1) the relative duration with which gains were fixated compared to losses (FixationGainLoss) and (2) the relative proportion of trials on which the last fixation before making a decision was to the gain information or the loss information (LastGainLoss). We calculated the measures for high and low outcome gambles separately. Because the reference gamble was always the same, we focused on the target gambles. The FixationGainLoss was calculated by measuring the duration of fixations in each AOI (gains, losses and probabilities) for each trial. Next, we computed how long gains were fixated relative to losses and calculated the average for trials with high and low outcome gambles with an expected value of 10 or higher. The LastGainLoss was calculated by taking the difference between the proportion of trials with high and low outcome gambles with an expected value of 10 or higher in which the last focus was to the gain AOI relative to the loss AOI; see Table 3 for means and SD.

We then investigated whether the two measures of eye movements were related to the proportion of risky choices. Correlations indicated that the longer gains were fixated compared to losses and the more often the last fixation was to the gain AOI relative to the loss AOI, the more participants chose the risky option, particularly in the high outcome gambles (see Table 4).

To investigate whether the attention to gains and losses changed with stress, we conducted two mixed ANOVAs with session and variance as within-subject factors and stress condition as between-subjects factor.

We did not find an effect of session, stress condition or variance for the relative time gains and losses were
looked at (all $p \mathrm{~s}>.18$ ). The analysis on the location of the last fixation before making a decision also showed no main effects of session, gamble type or stress condition (all $p \mathrm{~s}>.45$ ), but indicated a significant interaction between gamble type and stress condition, $F(1,67)=4.09$, $p=.05$.

Follow-up analyses for participants in the stress condition and the no stress condition separately showed an effect of gamble type in the no stress condition, $F(1,28)=4.24, p=.05$, indicating that the participants more frequently looked to gains compared to losses for the low outcome gambles than for the high outcome gambles (see Table 3). In the stress condition, however, we did not find an effect of session or gamble type (all $p$ s $>.37$ ).

Table 4: Correlation between measures of eye movement and risk taking

|  | Risky Choice <br> (H1) |  | Risky Choice <br> (H2) |  |
| :--- | :---: | :---: | :---: | :---: |
|  | $r$ | $p$ | $r$ | $p$ |
| FixationGainLoss (H1) | .33 | .005 | .37 | .002 |
| FixationGainLoss (H2) | .35 | .003 | .34 | .004 |
| LastGainLoss (H1) | .34 | .004 | .38 | .001 |
| LastGainLoss (H2) | .30 | .01 | .30 | .02 |

Note: $N=69 ; \mathrm{H} 1=$ high outcome gambles, session 1; H2 $=$ high outcome gambles, session 2

## Discussion

The effect of stress on decisions under risk seems to depend on the risk the decision involves. Whereas we did not find an overall influence of stress on Although taking, a detailed analysis showed that the influence of stress depended on the variability in the gambles' outcomes. After immersing their hand in ice-cold water, participants chose the risky gamble more frequently when the difference between outcomes was relatively low, but less frequently when the difference between outcomes was high. This suggests that the influence of stress on risk taking depends on the riskiness of the decision-making task, resonating with research showing that stress increases risk taking in the loss domain but decreases risk taking the gain domain (Porcelli \& Delgado, 2009). These results can help reconcile the diverse effects of stress on risky decision making in the literature by showing that to understand the influence of stress it is necessary to take task characteristics such as the involved risk of a decision into account.
A second goal of the research was to investigate whether the relative attention given to gains and losses is a potential mechanism underlying the influence of stress. Overall, participants who gave relatively more attention to gains than to losses tended to choose the risky option more frequently. This resonates with previous work suggesting that the time spent on information is related to its importance for the choice (e.g., Ben Zur \& Breznitz,

1981; Glaholt et al., 2009). Additionally we found that the last fixation before making a choice was related to risk taking, dovetailing with research on gaze cascade effects in risky decision making (e.g., Fiedler \& Glöckner, 2012). Moreover, it suggests that gaze cascade effects extend to the attribute that was most important in determining choice.

We did not find any evidence, however, that stress changed the relative attention given to gains over losses or the last information looked at. This could suggest that the influence of stress is not mediated by the attention given to gains and losses. On the other hand, the effect of stress could have been masked by noise given to the relatively few gambles in our task.

In sum, our results suggest that stress changes how risky decisions are made. Although the mechanism by which stress exerts its influence requires further research, it becomes clear that the effect of stress can only be understood when considering the characteristics of the decision task.

# Negative observations, induction and the generation of hypotheses 

Wouter Voorspoels (wouter.voorspoels@ppw.kuleuven.be)<br>Chayenne Van Meel (chayenne.vanmeel@student.kuleuven.be)<br>Gert Storms (gert.storms@ppw.kuleuven.be)<br>KU Leuven, Department of Experimental Psychology, Tiensestraat, 102<br>Leuven, 3000, Belgium.

#### Abstract

In category-based induction tasks, it is a robust finding that positive observations raise the judged likelihood of a conclusion and negative observations lower judged likelihood. We present evidence that negative observations can raise the judged likelihood. In particular, we asked participants to judge the likelihood of a conclusion after introducing them to different sets of premises either containing one positive observation or the same positive observation and a negative observation. We found that when the negative observation is dissimilar to the positive observation, willingness to accept a conclusion is raised. Moreover, results from a simultaneous hypothesis generation task suggest that the rise in judged conclusion likelihood is due to a peculiar shift in the hypothesis space of the reasoner, in that the hypothesis with the largest extension, yet still consistent with all premises gains disproportionate popularity when introducing dissimilar negative observations.

Keywords: induction; non-monotonicity; reasoning; sampling assumptions;

## Introduction

People often find themselves in situations that require judgments based on incomplete knowledge, derived from an incomplete set of observations. From experience with traffic lights, we can conclude that red is diagnostic for dangerous situations (positive observations), and we will refrain from crossing the road. However, we have also encountered traffic lights on lonely nights, when there is no traffic. In that situation, red does not necessarily indicate danger (negative observation). How do we combine these observations to make a decision about crossing the road? The world is not sufficiently friendly to provide us with an exhaustive set of observations. But we do not want to stay on the same side of the road all our lives. We want to see the other side of the road! Therefore inference to uncertain conclusions, generally referred to as induction, is omnipresent in everyday life and almost equally widely studied in cognitive science (Heit, 2000).

A common paradigm to study induction a is the categorybased induction task: Participants are asked to infer the presence of a feature in a conclusion category on the basis of a set of observations. The observations are presented as premises of the argument. For example:

## Premise: Tigers have sesamoid bones

## Conclusion: Lions have sesamoid bones

A number of regularities have been reported regarding how people respond to such problems, one of which forms the
topic of the present paper. Following intuition, but also according to the main theories of inductive reasoning (see, e.g., Heit, 2000), there exists a monotonic relation between the number of observations and the strength of an argument: As more objects displaying the property are observed, a conclusion will be judged more likely (see, e.g., Osherson, Smith, Wilkie, Lpez, \& Shafir, 1990). Similarly, as objects are observed that do not have the property, the judged likelihood of a conclusion decreases (e.g., Heussen, Voorspoels, Verheyen, Storms, \& Hampton, 2011). We will refer to this general finding as the monotonicity principle.

Put differently, the monotonicity principle predicts that a positive observation ${ }^{1}$ raises argument strength, and a negative observation ${ }^{2}$ lowers argument strength. In case the observation is extremely dissimilar, and thus irrelevant to the conclusion, argument strength remains the same. For example, the likelihood of the conclusion 'Lions have sesamoid bones' is raised by the observation that tigers have sesamoid bones, is lowered by the observation that leopards do not have sesamoid bones and remains the same following the observation that tea cups do not have sesamoid bones. Additional relevant positive and negative observations will respectively raise and lower the argument strength further (asymptotically, obviously).

Recently we have presented evidence that suggests that negative observations can in some cases increase argument strength, contrary to what the monotonicity principle predict (Heussen et al., 2011). In a forced choice paradigm, participants showed a preference for an argument of the following form as compared to an argument without the second, negative premise:

Mozart's music elicits alpha waves in the brain
Metallica's music does not elicit alpha waves in the brain

## Bach's music elicits alpha waves in the brain

A potential explanation for the results of (Heussen et al., 2011) is that negative observations point the reasoner to a relevant dimension to base inference upon (Medin, Goldstone, and Gentner (1993)). In the above argument, the negative observation highlights a commonality between Mozart and Bach, not shared by Metallica, i.e., that being classical music is the crucial feature to base inference upon. As a conse-

[^249]quence, the argument will be considered stronger. In addition, by explicitly contradicting some of the potential hypotheses (e.g.,all music elicits alpha waves), negative evidence clearly helps in reducing the number of hypotheses. This is expected to raise believe in the hypotheses that remain consistent with the premises after the negative observation.

## Outline

The present study aims at further investigating the rise in argument strength following a negative observation. In particular, our aim is twofold. First, we want to replicate the effect in a rating task, in which we compare generalization judgments of participants who were not presented with negative observations to judgments by participants who were. This differs considerably from Heussen et al. (2011), where a forced choice paradigm was used. Second, we ask participants to generate hypotheses after introducing the observations. In this way, we can examine how the hypothesis space of people confronted with negative observation changes and how this relates to their generalization judgments.

Following Heussen et al. (2011), we hypothesize that a negative observation will raise the willingness to accept a conclusion whenever it points to a dimension that can be used to make the required generalization. In effect, we expect that the projection of a feature from Mozart's music to Bach's music is facilitated when a negative observation excludes other types of music, and points to classical music as the correct extension of the novel feature. Similarly, when projecting a property from Bach's music to Nirvana's music, the projection is expected to be facilitated by a negative observation outside the category that entails both subcategories (music). Adding the premise that the sound of a falling rock does not have the property, is thus expected to increase the willingness to project the property to Nirvana's music. Moreover, we expect that the hypothesis space of participants will vary accordingly.

## Experiment

## Method

Participants Participants were 172 bachelor students psychology who volunteered for course credits.

Materials We used 12 argument topics taken from Heussen et al. (2011) (music, painters, public figures, types of ships, types of glass, types of displays, water bodies, fruit, water birds, insects, polar animals). In each topic, a hierachical structure is present, comprising of a category (e.g., music), two subcategories (A: classical music and B: rock music) and a supordinate category ( C : sound).

Each of the topics has a base argument built from one premis from subcategory A (e.g., Mozart's music has X). Depending on the condition, negative premises are added from the other subcategory (B), or a different category (C). Thus, either the additional premise contains information regarding a member of subcategory A (e.g., Vivaldi's music), or the premise contains information on a member of subcategory

B (e.g., Metallica's music) or the premise presents information from category C (e.g., the sound of a waterfall). Table 1 presents an overview of the premises for the topic music.

In Heussen et al. (2011), only one conclusion from subcategory A was used. For the present experiment, we added two conclusion categories to each topic: One from subcategory B (e.g., Nirvana's music), and one from category C (e.g., the sound of a falling rock). The properties that were to be generalized from premises to conclusions, were intuitively realistic characteristics that participants were likely to have very little knowledge about (e.g., contain lycopene; create conversion currents; elicit alpha waves in the brain).

Table 1: an overview of the simtulus material for the topic 'music'. Entries in bold refer to items that are presented in every condition (e.g., the base premise "Mozart's music elicits alpha waves").

| Type | Premise | Conclusion |
| :--- | :--- | :--- |
| subcategory (A) | Mozart, Vivaldi | Bach |
| subcategory (B) | Metallica | Nirvana |
| superordinate (C) | falling rock | waterfall |

Procedure The experiment had the form of a web-based survey. On each trial, participants were presented with a short scenario describing that specialists in the domain of interest (e.g., neuroscientists) had recently made novel discoveries. This was followed with the premise (or premisses) of an argument. For example, participants were given following premise:

Mozart's music elicits alpha waves in the brain.

After reading the information, participants received two successive tasks. First, in the hypothesis generation task, they were asked to come up with a rule underlying the observations, (e.g., "classical music elicits alpha waves in the brain"). They were asked to type their hypothesis in a textbox in one or two sentences. Second, in the generalization task, participants were asked to judge how likely the three conclusions associated with the argument were by moving a bar on a continuous scale running from 1 to 100 for each of the conclusions.

For each topic, we constructed six premise sets, varying the type of observations, and the "'sign"" (positive or negative). For each premise set the exact same three conclusions were judged for likelihood, but the premise set varied across condtions. Here, we will discuss only three conditions that allow crucial comparisons to test for the effect of negative observations. In the base condition, referred to as posA, participants were presented with the base premise, as in (1). In condition posAnegB, a negative observation from a different subcategory is added to the base premise:

## Mozart's music elicits alpha waves in the brain. Metallica's music does not elicit alpha waves in the brain.

In a third condition, posAnegC a negative observation was added to the base premise, disclosing information on a member of the same superordinate category:

## Mozart's music elicits alpha waves in the brain. The sound of a falling rock does not elicit alpha waves (3) in the brain

In total, $12 \times 6$ arguments were constructed. The 72 arguments were distributed across 6 lists so that each list contained each of the twelve topics (so participants did not see the same topic twice), and a list contained 2 arguments for every type of premise set (so each participant got two arguments from every condition). The lists were distributed randomly across participants. The order of arguments within a list was random for each participant, as well as the order of the conclusions in each argument. The same two practice items preceded each list in order to familiarize the participants with the procedure. These two items were not included in the analyses. The experiment took no longer than 20 minutes

Premise sets posA, posAnegB and posAnegC form the object of the present examination. The structure of premise sets 4 to 6 is listed in Table 2, but will not be discussed in the present paper. As can be seen in table 2, these premise sets do not contain negative observations, except the "completely saturated" premise set 6 .

Table 2: Schematic overview of the experiment. ' + ' refers to a positive observation, '-' to a negative observation. '++' means that two premises from the same subcategory were presented in the corresponding condition. In the present paper we focus on the first three premise sets.

| Cond | subcat A | subcat B | cat C | \# premises |
| :--- | :--- | :---: | :---: | :---: |
| posA | + |  |  | 1 |
| posAnegB | + | - |  | 2 |
| posAnegC | + |  | - | 2 |
| 4 | ++ |  |  | 2 |
| 5 | + | + | 2 |  |
| 6 | ++ | - | 3 |  |

## Results

## Generalization

To recapitulate, participant were shown a set of premises (observations), and asked to judge the likelihood of three conclusions. One conclusions concerned a member of the same subcategory as the base premise (subcategory A), a second conclusion concerned a member of a different subcategory (subcategory B) and a third conclusion a member of the shared superordinate category (category C). In this section, we examine the manner in which these generalization judgments
vary as a function of the premise set that is presented, and in particular, whether adding a negative observation to the premise set can raise argument strength. In what follows, it is informative to keep in mind that, according to the monotonicity principle, negative observations are expected to lower the likelihood of a conclusion (or leave it unaltered).

Figure 1 presents the average scores of all three conclusion likelihood judgments, averaged across participants and items, as a function of the premise set. PosA introduces only the base premise, posAnegB adds a negative observation of subcategory $B$ to the base premise and posAnegC adds a negative observation of category C. In the two following sections, statistical analyses are presented to test for the effects of adding negative observations to a premise set.

Figure 1: Average judged conclusion likelihood for the three types of conclusions, as a function of the premise set.

Generalizing to the same subcategory For the conclusions that concern a member of subcategory A (e.g., conclusions to Bach's music if Mozart's music is the base premise), we are interested in two conditions that should lead to a raise in conclusion likelihood as compared to the base argument, despite the negative observation in a premise set. As in Heussen et al. (2011), we expect to observe a difference between premise set posA and posAnegB, in which a negative observation from subcategory $B$ is added to the premise set. Additionally, we hypothesize that adding negative observation from an entirely different category, as in premise set posAnegC, also raises argument strength. In Figure 1 the left bars present the average judged likelihood of the conclusion to a member of subcategory A as a function of the premise set preceding the conclusion, and visual inspection confirms our hypotheses.

We performed a mixed-effects model analyses with two random effects (participants and topics), and two fixed effects (list and premise set), and their interaction ${ }^{3}$. Premise set is a within subjects factor and list is a between subject variable.

Table 3 gives an overview of the main (fixed) effects of

[^250]premise set, and can be interpreted as follows: For premise set posA, participants on average judge the likelihood of a conclusion to a member of subcategory A to be 75.14. For premise set posAnegB, in which a negative observation from subcategory B is added, the judged likelihood drops with 2.26 according to the model ${ }^{4}$, a change that is not significant. For premise set posAnegC, in which a negative observation from a different category C is added, the judged likelihood is significantly higher 11.12 points $(p=.016)$.

Table 3: Effects of premise set on generalizing to a member of subcategory A.

| premise set | MCMC estimate | MCMC p-value |
| :--- | ---: | ---: |
| posA (base level) | 75.14 | $<.001$ |
| posAnegB | -2.26 | .72 |
| posAnegC | 11.12 | .016 |

In sum, we only find partial support for our hypothesis. In particular, premise sets as used in (Heussen et al., 2011), adding a negative observation from a different subcategory, do not lead to a significant rise in argument strength. We do, however, observe a strong rise in argument strength, when a more distant negative observation - from a different category - is added to the premise set.

Generalizing to a different subcategory For the conclusion to a member of subcategory B (e.g., Nirvana has $X$; the base premise is Mozart), we hypothesize that a negative observation from a different category (but shared superordinate category, e.g., the sound of a falling rock) can raise judged conclusion likelihood. In Figure 1 the average judged likelihood of conclusions to subcategory B for the relevant premise sets is presented in the middle bar of every group, and a rise in mean judged likelihood from premise set posA to premise set posAnegC can be observed. A quantitative test of the difference was performed using mixed model analyses with two random effects (items and participants) and two fixed effects (list and premise set). As in the previous section, this model was preferable to alternative models in terms of AIC and log likelihood deviance.

Table 4: Effects of premise set on generalizing to a member of subcategory B.

| premise set | MCMC estimate | MCMC p-value |
| :--- | ---: | ---: |
| posA (base level) | 33.93 | $<.001$ |
| posAnegB | -16.55 | .08 |
| posAnegC | 33.61 | $<.001$ |

Table 4 summarizes the effects of premise set. When adding a negative observation from subcategory B , judged

[^251]likelihood of the conclusion is lowered by 16.55 , nearly significantly ( $\mathrm{p}=.08$ ). Note that in this case the premise set contains a negative observation form the same subcategory as the conclusion. More interestingly, when adding a negative observation from a different category (the sound of a falling rock does not have X), judged likelihood increases an impressive 33.61 .

Conclusions Our analyses of the judged likelihood of the conclusions have revealed convincing evidence that negative observations can raise argument strength in some circumstances. In particular, we found that a negative observation from a seemingly irrelevant category, can substantially raise the judged likelihood of the conclusion to a member of the same subcategory as the base premise as well as to a member of a different subcategory.

Contrary to (Heussen et al., 2011), we do not find support for a rise in judged likelihood of a conclusion to a member of the same subcategory when a negative observation from a different subcategory is introduced. Note that Heussen et al. used a forced choice paradigm, and report effects that, while significant, were very subtle. Perhaps our methodology was not able to identify these effects.

## Hypothesis generation

Before making the generalization judgments, participants were asked to generate a hypothesis that they believed explained the observations in the premises. This allows us to peak at the type of hypotheses participants entertained when confronted with negative observations

We differentiated between four types of hypotheses: First, a hypothesis can state that the property is only applicable to the base premise (e.g., "only Bach has X"). Second, a hypothesis can generalize the property to the subcategory of which the base premise is a member (e.g., "all classical music has X "), or, the third type, to the entire category ("all music has $X^{\prime \prime}$ ) or, in the fourth case, to the entire superordinate category ("all sound has X"). We classified each rule according to its consequential region following this scheme. Hypotheses that did not fit the scheme, for example due to reporting another subcategory, an unspecified subcategory (e.g., "some types of music") or a causal explanation, were coded as "other" 5 .

Figure 2 presents the relative frequencies of each type of hypothesis being generated as response to premise sets posA, posAnegB and posAnegC. To quantify and test differences in hypothesis generation between premise sets, we performed logistic regressions with premise set and list as predictors and a binary variable indicating whether the type of hypothesis was generated as dependent variable. The regressions were performed seperately for each type of hypothesis.

Figure 2 reveals three patterns. First, hypotheses that restrict the property to the base premise are significantly less frequent when a negative observation is introduced (with comparison level posA, for posAnegB: Wald $=-2.4, p=$

[^252]

Figure 2: Relative frequency of generating a certain type of hypothesis as a function of the premise set.
.01; and for posAnegC: Wald $=-4.7, p<.001$ ). Second, hypotheses that attribute the property to the entire subcategory A are more frequent when a negative observation from subcategory B is introduced (but not significantly, Wald $=$ $.76, p=.45$ ), and significantly less frequent when a negative observation from category C is introduced (Wald $=$ $-3.74, p<.001$ ). Third, hypotheses that project the feature to the entire category are less common when introducing a negative observation from a subcategory (Wald $=-6.23, p<$ .001), yet more common when introducing a negative observation from a different category (Wald $=6.02, p<.001$ ).

Conclusions The hypothesis space following arguments with negative observations from subcategory B or category C is substantially altered as compared to the one premise arguments (posA). Moreover, the shifts in generation frequency seem to follow results in the generalization tasks. In particular the increase in subcategory $B$ conclusion likelihood when premise set posAnegC is observed, is clearly associated to an increase in the hypothesis that music is the relevant category.

Not only do some hypotheses become more frequently generated (as can be expected when a number of hypotheses are excluded due to a negative observation), the relative differences between types of hypotheses change considerably across different conditions. In particular, for premise set posAnegB, hypotheses that refer to subcategory A are disproportionately more popular. For premise set posAnegC, hypotheses that refer to the entire category are disproportionately more frequent. Note that for these premise sets, other hypotheses that are also consistent with the observations become less popular. This suggests that more is going on than evenly redistributing the belief of excluded hypotheses across remaining hypotheses. We will come back to this issue in the discussion.

## General discussion

We have presented evidence against the universality of the monotonicity principle in inductive reasoning. Negative ob-
servations can indeed raise argument strength when they come from a different category than the one shared by the positive observation and the conclusion. Moreover, we found a clear relation with the type of hypotheses that are generated to account for the premise observations. In general, there seems to be a dramatic rise in the weight of the largest hypothesis that is consistent with both positive and negative observations in the premise set. In what follows, we will discuss the relation of these findings to earlier violations of monotonicity in inductive reasoning, and in relation to the sampling assumptions that people have that is, ideas about how the observations are presented to them.

## Relation to positive non-monotonicity

For positive observations, a violation of the monotonicity principle has already been documented Medin, Coley, Storms, and Hayes (2003), in that under some circumstances positive observations can lower conclusion likelihood. For example, consider following two arguments:

## Brown bears have X

## Goats have X

## Brown bears have $X$ <br> Polar bears have $X$

## Goats have X

Medin et al. (2003) report that participants judge argument (4) stronger than argument (5). According to Medin et al., the addition of the positive observation in (5) reinforces a property that is shared among the premises but is not applicable to the conclusion. Put differently, by adding a positive observation, more weight is given to the hypothesis that the being a bear is crucial for the novel property, and since this property is not shared by the conclusion, it is judged less likely.

The non-monotonicity from adding a negative observation is strikingly symmetric to the non-monotonicity reported by (Medin et al., 2003). Consider following two arguments:

## Mozart's music has X

## Metallica's music has $X$

## Mozart's music has $X$ <br> The sound of a falling rock does not have $X$

## Metallica's music has X

In the present study, argument (6) was judged stronger than (5). Following our analyses of the hypotheses generated by participants, the addition of the negative observation from outside the music category, drives people to think that "being music" is the most likely hypothesis, rather than, e.g., classical music or Mozart's music. By virtue of giving more weight to the music hypothesis, belief is raised that Metallica's music has X as well.

In sum, whereas in the positive case, a reasoner's hypothesis "tightens" to a small subcategory (e.g., bears) by introducing an observation that is very similar to the base premise (e.g., another type of bear), in the negative case, a reasoner's hypothesis seems to "broaden" to a large category, by introducing an observation that is very dissimilar to the base premise.

## Sampling assumptions and non-monotonicity

The question then is how reasoners arrive at weighting exactly these hypotheses more. From a naive probability point of view, excluding certain hypotheses by adding negative observations will automatically lead to a redistribution of the probability mass from the excluded hypotheses to remaining hypotheses. In effect, it makes sense that other hypotheses would indeed become more likely, and as a consequence a particular conclusion could also become more likely. However, it is important to appreciate that, in the naive case, the probability mass would be distributed evenly across the remaining hypotheses, so relative differences between different hypotheses remain. This does not seem to hold in the present results. Indeed, when a negative observation from a different category is observed, as in (6), participants generated the category hypothesis (all music has X) disproportionally more frequently. While consistent with the observations in (6), the subcategory hypothesis (all classical music has X) and the base premise hypothesis (Mozart has X ) experience a substantial drop in generation frequency, contrary to what one would expect on the basis of naive probability theory.

Interestingly, the manner in which Bayesian models of induction (e.g., Tenenbaum \& Griffiths, 2001) cope with the positive non-monotonicty effect, is by reweighting the remaining hypotheses when an observation is made. More precisely, depending on assumptions on how the particular observation is sampled from the environment, a Bayesian model would predict that reasoners give more weight as a consistent hypothesis is smaller (e.g., Navarro, Dry, \& Lee, 2011; Tenenbaum \& Griffiths, 2001.

While technical adjustments to Bayesian inference in nature ${ }^{6}$, sampling assumptions also represent a psychological reality and implement what the reasoners' assumptions are on how the observations are presented to him. For example, if a reasoner assumes that the observations in (5) are sampled from the correct hypothesis (for example, because he or she thinks the experimenter intentionally is trying to reveal the correct hypothesis), it is rational to attribute more believe to the hypothesis that it is about bears. Yet, if the reasoner believes the observations are made randomly in the world, and he or she might as well have observed a refridgerator (presumably not having the property in that case) instead of a polar bear, the hypothesis that it is about bears does not gain relative importance (for a more elaborate discussion, see Navarro et al., 2011). Indeed, it would be bad luck on part

[^253]of the reasoner that he or she did not encounter a more informative observation. The non-monotonicity effects, both positive and negative, suggest that reasoners do not share that assumption.

While the specific implementation of sampling assumptions discussed does not yet apply to negative evidence, a similar reweighting mechanism might be at work when a reasoner is presented with negative evidence. Perhaps reasoners assume that a negative observation is intentionally presented, in such a way that it does not only exclude inconsistent hypotheses, but is informative as to which hypothesis is the correct one.

#### Abstract

Three experiments test the hypothesis that engaging in explanation prompts children to favor inductively rich properties when generalizing to novel cases. In Experiment 1, preschoolers prompted to explain during a causal learning task were more likely to override a tendency to generalize according to perceptual similarity and instead extend an internal feature to an object that shared a causal property. In Experiment 2, we replicated this effect of explanation in a case of label extension. Experiment 3 demonstrated that explanation improves memory for internal features and labels, but impairs memory for superficial features. We conclude that explaining can influence learning by prompting children to favor inductively rich properties over surface similarity.

Keywords: Explanation; causal learning; category labels; non-obvious properties; inductive inference

## Introduction

The world has a complex structure, and the challenge of causal learning is to discover the nature of this structure to facilitate prediction and action. This is not a trivial task; it is sometimes impossible to predict how an object will behave based on its appearance. In fact, perceptually similar objects can be endowed with very different causal properties: Poison hemlock may look identical to wild carrot, but it is certainly not good to eat. Learning to override perceptual features in favor of non-obvious but inductively rich properties is thus an important achievement.

Previous research has examined the role of obvious (perceptual) properties versus non-obvious (internal or abstract) properties in children's inferences. Young children can use both perceptual and non-perceptual properties in categorizing objects (e.g., Gelman \& Markman, 1987; Gopnik \& Sobel, 2000), but adults often group objects according to common internal properties, labels, and causal affordances (regardless of perceptual similarity) in cases where young children tend to group objects based on salient perceptual similarity.

To illustrate this shift, consider the findings from Nazzi and Gopnik (2000). Children observed four objects placed on a toy, one at a time. Two of these objects were shown to be causally effective - they made the toy play music - and two were inert. One of the causal objects was then held up and labeled (e.g., "This is a Tib."), and children were asked to give the experimenter the other "Tib." In no-conflict trials, perceptual and causal properties were always correlated. However, in conflict trials, the same perceptual properties appeared across causal and inert objects. All children were more likely to choose the causal object in the no-conflict trials than in the conflict trials, but analyses of
conflict trials revealed a developmental shift: when generalizing the novel label, 3.5 -year-olds relied on perceptual cues over causal cues, while 4.5-year-olds relied on causal cues over perceptual cues.

Subsequent work has demonstrated a comparable shift in generalizing internal parts (as opposed to a category label). Sobel et al. (2007) used a similar procedure to demonstrate that 4-year-olds, but not 3-year-olds, are more likely to infer that objects have shared internal parts when they share causal properties than when they share external appearance.

These examples - and many others (see Keil, 1989; Gelman, 2003) - demonstrate that by 5 years of age, children begin to favor inductively rich but subtle cues, such as category membership and internal parts, over perceptual similarity when generalizing from known to unknown cases. But how is this transition achieved? Here we explore the hypothesis that the process of generating explanations is an important mechanism in scaffolding this transition.

## Explanation and Causal Learning

Accounts of explanation from both philosophy and psychology suggest an important relationship between explanation and causal learning: By explaining past observations we uncover information likely to support future judgments and interventions (e.g., Lombrozo, 2012; Walker, Williams, Lombrozo, \& Gopnik, 2012).

Consistent with this idea, research with adults finds that prompts to explain can improve learning (e.g., Chi et al., 1994) and promote the discovery and application of broad generalizations underlying what is being explained (e.g., Williams \& Lombrozo, 2010). Prior research also suggests that even young children's explanations have characteristics that make them well suited to highlighting inductively rich properties: they often invoke broad generalizations (Walker et al., 2012) and go beyond appearances (Legare, 2012).

For example, Walker et al. (2012) found that prompting preschool-aged children to explain causal events made them more likely to favor broad patterns in generalizing causal properties to novel objects. In the first of these studies, children were presented with evidence that was consistent with two candidate causes (e.g., "green objects make the toy go" versus "yellow objects make the toy go"), where one accounted for more observations. Children who were prompted to explain were more likely than controls to generalize according to the candidate cause that accounted for more of the data. In the second study, the cause that accounted for more of the data was contrasted with an alternative cause that was more consistent with children's
prior knowledge (e.g., "large blocks make the toy go"). In this case, those who explained were less likely to generalize according to the cause that accounted for more of the evidence, and instead privileged their prior knowledge.

Additionally, young children's explanations often appeal to non-perceptual properties, including unobservable causes (Legare, Wellman \& Gelman, 2009) and labels (Legare, Gelman, \& Wellman, 2010), and studies find that prompting children to explain can lead them to favor causal over perceptual learning (Legare \& Lombrozo, under review).

We therefore predict that by encouraging learners to consider broad generalizations, explaining can encourage learners to go beyond appearances to favor non-obvious but inductively rich properties as a basis for generalization.

In the following experiments, we use a method similar to Nazzi and Gopnik (2000) and Sobel et al. (2007) to examine whether generating explanations prompts children to favor generalizing internal parts (Experiment 1) and labels (Experiment 2) on the basis of causal over perceptual similarity. In Experiment 3, we examine whether the effects of explanation derive from a special relationship between explanation and inductively rich properties, or from a global boost in performance, as might be expected if explaining simply increased attention. Together, these experiments shed light on the role of explanation in the construction of generalizations that support causal inference.

## Experiment 1

Experiment 1 examined whether explanation influenced preschoolers' extension of a hidden, internal property to other objects that shared either perceptual or causal properties. Children observed four sets of three objects individually placed on a toy that played music when "activated" (see Gopnik \& Sobel, 2000). Each set contained three objects: one that activated the toy (target object), one that was perceptually identical to the target object, but failed to activate the toy (perceptual match), and one that was perceptually dissimilar to the target object, but successfully activated the toy (causal match). After each outcome was observed, children were asked to either explain (explain condition) or report (control condition) that outcome. Next, children received additional information about the target object: an internal part was revealed. Children were asked which one of the two other objects in the set (i.e., the perceptual match or causal match) shared the internal property with the target object. This method pit highly salient perceptual similarity against shared causal properties; children could base their generalizations on either one, but not both. We hypothesized that children who were asked to explain each outcome would be more likely than children in the control condition to consider the property with the greatest inductive richness and therefore select the causal match over the perceptual match.

## Method

Participants A total of 108 children were included in Experiment 1, with 363 -year-olds ( $M=40.9$ months; $S D=$
3.7, range: $35.8-47.7$ ), 364 -year-olds ( $M=53.3$ months; $S D=3.6$, range: $48.5-59.8$ ), and 365 -year-olds ( $M=64.4$ months; $S D=3.0$, range: $60.1-70.4$ ). Eighteen children in each age group were randomly assigned to each of the two conditions (explain and control).

Materials The toy was similar to the "blicket detectors" used in past research on causal reasoning (Sobel \& Gopnik, 2000), and consisted of a 10 " $\times 6$ " $\times 4$ " opaque cardboard box containing a wireless doorbell that was not visible to the participant. When an object "activated" the toy, the doorbell played a melody. The toy was in fact surrepticiously activated by a remote control.

Twelve wooden blocks of various shapes and colors were used (see Fig. 1). A hole was drilled into the center of each block. Eight blocks contained a large red plastic map pin glued inside the hole; the remaining four blocks were empty. All of the holes were covered with a dowel cap, which covered the opening to conceal what was inside. Each of the four sets of blocks was composed of three individual blocks. Two were identical in color and shape. One of these blocks (the target object) contained a map pin. The other of these blocks (the perceptual match) did not. The third block (the causal match) was perceptually dissimilar to the other two, and, like the target object, it contained a map pin.

Figure 1: Sample set of objects used in Experiment 1 (top) and Experiment 2 (bottom). Each row corresponds to a single set of items. There were a total of four sets.

Procedure Children participated in a brief warm-up game with the experimenter. Following this warm-up, the toy was placed on the table. The child was told, "This is my toy. Some things make my toy play music and some things do not make my toy play music." Then the first set of three blocks was brought out and placed in a row on the table. The order of presentation of the three blocks was randomized. One at a time, the experimenter placed a block on the toy. Two of the three blocks in each set (the target object and the causal match) caused the toy to activate and
play music. The perceptual match did not. After children observed each outcome, they were asked for a verbal response. In the explain condition, children were asked to explain the outcome: "Why did/didn't this block make my toy play music?" In the control condition, children were asked to describe the outcome (with a yes/no response): "What happened to my toy when I put this block on it? Did it play music?" After all three responses had been recorded, the experimenter demonstrated each of the three blocks on the toy a second time to facilitate recall.

Next the experimenter pointed to the set of objects and said, "Look! They have little doors. Let's open one up." The experimenter selected the target object and removed the cap to reveal the red map pin that had been hidden inside. The experimenter said, "Look! It has a little red thing inside of it. Can you point to the other one that also has something inside?" Children were then encouraged to point to one of the two remaining objects (i.e., the perceptual match or the causal match) to indicate which contained the same inside part, and this selection was recorded. Children could either select the block that was perceptually identical to the target or the object that shared the causal property, but not both.

Following their selection, children were not provided feedback, nor were they allowed to explore the blocks. Instead, all blocks were removed from view, and the next set was produced. This procedure was repeated for the three remaining sets. Each child participated in a total of four sets. Children were given a score of " 1 " for selecting the causal match and a " 0 " for selecting the perceptual match; children thus received $0-4$ points across the four sets.

## Results and Discussion

Data were analyzed with a 2 (condition) x 3 (age group) ANOVA, which revealed main effects of condition, $F(1$, $102)=50.70, p<.001$, and age, $F(2,102)=7.34, p<.01$ (see Fig. 2), with no significant interaction. Overall, children who were asked to explain $(M=2.98, S D=1.23)$ were more likely than controls $(M=1.61, S D=1.58)$ to generalize the internal part of the target object to the causal match rather than the perceptual match. Pairwise comparisons revealed no difference in performance between 3 - and 4 -year-olds, $p=.86$. However, 3- and 4-year-olds each selected the causal match significantly less often than 5-year-olds, $p<.01$.

One-sample $t$-tests were performed to assess whether explaining prompted children to override a preference for perceptual similarity and select the causal match. The 3-year-olds and 4-year-olds in the control condition selected the perceptual match significantly more often than chance, $t(17)=-3.69, p<.01$, and $t(17)=-2.53, p<.05$, respectively. Those in the explain condition selected the causal match significantly more often than chance, $t(17)=$ $3.01, p<.01$, and $t(17)=2.48, p<.05$, respectively. Five-year-olds in the control condition performed no differently from chance $(M=2.61, S D=1.72), t(17)=1.51, p=.15$, and 5 -year-olds in the explain condition selected the causal
match significantly more often than expected by chance, $t(17)=4.57, p<.001$.

These data suggest that in the absence of an explanation prompt, children relied primarily on information about the target object's salient perceptual features to predict whether a novel object would share an internal property. However, when children of the same age were asked to generate an explanation for the evidence that they observed, they instead privileged the target object's causal efficacy in making inferences about internal properties.

Figure 2: Average responses in explain and control conditions for Experiment 1 (top) and Experiment 2 (bottom). Higher numbers indicate a larger number of trials (of 4) on which an internal part (Experiment 1) or a label (Experiment 2) was generalized in line with a shared causal property over perceptual similarity.

Qualitative Data Explanations for the first object most often appealed to appearance (38\%), with a minority (5\%) appealing to internal properties. Explanations for the second set of objects, which occurred after observing the first set, appealed to appearance (33\%) and internal properties (32\%) equally often. By the final set, explanations most often appealed to internal parts $(38 \%) .{ }^{1}$

## Experiment 2

Experiment 2 examined whether the influence of explanation on children's inferences was restricted to consideration of internal parts, or whether these effects generalize to other inductively rich properties as well. A similar method was used to examine children's generalization of a novel label from a target object to either a perceptually-matched or a causally-matched object.

[^254]
## Method

Participants A total of 108 children were included in Experiment 2, with 36 3-year-olds ( $M=42.1$ months; $S D=$ 3.8, range: $35.9-48.0$ ), 364 -year-olds ( $M=54.0$ months; $S D=3.0$, range: $48.4-59.9$ ), and 365 -year-olds ( $M=65.0$ months; $S D=3.8$, range: $60.6-70.9$ ). Eighteen children in each age group were randomly assigned to each of the two conditions (explain and control).

Materials The same toy was used in Experiment 2. Twelve wooden blocks of various shapes and colors were also used. There were a total of four sets of objects, each containing three blocks. As in Experiment 1, two of these blocks (the target object and the perceptual match) were perceptually identical (same color and shape) and one of these blocks (the causal match) was distinct (see Fig. 1).

Procedure The procedure for Experiment 2 was identical to Experiment 1, with one major exception: Instead of revealing a hidden internal property, the experimenter held up the target object and labeled it, saying, "See this one? This one is a blicket! Can you point to the other one that is also a blicket?" Again, children received a total of four sets of objects, and could receive $0-4$ points.

## Results and Discussion

Data were analyzed with a 2 (condition) x 3 (age group) ANOVA, which revealed a main effect of condition, $F(1$, 102 ) $=13.51, p<.001$ (see Fig. 2), and no other significant effects. Overall, children who were asked to explain ( $M=$ $1.91, S D=1.83$ ) were more likely than controls ( $M=.72$, $S D=1.47$ ) to generalize the label to the causal match.

We next considered the data against chance responding. One-sample $t$-tests revealed that 3 -, 4 -, and 5 -year-olds in the control condition selected the perceptual match significantly more often than chance, $t(17)=-2.93, p<.01$, $t(17)=-3.69, p<.01$, and $t(17)=-3.10, p<.01$, respectively. In the explanation condition, the average of children's selections did not differ significantly from chance, $t(17)=.12, p=.90, t(17)=-1.26, p=.23$, and $t(17)$ $=.375, p=.712$, respectively. However, the data for this condition were distributed bimodally, with approximately half the children providing a majority of causal choices and half perceptual choices. The percentage of children selecting the causal match on 3 or 4 trials was $50 \%$ for 3 -year-olds, $44 \%$ for 4 -year-olds, and $56 \%$ for 5 -year-olds. The distribution of children's selections did differ significantly from that expected by chance in all age groups, $\chi^{2}(4)=$ 84.26, $p<.001, \chi^{2}(4)=66.49, p<.001$, and $\chi^{2}(4)=83.97, p$ $<.001$, respectively.

Like the younger children in Experiment 1, children in the control condition relied primarily on information about a target object's salient perceptual features to predict whether a novel object would share a category label. However, when children of all ages were asked to generate an explanation for the evidence that they observed, they
considered the target object's causal efficacy significantly more often in making inferences about shared labels.

Qualitative Data Appearance explanations were most common overall ( $28 \%$ ); however, there was an increase in the proportion of explanations appealing to kind or explicitly mentioning a label, with $7 \%$ in the first set and $19 \%$ in the final set.

## Experiment 3

The findings from Experiments 1 and 2 confirm our prediction that explanation encourages children to favor inductively rich properties (i.e., causality) as a basis for generalization. However, the findings are also consistent with an alternative explanation: that prompts to explain increased children's overall attention or engagement, resulting in "better" performance. Experiment 3 tests this alternative.

In Experiment 3, children were asked to explain or report causal outcomes after observing four unique objects, two of which activated the toy. Because we did not observe relevant age differences in Experiments 1-2, Experiment 3 was restricted to 4 -year olds. After each object was placed on the toy, three properties were revealed: an internal part, a label, and a sticker (added to the object). The internal parts and the labels correlated with the toy's activation (i.e., all and only objects that activated the toy had a particular inside part and label) while the sticker did not. Children then completed a memory task.

The purpose of Experiment 3 was to assess whether the effects of explanation observed in Experiments 1-2 could be due to a global and indiscriminate boost in attention. Based on our interpretation of Experiments 1 and 2, we predicted that a prompt to explain would improve memory for inside parts and labels, but not for the sticker, which was neither correlated with other properties nor plausibly inductively potent. If the effects of explanation can instead be attributed to a global increase in attention or engagement, one would predict improved memory for all features.

## Method

Participants A total of 364 -year-olds were included in Study 3 ( $M=53.8$ months; $S D=3.7$ months; range $=47.9-$ 59.7). Eighteen children were randomly assigned to one of two conditions (explain and control).

Materials Experiment 3 used the same toy as in the previous experiments. Four unique wooden blocks (distinct colors and shapes) were also used (see Table 1). As in Experiment 1, all blocks had a hole drilled into the center. Two of the blocks had a red, round plastic map pin glued inside and two of the blocks had a white, square eraser glued inside the hole. Four stickers were used during the experiment (two heart stickers and two star stickers). Several small cards were constructed as memory aids during the test phase of the experiment. Half of the cards had an image of a black music note (placed in front of the objects that children believed activated the toy), and half of the
cards had an image of a black music note crossed out with a red " $X$ " (placed in front of the objects that children believed did not activate the toy). Four additional cards were constructed: one with a red circle, one with a white square, one with a heart sticker, and one with a star sticker. These cards were used to facilitate the forced choice test.

Table 1. List of properties for objects used in Experiment 3.

|  | Object 1 | Object 2 | Object 3 | Object 4 |
| :--- | :---: | :---: | :---: | :--- |
| Causal | Yes | No | Yes | No |
| Internal | Red | White | Red | White |
| Label | Toma | Fep | Toma | Fep |
| Sticker | Heart | Heart | Star | Star |

Procedure As in Experiments 1 and 2, the experimenter introduced the toy. The experimenter then produced a single block and placed it on the toy. The child observed as the block did or did not cause the toy to play music. As before, children in the explain condition were asked to explain the outcome for each of the blocks and children in the control condition were asked to report the outcome (with a "yes/no" response). After the response was recorded, the experimenter repeated the demonstration a second time.

The experimenter provided three additional pieces of information about the object: the type of internal part was revealed ("Look! It has a little door on it! Let's open it up. Look, there is a [red]/[white] thing inside."), a label was provided ("See this one? This one here? This one is a [Fep]/[Toma]!"), and a sticker was placed on the bottom ("Now I am going to put a sticker on it! I am going to put a [heart]/[star] sticker on the bottom, see?"). The experimenter repeated each property twice, and then the block was removed from view. The entire procedure was repeated for the three remaining blocks, one at a time. All children observed the causal property first. The order of the remaining three properties was counterbalanced.

Next, the experimenter placed all four objects on the table in front of the child in random order, and told the child that they would now play a "memory game." To assess recall for the causal property of each object, the experimenter produced two cards - one with a music note, and one with a crossed out music note. The experimenter asked the child to point to the card that indicated whether the block did or did not play music. The child responded once for each of the four objects. Depending upon the child's response, the experimenter would then place an additional card (with a music note or a crossed-out music note) in front of the object, which would remain throughout.

To assess recall for the internal part, the experimenter produced two cards - one with a red circle and one with a white square. The experimenter asked the child to point to the card that indicated the type of thing inside the block. The child responded once for each of the four objects. To assess recall for the label, the experiment said, "Some of these blocks were called 'Tomas' and some of these blocks
were called 'Feps'. What was this one called, a 'Toma' or a 'Fep'?" The child responded once for each object. The order of presentation was counterbalanced across trials.

Finally, to assess recall for the type of sticker added to the block, the experimenter produced two cards - one with a heart sticker and one with a star sticker. The experimenter asked the child to point to the card that indicated the type of sticker added to the bottom of the block. The child responded once for each of the four objects.

Memory for internal parts, labels, and stickers was solicited in the same order as the corresponding properties were presented to that child in the demonstration phase of the experiment. For each property, children were given a score of " 1 " for accurate recall and a " 0 " for inaccurate recall. Because there were a total of four objects, each child could receive between 0 and 4 points for each property.

## Results and Discussion

Memory for the objects' causal properties was analyzed with a one-way ANOVA, which revealed that children in the explain condition were significantly more accurate ( $M=$ 3.93) than controls $(M=3.39), F(1,34)=8.42, p<.01$.

Next, a repeated measures ANOVA with the other object properties (internal part, label, sticker) as the repeated measure and condition (explain, control) as the between subjects variable revealed a main effect of object properties, $F(2,68)=6.96, p<.01$, and the predicted interaction between object properties and condition, $F(2,68)=8.30$, $p<.01$ (see Fig. 3). Children who were prompted to explain were significantly more accurate than controls in reporting the labels, $F(1,34)=9.34, p<.01$, but less accurate than controls in recalling the sticker type, $F(1,34)=5.16, p<.05$.

Figure 3: Average memory score (out of 4 trials) for each property assessed in Experiment 3. Error bars correspond to one SEM in each direction.

These data provide evidence against the possibility that engaging in explanation simply improves overall attention to the task. Instead, children who explained were more likely to recall the properties that were inductively rich, while ignoring a superficial, perceptual property that did not correlate with other features.

## General Discussion

In each of these experiments, prompting young children to explain made them more likely to privilege inductively rich, non-obvious properties over salient surface similarity in
making novel inferences. Children in the control condition, who were not prompted to explain, based their judgments on perceptual similarity. These effects were not restricted to a particular property or domain, as comparable effects were observed across two quite different properties: internal parts (Experiment 1) and novel labels (Experiment 2).

Although explanation led to fewer perceptual responses in Experiment 1 than in 2, this difference parallels the disparity in children's baseline performance in the control condition (see Fig. 2). In other words, children were more willing to privilege internal parts over appearances than labels over appearances, in line with previous research (Gopnik \& Sobel, 2000; Sobel et al., 2007). For our purposes, the critical finding is that explanation decreased perceptual responding in both cases.

Finally, the results of Experiment 3 provide additional support by demonstrating improved memory for a correlated cluster of inductively rich properties in children prompted to explain. Importantly, Experiment 3 also provides evidence that effects of explanation are selective: Children who explained had impaired memory for the superficial property. This provides evidence against the idea that explanation produces a general benefit for learning by globally and indiscriminately increasing engagement or motivation.

Why might explaining lead children to favor inductively rich properties? Wellman and Liu (2007) suggest that explaining makes an occurrence sensible by reference to a larger framework: The explainer appeals to the interplay between evidence and current theories to construe the phenomenon as an instance of a larger, coherent system. In line with this idea, recent computational approaches to cognitive development have proposed that the formation of generalizations at multiple levels of abstraction enables learners to learn quickly and generalize effectively to novel cases (Kemp, Perfors \& Tenenbaum, 2007). By prompting children to favor inductively rich regularities, explanation could play a role in pushing children beyond immediate observations to consider higher-order generalizations that support abstract knowledge.

Similarly, we have argued that engaging in explanation constrains the learner to consider an event as an instance of a broad generalization (see also Lombrozo, 2012). Recall that previous research found that explaining magnified effects of prior knowledge in the service of broad generalization (Walker et al., 2012). In the current study, the belief that internal parts and labels are inductively rich is itself an important instance of higher-order prior knowledge. We propose that explaining contributes to the formation of causal theories by constraining learners to consider properties that are most likely to generalize to novel cases. In the experiments presented here, this constraint improved children's ability to override highly salient perceptual cues.

# 24-Month-Olds Engage in Relational Causal Reasoning

#### Abstract

Children make inductive inferences about the causal properties of individual objects from a very young age. When can they infer higher-order relational properties - a task that has proven difficult for non-human primates? In two experiments, we examined 18 -24-month-old infants' relational inferences using a causal version of a relational match-to-sample task. Results suggest that by 21-24 months of age, infants are able to infer a relational causal principle from just a few observations and use this inference to guide their own subsequent actions and bring about a novel causal outcome. Findings are considered in light of recent discussion about the nature of relational and causal reasoning, and their evolutionary origins.

Keywords: Cognitive development; infancy; relational reasoning; causal learning; inference

## Introduction

Learning about causal relationships is one of the most important and challenging problems young humans face. Causal knowledge allows you to act on the world - if you know A causes B, you can act on A to bring about B. Recent research shows that children as young as 19 to 24 months of age can quickly learn causal properties of objects from patterns of statistical contingency and can act on that knowledge to bring about effects (Gopnik, 2012; Gopnik \& Wellman, 2012; Sobel \& Kirkham, 2006; Meltzoff, Waismeyer \& Gopnik, 2012). At 20 months, children can infer the desires of others from sampling patterns (Kushnir, $\mathrm{Xu} \&$ Wellman, 2010) and at 16 months, they can use contingency information to determine whether an effect was caused by their own actions (Gweon \& Schulz, 2011). Other lines of research suggest that infants can infer abstract linguistic structure from statistical data (e.g. Saffran, Newport \& Aslin, 1996; Lany \& Gomez, 2008).

However, little is known about the development of children's ability to infer higher-order relational causal principles from data. In particular, an effect might be caused by an object property (e.g., red blocks activate a toy) or by a higher-order relationship between properties (e.g. two blocks that are the same, regardless of their color, activate a toy). Inferring higher-order relations is essential for building abstract knowledge (Kemp, Perfors \& Tenenbaum, 2007; Dewar \& Xu, 2010) and reasoning about concepts that are not tied to perceptual properties. The ability to form generalizations about higher-order relations
from limited data allows children to make principled abstractions that go beyond the particular properties they have observed.

To investigate this, we used a causal version of Premack's (1983) match-to-sample task. In this task, animals observe an abstract relational pattern - AA', BB', and CC' all lead to a reward. Then they are given a choice between AB (object match) and DD' (relational match). Although A and B have each individually been associated with the reward, an animal who has inferred the more abstract relational pattern ("same") should choose DD'. Premack found that chimpanzees could not solve this relational task without hundreds of trials (Premack, 1988) or explicit training to use linguistic symbols for "same" (Premack, 1983; Premack \& Premack, 1983; 2002). Additional comparative studies have confirmed this pattern for non-human primates and other animals (Penn, Holyoak, \& Povinelli, 2008). These observations have led some researchers to conclude that abstract relational reasoning may be uniquely human.

Research examining the origins of relational reasoning using looking-time measures suggests that human infants, like primates, may be able to recognize relational patterns of data (Dewar \& Xu, 2010; Tyrell, Stauffer \& Snowman, 1991; Ferry, Hespos \& Gentner, 2012). However, there is no evidence that infants can use those patterns to make causal inferences or guide actions. In fact, earlier studies have concluded that even preschoolers have difficulty with relational tasks (Christie \& Gentner, 2010; Gentner, 2010). Not unlike chimpanzees, children succeeded only when given linguistic coaching to point out the pattern of similarity between two simultaneously presented cases. Even when explicitly instructed to compare objects, 3-yearolds' performance on these relational tasks was rather tenuous, dropping significantly below chance when the test items were presented sequentially, rather than simultaneously (Christie \& Gentner, 2010). This might lead to the conclusion that, even in humans, learning higherorder relations and using them to guide actions is a relatively late-developing ability, which depends on direct instruction, language, and cultural scaffolding.

However, the striking success of young children on causal tasks suggests that placing these problems in a causal context might enhance performance. For example, recent evidence suggests that by 24 months, toddlers readily learn
novel causal relations by observing others acting causally on the world, and use this information to fashion their own actions to achieve the same causal outcomes (Meltzoff, Waismeyer, \& Gopnik, 2012). In the current study, we used a similar observational learning paradigm to examine whether infants as young as 18 - to 24 -months could abstract a relational property from their observations in a manual causal task. If infants succeed, this would suggest that the human ability to learn abstract relations is in place earlier than previously thought. It would also suggest that these abilities might be responsible for the impressive learning of very young children. Could infants solve these relational problems spontaneously, and without linguistic cues or explicit directives to compare, if evidence for the existence of a relational property were provided in a causal context?

## Experiment 1

In Experiment 1, the experimenter introduced 18- to 24-month-old infants to a novel toy that played music when "activated," and 3 unique pairs of identical blocks AA', BB', and CC'. Infants observed as the experimenter placed blocks on the toy, one at the time. In 3 demonstrations, infants observed that while individual blocks failed to activate the toy alone, pairs of identical blocks did produce the effect. Immediately after this brief training, we examined whether these infants learned the novel relational property (i.e., pairs of identical objects make the toy play music) by placing a novel block on the machine, asking the infants to generate the effect on their own and observing their first selection.

## Methods

Participants A total of 46 18- to 24-month-old infants participated in Experiment 1 ( $M=20.9$ months; $S D=2.0$ months; range $=18.0-24.4$ months; 22 girls). Five additional children were tested but excluded for fussiness during the training phase or for failing to respond to the experimenter during test trials. Children were recruited from daycare centers and museums, and a range of ethnicities resembling the diversity of the population was represented.

Materials The toy was designed to be similar to the "blicket detectors" used in past research (see Gopnik \& Sobel, 2000). The toy consisted of a 10 " $\times 6$ " $\times 4$ " opaque box constructed from cardboard and painted white with blue borders. The box contained a wireless doorbell that was not visible to the participant. When a block "activated" the toy, the doorbell played a novel melody. The toy was in fact surrepticiously activated by a remote control that was held out of view by the experimenter. Six painted wooden blocks in assorted colors and shapes ( 3 unique pairs of 2 identical blocks) were placed on the toy during the training phase in Experiment 1. Six additional blocks were used during the test phase in Experiments 1 and 2, including 2 novel pairs of identical blocks and 2 unique individual blocks.

Procedure The procedure for Experiment 1 is illustrated in Figure 1. Following a warm-up period in which the child was familiarized with the experimenter, the toy was placed on the table. The experimenter said, "This is my toy. Some things make my toy play music and some things do not make my toy play music." Children then observed while the experimenter placed 6 blocks ( 3 unique pairs: AA', BB', $C^{\prime}$ ') on the table in front of the toy. The experimenter said, "Let's try!", selected a block (A), and placed it on top of the toy. No effect was produced. After a brief pause, the experimenter again said, "Let's try!" and selected the paired block (A') and placed it next to the first block (A) on top of the toy. This pair of objects (AA') activated the toy, which played a novel melody. The experimenter smiled and said, "Music!" Both blocks were removed from the toy and returned to the pile of 6 blocks. This procedure was repeated with the two remaining pairs ( $\mathrm{BB}^{\prime}$ and $\mathrm{CC}^{\prime}$ ). The order of the pairs was randomized. Following all three demonstrations, the 6 training blocks were removed from view. Blocks were placed on the toy one at a time due to the causal nature of the task: In order to provide evidence for the conjunctive causal relation (that both blocks were necessary to activate the toy), infants must observe a single block fail to activate the toy on its own.

Immediately following the training phase, the experimenter produced 3 test blocks ( 1 novel paired block (D), 1 familiar block (A), and 1 novel distractor block (E) and placed them in a row on the table. The order of presentation was randomized. The experimenter said, "Let's try!", produced the target block (D'), and placed it on top of the toy. No effect was produced. The experimenter then pushed the toy and a tray with all 3 test blocks towards the child, and asked, "Can you pick one of these (pointing to the row of test blocks) to make my toy play music?" The first test block that the child placed on the toy was recorded. The toy activated if the child correctly selected the novel paired block (D). If the child selected the familiar block (A) or the novel distractor block (E), the toy failed to activate. After this feedback was provided, this procedure was repeated a second test trial with a new set of test blocks.

If infants were acting based upon the previous association between the block and the effect, they should choose the familiar block (A). If they simply preferred to try novel blocks they should pick the novel distractor block (E) as often as the novel paired block (D). However, if infants were able to learn the relational causal property, then they should select the novel paired block (D) to produce the effect.

Coding Children received 1 point for selecting the novel paired block and 0 points for selecting either of the other two blocks. Therefore, children in the Experiment 1 could receive up to 2 points for their performance across the two test trials. Children's responses were recorded by a second researcher during the testing session, and all sessions were video recorded for independent coding by a third researcher who was naïve to the the hypotheses of the experiment.

Interrater reliability was very high; the two coders agreed on $99 \%$ of the children's responses to the test questions. Two minor discrepancies were resolved by a third party.

Test Trials $1 \& 2$

Figure 1: Schematic representation of training and test trials in Experiment 1. On each training trial, the experimenter first placed a single block on the toy (no activation) and then added an identical block, activating the toy. The procedure was repeated for all 3 training pairs. On each test trial, 3 test blocks (novel distractor block [ND], familiar block [F], novel paired block [NP]) were presented. The experimenter then placed the target block on the toy, yielding no effect. The child was asked to select one test block to activate the toy.

## Results \& Discussion

Across the two test trials, infants inferred the relational property and selected the novel paired block (D) more often than expected by chance $(M=.91, S D=.69$; chance $=.66)$, $t(45)=2.47, p<.02$ (Fischer exact test revealed no order effects for test trials, $p=.39$ ).

Linear regression revealed a significant developmental change in performance on test trials between 18 and 24
months of age, $F(1,44)=8.23, p<.01$. The regression model predicts that while the youngest children in our sample (18-month-olds) perform just above chance values (chance $=.66$ ), by 21 months, children select the novel paired block on at least half of the test trials.

To further investigate this change, we divided infants into two age bins: 18-21 months and 21-24 months. Older infants performed significantly better than chance, $(M=$ 1.13, $S D=.82$ ), $t(22)=2.77, p<.02$, and significantly better than younger infants, $F(1,44)=4.91, p<.05$ who performed at chance, $(M=.70, S D=.47), t(22)=.36, p=$ .72. Older infants chose the novel paired block significantly more often than the novel distractor block (binomial, $p<.05$ for both trials 1 and 2) and the familiar block (binomial, $p<$ .01 for both trials 1 and 2) .

Previous proposals have suggested that children are unable to reason relationally because they tend to focus on the individual objects which have been previously associated with the outcome, thus interfering with their ability to detect the relation (e.g., Gentner, 2010). We show no evidence of this. In fact, only $33 \%$ of infants who answered incorrectly on a given trial selected the familiar block over the novel distractor block. This is particularly surprising, given that this block had been associated with the effect during the training trials. Instead, significantly more incorrect selections were due to infants' choice of the novel distractor block ( $60 \%$ ) over the familiar block, $p<$ .05. This suggests that the younger infants' failure may have been due to a preference for exploring the novel block.

Results indicate that by 21-24 months of age, infants are able to infer a relational causal principle from a few pieces of evidence, and use this inference to bring about a novel causal outcome. However, these data do not rule out some alternative interpretations: Infants may have succeeded on this task by "matching" the experimenter's selection or because they preferred to create pairs on the toy, regardless of training. Experiment 2 was designed to address these alternatives.

## Experiment 2

The procedure for Experiment 2 was identical to Experiment 1, except that infants did not observe the training trials. Infants were therefore given no evidence for the relational property. Instead, after being introduced to the toy, infants were immediately presented with a test trial. If infants were simply matching the experimenter or had a preexisting preference for pairs of blocks, then performance should not differ significantly from the infants in Experiment 1. However, if these alternatives are insufficient to explain the infants' success, then infants should perform at chance.

## Method

Participants Twenty-two 21-24-month-olds participated ( $M$ $=22.8$ months; $S D=1.3$ months; range $=21.5-24.8$ months; 10 girls). Two additional children were tested but
excluded for failing to respond. Recruitment procedures and demographics were identical to Experiment 1.

Materials \& Procedures Materials and procedures were identical to Experiment 1. However, infants did not observe the training trials. Instead, after infants were introduced to the toy, they were given a single test trial. Only one test trial was administered, in order to avoid providing feedback. Therefore, infants could receive 0 or 1 point. Interrater reliability for Experiment 2 was $100 \%$.

## Results \& Discussion

In the absense of evidence for the relational principle, only $36 \%$ ( 8 out of 22) of infants selected the paired block, [binomial test, $p=.72, \mathrm{~ns}$, which was significantly different from the infants of the same age on their first trial in Experiment $1, p<.05$ by Fischer's exact test. These results demonstrate that the findings from Experiment 1 could not have been the result of imitation or a preexisting bias to prefer pairs.

## General Discussion

These findings suggest that the differences in relational reasoning between humans and non-human primates may be in place very early, and that human infants can succeed on match-to-sample tasks in a causal context without explicit linguistic cues or instruction. On the other hand, the failure of younger infants may suggest that the ability to use language may play a role. Alternatively, failure may be due to other factors that make it difficult for younger infants to display competence in manual tasks, such as a general impulse to explore novel objects. Additional research is needed to examine whether relational abilities are supported by the development of linguistic capacities - and language production in particular. To this end, we are currently examining the relationship between infants' performance on the causal match-to-sample task and their general language skills. In particular, we are examining infants' comprehension and production of relational words (e.g., "more").

The method outlined in this paper provides a novel and powerful paradigm for assessing relational reasoning in a causal context. Importantly, this method minimizes the need for verbal guidance, and is thus suitable for very young children. Earlier "blicket detector" studies using very similar methods have confirmed that children's inferences in these tasks go beyond simple associative learning and have the distinctive profile of causal inferences. For example, children will use inferences about the causal relation of the block and machine to design novel interventions - patterns of action they have never actually observed - to construct counterfactual inferences and to make explicit causal judgments, including judgments about unobserved hidden features of the objects (e.g. Gopnik \& Sobel, 2000; Schulz, Gopnik, \& Glymour, 2007; Sobel, Yoachim, Gopnik, Meltzoff, \& Blumenthal, 2007).

However, due to the constraints of the particular causal context (i.e., the need to provide evidence for the conjunctive relation over the disjunctive relation, noisy OR ), we opted to present evidence one block at a time, rather than in simultaneously presented pairs. In the earlier primate studies, the canonical relational tasks presented the pairs simultaneously, so that the animals had to choose between pairs of AA and BB . This difference in procedure may have led to the divergent results between infants and primates.

We have recently completed an additional follow-up experiment exploring this possibility (Walker \& Gopnik, under review). In this study, 18- to 30 -month-old infants ( $M=25.7$ months) were divided into one of two conditions: same or different. In the same condition, infants were given two pieces of evidence that pairs of "same" objects (AA', BB', CC') simultaneously placed on the toy produce the effect. In order to provide evidence for a conjunctive causal relationship, we also provide two pieces of evidence that pairs of "different" objects (DE, FG, HI) fail to produce the effect. In the different condition, infants were given the same four pieces of evidence, with the causal pattern reversed: "different" pairs (i.e., DE) produced the effect, while "same" pairs (i.e., AA') failed to do so. By combining positive and negative evidence, we were able to use a similar causal method to demonstrate that infants are able to learn the relational properties "same" and "different." Results of this study provide strong evidence that 2-yearolds are able to quickly learn relational causal principles, with $81 \%$ of children selecting the relational match in both the same and different conditions.

Clearly, toddlers are able to rapidly learn abstract relational causal principles from minimal evidence and use them to guide their subsequent actions in the world. This ability appears to be in place surprisingly early in human development. It emerges only a few months after the first evidence of the ability to learn about specific causal properties from contingency. This may help explain how children acquire the impressively general and abstract causal knowledge evident in early "intutive theories" (Gopnik \& Wellman, 2012; Carey, 2010).

## Acknowledgments

Research was funded by the James S. McDonnell Foundation and the National Science Foundation (BCS1023875) to A. Gopnik. We thank the parents and children who participated and the University of California, Berkeley Early Childhood Centers, Lawrence Hall of Science, and Habitot. We are grateful to Fei Xu and Tania Lombrozo for their feedback. Finally, we thank Rosie Aboody, Anna Akullien, Ela Banerjee, Sierra Eisen, and Brynna Ledford for facilitating data collection.

# Programming of saccades to double-step targets in scene viewing: A test of assumptions present in the CRISP model 

R. Calen Walshe (r.c.walshe@sms.ed.ac.uk)<br>Antje Nuthmann (antje.nuthmann@ed.ac.uk)<br>University of Edinburgh, Psychology Department, 7 George Square, Edinburgh EH8 9JZ

#### Abstract

Several computational models explaining fixation durations in scene viewing (Nuthmann, Smith, Engbert, \& Henderson, 2010) and in reading (Engbert, Nuthmann, Richter, \& Kliegl, 2005; Reichle, Pollatsek, Fisher, \& Rayner, 1998) assume that saccade programming is completed in two stages: an initial, labile stage that is subject to cancellation and an subsequent, non-labile stage in which the program can no longer be cancelled. This distinction is motivated by findings from doublestep experiments that used much simpler situations than scene viewing or reading. Here, we adopt a classic double-step paradigm to a scene-viewing context. In a Static condition targets are presented to the left or right of a central fixation cross along a horizontal axis while in a Scene condition targets are presented in a gaze contingent manner along a trajectory defined by the location of recent fixations. We found evidence in support of the claims that saccade cancellation occurs within a naturalistic scene-viewing context and that saccade cancellation can account for increases in observed fixation duration distributions. The duration of the non-labile stage was estimated to be longer in the Scene condition compared to the Static condition.

Keywords: Double-step; Scene viewing; Saccade programming; Mixed-effects modelling

## Introduction

There is a long history of utilizing the double-step paradigm to explore the lower level details of the programming and execution of eye-movements (Westheimer, 1954). Classic variations of the double-step paradigm involve presenting participants with two targets along a horizontal axis with a varying inter-stimulus interval separating the two targets. For instance, in one classic study of saccade programming that utilized double-step stimuli, Becker and Jürgens (1979) had a condition in which a first target was presented at $15^{\circ}$ to the left or right of fixation with a second target presented at $30^{\circ}$ in the same direction at delays of $50,100,150$ and 200 ms . The participants task was to fixate the target as quickly as possible, which meant that in order to fixate the more distal target, a saccade program initiated to the first target was put in competition with a program to the second target.

By studying the characteristics of the response pattern, the paradigm affords numerous avenues to investigate the processes underlying the programming of saccades. One method of formalizing double-step data has been to produce what is called an amplitude transition function (ATF) (Becker \& Jürgens, 1979). The ATF provides a measure of the saccade amplitude resulting from the stimuli as a function of the delay $(D)$ which measures the time elapsed between the onset of the second target step and the first measured response saccade. Therefore, in this analysis only those trials in which both targets appeared prior to the first response saccade are analysed.
$D$ can therefore be thought of as the amount of time available to the saccadic system to reprogram an eye-movement to the second target. Frequently replicated results demonstrate that when reprocessing time in low (short values of $D$ ) saccades are typically directed towards the first target step, and when reprocessing time is high (high values of $D$ ) then saccades compensate for the updated target position and move to the second target step (Ludwig, Mildinhall, \& Gilchrist, 2007).

From inspection of the ATF it is also apparent that there is a point at which the appearance of the second target step can no longer have an influence on saccade programming. This region of the distribution represents a "point of no return" in the saccade processing to the first target and as such the program to the first target is executed despite the availability of countermanding information from the second target. The point in processing at which a saccade program can no longer be modified by a second target is also referred to as saccadic dead time (SDT) and has been estimated at approximately 80 ms prior to the execution of a saccade (Ludwig et al., 2007).

The double-step paradigm has been a fruitful one in elucidating the basic properties of the occulomotor system. The principles derived from such investigations have formed the basis of several models of eye-movement control in a variety of fields. These investigations have proven particularly useful in models that attempt to explain the mechanisms that control how long aspects of the visual environment are fixated. For instance, Nuthmann et al. (2010)'s CRISP model which explains fixation durations in scene viewing, utilized a two stage saccade programming mechanism. In the first labile stage of programming a saccade could be cancelled and reprogrammed, while a program that had moved into the nonlabile stage could no longer be cancelled. In the CRISP model architecture saccade cancellation acts as a causal mechanism that accounts for systematic delay in fixation durations. The theoretical dichotomy between a labile and nonlabile stage of programming was first introduced in Reichle et al. (1998)'s EZ Reader model of eye-movement control in reading. While these models borrow the distinction from classic double-step results, it has never been formally tested within the domains to which the models apply. In the current study, a classic approach to studying double-step stimuli is adapted to a naturalistic scene viewing context.

In summary, the scene-based double step experiment has several concrete aims. Firstly, the assumption that is inherent in several influential models both in scene viewing and in reading is that delays in the latency of fixations can be
partially accounted for by the time required to cancel and reinitiate a saccade program to a novel stimulus. These models often cite basic research into saccadic programming although little work has been done to verify these findings for the more naturalistic case. Therefore, our study investigates saccade programming within scene viewing by adapting a classic double-step paradigm to the scene viewing context. Secondly, by including a classic version of the double-step paradigm as an experimental condition we are able to directly compare performance across tasks.

## Method

Participants were all University of Edinburgh undergraduate students that were paid $£ 7$ in compensation for their time. Each participant was presented with 100 trials in each condition (Static vs Scene). In the scene condition 100 unique colour photographs were presented at a resolution of $800 \times 600$. Stimuli were presented on a 21 -inch CRT monitor and participants were seated at a distance of 67 cm from the monitor. Eye-movements were recorded with an SR Research Eyelink 1000 desktop system operating at 1000 Hz . Out of the 16 subjects tested, 4 were rejected for poor data quality. Of the remaining 12 participants the mean age was 23 and 10 participants were female and 2 were male.

## Experiment Overview

Double-step experiments typically involve having a participant fixate to a location while a stimulus is displayed at a distal location. At varying delays, this target is then shifted to a new location. The participant is instructed to make a fixation to the final location of this double-stepped stimuli. At short delays, the participant is frequently able to interrupt whatever processing may have been made to the first target, and instead program a saccade to the second target location. Important aspects of the saccade motor system can be derived by looking at the time course of the response. In order to investigate double-step performance in a more naturalistic environment we adapted a single experimental condition from a classic double-step experiment (Becker \& Jürgens, 1979) to a context in which participants received the double-step stimulus while they were actively viewing a natural scene. Furthermore, a replication of the Static double-step condition was included as a baseline measure.

## Static Condition

Participants fixated a cross located in the centre of the screen. The first target step was presented after a variable delay of between 2000-3000 ms. The first target step was presented to either the left, or to the right of the fixation cross. The target step delay (TSD), the duration elapsed between presentation of the first and second targets, was either 50, 100, 150 , or 200 ms . The presentation side and delay durations were counterbalanced. Furthermore, in order to ensure that participants did not simply postpone their responses and wait until the presentation of the second target step had appeared before making a response, $20 \%$ of trials were single step trials
in which only a single target was presented to the first target location. These single steps also provide a baseline for saccade response parameters that can be compared to those on the double-step trials. The first target was always presented at exactly $7^{\circ}$ on the horizontal axis and the second target was always presented at $14^{\circ}$ along the same axis.

Figure 1. Target steps in the Static condition move in the horizontal plane either to the left or right of fixation cross. The first target step moves to an eccentricity of $7^{\circ}$ and the second target step moves in the same direction to an eccentricity of $14^{\circ}$. The second step follows the first at a delay of either $50,100,150$ or 200 ms . In no-step trials, the first target step to $7^{\circ}$ is not followed by a movement to the second target step at $14^{\circ}$.

The instructions to the participant were that they were to "chase the pink box" with their eyes. Their task was to fixate the box as quickly as possible.

After 1000 ms the trial was terminated and a new trial was initiated once the fixation detection procedure had assured that the participants' gaze was directed towards the central fixation cross.

## Scene Condition

The instructions to the participant in the scene condition were that they would be required to memorise a scene for a later recall test. However, this recall test was never applied. Furthermore, participants were instructed that they would see pink boxes appear while memorising the image, and that when they see these pink boxes that they should "chase the pink box" with their eyes. The memorisation task was included in order to observe performance in a more naturalistic and cognitively demanding context. All temporal characteristics of the double-stepped stimuli were identical to those of the Static condition. In the scene condition $20 \%$ of trials only had a single step at an eccentricity of $7^{\circ}$ in order to avoid participants making anticipatory saccades to the second target location at $14^{\circ}$. The first target step was presented once 15 saccades had been made and the scene had been viewed for at least 4 seconds. The first target step was always presented while a fixation was in progress, and this fixation could be at any possible location on the screen. A further difference from the Static double-step condition is that steps were not simply placed on the central horizontal plane as was done in the Static condition. In order to maximize the similarity be-
tween the Static and Scene conditions, while also adapting the study to a naturalistic context, the double-step manipulation trajectory was determined by the line intersecting the current fixation and the last recorded fixation. The first target was presented at $7^{\circ}$ along this line in the same direction as the eye-movement plotted from the nth and $n-1$ th saccade. The second target was presented at $14^{\circ}$ on the same line. As was done in the Static condition the second target was presented in the same direction as the first (See Figure 2 for details). In circumstances such that projecting the targets along the line of presentation would result in a target being presented off the dimensions of the screen, the presentation procedure was delayed until a fixation occurred such that the presentation of the targets would not occur off screen.

The decision to place the targets along any trajectory intersected by the most recent two fixations was done for two reasons. Firstly, we wanted to control for the effect that angular changes of successive saccades has on resulting fixation durations (Tatler \& Vincent, 2008). Furthermore, it is known that saccades in scene viewing are primarily executed along a horizontal axis (Nuthmann \& Henderson, 2010). Due to such a bias it was expected that manipulations would primarily be placed along the horizontal axis and this was confirmed with a post-hoc analysis.

Figure 2. In the scene condition targets are presented at $7^{\circ}$ and $14^{\circ}$. Unlike the Static condition targets can be placed on any axis within the image. The angle at which the boxes are presented is determined by the location of the current and previous fixations and was presented in the direction of the eye-movement. The delay between target presentations is either $50,100,150$ or 200 ms . As in the Static condition $20 \%$ of trials consisted of only a single step to $7^{\circ}$.

## Gaze contingent fixation detection

In order to present targets to participants within the scene condition it was necessary to accurately detect the presence of a fixation with as much temporal precision as possible. The native Eyelink gaze contingent algorithms were used in order to detect the onset of fixation. Once the conditions for presenting the first target had been met, and the Eyelink detected a fixation, the first target was presented to the participant. Delays in the online detection of fixations resulted in the targets being presented after the onset of fixation at a delay (ms) of
$\mu=45.2 ; \sigma=19.0$.

## Results

## Amplitude transition function in the Scene condition

The aim of the first analysis is to provide evidence in support of the hypothesis that saccade cancellation does indeed occur within a more natural scene viewing context than is typically studied with double-step stimuli. In order to construct an ATF, only trials in which both the first and second target steps occurred during a single critical fixation were analysed. Trials were also rejected when the response saccade was not made in a direction consistent with the target steps. Therefore, in the Scene condition 33 trials were removed due to movement of the eyes prior to presentation of the second target, and 6 were removed due to detection of a misdirected saccade. In the Static condition 22 and 2 trials were removed, respectively.

The amplitude transition function for the scene condition was constructed by fitting a four parameter logistic function with a form:

$$
\begin{equation*}
y=a+\frac{b-a}{1+e^{c(d-x)}} \tag{1}
\end{equation*}
$$

where $a$ represents a lower bound for the sigmoid, $b$ represents an upper bound, $c$ scales the response to x (Delay) about the midpoint and $d$ is the inflection point of the sigmoid.
Model fitting The data were fit with a nonlinear mixed effects model (NLME) (Pinheiro \& Bates, 2000). Firstly, we added fixed effects which allow us to directly estimate the effect of experimental condition (Static vs Scene) on the parameters of the nonlinear response function described in (1). Secondly, random effects were included in the model in order to reduce the effect of unreliable differences between participants due to unbalanced observations and individual variability in task performance.

In the analysis of the Scene condition we fit a model which included the effect of only a single condition on the parameters $a, b, c$ and $d$. Random effects of participant on the parameters $a, b, c$ and $d$ were also included in the model. For the comparison between the Static vs Scene conditions the model was extended to include a fixed effect of condition on the four model parameters. The R statistical programming language ( R Development Core Team, 2008) and the nlme package (Pinheiro, Bates, DebRoy, Sarkar, \& R Core Team, 2013) were used to conduct the analysis.

Effect of Scene on model parameters The parameters of the best fitting model are reported in Table 1. From the scatter the typical ATF evoked by double-step stimuli is observed with a characteristic sigmoidal shape. The horizontal dotted lines indicate the location of target 1 at $7^{\circ}$ and target 2 at $14^{\circ}$. Furthermore, the scatter confirms that within the Scene condition lower values of $D$ are typically associated with saccades directed towards the location of the first target step whereas at larger values of $D$ reprogramming occurs and saccades are directed towards the second target location.

Table 1. Mixed effects model parameters

| Effect | $M$ | $S E$ | $t$ | $p$ |
| :--- | :--- | :--- | :--- | :--- |
| $a$ | 6.47 | .160 | 40.48 | $(<0.01)$ |
| $b$ | 12.35 | .351 | 35.23 | $(<0.01)$ |
| $c$ | 0.12 | .027 | 4.33 | $(<0.01)$ |
| $d$ | 113.18 | 5.46 | 20.72 | $(<0.01)$ |

Summary of the estimated values of the fixedeffects parameters along with their means (M), standard errors (SE), $t$ and $p$ values, units of the parameters are reported in milliseconds. The parameters $a$ and $b$ are respectively the lower and upper asymptote of the sigmoid while $c$ scales the response about the midpoint and $d$ is the inflection point of the sigmoid.

Figure 3. Amplitude transition function constructed from responses in the Scene double-step condition. $D$ represents the amount of time elapsed between the onset of the second target stimulus and detection of the first response saccade. Horizontal lines represent the locations of target steps 1 and 2.

The results of the model fits estimated that the lower and upper bounds of the saccadic endpoints were $6.47^{\circ}$ ( $S E=$ $.160, t=40.48)$ and $12.35^{\circ}(S E=0.35, t=35.23)$ respectively. While there was undershoot for saccades targeting both the initial and final target steps, the undershoot to the final step was larger ( $0.53^{\circ}$ vs $1.65^{\circ}$ ).

## Cumulative distribution function of saccade latencies

Saccade programming latencies were compared on trials in which there was no target step (no-step) with trials in which there was a target step ( $50,100,150,200 \mathrm{~ms}$ ). This analysis aims to investigate whether trials in which a saccade was reprogrammed from the first target to the second target require longer latencies when compared to no-step trials in which no such reprogramming occurs.

In no-step trials saccade latency was calculated as the
elapsed time (ms) from the appearance of the $7^{\circ}$ target and the first observed response saccade. For trials of all other delays, latencies were analysed for saccades in which the first response saccade occurred after the second target step had appeared and in addition that the first response saccade compensated for the second target step. Compensation was defined such that the saccadic endpoint was within a distance $2^{\circ}$ of visual angle from the second target location. Latency was calculated as the elapsed duration between the onset of the first target step and the onset of first response saccade.

A cumulative distribution function (CDF) was fit to compare latencies between delays of different lengths. Latencies from 200 ms TSD trials were excluded as too few compensated saccades were observed. Latencies for compensated saccades are clearly longer than those of saccades elicited by no-step stimuli indicating that in order to incorporate the second target step into the response, increased latencies are required. Furthermore, we observe that as the TSD increases a corresponding increase in latency is also observed.

Figure 4. Cumulative distribution function of latencies at target step delays of $50,100,150 \mathrm{~ms}$ compared to the no-step latencies. The no-step latencies are constructed from latencies on trials in which there was only a step to the first target response.

## Comparison of Static vs Scene conditions

While the primary aim was to provide evidence that results from static double-step conditions generalize to a more dynamic scene based context, our dataset also offers an opportunity to directly compare performance differences between the Static and Scene conditions. A description of the model used to fit the Static vs Scene data can be found in the Model fitting section of the Scene only analysis.

Comparing the scatter in the Static vs Scene condition (Fig. 5) it is apparent that there is considerably more variability in the data that comprise the ATF in the Scene as compared to Static condition. Due to the more dynamic nature of the Scene task this is to be expected. For instance, in the Static condition participants stay fixated on a central cross while they wait for the target stimuli to appear. It is therefore likely that any anticipatory processes preparing future eyemovements are suppressed. In contrast, during the Scene con-

Table 2. Mixed effects model parameters

| Effect | $M$ | $S E$ | $t$ | $p$ |
| :--- | :--- | :--- | :--- | :--- |
| $a$ (Intercept) | 6.63 | 0.14 | 48.62 | $(<0.01)$ |
| $a$ (Scene) | -0.17 | 0.16 | -1.1 | $(=0.27)$ |
| $b$ (Intercept) | 13.0 | 0.11 | 119.9 | $(<0.01)$ |
| $b$ (Scene) | -0.74 | 0.20 | -3.82 | $(<0.01)$ |
| $c$ (Intercept) | 0.14 | 0.02 | 7.57 | $(<0.01)$ |
| $c$ (Scene) | -0.05 | 0.02 | -2.18 | $(=0.03)$ |
| $d$ (Intercept) | 76.14 | 2.30 | 32.91 | $(<0.01)$ |
| $d$ (Scene) | 33.86 | 2.51 | 13.44 | $(<0.01)$ |

Summary of the estimated values of the fixed-effects parameters along with their means (M), standard errors (SE) and $t$ and $p$ values, units of the parameters are reported in milliseconds. The parameters $a$ and $b$ are respectively the lower and upper asymptote of the sigmoid while $c$ scales the response about the midpoint and $d$ is the inflection point. The intercept indicates the estimated parameter in the Static condition, while (Scene) indicates the influence of condition Scene.
dition participants are actively engaged in search, the display and measurement of their double-step response is likely to incorporate processes involved in preparing an eye-movement prior to the presentation of the double-step stimuli.

Figure 5. Comparison of the amplitude transition functions in Static vs Scene conditions. D represents the amount of time elapsed between the onset of the second target stimulus and detection of the first response saccade. Horizontal lines represent the locations of target steps 1 and 2.

Effect of experimental condition (Scene vs Static) on model parameters Model parameters are summarized in Table 2. The lower and upper bounds of the fitted functions measure the saccadic endpoints of responses to either the first (lower bound) or second (upper bound) targets. No effect of condition was observed on the lower bound $(t=-1.1$, $p=0.27$ ) however, there was an effect of condition on the
amplitude of responses targeting the final location $(t=-3.82$, $p<0.01$ ), indicating greater undershoot in the Scene condition.

A final observation can be made regarding the markedly slower compensation response in the Scene condition. The ATF in the Scene condition appears to be shifted to the right, and this reflects that increasing values of $D$ are required to make a response of corresponding amplitude to that of the Static condition. Furthermore, we observe a significant effect of condition on $d$ (inflection point) $(t=13.44, p<0.01)$ supporting the observation that responses of comparable amplitude require longer values of $D$ in the Scene condition as compared to the Static condition.

Ludwig et al. (2007) have referred to saccadic dead time (SDT) as the last moment at which a new stimulus can modify a saccade program currently under preparation. They describe that the SDT may be extracted from the ATF by estimating the point at which the compensation function begins to incorporate the location of the second target step. The SDT was extracted from our ATF by deriving the point on the curve which represents a cumulative increase of $5 \%$ from the lower asymptote. We estimated this point in the Static condition as 55 ms and in the Scene condition as 77 ms .

## Discussion

The research question that this paper addresses is whether established results utilizing double-step stimuli to explore saccade programming can be extended to scene viewing. It has been argued that the ATF constructed from double-step responses provides evidence for a distinction between a labile and nonlabile stage of saccadic programming. A target stimulus is only able to modify the current goals of a saccade while it is in the labile stage of programming and can no longer have an influence once the program becomes nonlabile. The sigmoidal shape of the ATF (Fig. 3) reveals that when the target stimulus is presented shortly before the saccade (low values of $D$ ) that processing had reached the nonlabile threshold and therefore had no influence on the resulting saccade. When the second target is presented in earlier stages of saccade preparation (higher values of $D$ ) we see saccades that compensate for the second target location due to programming still being within the labile stage. These results have been previously established in double-step studies utilizing static conditions (Becker \& Jürgens, 1979; Ludwig et al., 2007), and our study provides evidence for an analogous process occurring within a condition more akin to naturalistic scene viewing.

Cancellation has also been suggested as a causal mechanism for the systematic increase in observed fixation durations. For instance, in the CRISP model, saccade cancellation accounts for the increase in fixation durations that is observed directly following a delay of stimulus onset (see Figure 7, Nuthmann et al., 2010 for details). The CDF (Fig. 4) illustrates that latencies are increased in trials in which a reprogramming of a saccade is likely to have occurred. However, caution must be taken when assigning a causal interpre-
tation to the role of saccade cancellation in observed latency increases. The TSD trials analysed are specifically those for which a saccade was not executed prior to the appearance of the second saccade target. Therefore, we expect to see a complementary increase in latency alongside increases in TSD. One possibility is that increased latencies are observed specifically because compensated saccades are those in which the programming to the first target progressed slowly enough to wait out and incorporate the appearance of the second target. While this analysis does provide confirmatory evidence that saccade cancellation is consistent with increased fixation durations, it does not necessarily shed light on the causal connection between cancellation and increased latencies.

The comparison between the Static and Scene condition also indicate the presence of several notable differences. Ludwig et al. (2007) analyse a concept termed saccadic dead time (SDT) which corresponds closely to the concept of a nonlabile stage of programming. The SDT corresponds to the last point in time at which a saccadic eye-movement may be modified. We estimated SDT as 55 ms in the Static condition and 77 ms in the Scene condition. Differences in the SDT across experimental conditions have been observed in prior work (Ludwig et al., 2007). An important implication of this result with regard to models of gaze control in naturalistic scene viewing is that it provides an empirical bound for the duration of the nonlabile stage. In CRISP for instance, a mean duration of 40 ms was assigned to the duration of the nonlabile stage. This value was determined from classic double-step results conducted under static conditions. This value is also roughly consistent with the duration of the nonlabile stage estimated in our own Static condition ( 55 ms ) but represents an underestimate when compared to the nonlabile duration in the Scene condition. As CRISP is a model of fixation durations in scene viewing it is likely that the estimated mean duration of the nonlabile stage in our Scene condition represents an improvement over the corresponding Static estimate.

It should be noted that the comparison reported here may still reflect important differences not solely attributable to the influence of scene processing. For instance, the Scene but not Static condition double-step targets were presented on any axis. Future work may consider including a task in which performance in our Scene condition is compared directly to a similar task but one in which the scene is replaced by a noise filtered image.

Further comment is warranted on the applicability of the data reported here to models such as CRISP that claim a causal interpretation for saccade cancellation in observed fixation duration delays. In CRISP, when a saccade program is within the labile stage of programming a cancellation signal may interrupt the current program. The time required to reinitiate a new saccade program results in a delay to the current fixation duration. In an alternative formulation aimed at explaining saccade latencies within a Static double-step context, Camalier et al. (2007) suggest that cancellation occurs
due to a race between a process initiated to execute a saccade (GO) and process initiated to cancel that saccade (STOP). While there is some similarity in the assumptions between these two models the race model does not insist on a nonlabile/labile dichotomy. Rather, the race model accounts for double-step performance with reference to the timing of the GO and STOP accumulation processes. In order to further explore the role of saccade cancellation it may be of interest to directly compare the predictions of the saccade programming mechanisms in the CRISP model with those of the race model described in Camalier et al. (2007).

#### Abstract

Recent findings show that human inferences and decisions interfere in ways analogous to incompatible quantum observables, and conceptual judgments are inseparable in ways similar to entangled quantum states. This discovery has led a group of physicists and psychologists to form a new field called "quantum cognition," which uses mathematical principles of quantum theory to explain human cognitive behavior. The power of this new theoretical approach is illustrated here by testing an a priori and precise prediction derived from quantum theory regarding question order effects commonly observed in survey research. The test of quantum theory was statistically satisfied across a set of 26 national surveys on presidential job approval and country satisfaction in past 10 years. These results suggest that quantum theory, initially invented to explain order effects on measurements in physics, provides a powerful prediction for measurement order effects in social and behavioral sciences too.

The human brain is a powerful and massively complex neural system. It provides the biological substrate for an emergent mind capable of producing highly intelligent cognitive behaviors, such as inferences and decisions. How this happens remains a topic of intense investigation in cognitive neuroscience. The possibility that the brain's tremendous power arises from parallel computations of quantum physical neuronal interactions has been raised (Hameroff \& Penrose, 1996; Hagan, Hameroff \& Tuszynski, 2002) but strongly criticized (Tegmark, 2000; McKemmish, Reimers, McKenzie, Mark \& Hush, 2009). However, what if it is our behavior - rather than our brains - that follows quantum rules?

Supporting this idea, latest evidence shows that human inferences and decisions interfere in ways analogous to incompatible quantum observables (Pothos \& Busemeye, 2009; Busemeyer, Wang \& Lambert-Mogiliansky, 2008), and conceptual judgments are inseparable in ways similar to entangled quantum states (Aerts \& Sozzo, 2011). Formal principles that quantum theorists invented to deal with properties of complex physical systems provide a powerful mathematical description of human behavior (Busemeyer \& Bruza, 2012; Khrennikov, 2010). This discovery has led a
group of physicists and psychologists to work together and form the new field of "quantum cognition," which uses mathematical principles of quantum theory to explain human cognitive behavior. It has successfully accounted for various puzzling findings in psychological literature, ranging across perception (Atmanspacher, Filk \& Romer, 2004), associative memory (Bruza, Kitto, Nelson \& McEvoy, 2009), conceptual reasoning (Aerts, 2009), probability judgments (Busemeyer, Pothos, Franco \& Trueblood, 2011), decision making (Yukalov \& Sornette, 2011), and strategic game behavior (Lambert-Mogiliansky \& Busemeyer, 2012). It is plausible that the underlying neural systems follow classical dynamic laws, but the emergent cognitive behaviors are coarse "quantized" descriptions (Atmanspacher \& Graben, 2007). In fact, more than half a century ago, founding fathers of quantum theory speculated that fundamental quantum principles have implications outside of physics to human cognitive behavior (Pauli, 1950; Bohr, 1958).

Here we tested a new, a priori and precise prediction derived from quantum theory regarding question order effects commonly observed in survey research. This type of exact prediction is rare in social and behavioral sciences. The prediction was statistically supported across a set of 26 national surveys in past 10 years on two important public opinion questions in the U.S.: presidential job approval and country satisfaction. This surprisingly accurate test illustrates the theoretical power of our new approach to use quantum theory as a mathematical tool to explain and predict human cognitive behaviors. We show that quantum theory, initially invented to explain order effects of measurements in physics, provides a powerful prediction for order effects of measurements in psychology.

## Measurement Order Effects

One of the prime paradoxes of physics explained by quantum mechanics is that the order of measurements affects the observed statistics. For example, when testing the direction of spin $1 / 2$ particles, the results depend on whether the "up-down" direction is tested before versus after the
"left-right" direction (Sakurai, 1994). In the terminology of quantum theory, observables like these are defined as incompatible, and the theory was built on a noncommutative algebra of operators (Von Neumann, 1932).

Order effects of measurements are not unique to physics. It has long been recognized that the order of questions can influence human judgments and decisions (Schuman \& Presser, 1981; Sudman \& Bradburn, 1974). For example, the Pew Research Center conducted a telephone survey experiment during June $10-14,2009$ with a nationally representative sample of 1,502 U.S. adults. A random half of the sample was asked, "Do you approve or disapprove of the way Barack Obama is handling his job as President?" followed by "All in all, are you satisfied or dissatisfied with the way things are going in this country today?" The other half was asked the exact same questions but in the opposite order. It turns out that the presidential job approval rate was $63.38 \%$ when it was asked first and dropped to $58.58 \%$ when asked second.

Gauging public opinions is an enormously important task in any democracy. Among many challenges that survey researchers must manage, question order effects are one of the most important (Schuman \& Presser, 1981; Moore, 2002). A common practice is rotating question orders between randomly-split samples to balance out question order effects. Whether the order of two questions produces significant effects can be easily tested. Denote $p(\mathrm{AyBn})$ as the probability of agreeing ("yes") to question A and then disagreeing ("no") to question B , and $p(\mathrm{BnAy})$ as the probability of the same answers when the questions were asked in the opposite order. Similarly, probabilities of the remaining response combinations, $p(\mathrm{AnBy})$ and $p(\mathrm{ByAn})$, are defined. The two order conditions produce a pair of $2 \times 2$ contingency tables, which, according to the null hypothesis, should be equivalent except for sampling error (e.g., $p(\mathrm{AyBn})=p(\mathrm{BnAy}))$. Discrepancy from the null hypothesis is measured by $\chi^{2}$. If the null hypothesis is correct, the $\chi^{2}$ statistic should have a $\chi^{2}(3)$ distribution.

Table 1 shows $\chi^{2}$ results for two Gallup survey experiments reported in a seminal article on question order effects (Moore, 2002). Each sampled around 1,000 U.S. adults using the split sample paradigm. In the first poll, people were asked whether Bill Clinton was honest and trustworthy, and whether Al Gore was honest and trustworthy. In the second poll, people were asked whether white people dislike black people, and whether black people dislike white people. Each $2 \times 2$ contingency table in Table 1 summarizes the observed proportions for the four response combinations in one question order. As shown by the $\chi^{2}$ test on the order effects, both experiments produced large order effects with strikingly different patterns. Now we come backto the presidential job approval and country satisfaction questions. Is there a robust order effect for this pair of important public opinion questions? To examine this, we obtained from the Pew Research Center all its survey experiments that included this pair of questions in past 10

Table 1: Observed proportions for each order condition,
and $\chi^{2}$ tests for testing order effects and the QQ equality. See Appendix on the $\chi^{2}$ tests.

| Observed proportions in the two different question orders |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Clinton-Gore |  |  | White-Black |  |  |
|  | Gy | Gn |  | By | Bn |
| Cy | . 4899 | . 0447 | Wy | . 3987 | . 0174 |
| Cn | . 1767 | . 2886 | Wn | . 1612 | . 4227 |
| Gore-Clinton |  |  | Black-White |  |  |
|  | Cy | Cn |  | Wy | Wn |
| Gy | . 5625 | . 1991 | By | . 4012 | . 0597 |
| Gn | . 0255 | . 2130 | Bn | . 1379 | . 4012 |
| Discrepancy tests |  |  |  |  |  |
| Order effects |  | $\chi^{2}(3)=10.14, p<.05$ | $\chi^{2}(3)=73.04, p<.001$ |  |  |
| QQ equality |  | $\begin{aligned} & q=-.003 \\ & \chi^{2}(1)=.01, p=.91 \\ & \hline \end{aligned}$ | $\begin{aligned} & \hline q=-.02 \\ & \chi^{2}(1)=.56, p=.46 \end{aligned}$ |  |  |

years. There are 26 surveys in total, with a nationally representative sample between 815 and 3,006 U.S. adults ( $M$ $=1,644, S D=422.24$ ). Of each sample in each survey, a random half was asked the presidential job approval question first while the other half was asked the country satisfaction question first. The $\chi^{2}$ test indicates significant question order effects across the 26 surveys (see Figure 1).

Figure 1: $\chi^{2}$ frequency distributions for testing the order effects and the QQ equality. The navy bars show the observed frequencies of $\chi^{2}$ values for order effects distributed across 10 categories separated at 9 deciles (.1, .2, $.3, .4, .5, .6, .7, .8, .9)$; the green bars show those for the QQ equality test; the dotted line shows the expected frequency by the null hypothesis. The observed frequency distribution of order effects significantly differs from the expected frequency $\left(\chi^{2}(9)=37.675, p<.0001\right)$, but that of the QQ equality is not $\left(\chi^{2}(9)=9.5485, p=.3935\right)$. So, as predicted by the quantum model, there is a significant measurement order effects but the QQ equality holds across the 26 nationals surveys. See Appendix on the $\chi^{2}$ tests.

## A Quantum Model for Question Order Effects

It would be a speculative leap, however, to think that quantum theory can be applied to human behavior simply because the behavior displays measurement orders effects. Indeed, quantum models of cognition need to be rigorously tested. A precise and empirically testable prediction has been derived from a quantum model for the question order
experimental paradigm (Busemeyer \& Bruza, 2012; Wang \& Busemeyer, in press). The model is simple, intuitive, but general. First, as illustrated in Figure 2, a person's prior belief state is represented by a unit length vector (denoted by S ) within an $N$-dimensional vector space. This use of feature vectors to represent belief or knowledge is consistent with many other cognitive models of memory. Second, each answer to a question is represented by a subspace within the vector space. Each subspace corresponds to a projector (see Figure 2). Denote $P_{X}$ as the projector corresponding to agreement to a question, and $I-P_{X}$ is the projector corresponding to disagreement to the question, where $I$ is the identity operator. Third, how to compute response probabilities in quantum models? For example, following quantum probability rules, the probability of agreeing to question $A$ and then disagreeing to question $B$ equals the squared length of the result obtained by sequentially projecting the prior belief state on the subspace for agreeing to $A$ and then on the subspace for disagreeing to $B$, that is, $p(\mathrm{AyBn})=\left\|\left(I-P_{B}\right) P_{A} \mathrm{~S}\right\|^{2}$. If the subspaces for the two questions are incompatible (i.e., not spanned by a common basis), then their projectors are non-commutative (i.e., $P_{B} P_{A}$ $\neq P_{A} P_{B}$ ), and question order effects are predicted to occur.

Figure 2: An illustration of basic quantum principles used in the question order model. The figure illustrates a simple 3-dimensional vector space, but the space can be arbitrarily high-dimensional. The probability of agreeing to question $X$ is the squared length of the projection $\mathrm{Px} * \mathrm{~S}$ obtained by projecting the belief state $S$ to the $\mathrm{X}-\mathrm{Y}$ plane representing the subspace for agreeing to question X . If question X was asked after another question, the belief state would have already been changed by answering the preceding question, and the probability of agreeing to question X (conditioned on the preceding answer) becomes the squared length of the result obtained by projecting the adjusted belief state on the subspace for question X .

This model makes an a priori and precise prediction, named the Quantum Question (QQ) equality (see Appendix
for proof $):[p(\mathrm{AyBn})+p(\mathrm{AnBy})]-[p(\mathrm{ByAn})+p(\mathrm{BnAy})]=0$. Intuitively, this means, the probability of having different responses to the two questions (e.g., saying "yes" to one and "no" to the other) should remain the same across the two question orders. As shown in the proof, this equality must hold for any belief state and any pair of projectors in any high-dimensional vector space. This precise prediction can be easily tested empirically: if it holds, the difference in observed proportions on the left hand of the QQ equality, defined as $q$, should not statistically differ from zero as tested by $\chi^{2}$ for difference in proportions.

The QQ equality prediction was tested using the aforementioned two Gallup data sets and was supported with high accuracy (see Table 1). To generalize the results, it was further tested using the 26 Pew national survey experiments. If it holds, the observed frequency distribution of $\chi^{2}$ (shown as the green bars in Figure 1) should be distributed according to a $\chi^{2}$ (1) distribution. Indeed as predicted, the observed distribution is not significantly different from the expected distribution (see Figure 1). In summary, although the 26 Pew studies exhibit significant questions order effects, there are not significant deviations from the predicted QQ equality.

## Can a Classical Brain Give Rise to Quantum Cognitive Behaviors?

The surprisingly accurate predictions generated by the quantum model for question order effects is one example of an accumulating body of evidence supporting the general applicability of quantum theory for explaining a wide range of human cognitive behavior findings that are paradoxical from a classical probability perspective (Busemeyer \& Bruza, 2012). This, however, leaves a question: can a classical brain give rise to behavior that follows quantum principles? Recently, mathematical physicists have provided a mathematical answer to this puzzle. Essentially, coarse measurements of a classical dynamic system typically generate incompatible observables that result in unresolvable uncertainty relations and entangled correlations (beim Graben \& Atmanspacher, 2006; beim Graben, Filk \& Atmanspacher, in press). According to quantum theory, order effects occurs for incompatible observables.

A key idea is to distinguish "ontic" states (e.g., states of a dynamic neural network) in a classical phase space from "epistemic" states (e.g., discrete choices or judgments across time) obtained from an observable. The mapping from ontic to epistemic states usually is many to one, where the epistemic states generated by an observable form a partition of the ontic phase space. Knowing the epistemic state does not completely determine the ontic state, but a sequence of measurements across time refines the partition of the phase space. In the limit, the partition reaches a "finest dynamic refinement," denoted by $\wp$. Now suppose two observables ( $\boldsymbol{f , g}$ ) produce different finest dynamic refinements ( $\wp_{f} \neq \wp_{g}$ ) and neither converge to the identity
partition, as illustrated in Figure 3. This means that no ontic state is accessible by a sequence of measurements from either observable. Then there exists an epistemic state (a set of ontic states) $F_{a} \in \wp_{f}$ that determines the value $a$ produced by the observable $f$, but the value of the observable $g$ must remain dispersive. Likewise, there exists an epistemic state

Figure 3. An illustration showing how uncertainty relations are generated by coarse descriptions of classical dynamic systems. The underlying classical phase space $X$ is inconsistently partitioned by two different observables, $f$ and $g$. The cell within $X$ that always assigns a value $a$ to the observable $f$ assigns a range of different possible values ( $w, u, z$ ) to the observable $g$. In this case, there exists an epistemic state that determines the value $a$ produced by the observable $f$, but the value of the observable $g$ must remain dispersive.
(a set of ontic states) $G_{v} \in \wp_{g}$ that determines the value $v$ produced by the observable $\boldsymbol{g}$, but the value of the observable $\boldsymbol{f}$ remains dispersive. It is impossible to simultaneously determine the value $a$ from observable $\boldsymbol{f}$ and the value $v$ from the observable $g$ with arbitrary precision, so that the two observables are incompatible. Consequently, the partitions generated by the two incompatible observables produce incompatible Boolean algebras of events, and the entire collection forms a partial rather than a complete Boolean algebra. Quantum theory is specifically suitable to assign probabilities to events defined on a partial Boolean algebra.

## Discussion

Scientists are still far from understanding how mental states emerge from the neural substrates. It is too early to conclude whether or not quantum physics plays a significant role in neural processing. Nevertheless, even if the brain is classical, the ubiquitous nature of incompatible observables provides a good reason to consider using quantum theory as a mathematical tool for predicting human behavior (Busemeyer \& Bruza, 2012; Khrennikov, 2010). As our quantum question order model encapsulates and illustrates, at least four motivations drives the development of this new field of quantum cognition. (a) Judgments and decisions are
not simply read out from memory, but rather, they are constructed from the cognitive state for the question at hand; and (b) drawing a conclusion from one judgment or decision changes the context and disturbs the cognitive system, which then (c) affects the next judgment or decision, producing order effects, so that (d) human judgments and decisions do not obey the commutative rule of Boolean logic. If we replace "judgments or decisions" with "physical measurements" and replace "cognitive system" with "physical system," then these are exactly the same reasons that forced physicists to develop quantum theory in the first place. Traditionally, quantum theory has rarely been applied outside of physics, but now a growing number of researchers are successfully using it to explain human cognitive behavior.

## Appendix

## 1. Proof of the QQ equality.

Here we briefly introduce the basic axioms of quantum theory and then derive the QQ equality. We use the Dirac bracket notation so that $\langle S \mid T\rangle$ represents the inner product between two vectors. According to quantum theory, events represented as subspaces of a Hilbert space. Corresponding to each event A there is a orthogonal projector $\boldsymbol{P}_{\mathrm{A}}$. The state of a quantum system is represented by a unit length vector $S$ within the Hilbert space. The probability of event A equals the squared length of the projection $p(\mathrm{~A})=\left\|\boldsymbol{P}_{\mathrm{A}} S\right\|^{2}$. If event A is observed, then the state is updated according to Lüder's rule $S_{\mathrm{A}}=\boldsymbol{P}_{\mathrm{A}} S /\left\|\boldsymbol{P}_{\mathrm{A}} S\right\|$.

Define $S$ as the initial state. Denote the projector for saying yes to question C as $\boldsymbol{P}_{\boldsymbol{C}}$ and denote $\boldsymbol{P}_{G}$ as the
projector for saying yes to question G. We start by expanding the probability for answering "yes" to question C:

$$
\begin{aligned}
&\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot S\right\|^{2}=\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{I} \cdot S\right\|^{2}=\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot\left(\boldsymbol{P}_{\boldsymbol{G}}+\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right)\right) \cdot S\right\|^{2}=\| \boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}} \cdot S \\
&+\boldsymbol{P}_{\boldsymbol{C}} \cdot\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}} \cdot S \|^{2}\right. \\
&=\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}+\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right) \cdot S\right\|^{2}+\langle S| \cdot \boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{C}} \\
& \cdot\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right)|S\rangle+\langle S|\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right) \cdot \boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}}|S\rangle \\
&=\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}+\| \boldsymbol{P}_{\boldsymbol{C}} \cdot\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}} \cdot S \|^{2}+\langle S| \boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{C}}\right. \\
& \cdot\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right)|S\rangle+\langle S| \cdot \boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{C}} \cdot\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right)|S\rangle * \\
&=\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}+\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right) \cdot S\right\|^{2}+2 \cdot \operatorname{Re}\left[\langle\mathrm{~S}| \boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{C}}\right. \\
&\left.\quad\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right)|S\rangle\right] \\
&\left.\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}+\| \boldsymbol{P}_{\boldsymbol{C}} \cdot\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right)|S\rangle\right],
\end{aligned}
$$

and the latter follows from the idempotent property of projectors. (The symbol $x^{*}$ used in the above derivation refers to the complex conjugate of $x$.) Define the total probability to say yes to question C when G was asked first as

$$
\begin{aligned}
T P_{C} & =\left\|\boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2} \cdot\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot S_{G}\right\|^{2}+\left\|\left.\boldsymbol{P}_{\sim \boldsymbol{G}} \cdot S\right|^{2} \cdot\right\| \boldsymbol{P}_{\boldsymbol{C}} \cdot S_{\sim G} \|^{2} \\
& =\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}+\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right) \cdot S\right\|^{2} .
\end{aligned}
$$

An order effect for question C when G was asked first expressed as
$C_{C}=T P_{C}-\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot S\right\|^{2}=-2 \cdot \operatorname{Re}\left[\langle S| \boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}} \cdot\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right)|S\rangle\right]$.
Immediately we see that if $\boldsymbol{P}_{\boldsymbol{G}}$ and $\boldsymbol{P}_{\boldsymbol{C}}$ commute so that $\boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}}=\boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}}$ then $\boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}} \cdot\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right)=\boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}} \cdot\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right)=0$ and we predict NO order effect. Thus non-commuting projectors are a necessary condition for order effects. Now let us re-examine

$$
\begin{aligned}
C_{C} & =T \boldsymbol{P}_{C}-\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot S\right\|^{2}=-2 \cdot \operatorname{Re}\left[\langle S| \boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}} \cdot\left(\boldsymbol{I}-\boldsymbol{P}_{\boldsymbol{G}}\right)|S\rangle\right] . \\
& =-2 \cdot \operatorname{Re}\left[\langle S| \boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}}|S\rangle-\langle S| \boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}}|S\rangle\right] \\
& =-2 \cdot \operatorname{Re}\left[\langle S| \boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}}|S\rangle-\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}\right] \\
& =-2 \cdot \operatorname{Re}\left[\langle S| \boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}}|S\rangle\right]+2 \cdot\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2} \\
& =2 \cdot\left\|\boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2} \cdot\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot S_{G}\right\|^{2}-2 \cdot \operatorname{Re}\left[\langle S| \boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}}|S\rangle\right] .
\end{aligned}
$$

In general, the inner product is a complex number which always can be expressed as $\langle S| \boldsymbol{P}_{\boldsymbol{G}} \quad \cdot \boldsymbol{P}_{\boldsymbol{C}}|S\rangle \quad=$ $\left.\left|\langle S| \boldsymbol{P}_{G} \cdot \boldsymbol{P}_{C}\right| S\right\rangle \mid \cdot[\cos (\phi)+i \cdot \sin \phi]$. The real part equals $\operatorname{Re}\left[\langle S| \boldsymbol{P}_{G}\right.$ $\left.\left.\cdot \boldsymbol{P}_{C}|S\rangle\right]=\left|\langle S| \boldsymbol{P}_{G} \cdot \boldsymbol{P}_{C}\right| S\right\rangle \mid \cdot \cos (\phi)$. By defining the ratio

$$
\left.R=\left|\langle S| \boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}}\right| S\right\rangle \mid /\left(\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot S\right\| \cdot\left\|\boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|\right)
$$

then according to the Cauchy-Schwarz inequality, $0 \leq R \leq 1$. Finally we can express

$$
\begin{aligned}
C_{C}= & T P_{C}-\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot S\right\|^{2}=2 \cdot\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}-2 \cdot R \cdot \cos (\phi) \cdot \| \boldsymbol{P}_{\boldsymbol{C}} \\
& \cdot S\|\cdot\| \boldsymbol{P}_{\boldsymbol{G}} \cdot S \| \\
= & 2 \cdot\left\|\boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2} \cdot\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot S_{G}\right\|^{2}-2 \cdot \theta \cdot\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot S\right\| \cdot\left\|\boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|,
\end{aligned}
$$

with $\theta=R \cdot \cos (\phi)$ and $-1 \leq \theta \leq+1$, which is the similarity index referred to in the main text. Similarly, the order effect for question G when C was asked first equals

$$
\begin{aligned}
C_{G}= & T P_{G}-\left\|\boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}=2 \cdot\left\|\boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}} \cdot S\right\|^{2}-2 \cdot \operatorname{Re}\left[\langle S| \boldsymbol{P}_{\boldsymbol{C}}\right. \\
& \left.\cdot \boldsymbol{P}_{\boldsymbol{G}}|S\rangle\right], \text { but } \operatorname{Re}\left[\langle S| \boldsymbol{P}_{\boldsymbol{C}} \cdot \boldsymbol{P}_{\boldsymbol{G}}|S\rangle\right]=\operatorname{Re}\left[\langle S| \boldsymbol{P}_{\boldsymbol{G}} \cdot \boldsymbol{P}_{\boldsymbol{C}}|S\rangle\right]
\end{aligned}
$$

so that

$$
C_{G}=2 \cdot\left\|\boldsymbol{P}_{C} \cdot S\right\|^{2} \cdot\left\|\boldsymbol{P}_{G} \cdot S_{C}\right\|^{2}-2 \cdot \theta \cdot\left\|\boldsymbol{P}_{C} \cdot S\right\| \cdot\left\|\boldsymbol{P}_{G} \cdot S\right\|
$$

These two order effects share the same term, $2 \cdot \theta \cdot\left\|\boldsymbol{P}_{C} \cdot S\right\| \cdot \| \boldsymbol{P}_{G}$ $\cdot S \|$, and therefore together they imply the relation

$$
\begin{aligned}
0= & \left(2 \cdot\left\|\boldsymbol{P}_{\boldsymbol{C}} \boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}-C_{C}\right)-\left(2 \cdot\left\|\boldsymbol{P}_{\boldsymbol{G}} \boldsymbol{P}_{\boldsymbol{C}} \cdot S\right\|^{2}-C_{G}\right) \\
= & \left(2 \cdot\left\|\boldsymbol{P}_{\boldsymbol{C}} \boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}-\left\|\boldsymbol{P}_{\boldsymbol{C}} \boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}-\left\|\boldsymbol{P}_{\boldsymbol{C}} \boldsymbol{P}_{\sim \boldsymbol{G}} \cdot S\right\|^{2}+\left\|\boldsymbol{P}_{\boldsymbol{C}} \cdot S\right\|^{2}\right)- \\
& \left(2 \cdot\left\|\boldsymbol{P}_{\boldsymbol{G}} \boldsymbol{P}_{\boldsymbol{C}} \cdot S\right\|^{2}-\left\|\boldsymbol{P}_{\boldsymbol{G}} \boldsymbol{P}_{\boldsymbol{C}} \cdot S\right\|^{2}-\left\|\boldsymbol{P}_{\boldsymbol{G}} \boldsymbol{P}_{\sim \boldsymbol{C}} \cdot S\right\|^{2}+\left\|\boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}\right)
\end{aligned}
$$

$$
\begin{aligned}
& =\left(\left\|\boldsymbol{P}_{C} \boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}-\left\|\boldsymbol{P}_{C} \boldsymbol{P}_{\sim G} \cdot S\right\|^{2}+\left\|\boldsymbol{P}_{C} \cdot S\right\|^{2}\right)-\left(\left\|\boldsymbol{P}_{G} \boldsymbol{P}_{C} \cdot S\right\|^{2}-\right. \\
& \left.\left\|\boldsymbol{P}_{G} \boldsymbol{P}_{\sim} \cdot S\right\|^{2}+\left\|\boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}\right) \\
& =\left[\left\|\boldsymbol{P}_{C} \boldsymbol{P}_{G} \cdot S\right\|^{2}-\left\|\boldsymbol{P}_{C} \boldsymbol{P}_{\sim G} \cdot S\right\|^{2}+\left(\left\|\boldsymbol{P}_{G} \cdot S_{C}\right\|^{2}+\left\|\boldsymbol{P}_{\sim} \cdot S_{C}\right\|^{2}\right) \cdot \| \boldsymbol{P}_{C}\right. \\
& \left.\cdot S \|^{2}\right]-\left[\left\|\boldsymbol{P}_{G} \boldsymbol{P}_{C} \cdot S\right\|^{2}-\left\|\boldsymbol{P}_{G} \boldsymbol{P}_{\sim} C \cdot S\right\|^{2}+\left(\left\|\boldsymbol{P}_{C} \cdot S_{G}\right\|^{2}+\right.\right. \\
& \left.\left.\left\|\boldsymbol{P}_{\sim} \cdot S_{G}\right\|^{2}\right) \cdot\left\|\boldsymbol{P}_{G} \cdot S\right\|^{2}\right] \\
& =\left(\left\|\boldsymbol{P}_{C} \boldsymbol{P}_{G} \cdot S\right\|^{2}-\left\|\boldsymbol{P}_{C} \boldsymbol{P}_{\sim G} \cdot S\right\|^{2}+\left\|\boldsymbol{P}_{G} \cdot S_{C}\right\|^{2}\left\|\boldsymbol{P}_{C} \cdot S\right\|^{2}+\right. \\
& \left.\left\|\boldsymbol{P}_{\sim} \cdot S_{C}\right\|^{2}\left\|\boldsymbol{P}_{C} \cdot S\right\|^{2}\right)-\left(\left\|\boldsymbol{P}_{G} \boldsymbol{P}_{C} \cdot S\right\|^{2}-\left\|\boldsymbol{P}_{G} \boldsymbol{P}_{\sim} \cdot S\right\|^{2}+\right. \\
& \left.\left\|\boldsymbol{P}_{C} \cdot S_{G}\right\|^{2}\left\|\boldsymbol{P}_{G} \cdot S\right\|^{2}+\left\|\boldsymbol{P}_{\sim} \cdot S_{G}\right\|^{2}\left\|\boldsymbol{P}_{G} \cdot S\right\|^{2}\right) \\
& =\left(\left\|\boldsymbol{P}_{C} \boldsymbol{P}_{G} \cdot S\right\|^{2}-\left\|\boldsymbol{P}_{C} \boldsymbol{P}_{\sim G} \cdot S\right\|^{2}+\left\|\boldsymbol{P}_{G} \boldsymbol{P}_{C} \cdot S\right\|^{2}+\left\|\boldsymbol{P}_{\sim G} \boldsymbol{P}_{C} \cdot S\right\|^{2}\right) \\
& -\left(\left\|\boldsymbol{P}_{G} \boldsymbol{P}_{C} \cdot S\right\|^{2}-\left\|\boldsymbol{P}_{\boldsymbol{G}} \boldsymbol{P}_{\sim} \cdot S\right\|^{2}+\left\|\boldsymbol{P}_{C} \boldsymbol{P}_{\boldsymbol{G}} \cdot S\right\|^{2}+\| \boldsymbol{P}_{\sim C} \boldsymbol{P}_{\boldsymbol{G}}\right. \\
& \left.\cdot S \|^{2}\right) \\
& \begin{array}{l}
=\left(\left\|\boldsymbol{P}_{\sim G} \boldsymbol{P}_{C} \cdot S\right\|^{2} \quad-\left\|\boldsymbol{P}_{C} \boldsymbol{P}_{\sim G} \cdot S\right\|^{2}\right)-\left(\left\|\boldsymbol{P}_{\sim C} \boldsymbol{P}_{G} \cdot S\right\|^{2}-\right. \\
={ }_{\|}^{\left\|\boldsymbol{P}_{G} \boldsymbol{P}_{c} \cdot S\right\|^{2} \|^{2}}\left(\left\|\boldsymbol{P}_{\sim G} \boldsymbol{P}_{C} \cdot S\right\|^{2}+\left\|\boldsymbol{P}_{G} \boldsymbol{P}_{\sim C} \cdot S\right\|^{2}\right)-\left(\left\|\boldsymbol{P}_{\sim C} \boldsymbol{P}_{G} \cdot S\right\|^{2}+\right. \\
\left.\left\|\boldsymbol{P}_{C} \boldsymbol{P}_{\sim G} \cdot S\right\|^{2}\right)=0 . \quad \text { Q.E.D. }
\end{array}
\end{aligned}
$$

The last line is the QQ equality expressed as quantum probabilities.

## 2. $\chi^{2}$ tests used in Table 1.

First we present the $\chi^{2}$ test for order effects. Define $n_{Y N}$ as the frequency of saying "yes" to question C when C was asked first and saying "no" to question G when G was asked second, and the other combinations of answers are defined similarly. Define $n=n_{Y Y}+n_{Y N}+n_{N Y}+n_{N N}$. Define $m_{Y N}$ as the frequency of "yes" to question G when G was asked first and "no" to question C when C was asked second, and the other combinations of answers are defined similarly. Define $m=m_{Y Y}+m_{Y N}+m_{N Y}+m_{N N}$. The log likelihood for the unconstrained model that allows order effects is defined by

```
\(\mathrm{G}_{\mathrm{U}}=\left[n_{Y Y} \cdot \ln \left(n_{Y Y} / n\right)+n_{Y N} \cdot \ln \left(n_{Y N} / n\right)+n_{N Y} \cdot \ln \left(n_{N Y} / n\right)+\right.\)
    \(n_{N N} \cdot \ln \left(n_{N N} / n\right)+m_{Y Y} \cdot \ln \left(m_{Y Y} / m\right)+m_{Y N} \cdot \ln \left(m_{Y N} / m\right)+\)
    \(\left.m_{N Y} \cdot \ln \left(m_{N Y} / m\right)+m_{N N} \cdot \ln \left(m_{N N} / m\right)\right]\).

The \(\log\) likelihood for the constrained model that assumes no order effects is defined by
\[
\begin{align*}
\mathrm{G}_{\mathrm{C}}= & {\left[\left(n_{Y Y}+m_{Y Y}\right) \cdot \ln \left(\left(n_{Y Y}+m_{Y Y}\right) /(n+m)\right)+\left(n_{Y N}+\right.\right.} \\
& \left.m_{N Y}\right) \cdot \ln \left(\left(n_{Y N}+m_{N Y}\right) /(n+m)\right)+\left(n_{N Y}+m_{Y N}\right) \cdot \ln \left(\left(n_{N Y}\right.\right. \\
& \left.\left.+m_{Y N}\right) /(n+m)\right)+\left(n_{N N}+m_{N N}\right) \cdot \ln \left(\left(n_{N N}+\right.\right. \\
& \left.\left.\left.m_{N N}\right) /(n+m)\right)\right] . \tag{1b}
\end{align*}
\]

The \(\chi^{2}\) statistic is defined by the difference \(\chi^{2}=-2 \cdot\left(\mathrm{G}_{\mathrm{C}}-\right.\) \(\mathrm{G}_{\mathrm{u}}\) ). The unconstrained model involves (4-1) \(+(4-1)=6\) free parameters and the constrained model involves 4-1 \(=3\) free parameters, and so the \(\chi^{2}\) statistic has \(d f=3\).

Next we define the \(\chi^{2}\) test for the QQ equality. The log likelihood for the unconstrained model is defined as
\[
\begin{align*}
\mathrm{G}_{\mathrm{U}}= & {\left[\left(n_{Y N}+n_{N Y}\right) \cdot \ln \left(\left(n_{Y N}+n_{N Y}\right) / n\right)+\left(n_{Y Y}+n_{N N}\right) \cdot \ln \left(\left(n_{Y Y}+\right.\right.\right.} \\
= & \left.\left.n_{N N}\right) / n\right) \\
= & \left(m_{Y N}+m_{N Y}\right) \cdot \ln \left(\left(m_{Y N}+m_{N Y}\right) / m\right)+\left(m_{Y Y}+m_{N N}\right) \cdot \ln \left(\left(m_{Y Y}\right.\right. \\
& \left.\left.\left.+m_{N N}\right) / m\right)\right] . \tag{2a}
\end{align*}
\]

The log likelihood for the model constrained by the QQ equality equals
\[
\begin{align*}
\mathrm{G}_{\mathrm{C}} & =\left[( n _ { Y N } + n _ { N Y } + m _ { Y N } + m _ { N Y } ) \cdot \operatorname { l n } \left(\left(n_{Y N}+n_{N Y}+m_{Y N}+\right.\right.\right. \\
& \left.m_{N Y} /(n+m)\right)+\left(n_{Y Y}+n_{N N}+m_{Y Y}+m_{N N}\right) \cdot \ln \left(\left(n_{Y Y}+n_{N N}\right.\right. \\
& \left.\left.\left.+m_{Y M}+m_{N N}\right) /(n+m)\right)\right] . \tag{2b}
\end{align*}
\]

The \(\chi^{2}\) statistic is defined by the difference \(\chi^{2}=-2 \cdot\left(\mathrm{G}_{\mathrm{C}}-\right.\) \(\mathrm{G}_{\mathrm{U}}\) ). The unconstrained model involves \((2-1)+(2-1)=2\)
free parameters and the constrained model involves \(2-1=1\) free parameter, and so the \(\chi^{2}\) statistic has \(d f=1\).

\section*{3. \(\chi^{2}\) tests used in Figure 1.}

First we describe the \(\chi^{2}\) test for order effects. The \(\chi^{2}\) statistic for testing an order effect for each of the 26 data sets was computed using Equations 1a and 1 b defined above, producing 26 observed \(\chi^{2}\) values. If the null hypothesis is correct, these should be distributed according to a \(\chi^{2}\) distribution with \(d f=6\). Ten categories were constructed by computing the 9 category bounds: . 5844 equals the \(10^{\text {th }}\) percentile, 1.0052 equals the \(20^{\text {th }}\) percentile, 1.4237 equals the \(30^{\text {th }}\) percentile, 1.8692 equals the \(40^{\text {th }}\) percentile, 2.3660 equals the \(50^{\text {th }}\) percentile, 3.9462 equals the \(60^{\text {th }}\) percentile, 3.6649 equals the \(70^{\text {th }}\) percentile, 4.6416 equals the \(80^{\text {th }}\) percentile, and 6.2514 equals the \(90^{\text {th }}\) percentile. (For example, \(\operatorname{Pr}\left[\chi^{2}(6)<6.2514 \mid \mathrm{H}_{0}\right]=.90\).) These category bounds divide the expected frequency distribution (under the null hypotheses) into two 10 equally likely categories, with 2.6 expected frequency within each of the 10 categories using these cutoffs. Then frequency of the 26 observed \(\chi^{2}\) values were counted for each category. Denote \(f_{i}\) as the observed frequency for category \(i=1,10\). The log likelihood for the unconstrained model equals
\[
\begin{equation*}
\mathrm{G}_{\mathrm{U}}=\sum_{i} f_{i} \cdot \ln \left(f_{i} / 26\right) . \tag{3a}
\end{equation*}
\]

The log likelihood for the expected frequencies according to the null hypothesis equals
\[
\begin{equation*}
\mathrm{G}_{\mathrm{C}}=\sum_{i} f_{i} \ln (2.6 / 26) . \tag{3b}
\end{equation*}
\]

The \(\chi^{2}\) statistic is defined by the difference \(\chi^{2}=-2 \cdot\left(\mathrm{G}_{\mathrm{C}}-\right.\) \(\left.\mathrm{G}_{\mathrm{U}}\right)\). The unconstrained model involves \(10-1=9\) free parameters and the constrained model has no free parameters, and so the \(\chi^{2}\) statistic has \(d f=9\).

Next we describe the \(\chi^{2}\) test for the QQ equality. The \(\chi^{2}\) statistic for testing the QQ equality for each of the 26 data sets was computed using Equations 2a and 2b defined above, producing 26 observed \(\chi^{2}\) values. If the null hypothesis is correct, these should be distributed according to a \(\chi^{2}\) distribution with \(d f=1\). Ten categories were constructed by computing the 9 category bounds: . 0158 equals the \(10^{\text {th }}\) percentile, .0642 equals the \(20^{\text {th }}\) percentile, .1485 equals the \(30^{\text {th }}\) percentile, .2750 equals the \(40^{\text {th }}\) percentile, .4549 equals the \(50^{\text {th }}\) percentile, .7083 equals the \(60^{\text {th }}\) percentile, 1.0742 equals the \(70^{\text {th }}\) percentile, 1.6424 equals the \(80^{\text {th }}\) percentile, and 2.7055 equals the \(90^{\text {th }}\) percentile. (For example, \(\operatorname{Pr}\left[\chi^{2}(1)<2.7055 \mid \mathrm{H}_{0}\right]=.90\).) These category bounds divide the expected frequency distribution (under the null hypotheses) into two 10 equally likely categories, with 2.6 expected frequency within each of the 10 categories using these cutoffs. Then frequency of the 26 observed \(\chi^{2}\) values were counted for each category. Denote \(f_{i}\) as the observed frequency for category \(i=1,10\). Then Equations 3 a and 3 b were used to compute the \(\log\) likelihoods of the unconstrained and constrained models. Once again, the \(\chi^{2}\) statistic is defined by the difference \(\chi^{2}=\) \(-2 \cdot\left(\mathrm{G}_{\mathrm{C}}-\mathrm{G}_{\mathrm{U}}\right)\). The unconstrained model involves \(10-1=9\) free parameters and the constrained model has no free parameters, and so the \(\chi^{2}\) statistic has \(d f=9\).

\begin{abstract}
Idioms and common multi-word expressions are often argued to be stored as chunks of words or fixed configurations in the mind, and to therefore be accessed faster and interpreted more easily than fully compositional word combinations. Experimental research has furthermore shown that a specific "recognition point" can be identified in such expressions, at which enough information is present to access the meaning of the whole expression and predict the remaining words of the collocation.
In this paper, we suggest measures for automatically identifying those multi-word expressions where the first part is particularly predictive of the rest, and evaluate our measures against human association data collected in a cloze test.
\end{abstract}

Keywords: Predictivity; Multi-Word Expressions; Collocations; Entropy

\section*{Introduction}
"When her boyfriend proposed to her, she was in seventh heaven." "After jogging, he quenched his thirst with some nice orange juice." The above sentences contain collocations where the first part of the collocation (e.g., "in seventh", "quench") is very predictive of the second part ("heaven" and "thirst", respectively). Such predictive collocations can be idiomatic (as in the first example), or literal, fully compositional configurations. Previous studies observing human processing of idioms have argued that there exists a "recognition point", at which comprehenders have identified the idiom and can predict the rest. Some also argue that not only idioms, but also frequent collocations, may be stored in the lexicon.

However, by far, not all collocations are predictive, consider for example light verb constructions where a very unpredictive verb is combined with a sense-carrying noun. Being able to pick out predictive collocations among the set of all collocations, and automatically identifying the recognition point in idioms could be very useful for psycholinguistic models of language processing: Processes of predicting specific upcoming words, and accessing idiomatic meaning could then potentially be captured in a broad-coverage model.

This paper takes a first step in this direction by proposing a number of alternative statistical methods for identifying predictive collocations and evaluating them with respect to a cloze task where people were asked to complete verbs with the argument they associated most strongly. This evaluation captures the predictive strength of a verb in the absence of further predictive context, and is supposed to compare which of the measures works best at identifying good candidates for predictive collocations.

\section*{Background and Related Work}

Collocations are commonly used phrasal expressions which have become characteristic for a language or jargon (Smadja,
1993). They are idiosyncratic because there is no rule which can tell us why a some specific lexemes (e.g., "strong tea" instead of "powerful tea") are combined to express a particular concept (McKeown \& Radev, 2000).

\section*{Representation of Collocations in Humans}

Idioms are a special type of collocations whose semantic meaning is not compositional of the meaning of the words it contains, but are more idiosyncratic such as "give a whirl" (meaning to try) or "spill the beans". The status of these expressions in the lexicon is still under debate. It has often been argued (Swinney \& Cutler, 1979) that these idiomatic expressions should be part of the lexicon. Some have even argued that non-idiomatic collocations may likewise be stored as chunks in longterm memory (Ellis, 2001; Ellis, Frey, \& Jalkanen, 2009).

An alternative model was proposed by Cacciari and Tabossi (1988) and holds that both decomposable and idiomatic expressions are represented in the lexicon "as configurations" and that these configurations can get activated during processing as soon as enough information has been perceived to render the collocation recognizable. Tabossi, Fanari, and Wolf (2009) present evidence that both idiomatic and literal collocations may be stored in memory as such configurations.

On the other hand, Vespignani, Canal, Molinaro, Fonda, and Cacciari (2010) find in an ERP experiment which compares the processing of idiomatic expressions with literal phrases that language comprehenders have categorial templates for idioms in their lexicon, and that these can be activated at a specific recognition point after which a prediction process is initiated. Their results suggest that this prediction process can be distinguished from non-idiomatic predictive mechanisms. If such effects are to be modelled in a computational model, it is necessary for the model to have access to a set of idiomatic expressions and their recognition points.

The goal of this paper is not to answer the question concerning which types of collocations may be stored in memory and which ones may be processed compositionally. Instead, we evaluate statistical measures for automatically identifying predictive collocations. The methods and measures are generally applicable and may later be used in combination with a filter for identifying idiomatic expressions.

An important point for our study however is the relevance of a recognition point and the notion of predictability of a multi-word expression. Tabossi, Fanari, and Wolf (2005) showed that only the meanings of predictable idioms, but not of all idioms, become available early on in idiom processing. Such a prediction process may be beneficial to language understanding because, as Tabossi et al. (2005) finds, recog-
nizing an initial fragment of a predictable idiom inhibits the recognition of the literal meaning of the rest of the expression and hence facilitates comprehension by reducing ambiguity.

\section*{Automatically Identifying Collocations}

The basic idea in automatically identifying collocations (for a good overview, see (Manning \& Schütze, 1999)) is to count how often a set of words occur together within a specific distance of one another (e.g., always adjacent) or within a syntactic relationship (e.g., verb-argument). Many word-pairs or multi-word expressions with frequent co-occurrence however aren't interesting collocations (like "in the") because the reason for their high co-occurrence frequency is the high frequency of each of the words and the syntactic constraints with which they occur.

Two strategies are commonly used to ignore such cases: the first one is to use statistical tests that indicate whether two words were observed together more often than would be expected otherwise. Collocation candidates are then ranked with respect to significance scores. Note though that only the ranking, but not the exact significance level, is usually considered interesting, as most co-occurrences are significant simply due to the fact that language has some regular patterns due to syntactic rules (Manning \& Schütze, 1999). Another common approach is to calculate the pointwise mutual information (PMI) between two words.

The second strategy is to specify what types of collocations should be found by specifying POS tag patterns or dependency relations between words (e.g., only considering adjective-noun pairs or only considering modifiers of nouns).

Finally, automatic methods developed for detecting idiomatic collocations often also use semantics to identify these expressions: in non-compositional expressions, the meaning of the words in the idiom are less likely to be semantically related to the rest of the context (Katz \& Giesbrecht, 2006).

The following paragraphs are going to explain the most commonly used measures for detecting collocations, as well as the word patterns used in this work.

Association Measures for Identifying Collocations To assess whether a pair of words \(w_{1} w_{2}\) is a collocation, we can count how often these words can be observed together \(O_{1,1}\), and calculate how often we would expect to see them together given their unigram frequencies and the size \(N\) of our data set: \(E_{1,1}=\frac{f r e q\left(w_{1}\right)}{N} \times \frac{f r e q\left(w_{2}\right)}{N} \times N\). If we observe them together much more often than would be expected given their unigram frequencies, we conclude that they are strongly associated and represent a collocation.

The most commonly used association measures (AMs) are the following: In a t-test (see for example (Manning \& Schütze, 1999)), the higher the \(t\)-value, the more likely that the observed co-occurrence of the words \(w_{1}\) and \(w_{2}\) would not have happened by chance.
\[
\mathrm{t}-\text { Test }: \quad t=\frac{\frac{O_{1,1}-E_{1,1}}{N}}{\sqrt{O_{1,1}}}
\]

An alternative is the z-score (variant suggested by Evert (2008)). The formula below estimates the mean of the distribution as \(E_{1,1}\) and its standard deviation as \(\sqrt{E(1,1)}\)
\[
\mathrm{z}-\text { score : } \quad z=\frac{O_{1,1}-E_{1,1}}{\sqrt{E_{1,1}}}
\]

Pearson's \(\chi^{2}\) test (for a more detailed description, see (Manning \& Schütze, 1999)) is very similar to the \(z\)-score, except it uses the square of the z -values and takes into account not only the probability of the words occurring together ( \(O_{1,1}\) ), but compares also the estimated and observed frequencies of a \(w_{1}\) not occurring with \(w_{2}, w_{2}\) not occurring with \(w_{1}\) and the co-occurrence of words different from both \(w_{1}\) and \(w_{2}\).
\[
\chi^{2}=\sum_{i, j} \frac{\left(O_{i, j}-E_{i, j}\right)^{2}}{E_{i, j}}
\]

Finally, the \(\log\) likelihood ratio \(\lambda\), similarly to \(\chi^{2}\), uses weighted on the similarity of the words \(w_{1}\) and \(w_{2}\) occurring together or with different words.
\[
\lambda=2 \sum_{i, j} O_{i, j} \log \frac{O_{i, j}}{E_{i, j}}
\]

Pointwise Mutual Information (PMI; Church and Hanks (1989)) is and information-theoretic concept and measures how much information is shared between words \(w_{1}\) and \(w_{2}\) - it is a symmetric measure. If there are two words with only occur in the context of each other, then one of the words conveys all the information that the two of them convey and their mutual information is maximal.
\[
P M I=\log _{2} \frac{O_{1,1}}{E_{1,1}}
\]

Filters Previous work on collocation extraction has shown (Seretan \& Wehrli, 2009; Fazly, Cook, \& Stevenson, 2009; Lin, 1998) that result quality depends also on choosing good patterns in which to observe collocation candidates. These have been defined via windows of observation, via fixed POS tag sequences or via syntactic dependencies, as for example from a dependency parser. The present study focusses on verb-argument pairs as extracted from a large text resource using a dependency parser.

Asymmetric Association Measures While there is a large body of literature on the topic of automatic recognition of multi-word expressions and idioms, there is almost no work on asymmetric association measures. An exception is Michelbacher, Evert, and Schütze (2007, 2011), who use conditional probability (see below), as well as a number of rank measure which are based on the traditional association measures explained above. As we found out after first submitting this paper, a related proposal for developing directional association measures has been made by Gries (to appear). A comparison between our measures and the associative-learning based approach should be addressed in future work.

\section*{Proposed Predictive Measures}

One way of capturing how predictive one word is of another word is to calculate the conditional probability ( CP ; also suggested by Michelbacher et al., 2007; 2011) of the second word given the first word. High CP indicates that the first word is highly predictive of the second word.
\[
C P\left(w_{1}, w_{2}\right)=P\left(w_{2} \mid w_{1}\right)
\]

A straightforward approach to predictive collocations is to use conditional probability as an association measure, or to combine existing measures for association between two words with the conditional probability of the second word given the first word. Different ways of combining the measures are possible, such as for example weighted additive combination \((a \times C P+b \times A M)\), or multiplicative combination \((C P \times A M)\).

In our preliminary experiments, it turned out that the additive models (which essentially represent a form of averaging between the measures) do not perform well. While they boost the score of collocation candidates which are both strongly associated and predictive, they do usually not boost it enough to achieve rankings higher than those of candidate collocations which are extremely good on just one of the measures, such that the resulting highest ranked candidates still contain a lot of highly associated but non-predictive word pairs.

Multiplicative combination, on the other hand, can be thought of as a filter that ranks down any collocation candidates which are highly associated but not predictive, and boost highly predictive candidates, resulting in a cleaner list of predictive collocations. Based on this observation, we propose the following new measures: \(\mathrm{CP}, \mathrm{CP} \times \chi^{2}, \mathrm{CP} \times \mathrm{PMI}\) and \(\mathrm{CP} \times \lambda\), which we will evaluate in the remainder of this paper.

\section*{Comparison of Association Measures}

It is instructive to inspect how similar the alternative association measures are to one another. To this end, we sorted 3.6 million adjective-noun pairs from the ukwac corpus (Ferraresi, Zanchetta, Baroni, \& Bernardini, 2008) according to each of our association measures and calculated the correlations between these sorted lists. Table 1 shows that four of our measures, \(\chi^{2}, Z, \lambda\) and PMI actually result in very similar rankings, with correlations \(\rho>.9\). Only rankings by \(t\)-value look a bit more dissimilar, and relatively more similar than other measures to the overall frequency of word pairs (indicated as FRQ in Table 1). It is also important to observe that conditional probability (CP) leads to a very different ranking and is only correlated at \(0.28<\rho<0.4\) with the other measures.

\section*{Identification of Predictive Collocations}

We dependency-parsed the Gigaword Corpus \({ }^{1}\) using the Stanford parser (Marneffe, MacCartney, \& Manning, 2006). From

\footnotetext{
\({ }^{1}\) http://www.ldc.upenn.edu
}

Table 1: Correlation (Spearman's rho) between different association measures for top 500 ranks.
\begin{tabular}{r||l|lllll|l}
\(\rho\) & FRQ & T & Z & \(\chi^{2}\) & \(\lambda\) & PMI & CP \\
\hline \hline FREQ & 1 & .62 & .28 & .29 & .46 & .06 & .2 \\
\hline T & .62 & 1 & .86 & .83 & .88 & .72 & .28 \\
Z & .28 & .86 & 1 & .97 & .91 & .96 & .38 \\
\(\chi^{2}\) & .29 & .83 & .97 & 1 & .97 & .93 & .4 \\
\(\lambda\) & .46 & .88 & .91 & .97 & 1 & .82 & .4 \\
PMI & .06 & .72 & .96 & .93 & .82 & 1 & .33 \\
\hline CP & .2 & .28 & .38 & .4 & .4 & .33 & 1
\end{tabular}
the Gigaword's 1.7 billion tokens, we extracted all dependency triples of the type "VB*:dobj:NN*" (i.e., verbs and their direct arguments), for which the verb occurred to the left of the argument in the text. Verb-argument pairs which occurred less than 16 times in the corpus were excluded from the analysis, as some of the association measures are not applicable when counts are too low. Furthermore, we removed all verb-argument pairs containing words which were not in WordNet under the correct POS tag. This later step filtered out POS-tagging errors like "unsalted butter" or "quantum mechanic" where "unsalted" and "quantum" were tagged as verbs, or "smile slyly" where "slyly" was tagged as a noun, as well as foreign language material.

\section*{Cloze Task}

The goal of our experiment is to evaluate whether combining one of the established measures for collocation extraction with conditional probabilities will lead to a good measure for identifying predictive collocations, and which of the proposed measures works best. For the evaluation, we use a simple task which is independent of any sentential context: we ask human participants to complete a list of verbs with a noun they associate first, and then compare which of our measures predicts best the cloze probabilities of each verb. A reason for evaluating with a completion experiment instead of simply comparing to a verb's entropy or conditional probability on the corpus itself is that many of the highly ranked collocations in our measures are in fact not necessarily generally valid predictive colloctions - some are very domain-specific, such as rise percent (from "rise 20 percent") and tell reporter.

\section*{Experimental Materials}

For evaluating predictive collocations, we were looking for a set of verbs which contains a good portion of potentially predictive verbs. We therefore selected verbs for our completion experiment by first calculating ranked lists of some of our target measures that we want to compare: \(\mathrm{CP} \times \chi^{2}, \chi^{2}\) and \(\mathrm{CP} \times \lambda\), and randomly chose 50 verbs out of the 200 bestranked verb-object pairs of each measure. This procedure left us with a set of 118 verbs for our completion experiment. The rationale behind choosing verbs this way instead of just selecting a random set of verbs is that we wanted to avoid ending up with only a very small number of predictive verbs.

Table 2: Arguments filled in for the verb "heal" during our completion experiment. We also collected completion times for each response.
\begin{tabular}{lr|lr} 
Answer.w2 & Seconds & Answer.w2 & Seconds \\
\hline the sick & 7 & wounds & 55 \\
a wound & 19 & bodies & 8 \\
the sick & 5 & a wound & 8 \\
the wound & 37 & yourself & 15 \\
a wound & 13 & a sore & 9 \\
a wound & 18 & the wound & 10 \\
sores & 4 & wounds & 4 \\
a wound & 7 & the wound & 7
\end{tabular}

\section*{Procedure}

We ran our experiment via Amazon Mechanical Turk (Paolacci, Chandler, \& Ipeirotis, 2010). In order to explain the task to our subjects, we gave them three examples of completed verb-argument pairs, using verbs which were not part of the 118 verbs that we wanted to collect completion data for: "to quench thirst", "to rob a bank" and "to feed the dog". We restricted our subjects to people living in the U.S. and instructed them to only take part in the experiment if they qualified as native speakers of English. Furthermore, we also restricted our pool of workers to ones that had in the past gotten \(>95 \%\) of their HITs \({ }^{2}\) approved and had successfully completed at least 1000 HITs. We collected a total of 1888 verbargument associations (i.e., 16 associations for each verb). Each worker was allowed to complete as many verbs as they wanted (but, of course, each verb only once). The 1888 associations were completed by 40 separate workers.

\section*{Collected Data}

For each verb, we collected 16 argument-associations. For example, see completions for the verb "heal" in Table 2. We lemmatized all answers, and dealt with typos (e.g., havok instead of havoc), orthographic variants (e.g., judgment vs. judgement) using minimum edit distance.

To assess the predictive strength of a verb, we calculated the entropy of each verb given the types of responses (after clustering them by lemma and dealing with typos etc, as described above). For example, the entropy of "heal" would be 1.53 . As we collected at most 16 associations per verb, entropy ranges between 0 and 4 for our data set. We can then use the entropy to classify our verbs into highly selective verbs (such as "grit", "honk", "flex", "sing", "twiddle"), less selective verbs (e.g., "pay", "fire", "attend") and nonselective ones (e.g., "quote", "shout", "request"). In a linear mixed effects regression analysis with random intercept and random slope for verb entropy under subject, we found that verb entropy is a significant positive predictor of completion times ( \(p<0.01\) ), i.e., when an argument of a verb is less predictable, people take longer to fill in the slot.

\footnotetext{
\({ }^{2}\) HIT stands for "Human Intelligence Task" and is used as the official term for tasks in Amazon Mechanical Turk.
}

\section*{Evaluation}

We evaluate our measures of predictive collocations in two ways. A good measure should rank highly those collocations where the first part is highly predictive of the second part.

Identifying Predictive Collocations We select a group of highly predictive verbs (determined by their entropy in the experiment) and generate verb-noun pairs by selecting the most common completion for those verbs in the experiment. This results in a list of verb-noun collocations where the verb is highly predictive of the noun. Next, we calculate the average rank of these verb-noun pairs for each of our measures, see table in Figure 1.

An important note to keep in mind when interpreting the average ranks in the table in Figure 1 is that the set of verbs was originally randomly chosen from among the top-ranked 200 verb noun pairs of the measures \(\mathrm{CP} \times \mathrm{CHI}, \mathrm{CHI}\) and \(\mathrm{CP} \times \lambda\); note also that Z is almost identical to CHI in the ranking it generates - these measures are therefore marked in bold in the table.

The newly proposed measure \(\mathrm{CP} \times \mathrm{CHI}\) clearly outperforms the other measues. It has the lowest average rank, meaning that the verb-noun pairs which we have identified as being particularly predictive are ranked highest in this measure. Note that 44 verb-noun pairs satisfied the criterion of the verb entropy in the experiment being under the threshold of 1.5 . This gives us an average rank of 22.5 as the best possible ranking which could possibly be achieved. Of course, not all possible verbs were tested in our experiment, hence direct comparison to this value is not meaningful. More important is the comparison to the average ranks of other measures. Clearly, the combined measure \(\mathrm{CP} \times \mathrm{CHI}\) is much better than either of its parts, and also clearly outperforms \(\mathrm{CP} \times \lambda\).

It is also fair to compare the measures which were not part of constructing the evaluation verb set (not in bold) to one another. Clearly, combining CP with the association measures improves identification of predictive collocations, in particular there is an interesting boost in the performance of the \(t\)-test measure when combined with conditional probabilities. We also conclude that \(\lambda\) is not a useful measure for identifying predictive collocations.

Additional insight comes from plotting average ranks for all verb-noun pairs with identical cloze probability, see Fig. 1. For a measure which is good at identifying predictive collocations, we expect there to be a linear relationship between cloze probabilities and \(\log\) rank (log rank makes sense because there are by definition more different noun pairs when cloze probability is lower). Monotonicity in the trend of the log rank indicates that the measure correctly distinguishes between different levels of cloze predictability. Furthermore, average log rank for verb noun pairs with cloze probability 1 should be close to 0 . The plots show that \(\mathrm{CP} \times \mathrm{CHI}\) comes closest to the described ideal correlation. The r squared measure given in the title of each plot in Figure 1 quantifies the fit between the plotted data points are from the regression line.
\begin{tabular}{lr}
\multicolumn{2}{l}{ verb entropy threshold 1.5} \\
\hline measure & rank \\
\hline \(\mathbf{C P x C H I}\) & 87.275 \\
CHI & 152.864 \\
\(\mathbf{Z}\) & 152.948 \\
CPxPMI & 237.692 \\
CPxT & 258.124 \\
CP & 291.342 \\
CPx \(\lambda\) & 404.471 \\
CPxFRQ & 709.715 \\
PMI & 1037.151 \\
\(\lambda\) & 2403.245 \\
Z & 6863.703 \\
T & 9378.727 \\
\hline ceiling & 22.5
\end{tabular}

Figure 1: Table at left: Average rank in lists ranked according to association measures; set of predictive verb-noun pairs defined based on different thresholds for verb entropy in experiment.
Plots: Average rank for \(\mathrm{CPxCHI}, \mathrm{CPx} \lambda\) and CHI grouped by cloze probabilities as obtained from MTurk experiment.

While measure \(\mathrm{CP} \times \lambda\) also follows a clear linear relationship, it does not locate the items with high predictability in its lowest ranks, indicating that it might be a good measure for quantifying collocations in general but not for predictiveness given the first part.

Correlation with human associations Our second evaluation compares the association values from all measures to the cloze probabilities obtained in the experiment. We again evaluate on average association values for each set of verb-noun pairs with a given cloze probability, see Figures 2 and 3. A good measure should increase monotonically with increasing cloze probabilities.

Among previously existing measures, PMI values can explain the largest amount of the variance in terms of average PMI values compared to cloze probabilities from our experiments. It is clear from Figure 2 that the common frequency of the two words, as well as the log likelihood measure are very poor predictors of predictive collocations.

Among traditional measures combined with conditional probabilities, \(\mathrm{CP} \times \mathrm{FRQ}, \mathrm{CP} \times \lambda\) and \(\mathrm{CP} \times \mathrm{T}\) perform very poorly. The problem for these measures is that they reflect strongly the overall frequency of a word pair. On the other hand, average \(\log \mathrm{CP} \times \mathrm{CHI}\) values have the strongest linear relationship with cloze probabilities, with few atypical points, as also reflected in the high \(R^{2}\). This result is thus consistent with the rank analysis in the first evaluation.

\section*{Conclusions and Outlook}

Our experiments indicate that the combination of conditional probability and the \(\chi^{2}\) measure might work best for identifying collocations where the first word is highly predictive of the second one. While this paper went a first step in devoting some attention to the problem of identifying predic-
tive collocations, suggesting possible measures and evaluating these measures on a cloze task of verb-argument associations, the next important step is to evaluate these methods on a more specific task such as automatically identifying recognition points of idioms. Furthermore, this paper has only dealt with one type of collocation (verb-argument pairs) and has focussed on collocations consisting of only two words.

In future work, we furthermore plan to evaluate the usefulness of predictive collocations by including them in a model of language processing in the form of lexical configurations.

\title{
The Cognitive Reflection Test: how much more than Numerical Ability?
}

\author{

\begin{abstract}
Frederick's (2005) Cognitive Reflection Test (CRT) is a 3item task shown to predict susceptibility to decision-making biases better than intelligence measures. It is described as measuring 'cognitive reflection' - a metacognitive trait capturing the degree to which people prefer to reflect on answers rather than giving intuitive responses. Herein, we ask how much of the CRT's success can be explained by assuming it is a test of numerical (rather than general) intelligence. Our results show CRT is closely related to numerical ability and that its predictive power is limited to biases with a numerical basis. Although it may also capture some aspect of a rational cognition decision style, it is unrelated to a metacognitive, error-checking and inhibition measure. We conclude that the predictive power of the CRT can, largely, be explained via numerical ability without the need to posit a separate 'cognitive reflection' trait.
\end{abstract}

Keywords: cognitive reflection; heuristics and biases; individual differences; numerical ability; intelligence.

\section*{Introduction}

Frederick's (2005) Cognitive Reflection Task (CRT) asks people to solve three, mathematically-simple problems on which intuitive answers are wrong. Frederick explains CRT performance as reflecting a person's preference for using either System 1 (intuitive) or System 2 (rational) processes (Stanovich \& West, 2000). Given the ease with which one can check whether intuitive answers are incorrect, the score on CRT shows how likely a person is to reflect on their answer rather than respond intuitively. Frederick's (2005) data shows that CRT is superior to intelligence measures in predicting susceptibility to various cognitive biases or errors made due to inherent, cognitive processes (see, e.g., Tversky \& Kaheman, 1974); a conclusion supported by Toplak, West and Stanovich's (2011) recent work.

Given the surprising finding - that a 3-item test better predicts decision-making ability than intelligence tests, Frederick's work has been influential (cited over 600 times). Its results, however, are in line with previous findings which show that, while intelligence is useful in predicting some decision-making biases, in other cases intelligence and bias susceptibility seem independent (Stanovich \& West, 2008).

These findings have led to suggestions that decision style (or a person's preference for thinking rationally or intuitively) may be more important than intelligence for predicting bias susceptibility. CRT shares variance with a number of decision style measures (Frederick, 2005) and 'cognitive reflection' is thought to be central to the metacognitive processes underlying the relationship between System 1 and System 2 thinking. The latter, System 2
processes, inhibit the automatic and frequently incorrect answers generated by System 1 thinking. It is reasonable, then, that intelligence might determine how efficiently a person uses System 2 reasoning but whether they use it may be determined by a separate, metacognitive process, thereby weakening the observed relationship between intelligence and bias susceptibility.

A potential criticism of Frederick's (2005) paper - and other work in this area - however, lies in the choice of intelligence measures. For example, a commonly used intelligence measure is self-reported SAT scores (see, e.g.: Frederick 2005; Stanovich \& West, 1998). Another is the Wonderlic Personnel Test (Wonderlic, 1973 - used in Frederick, 2005; and Furnham, Boo \& McClelland, 2012). Finally, Toplak et al. (2011), use the Vocabulary and Matrix Reasoning scales from the Wechlser Abbreviated Scale of Intelligence (WASI, Wechsler, 1999).

While all of these do measure 'intelligence' - and WASI divides this into Verbal and Non-verbal ability - none take into account the current understanding of the hierarchical nature of intelligence described by the Cattell-Horn-Carroll model (see, e.g., McGrew, 2005), which recognizes at least ten, related, cognitive abilities. By focusing on the relationship between general intelligence and bias susceptibility, it is, therefore, possible to underestimate the relevance of specific intelligences to specific biases.

A key omission is of numerical ability \(-G q\) or quantitative ability in CHC terms. Given that the CRT, and many decision-making problems, rely on numerical calculation to determine the correct response, it seems strange to report correlations between biases and general intelligence rather than the type of intelligence most likely to influence such tasks. Thus, it seems possible that the low predictive power of intelligence on bias susceptibility results from poor measure selection.

The way forward, then, is to incorporate measures of the specific abilities most likely to relate to the biases under consideration - thereby establishing an accurate baseline for the strength of the relationship before positing additional constructs like cognitive reflection. Concerning metacognition, this work has already begun, with Toplak et al. (2011) including measures of metacognitive abilities (e.g., working memory; Baddeley \& Hitch, 1974) that seem likely to be implicated in recognizing errors in intuition and thus switching from System 1 to System 2 reasoning.

\section*{CRT, Heuristics and Biases}

Given the numerical basis of the CRT questions, a key question is whether it predicts numerical biases better than
less numerical ones. For example, a between-subjects framing task such as the Asian Disease Problem (Tversky \& Kahneman, 1981) is structured so that a person can calculate the expected value of the options and recognize that the values of the options do not change with the frame reversal.
By comparison, the conjunction fallacy (Tversky \& Kahneman, 1983) requires an understanding of the logical rule of conjunction - and numerical ability per se may not assist in avoiding the bias. Similarly, while the anchoring bias (Tversky \& Kahneman, 1974) seems numerical - with a seen number affecting a subsequent estimate - numerical ability can not help a person calculate the correct response.
Other tasks are even less clear cut in this aspect. For example, delay discounting tasks like that used by Frederick (2005) can be regarded as a bias measure indicating the extent to which people misjudge the time value of money. This calculation, however, requires the inclusion of nonnumerical factors such as immediate need for money and degree of trust in the person offering the delayed reward. Recent work, however, has suggested that these actually measure a distinct personality trait - impulsivity (Odum, 2011) - and, thus, one might expect less covariance between numerical ability and delay discounting. Similarly, a base rate neglect task (see, e.g. Bar-Hillel, 1982) can be answered using a variety of distinct response strategies (Welsh \& Navarro, 2012) and, for this reason, it is not necessarily the case that estimates closer to the Bayesian solution actually reflect better numerical skills (Welsh, Burns, Delfabbro \& Begg, 2013) as has traditionally been assumed.

\section*{Method}

\section*{Participants}

Participants were 58 university students and 44 non-students (22 graduates and 22 who had never attended university), recruited via posters and research participation lists, aged between 18 and \(46(M=22.5, S D=4.9)\); sixty-eight were female and all received \(\$ 50\) for participating.

\section*{Materials \& Procedure}

Participants completed an online questionnaire, including demographic details, and the decision style measures described below prior to attending the lab for cognitive and metacognitive tests. The bias measures were included in the online questionnaire - excepting the anchoring task.

\section*{Cognitive Reflection Task}

Frederick's (1995) CRT was used to measure cognitive reflection. This test asks three questions requiring numerical responses with CRT score being the number answered correctly. For example, the first question asks:

A bat and a ball together cost \(\$ 1.10\). The bat costs \(\$ 1.00\) more than the ball. How much does the ball cost?

\section*{Bias Measures}

Anchoring. Anchoring bias refers to the unwarranted effect that presented numbers have on subsequent estimates
(Tversky \& Kahneman, 1974). The measure used here was derived from a computerized card game in which participants estimated the probability that they would win, given the hand they had been dealt (for details, see, Welsh, Delfabbro, Burns \& Begg, in press). Prior to this, they were asked whether their chance of winning was greater or less than a randomly generated number (the anchor) between 0 and \(100 \%\). The anchoring measure was the partial correlation (controlling for the true chance of winning) between the anchor and the person's estimate - measured across 140 hands. Higher values thus reflect greater influence of the anchor on estimates (i.e., more bias).

Base Rate Neglect. The Taxi Cab problem (Bar-Hillel, 1982) requires people to integrate base rate and reliability information to determine the probability of a taxi involved in an accident actually being the color a witness describes. As previously noted (Welsh, Burns, Delfabbro \& Begg, 2013), responses to such problems form distinct categories. We scored responses as Mathematical, Non-Mathematical and Unclassifiable according to whether the person: mathematically combined the probabilities given in the task (i.e., either the Bayesian solution or an incorrect calculation); selected one probability as their response; or did something other than either of these.

Conjunction Fallacy. The Linda Problem (Tversky \& Kahneman, 1983) asks participants to judge whether Linda, a woman described as politically active, is more likely to be a "feminist bank teller" or a "bank teller", with the former indicating the conjunction fallacy - as the conjunction can never be more likely than the simple probability of her being a "bank teller".

Delay Discounting. A series of questions asked how long a person would delay taking a smaller amount of money in order to receive a larger amount. The smaller amount varied from \(\$ 500\) to \(\$ 900\) while the delayed amount was always \(\$ 1000\). The maximum delay a participant would tolerate was indicated on an 8 point scale: 1) 6 hours; 2) 1 day; 3) 1 week; 4) 2 months; 5) 6 months; 6) 1 year; 7) 5 years; 8) 25 years). The average of a person's responses from five such questions was used as their overall score.

Framing. The Asian Flu problem (Tversky \& Kahneman, 1981) asks people to select a treatment schedule for dealing with a disease outbreak - with either certain (200 alive, 400 dead) or uncertain ( \(1 / 3\) chance of all alive, \(2 / 3\) chance of all dead) outcomes. The manipulation lies in the framing of the options. Positive framing describes the treatments in terms of the number of people who live, with the result that more people select the certain option. In contrast, negative framing describes the treatments in terms of the number of people who die, with the result that more people select the uncertain option. Our task included both versions and we categorized people according to whether their responses changed with the frame (displaying the framing bias) or were invariant to framing (unbiased).

\section*{Cognitive and Metacognitive Measures}

Numerical Abilities Test (NAT). A computerized, 12-item version of the 48 -item Numerical Abilities scale from the Differential Aptitudes Test (Bennett, Seashore \& Wesman, 1989), measuring quantitative ability ( \(G q\) ).

Symbol-Digit Test (SD). A computerized measure of cognitive processing speed (Gs) similar to the Wechlser IQ test's Digit-Symbol (see McPherson \& Burns, 2005).

Dot Matrix Task (DM). A computerized version of the Dot Matrix working memory measure (Law, Morrin \& Pelligrino, 1995).

Sustained Attention to Response (SART). A computerized test of executive function - requiring the identification and inhibition of a habituated response (Robertson, Manly, Andrade, Baddeley \& Yiend, 1997).

\section*{Decision Style Measures}

Need for Cognition (NfC). The 10 -item International Personality Inventory Pool (IPIP; Goldberg et al, 2006) version of Cacioppo \& Petty's (1982) scale measuring people's engagement and enjoyment of cognitive activities.

Decision Outcomes Inventory. A 20 -item version of Bruine de Bruin, Parker and Fischoff's (2007) test examining whether people have made various, poor decisions (e.g., bought things they did not use, et cetera). The version we used removed US-specific questions.

Rational Experiential Inventory. A 30-item test of risk style (Epstein, Pacinin, Denes-Raj \& Heier, 1996) yielding four measures distinguishing between 'Ability' and 'Engagement' for two different cognitive styles - Rational (conscious, analytical) and Experiential (intuitive, holistic).

Intellect. A 20-item inventory from the IPIP (Goldberg et al, 2006) combining Cattell's (1973) and Costa and McCrae's (1992) approaches. This measures openness to new ideas in an intellectual context - a facet of 'openness-to-experience' from Costa and McCrae's (1992) NEO-PI-R.

Rationality. Measured by a 14 -item test from the IPIP (Goldberg et al, 2006), high Rationality reflects high Conscientiousness and low Agreeableness in NEO-PI-R (Costa \& McCrae, 1992) terms.

Stimulating Instrumental Risk Inventory. A 28-item test yielding two risk attitude measures (Zaleskiewicz, 2001) Stimulating (positive arousal, short-term and impulsive) and Instrumental (negative arousal, long term and reflective).

\section*{Results}

\section*{CRT and Demographic Measures}

Age did not co-vary significantly with CRT (or with any
measures other than the SRT and IRT scales from the Stimulating Instrumental Risk Inventory). An independent samples \(t\)-test, however, showed that males ( \(M=1.53, S D=\) 1.11) scored significantly higher than females ( \(M=1.01, S D\) \(=0.98\) ), on CRT, \(t(57)=2.18, p=.033\), Cohen's \(d=.51-\) in line with Frederick's (2005) observation.

CRT also varied with level of education, with participants who had never attended university scoring lowest ( \(M=\) \(0.73, S D=0.94\) ), then current university students ( \(M=1.24\), \(S D=1.05\) ) and graduates the highest ( \(M=1.50, S D=1.06\) ) . A one-way ANOVA confirmed these differences were statistically significant, \(F(2,99)=3.31, p=.041\), with posthoc Bonferroni testing indicating that the no-university group differed significantly from both others.

\section*{CRT and Biases}

Table 1 summarizes the relationships between the CRT and the five bias measures - noting those that have numerically calculable correct responses and which showed significant relationships with the CRT.

Looking at the table, one sees an interesting pattern of responses. While CRT has relationships in the expected directions with the non-calculable biases (Anchoring and the Conjunction Fallacy) these are very weak. By comparison, its relationships with Framing and Discount Delay measures, where the unbiased answer can be calculated, are statistically significant if moderate and weak, respectively. The more complex, near significant relationship between CRT and Base Rate Neglect is discussed more fully below.

\section*{CRT and Numerical Ability}

Scores on the Numerical Ability Test (NAT) correlated significantly with CRT, \(r(102)=0.44, \mathrm{p}<.001-\) comparable to the correlations observed between CRT and cognitive ability measures in Fredrick (2005) and Toplak et al. (2011). This correlation is the strongest that CRT has with any measure in our analyses.

The relationships between NAT and the demographic variables were also calculated - to determine whether the pattern of responses matches those of the CRT. Welch's \(t\) test revealed a non-significant relationship between NAT and Sex in the same direction as the significant relationship shown by the CRT measure, \(t(57)=1.28, p=.204\).

The relationship between NAT and Education, by contrast, was significant, as indicated by a one-way ANOVA, \(F(2,99)=9.41, p<.001\). As with CRT, a Bonferroni post hoc test indicated that the no-university group's lower scores drove the significant result and the groups were ordered in the expected manner: no-university; current student; and, then graduates.

\section*{Factor Analysis}

To assess relationships between CRT and the individual differences measures, an exploratory factor analysis (minres extraction with geomin oblique rotation) was run, revealing the 4 -factor solution seen in Table 2. (NB - 2- and 3-factor
solutions were also considered; these did not appreciably alter the loadings of the CRT on the first two factors.)

Table 1. Summary of Bias Task Characteristics and Results
\begin{tabular}{|c|c|c|c|}
\hline Task & \begin{tabular}{l}
范 \\

\end{tabular} &  & Results \\
\hline Framing & Yes & Yes & \begin{tabular}{l}
\(t(64)=2.97, p=.004\), Cohen's \(\boldsymbol{d}=\mathbf{. 6 2}\). \\
People whose responses varied with the frame scored lower than those whose responses were invariant to the frame (CRT \(=0.76\) vs 1.39 ).
\end{tabular} \\
\hline \begin{tabular}{l}
Discount \\
Delay
\end{tabular} & Yes & Yes & \begin{tabular}{l}
\[
r(102)=0.25, p=.010
\] \\
Higher CRT accompanied a greater willingness to wait for the larger reward.
\end{tabular} \\
\hline Base Rate Neglect & Yes & No & \begin{tabular}{l}
\[
F(2,98)=2.79, p=.07
\] \\
People whose responses were classified as Mathematical (CRT=1.28) did not score better than the Non-Mathematical group (1.33) but both scored better than the Unclassified group (0.71).
\end{tabular} \\
\hline Anchoring & No & No & \begin{tabular}{l}
\[
r(102)=-0.11, p=.255
\] \\
People more susceptible to anchoring bias scored slightly lower on CRT
\end{tabular} \\
\hline Conjunction Fallacy & No & No & \begin{tabular}{l}
\[
t(56)=0.37, p=0.71
\] \\
People committing fallacy scored slightly lower on CRT (1.30 vs 1.21 ).
\end{tabular} \\
\hline
\end{tabular}

Looking at Table 2, one can see that a sensible structure emerges. The first factor captures the decision style measures relating to people's tendencies toward 'rational cognition'. The second seems to be an intelligence factor. The third has only the experiential measures from the Rational-Experiential Inventory (REI) loading on it reflecting a tendency toward intuitive thinking. Finally, the fourth factor reflects attitudes to risk as captured by both measures form the Stimulating-Instrumental Risk Inventory.
Only one variable, the Rational Ability measure from the REI, loads on more than one factor at the conventional 0.3
level and only the Sustained Attention to Response Task fails to load on any factor - indicating the metacognitive measure differs from both decision style and intelligence.

Table 2. Factor loadings of CRT, cognitive and decisionstyle measures.
\begin{tabular}{lrrrrr}
\hline & \multicolumn{5}{c}{ Factors } \\
Variable & 1 & 2 & 3 & 4 & \(h^{2}\) \\
\hline Intellect & \(\mathbf{. 9 2}\) & -.06 & .13 & .00 & .94 \\
Need for Cognition & \(\mathbf{. 9 1}\) & .02 & .03 & .05 & .85 \\
Rational Engagement & \(\mathbf{. 7 5}\) & -.06 & -.02 & .01 & .56 \\
Rationality & \(\mathbf{. 7 4}\) & .04 & .00 & -.05 & .55 \\
Rational Ability & \(\mathbf{. 6 2}\) & .32 & -.12 & -.01 & .48 \\
Dot Matrix & -.08 &. \(\mathbf{. 7 7}\) & -.03 & .12 & .61 \\
Symbol-Digit & .00 & \(\mathbf{. 6 8}\) & .16 & -.06 & .44 \\
Numerical Ability & .00 & \(\mathbf{. 6 6}\) & .02 & .01 & .43 \\
Cognitive Reflection & .26 & \(\mathbf{. 5 0}\) & .01 & -.05 & .32 \\
Exper. Engagement & -.01 & .02 & \(\mathbf{1 . 0 0}\) & .00 & .00 \\
Experiential Ability & .16 & -.02 & \(\mathbf{. 6 8}\) & .02 & .56 \\
Stimulating Risk & -.02 & -.02 & .04 & \(\mathbf{. 9 9}\) & 1.00 \\
Instrumental Risk & .04 & .24 & -.17 & \(\mathbf{. 4 5}\) & .26 \\
Sustained Attention RT & -.01 & -.01 & .05 & .18 & .05 \\
\hline Prim
\end{tabular}

Primary factor loadings are in bold. \(h^{2}=\) communality, the variance in each variable captured by the four factors.

\section*{Discussion}

The above results suggest that 'cognitive reflection', as measured by CRT, shares much in common with numerical ability - although there remains additional, unshared variance to account for. Key, individual results are discussed below, along with caveats and potential future research.

\section*{Cognitive Reflection and Sex}

An interesting result is the relationship between CRT and Sex - and the lack of similar relationships between Sex and the other measures loading on the 'intelligence' factor in Table 2. The sex difference on CRT was observed by Frederick (2005), who noted that it was unrelated to differences in intelligence and suggested that it might be related to differences in mathematical ability. This was not, however, supported by our data where no significant relationship was seen between numerical ability and sex.

The only variable with which both Sex and CRT shared a relationship was the Rational Ability scale of the RationalExperiential Inventory. CRT correlated with RA significantly, \(r(102)=0.33, p<.001\) and men's scores (22.7) were higher than women's (20.9) - significantly according to Welch's \(t\)-test, \(t(83)=2.34, p=.022\) suggesting that the sex difference in CRT may partly reflect a difference in Rational Ability - a person's self-reported ability to think analytically (Epstein et al, 1996).

\section*{Cognitive Reflection and Numerical Biases}

The pattern of bias results described above fit with a conception of the CRT as a primarily numerical measure.

On those bias tasks where numerical skill has no obvious role in arriving at the correct response - anchoring and the conjunction fallacy, the CRT has no predictive value.
By comparison, in the framing problem, where the irrelevance of the frame can be demonstrated numerically, CRT proved a good predictor of performance. Similarly, there is a significant effect for the delay discounting problem. Despite the complexity of the problem (in terms of potential, contextual factors) it appears that numerical ability pushes participants towards the economically rational choice. This is an interesting addition to Baumann and Odum's (2012) finding that delay behavior relates to temporal perception - potentially arguing for a relationship between numerical and temporal skills under the broad \(G q\) 'quantitative ability' umbrella.

Complexity is added by the base rate neglect task, where the results were somewhat unexpected - although not significant. As noted above, the groups using mathematical and non-mathematical strategies did not differ statistically from one another on the CRT. Instead, both groups outscored participants whose responses were unclassifiable. As noted by Welsh et al. (2013), however, the base rate neglect task differs from many numerical bias tasks in that the calculation of the correct solution is dependent on knowing how to undertake Bayesian updating. That is, while a person with high cognitive reflection or numeracy may realize that their intuitive response is wrong and activate System 2 thinking, they may not have the knowledge required to calculate the correct answer having done so. Given that CRT only requires very simple mathematical skills - as do numerical ability tests - this task's failure to predict response types on a base rate neglect task is less surprising than it first seems.

\section*{Cognitive Reflection and Intelligence}

The factor analysis shown in Table 2 indicates that the CRT is, primarily, an intelligence measure - loading on the second factor along with the three cognitive variables. It does, however, have the weakest loading of the four on this factor at 0.50 . Numerical ability is, however, the variable with the most similar loading - reflecting the strength of the relationship between these two measures. This is unsurprising as the Dot Matrix and Symbol-Digit tasks require learning a novel task, whereas the NAT and CRT require prior knowledge - of how to undertake mathematical operations. (CRT scores could also be affected by prior experience of questions similar to those used in the task making people wary of too-easy answers.)
CRT shows virtually no relationship (loadings of .01 and .05) with the third and fourth factors ('intuition' and 'risk attitude') but its relationship to the first factor bears some scrutiny. While not reaching the 0.3 level conventionally required to be included amongst the variables loading on a factor, its loading of 0.26 on the 'rational cognition' decision style factor approaches this level and is the second highest secondary loading in Table 2 - after Rational Ability's 0.32 secondary loading on the 'intelligence' factor.

This could be taken as offering some support for Frederick (2005) and Toplak et al.'s (2011) conclusions that CRT measures something more than cognitive ability although the factor loadings suggest that the cognitive aspect is more central.

\section*{Cognitive Reflection and Metacognition}

A final observation from the above results is the lack of any relationship between the CRT and the Sustained Attention to Response Task (SART), which measures executive functioning - specifically, a person's ability to monitor their performance for errors and to inhibit incorrect responses.

Given the description of the CRT as a measure of a person's preference for activating rational thinking and thus recognizing errors in intuitive responses, its failure to correlate with the SART seems strange. In light of our results, it thus seems possible that the CRT is measuring only a person's ability to recognize errors in intuitive, numerical results rather than the more general metacognitive function.

\section*{Caveats and Future Research}

While including measures not previously used in studies of cognitive reflection, the present analyses remain limited in their scope. The Cattell-Horn-Carroll model includes ten specific types of intelligence (acknowledging the possibility of more; McGrew, 2005). Of these, only two (plus the nonCHC working memory) were measured herein - Gs (processing speed) and \(G q\) (quantitative or numerical ability). Similarly, while five biases were included here, further effects from the biases literature could improve understanding of what CRT does and does not predict.

A further concern is the sample size. While 102 participants is sufficient to find most large or moderate effects, small effects may still be missed. Frederick's (2005) study, for example, involved more than 3000 participants, allowing statistical significance for even very weak relationships. Given this, the obvious direction for future research is a larger study of participants from a wide range of educational backgrounds, utilizing the widest possible range of biases and cognitive abilities in order to pin down exactly what the CRT is. Including a number of tasks measuring quantitative (numerical) ability would also allow further factor analyses to decide conclusively whether CRT is, as suggested here, primarily a numerical task.

Another key direction is to determine what role metacognitive abilities do play in the divide between System 1 (intuitive) and System 2 (analytic) reasoning and whether CRT is capturing any of these. Specific measures of impulsivity, as discussed by Baumann and Odum (2012), could inform this - as this seems likely to relate to the likelihood of a person relying on System 1.

Finally, additional work could address whether CRT scores are affected by prior experience of similar questions.

\section*{Conclusions}

The above results support the idea that CRT is, at heart, a
numerical task, correlating with quantitative ability and predicting bias only on tasks with a calculable, correct answer. It may, however, measure some aspect of a 'rational cognition' decision style. The CRT does not, however, relate to the executive functioning measure included here, suggesting that 'cognitive reflection' may not be metacognitive as Frederick (2005) describes but, rather, measure a person's ability to quickly recognize bad math.

\section*{Acknowledgments}

MBW and SHB thank ExxonMobil and Santos for their support of this research through the CIBP at the Australian School of Petroleum. The authors thank Karina Burns for her assistance with data collection and Reidar Bratvold and Steve Begg for discussions re the CRT's nature and use.

\title{
How do you know that? Sensitivity to statistical dependency in social learning
}

\author{

\begin{abstract}
Social learning has been shown to be an evolutionarily adaptive strategy, but can be implemented via many different cognitive mechanisms. Sensitivity to statistical dependency in the behavior of other people is a factor that discriminates between possible mechanisms: simple rule based strategies may be unaffected by dependency, while more sophisticated social learning strategies should take it into account. We use a Bayesian model to determine how rational agents should incorporate the effects of statistical dependency when learning from other people, conducting two experiments that examine whether human learners behave similarly. We find that people are sensitive to two different patterns of dependency, supporting the use of a sophisticated strategy for social learning.
\end{abstract}

\section*{Introduction}

Social learning is a key factor in the human ability to adapt to a wide variety of environments and plays an important role in cultural transmission of information (Boyd \& Richerson, 1988, 2005). Formal models have shown that social learning is an evolutionarily adaptive strategy, able to outcompete individual learning (Laland, 2004). However, there are many possible mechanisms by which social learning could be implemented, ranging from blind imitation to making sophisticated inferences about the beliefs that underlie that behavior. While evolutionary models tell us that social learning should be favored, they don't tell us which mechanism human learners might be using. This question is particularly important given results showing that both adults and children sometimes "overimitate", reproducing another's unnecessary actions (e.g., Lyons, Young, \& Keil, 2007; Nielsen \& Tomaselli, 2010; McGuigan, Makinson, \& Whiten, 2011).

In this paper, we explore the mechanisms behind human social learning by examining how sensitive people are to statistical dependency in the behavior of other people. For example, imagine hearing from two friends that they visited a particular restaurant. Taken at face value, this seems like strong evidence that the restaurant might be a good place to eat. But if you discover that one friend went there after finding out that the other had been, the two pieces of information are no longer statistically independent and the evidence they provide about the quality of the restaurant is reduced. And if one friend had taken the other there, it is reduced even further.

Examining whether human social learning is sensitive to statistical dependency provides an opportunity to discriminate between social learning strategies. Simpler rule-based approaches such as "imitate the majority" should be insensitive to the subtleties of how other people's behavior is generated, focusing just on the behavior itself. In contrast, if social learning is based on rational inferences from the available data, the way in which those data are generated should
matter a great deal (for an example see Buchsbaum, Gopnik, Griffiths, \& Shafto, 2011). Determining the consequences of dependencies in other's behavior involves reasoning about their mental states and the factors that contribute to their decisions, requiring a sophisticated approach to social learning.

To assess whether people are appropriately sensitive to statistical dependency in the behavior of others, we developed a Bayesian model for a simple social learning task. The model indicates what inferences a rational agent should draw when statistical independence is violated in different ways. We ran two behavioral experiments using this social learning task, finding that people are sensitive to two forms of dependency. These results support the idea that human social learning is based on reasoning about the mental states of other people, rather than simpler strategies such as imitating the majority.

\section*{Learning from others}

Before presenting our model and experiments, we will summarize some of the key theoretical and experimental results on cultural evolution and social learning. These results break down into three areas of research. At the largest scale, models of cultural evolution have examined how the learning strategies adopted by individuals impact the spread of different behaviors between generations. Within generations, models of what are called "information cascades" have been used to analyze the rapid spread of novel innovations among populations. Finally, a number of studies have explored how individual people learn from informant testimony.

\section*{Cultural evolution}

Theoretical studies of cultural evolution have shown that social learning has adaptive advantages (Boyd \& Richerson, 1988, 2005; Laland, 2004). However, many of these studies analyze systems where individuals are faced with the choice of either learning from the environment or learning socially (Rogers, 1988). In reality, learners are likely to combine both environmental and social information when making a decision. Perreault, Moya, and Boyd (2012) modeled agents who choose a behavior based on a Bayesian learning algorithm which integrates social and environmental information. In this model, agents assumed that the social cues provided by other agents were independent from one another. This assumption was justified by the fact that all behavioral transmission happened between generations where the probability that the informants learned from each other was low. However, many behaviors are transmitted within generations, where informants are likely to share information.

\section*{Information cascades}

Unlike the cultural evolution literature, the literature on information cascades, a within-generation model of social decision-making developed by economists, takes into account the statistical dependency between agents (Bikhchandani, Hirshleifer, \& Welch, 1992). The basic scenario has a sequence of agents each making a decision by combining the information provided by the decisions made by previous agents with that provided by a small amount of private data. An information cascade occurs when agents adopt the majority belief, regardless of their own private information. The cascade persists as more agents enter the population and adopt the majority belief. Bikhchandani et al. (1992) analyzed how rational agents who took into account dependencies in previous responses would act in this situation, and showed that information cascades are surprisingly common. This result provides a potential explanation for the adoption and spread of fads and fashions, as well as boom-bust cycles in the economy. Information cascades have been tested in the laboratory using a simple scenario that provided the inspiration for the experiments we present later (Anderson \& Holt, 1997), but this previous work did not examine the consequences of manipulating people's beliefs about statistical dependency.

\section*{Individual decision making}

Social learning, and imitation in particular, have been studied extensively by psychologists. This work has generally demonstrated that adults and even young children are sensitive to many aspects of the knowledge and mental states of their social informants (for some well known examples see Meltzoff, 1995; Gergely, Bekkering, \& Kiraly, 2002; Carpenter, Call, \& Tomasello, 2005). Related work on how children learn from testimony has similarly found that children take many factors into account, including the prior accuracy (e.g., Koenig \& Harris, 2005; Corriveau, Meints, \& Harris, 2009), expertise (e.g. Jaswal, 2006; Sobel \& Corriveau, 2010) and certainty (Jaswal \& Malone, 2007; Tenney, Small, Kondrad, Jaswal, \& Spellman, 2011) of informants. However, other work has found that in some situations, people appear to simply copy the beliefs of others. Adults often disregard their own judgments when socially pressured (for a review see Cialdini \& Goldstein, 2004), and both adults and children may sometimes conform to a majority opinion that conflicts with their own direct perceptions (Asch, 1956; Corriveau \& Harris, 2010). Looking at the effect of statistical dependency can help us determine if this conformity is the result of a simple rule-based strategy, or a more sophisticated inference process.

\section*{Rational social learning}

Many inferences that people make rely upon a combination of their own experience and the behavior of other people. In order to determine how a sophisticated agent should combine these forms of information, we developed a Bayesian model that can incorporate different patterns of dependency. This
model makes direct predictions that we can test experimentally, having no free parameters.

We assume that agents receive some directly observed data about the state of the world, \(d\), and testimony from \(n\) informants \(t_{1}, \ldots, t_{n}\). To make a decision, learners evaluate a potential hypothesis, \(h\), using Bayes' rule,
\[
\begin{equation*}
p\left(h \mid d, t_{1}, \ldots, t_{n}\right) \propto p\left(t_{1}, \ldots, t_{n} \mid d, h\right) p(d \mid h) p(h) \tag{1}
\end{equation*}
\]
where \(p\left(h \mid d, t_{1}, \ldots, t_{n}\right)\) is the posterior probability of \(h\), the degree of belief assigned to \(h\) after receiving the data and testimony, and \(p(h)\) is the prior probability of \(h\), the degree of belief assigned to \(h\) before receiving any evidence.

In order to estimate the probability of the testimony, \(p\left(t_{1}, \ldots, t_{n} \mid d, h\right)\), the learner should consider the sources of information that each informant had access to. If the data the learner observes, \(d\), is unknown to the informants, then \(p\left(t_{1}, \ldots, t_{n} \mid d, h\right)=p\left(t_{1}, \ldots, t_{n} \mid h\right)\). We will assume that this is the case, since it simplifies calculations and is consistent with the task we use in our experiments. The form of \(p\left(t_{1}, \ldots, t_{n} \mid h\right)\) depends on how the informants generate their testimony. We first consider the case of independent testimony, and then discuss two different patterns of dependency.

\section*{Independent testimony}

If the informants' testimonies are independent of one another given \(h\), then the probability of a series of testimonies is equal to the product of the probability of the individual testimonies:
\[
\begin{equation*}
p\left(t_{1}, \ldots, t_{n} \mid h\right)=\prod_{i=1}^{n} p\left(t_{i} \mid h\right) \tag{2}
\end{equation*}
\]

If the testimony produced by the informants is based on their own experiences, this needs to be taken into account in calculating the probability that they would produce their testimony. More formally, if we assume that informant \(i\) received private data \(d_{i}\), we obtain \(p\left(t_{i} \mid h\right)\) by marginalizing over \(d_{i}\),
\[
\begin{equation*}
p\left(t_{i} \mid h\right)=\sum_{d_{i}} p\left(d_{i} \mid h\right) p\left(t_{i} \mid d_{i}\right) \tag{3}
\end{equation*}
\]
where \(p\left(t_{i} \mid d_{i}\right)\) is the probability that the informant produces testimony \(t_{i}\) after observing \(d_{i}\). One possibility is that informants deterministically give testimony that supports the hypothesis with the highest posterior probability, with \(p\left(t_{i}=\right.\) \(\left.h_{i} \mid d_{i}\right)=1\) for \(h_{i}=\arg \max _{h} p\left(d_{i} \mid h\right) p(h)\). This is typically assumed in models of information cascades (e.g., Bikhchandani et al., 1992). Alternatively, empirical (Vulkan, 2000) and theoretical (Luce, 2005; Shepard, 1958) results in psychology suggest that in many cases people "probability match", so that informants would give testimony in support of a hypothesis proportional to the informant's posterior probability of the hypothesis, with \(p\left(t_{i}=h_{i} \mid d_{i}\right) \propto p\left(d_{i} \mid h_{i}\right) p\left(h_{i}\right)\). We evaluate both the maximizing and probability matching models.

\section*{Dependent testimony}

If multiple informants give testimony based on shared information, then the probability of any single testimony is not
independent from the others. We consider two cases: where informants give their testimony sequentially, with each informant hearing the preceding testimony, and where informants base their testimonies on shared private data.

Sequential testimony Much of the theoretical work on information cascades assumes that informants give their testimony sequentially. Each informant uses their own private information, and the testimony of previous informants to make a decision as to which option to support. Formally, the testimony of informant \(i\) is based on the previous testimony of the previous informants, \(t_{1}, \ldots, t_{i-1}\), and their own private data, \(d_{i}\). The probability of \(t_{1}, \ldots, t_{n}\) is then
\[
\begin{equation*}
p\left(t_{1}, \ldots, t_{n} \mid h\right)=p\left(t_{1} \mid h\right) \prod_{i=2}^{n} p\left(t_{i} \mid t_{1}, \ldots, t_{n}, h\right) . \tag{4}
\end{equation*}
\]

The value \(p\left(t_{i} \mid t_{1}, \ldots, t_{i-1}, h\right)\) can be found recursively by finding the values for \(p\left(t_{1} \mid h\right)\) up to \(p\left(t_{i-1} \mid t_{1}, \ldots, t_{i-2}, h\right)\) :
\[
\begin{equation*}
p\left(t_{i} \mid t_{1}, \ldots, t_{i-1}, d_{i}, h\right) \propto\left(\prod_{j=1}^{i-1} p\left(t_{j} \mid t_{1}, \ldots, t_{j-1}, h\right)\right) p\left(d_{i} \mid h\right) p(h) . \tag{5}
\end{equation*}
\]

As in the case of independent informants, we can find \(p\left(t_{i} \mid t_{1}, \ldots, t_{i-1}, h\right)\) by marginalizing over the private information, \(d_{i}\), and assuming informants apply Bayes' rule and then either maximize or probability match.

Shared private data If the informants all provided testimony based on a single piece of data (e.g., they all went to the restaurant together), then the probability of this testimony can be found by marginalizing over this shared private data. Denoting the shared data \(d^{\prime}\), we have
\[
\begin{equation*}
p\left(t_{1}, \ldots, t_{n} \mid h\right)=\sum_{d^{\prime}} p\left(d^{\prime} \mid h\right) \prod_{i} p\left(t_{i} \mid d^{\prime}, h\right) \tag{6}
\end{equation*}
\]
where the probabilities \(p\left(t_{i} \mid d^{\prime}, h\right)\) are calculated by applying Bayes rule and assuming either maximizing or probability matching to the posterior, as above.

\section*{Reasoning about balls and urns}

The consequences of different forms of dependency for rational social learning can be hard to imagine in abstract, so we will work through a concrete example in detail. One of the simplest examples that illustrates these consequences is the "ball and urn" scenario used in the information cascade experiment conducted by Anderson and Holt (1997). This scenario is also the basis for our own experiments.

Imagine there are two colored urns. One of the urns is colored red, the other urn is colored blue. An experimenter explains that in the red urn \(\frac{5}{6}\) of the balls are red, and the rest of the balls are blue. In the blue urn the proportions are reversed. In secret, the experimenter pours one of the urns into a bag. She then shows a ball to each of three informants, and one to the participant. The informants say which urn they think was used to fill the bag, based on the information available to them. The experimenter then asks the participant to decide

Figure 1: Probability of agreeing with the majority opinion in the simple balls and urns task used in Experiment 1, for both the Bayesian model and human participants.
which urn was used to fill the bag, based on the testimony of the informants and the ball seen by the participant.

If all three informants agreed with each other and thought the bag was filled from the red urn, but the participant got a blue ball, what should the participant say? We will analyze three conditions, corresponding to the three cases presented in the previous section. The predictions for the three conditions are shown in Figure 1(a) for the maximizing model and in Figure 1(b) for the probability matching model, using the true probabilities of red and blue balls for \(p(d \mid h)\) and assuming both hypotheses are equally likely for \(p(h)\).

\section*{Independent testimony}

Imagine that the three informants are all in separate rooms and each receive a different ball sampled from the bag, making their testimony completely independent. In this case, the model predicts that the participant should agree with the social testimony, picking the red urn. The model infers that all three informants all probably received red balls and three red balls outweigh the participant's single blue ball.

\section*{Sequential testimony}

In this case, all three informants might be sitting at the same table and each receive a different ball, but have the opportunity to hear the answer given by the previous informants before providing their testimony. This is the situation that was analyzed in Anderson and Holt's (1997) experiment. If the informants give their testimony sequentially, the model again predicts that the participant should agree with the social testimony. However, the model places less weight on the hypothesis that the red urn was used to fill the bag. The model takes into account the fact that the three informants shared information. If the first two people received red balls and the third person received a blue ball, they may still all agree that the red urn was used to fill the bag even if the third person goes against the private evidence she received - a mere blue ball against two likely red balls - and votes in favor of the majority. This possibility makes the model less sure of its decision compared to the independent condition.

\section*{Shared private data}

Now, consider what happens if all three informants are sitting at the same table and all observe exactly the same ball, rather than each seeing a separate ball drawn from the bag. If all three informants saw the same ball, the model is evenly
split between the two urns. On the one hand, the three informants probably received a single red ball, but the participant received a blue ball. With one red ball and one blue ball on the table, the balls provide equal evidence for either urn being used to fill the bag.

\section*{Summary}

Even in a simple scenario with two hypotheses and three informants, a rational social learner should act differently in response to different patterns of statistical dependency. To compare our model with human behavior, we ran an experiment to see how people incorporate their own understanding of the information each informant used to give their testimony.

\section*{Experiment 1: Consistent informants}

Experiment 1 used the scenario presented in the previous section, with three informants providing consistent testimony that went against the private data received by the participant. There were three conditions corresponding to the independent testimony, sequential testimony, and shared private data.

\section*{Methods}

Participants A total of 120 participants were recruited through Amazon Mechanical Turk (http://www.mturk.com). Participants were compensated \(\$ 0.25\) for their time. They were randomly assigned to one of three experimental groups: the independent condition ( \(n=37\) ) or the shared testimony \((n=41)\), or shared-data ( \(n=45\) ). No participants were dropped from the analysis.

Stimuli The experiment was a web-administered survey involving text and pictures. A cartoon of a brown haired woman was the experimenter. Three cartoon women were the informants. The informants differed in terms of hair color, hair style, skin color, and shirt color. Each urn was a picture of a red or blue opaque urn. The balls were colored red and blue.

Procedure First a woman named Jane (the experimenter) introduced the urns. She explained that five-sixths of the balls in the red urn were red, and one-sixth were blue. The opposite was true for the blue urn. She introduced her three friends (the informants), and explained that she was going to pour one of the urns into a bag and give a ball from the bag to each of her three friends. The friends would then tell the participant which urn they think the bag was filled from. In all three conditions the three informants agreed that the bag was filled from the red urn. The participant then saw a blue ball. \({ }^{1}\)

In the independent testimony condition the participant was shown three doors, and was told that one informant was waiting in each room. Inside, each informant sat behind a desk.

In the sequential testimony condition the informants sat behind a long table. The informants gave their testimony in order down the table and acknowledged that they had used their own ball and the testimony of previous informants to make

\footnotetext{
\({ }^{1}\) The actual colors were randomized, so half the participants received testimony favoring the blue urn and then saw a red ball.
}
their decision, but did not see anyone else's ball. Each informant agreed with the previous informants' testimony.

The shared private data condition was the same as the sequential testimony condition, except that a single ball was shared between the informants, and each informant said that they saw the same ball as the other informants. The experimenter then showed the participant a single blue ball, contrary to the three informants' testimony.

Finally, the experimenter asked participants to rate how likely it was that the bag was filled each urn. Participants responded to the survey on an 11-point scale, with 0 corresponding to "definitely the blue urn", 10 to "definitely the red urn", and 5 to "equally likely the blue urn or red urn".

\section*{Results and Discussion}

Ratings were placed on a consistent scale, corresponding to agreement with the majority, by recoding a rating \(x\) to \(10-x\) if testimony favored the blue urn. The mean rescaled ratings for all conditions are shown in Figure 1(c). Overall, participants sided with the informants' testimony over their own private information most in the independent condition, second in the sequential testimony condition, and least in the shared private data condition. The ordering of the means are consistent with the model predictions. The matching model provided a good model fit to the data (Pearson's \(r=.90\) ).

We analyzed the effect of condition on participant responses using an ANOVA. The effect of condition was significant \((F(2,99.1)=7.749, M S E=49.56, p<0.001)\). We explored the differences between conditions using planned t-tests. The difference between the independent and shared private data conditions was significant (two sample t-test, \(t(80)=3.88, p<.001)\) as well as the difference between the sequential testimony and shared private data conditions (two sample t-test, \(t(84)=2.66, p<.01\) ). The difference between the sequential testimony and independent testimony conditions was not (two sample t-test, \(t(76)=0.96, p=.34\) ).

The difference between the shared private data condition and the independent condition suggests that participants were able to use their knowledge of what information informants received to evaluate the informants' testimony. Because the three informants received the same ball and gave the same testimony, participants were able to weigh their judgments against their own conflicting ball.

However, both the maximizing and the probability matching models predict that in the shared private data condition the probability of the bag having mostly red balls is approximately \(50 \%\) : less than the participant's average value of \(60 \%\). Even though this difference was not significant (one sample t-test, \(t(44)=1.31, p>.05\) ), participants may place more weight on informant testimony than the model predicts.

At first glance, the null result between the sequential testimony and independent testimony conditions suggests that people respond similarly in the cases of independent testimony and sequential testimony. However, the magnitude of the difference between these two conditions predicted by the model is relatively small. This suggests instead that the sce-

Figure 2: Probability of agreeing with the majority opinion in the more complex task used in Experiment 2, for both the Bayesian model and human participants.
nario used in previous experiments on information cascades may not be sufficient to distinguish between how people use independent testimony over sequential testimony, a limitation that we address in our second experiment.

\section*{Experiment 2: Dissenting informant}

The ball-and-urn scenario presented above does not result in situations where there is a large expected difference between the independent testimony and sequential testimony conditions. In order to assess whether people are sensitive to the difference between these two patterns of dependency, we changed the scenario by having the third informant dissent from the previous two informants. To give a reason why the informant would dissent, a single diagnostic ball (either white or black) was added to each of the two urns. Since each diagnostic ball was present in only one of the two urns, any informant who received the diagnostic ball would know exactly which urn was used to fill the bag. We also made two other changes. First, the participant did not receive their own ball, having to make a judgment based purely on the testimony of the informants. Second, in the shared private data condition only the first two informants received the same ball. This was done so that the dissenter received her own ball, providing an explanation for why she might dissent.

The model predictions are given in Figure 2(a), for maximizing, and Figure 2(b), for probability matching. The addition of a low-probability diagnostic ball does not substantially change the model predictions in the independent condition. However, it makes an important change to the predictions in the sequential testimony condition, most dramatically in the maximizing model. The model predicts that the last informant will dissent only if she received a diagnostic ball. Since she does dissent, she most likely received a diagnostic ball and so the participant should side with the dissenter over the majority (a similar but somewhat more subtle effect occurs for the probability matching model). Finally, in the shared private data condition, the dissenter probably received a different colored ball than the two informants in the majority. This provides equal evidence for either urn.

\section*{Methods}

A total of 124 participants were recruited through Amazon Mechanical Turk. Participants were compensated \(\$ 0.25\) for their time. They were randomly assigned to one of three experimental groups: the independent condition \((n=41)\) or the
shared testimony ( \(n=41\) ), or shared private data \((n=42)\). No participants were dropped from the analysis.
Stimuli The stimuli were identical to those in Experiment 1, except for the urns shown. Instead of using opaque colored urns, the urns were replaced with a picture of a clear jar filled with a mix of red and blue balls. A single diagnostic ball (either white or black) was placed in each urn. Each urn was labeled either "Jar A" or "Jar B".
Procedure The procedure was the same as Experiment 1, except for the following changes. References to the "red urn" and the "blue urn" were replaced by references to "Jar A" and "Jar B". In all three conditions the last informant dissented from the previous informants, and supported the belief that the bag was filled from the other urn. In the shared private data condition, the first two informants received the same ball. The last informant received a different ball. At the end of the experiment the participant did not see their own ball and made their judgments based solely on the informants' testimonies. Responses were made on the same 11-point scale as in Experiment 1, changing the names of the urns appropriately.

\section*{Results and Discussion}

Ratings were rescaled as in Experiment 1. The mean rescaled ratings are shown in Figure 2(c). Participants sided with the majority testimony most in the independent testimony condition, second in the sequential testimony condition, and least in the shared private data condition. The means and order of the results are consistent with the probability matching model predictions, but not the maximizing model predictions. The probability matching model provides a good fit for the experimental data (Pearson's \(r=.94\) ).

We analyzed the effect of condition on participant responses using a one-way ANOVA. The effect of condition was significant \((F(2,54.3)=5.561, M S E=27.13, p<\) 0.005 ). We explored the differences between the conditions using planned t -tests. The difference between the independent testimony and sequential testimony conditions was significant (two sample t-test, \(t(80)=3.12, p<.005\) ) as well as the difference between the independent testimony and shared private data conditions (two sample t-test, \(t(81)=3.16, p<\) .001 ). The difference between the sequential testimony and shared private data conditions was not significant (two sample t-test, \(t(81)=0.22, p>.82\) ).

The difference between the independent testimony and sequential testimony conditions suggests the learning mechanism that participants use is sensitive to social information that is shared between informants. The difference between the shared private data condition and the independent testimony condition supports our conclusion from Experiment 1 that people are sensitive to non-social shared information.

Qualitatively, participants' performance resembles the probability matching model more than the maximizing model used in earlier work on information cascades. However, in both the sequential testimony and the shared private data con-
ditions participants sided with the majority slightly more than the probability matching model predicts, suggesting that even though individuals are able to utilize shared information that informants use to make their judgments, they may place more trust in the informants' testimony. This difference was significant in the Shared Private Data condition (one sample \(t\)-test, \(t(41)=2.867, p<.01)\), but not significant in the sequential testimony condition (one sample t-test, \(t(40)=.54, p>.05\) ).

\section*{General Discussion}

The goal of this research is to determine whether human social learning is based on a sophisticated strategy that appropriately takes into account dependencies in the behavior of other people. To answer this question, we developed a Bayesian model that indicates how patterns of dependency should affect social learning. The model makes clear predictions about two kinds of dependency - sequential testimony and shared private data - which we tested through two experiments. Experiment 1 showed that people are sensitive to shared private data, using a task that has been employed in previous experiments on information cascades. Experiment 2 showed that people are sensitive to sequential testimony, using a task that is more sensitive to this kind of dependency. However, in both experiments people's judgments were influenced by dependency less than they should have been.

Our results have implications for models of cultural evolution and information cascades. For models of cultural evolution, they offer insights into the mechanisms that underlie social learning, and suggest that patterns of dependency should be taken into account in contexts where agents might encounter dependent social cues. While models of information cascades typically assume sequential testimony, our results show that people are sufficiently sensitive to patterns of dependency that information cascades will be even more probable if it is assumed that informants provide independent testimony. In addition, the matching model provided a closer qualitative and quantitative fit to human performance than the maximizing model. This empirical evidence conflicts with the assumption that informants maximize their posterior used in previous work on information cascades (e.g. Bikhchandani et al., 1992) and helps explain some of the patterns of "errors" observed in the experiments by Anderson and Holt (1997).

Taken together, our findings suggest that human social learning mechanisms are fairly sophisticated. People do not just use simple rule-based imitation strategies. Instead they are able to integrate their own private information with informants' testimony, and take into account how each informant decided upon their testimony. This implies that human cultural evolution is not simply a result of individuals making a trade-off between acquiring their information socially or through trial-and-error learning, but is instead the result of complex decisions that draw on beliefs about informants' sources of information. When learning from testimony, learners are asking themselves the question: "and just how do you know that?"

\begin{abstract}
Making a choice between alternatives can influence our subsequent evaluation of the selected option (e.g. Sharot, Velasquez \& Dolan, 2010). Thus, in resolving psychological uncertainty, the act of making a judgment itself appears to have a constructive role in subsequent related decisions. This study focuses on emotional ambivalence and the development of affective evaluations over two stages, such that (just) making an intermediate evaluation in the first stage is shown to influence the overall affective evaluation in the second stage. Models based on classical probability theory, which assume that an intermediate evaluation simply reads off an existing internal state, cannot accommodate this result in a natural way. An explanation is offered with a quantum probability model, which, under specific circumstances, requires the measurement of an internal state to have a constructive role. The predictions of the quantum probability model were supported by the empirical results.
\end{abstract}

Keywords: Quantum probability; Interference effects; Affective uncertainty.

\section*{Introduction}

One basic fact about cognition is that it reflects uncertainty. In fact cognition appears to involve several kinds of uncertainty. As well as uncertainty regarding future events, there is uncertainty about internal states, an inevitable consequence of the fact that life events are often agglomerations of pleasant and unpleasant components. For example, consider 'emotional ambivalence', the apparent ability of the cognitive system to concurrently represent positive and negative affect. Emotional ambivalence is reflected in e.g., students' thoughts about graduation day or advertisements with mixed emotional appeals (Larsen, McGraw \& Cacioppo, 2001; Williams \& Aaker, 2002).

Understanding how the cognitive system resolves affective uncertainty presents challenges (e.g. Brehm \& Miron, 2006). For example, is positive and negative affect experienced sequentially or simultaneously? What happens when people are asked to make a judgment about their affective state whilst experiencing affective uncertainty? Does this judgment resolve uncertainty or does the act of
making the judgment itself influence their affect in the same way that choice has been shown to have a constructive influence on preference (e.g. Sharot, Velasquez \& Dolan, 2010)? Our objective in this paper is to propose an ambitious new perspective on this question, based on quantum probability (QP) theory (note that in this work by QP theory we simply mean the rules for how to assign probabilities to events from quantum theory; for more specific proposals see Aerts, 2009, or Atmanspacher, Romer \& Wallach, 2006).

We can acquire some preliminary intuition from models for response times in choice problems, such as random walk models (e.g., Ashby, 2000; Busemeyer \& Townsend, 1993; Ratcliff \& Smith, 2004; Usher \& McClelland, 2001). In this influential class of models, discriminating between two options involves an accumulation of evidence, so that, on every step, the weight for a particular option is increased. Crucially, at any time point, the system is assumed to be in a specific state. This state may reflect large or little weight for a particular option, but, regardless, it has to be at a specific state. Classical approaches must assume that the system is always at a particular state, even if knowledge of this state is uncertain. Such an assumption seems straightforward. How else could we build a model?

Yet, there is an alternative, intriguing possibility, which emerges from the recent uses of QP theory in cognitive modeling (Busemeyer \& Bruza, 2012; Pothos \& Busemeyer, in press). QP theory is a framework for assigning probabilities to observables and, therefore, potentially relevant wherever there is a need to formalize uncertainty. QP cognitive models often have the same intentions (Griffiths et al., 2010; Oaksford \& Chater, 2007) as classical probability models. But, classical and QP frameworks are founded on different axioms. QP models incorporate certain unique features, such as superposition and the capacity for interference, and there has been growing interest in exploring the relevance of such features for cognitive modeling (e.g., Aerts, 2009; Atmanspacher, Filk \& Romer, 2004; Blutner, 2009; Busemeyer, Pothos, Franco \& Trueblood, 2011; Khrennikov, 2010; Pothos \& Busemeyer, 2009; Wang et al, in press).

In QP theory, a superposition state has amplitude (weight) across more than one possibility. Suppose we are interested in representing whether a stimulus induces a positive or negative affect. Classically, the situation is straightforward: if we are uncertain about a person's state, we assign probabilities to the person having a positive or negative affect. Perhaps there is a dynamic process which evolves (reshuffles) the person's state, until a final state is reached. But, the person is always assumed to be at a particular state. The situation with a QP approach is markedly different: as long as there is weight for both possibilities, the person is in a superposition of possibilities, and it is impossible to interpret the person as being at a particular state, rather, there is a potentiality for each possibility. That this has to be the case is not obvious and it is the result of the famous Kochen-Specker theorem in QP theory. The key implication, which is fundamental to QP theory, is that a transition from a superposition to a definite state must have a constructive role.

The QP perspective enables a simple, but surprising, empirical prediction. The relevant difference between the classical and the QP approach is that in the former the system is always assumed to be at a particular state, while in the latter there is a distinction between particular states and superposition states. Therefore, consider a situation in which affective evaluation is developed over two steps, such that each step involves a stimulus presentation. Classically, it should not matter whether the person is asked to provide an affective evaluation just after the second step, or after the first step as well. In the latter case, the intermediate evaluation would simply 'read off' the existing state and so this should not affect the overall outcome of the affective evaluation. However, in the QP model, an action of affective evaluation (a "measurement") can have a profound impact on the state of the system and, therefore, the intermediate evaluation influences the eventual outcome of the second evaluation. Note that a classical model could incorporate the possibility that an evaluation (or rating etc.) has a constructive role, but this could only be done with additional assumptions, which are not part of classical probability theory.

In the current study stimuli were hypothetical advertisements, appearing as static images. In the positivenegative (PN) condition, a single positively valenced 'positive image' was presented, followed by a mixed advert, including the same positive image presented concurrently with a 'negative image', and vice versa for the negativepositive condition (NP). In the 'single rating' condition, participants viewed the single image advert and then provided an overall affective evaluation for the mixed advert. In the 'double rating' condition the same participants provided an intermediate rating to the single advert, before viewing the mixed advert and rating it. Note that the relative order of the images is likely to impact on the final evaluation. Moore (2002) demonstrated order effects in Gallup poll questionnaires (see also Bergus et al., 1998; McKenzie, Lee, \& Chen, 2002). Relatedly, Vlaev et al.
(2009) argued that pain perception depends on recent pain experiences.

Hogarth \& Einhorn's (1992) research on order effects in belief updating has obvious similarities with the current research, although as we shall see there are also some important differences. Their belief-adjustment model describes order effects as arising from the interaction of key variables including the complexity of stimuli, length of the sequence of items and whether participants respond using a Step-by-Step (SbS) procedure, where they report their judgment after integrating each piece of evidence, or an End-of-Sequence (EoS) procedure where they report their judgment only after they have viewed all stimuli in the sequence.

In a review of previous research as well as their own experiments they argue that in the case of short sequences (i.e. between 2 and 12 items) requiring simple judgments (i.e. a single item for each stimulus in the sequence) the majority of studies employing a SbS procedure result in a recency effect whereas the majority of studies using an EoS procedure result in a primacy effect. The belief-adjustment model describes a sequential anchoring-and-adjustment process in which the current belief is adjusted by the subsequent pieces of evidence.

Although there are similarities between our research and that described by Hogarth \& Einhorn, there are also several important differences. Most results described in Hogarth \& Einhorn's paper, including their own experiments, involved 3 or more items in a sequence, whereas the current experiment is concerned with two items. The effects they described were concerned with items that were related to each other whereas in the current experiment items were chosen to be unrelated. In our experiment participants are required to evaluate each individual item in its own right whereas in the studies described in the Hogarth \& Einhorn paper each subsequent piece of evidence is evaluated with respect to an overall judgment about a person or object (e.g. trait adjectives used to make social judgments about someone's "likeableness").

However, our objective here is not to demonstrate order effects in affective evaluation, but rather to understand the potential role of an intermediate evaluation on the final one. In Hogarth \& Einhorn's terms, whether there is a difference between evaluations produced using EoS and SbS procedures for the same items viewed in the same order. For this, we need to consider some elementary QP principles.

The states of a system are represented by vectors, \(\psi\), within a multidimensional space. Different subspaces represent possibilities for \(\psi\) and a projection of \(\psi\) onto a subspace involves laying \(\psi\) onto the subspace. The squared length of this projection gives the probability that \(\psi\) is the possibility represented by the subspace (cf. Sloman, 1993). Finally, the angles between subspaces correspond to the relation between the corresponding possibilities. This can be easily understood by noting that, if a state vector is
consistent with one possibility, then we want it to have large projections on related possibilities.

Figure 1: An illustration of how the state for the mixed image is created in the PN condition.

In Figure 1 we represent various possibilities for the affective state of the participant in the PN condition. The positive and negative affect subspaces correspond to purely positive and negative affect respectively; they are orthogonal, since a state in the positive affect subspace must have a zero projection onto the negative affect one. The positive and negative image subspaces represent the affective impact of seeing a positive and negative image during the experiment, respectively. These two subspaces are also nearly orthogonal since the images were chosen to be unrelated. Note that, in this example, the positive image subspace is close to the positive affect one, since perceiving a positive image is more likely to lead to a positive affect (the state vector created as a result of perceiving the positive image has a large projection to the positive affect subspace).

In the single rating condition, after perceiving the positive image, the state vector is aligned with the positive image subspace. The impact of introducing the negative image is represented by a rotation of the state vector, denoted as U , which leads to the state labeled as 'PN single rating'. The subsequent projection to the negative affect subspace is a measure of how negative we expect the resulting rating to be (the thick line along the bad feeling subspace). Specifically, the squared length of the projection of the mixed image state onto the negative affect subspace determines the probability of a negative rating; it is natural to assume that the higher this probability, the more negative the rating for the mixed image.

In the double rating condition, after perceiving the positive image, the intermediate rating is assumed to lead to a transition to the positive affect subspace. This is the critical difference between the single rating and the double rating conditions, which can lead to a prediction about behavioral differences depending on the presence of the intermediate rating or not. In the double rating case, once
the rating for the first image is completed, as before, the impact of introducing the negative image leads to the same angle rotation \({ }^{1}\). But, in this case the starting state is different (it is aligned with the positive affect subspace), therefore the resulting state corresponding to the mixed image is different too (labeled as 'PN double rating'). The resulting state is now closer to the negative affect subspace, which predicts a more negative rating.

Finally, in both the single and double rating PN conditions the final state is assumed to be closer to the negative affect subspace, than to the positive affect one, to reflect a recency effect in the importance of the negative, final image on the affective state (Trueblood \& Busemeyer, 2011).

For the NP case (Figure 2), we are led to the converse prediction, namely that the final evaluation in the double rating condition will be more positive than the one in the single rating condition. Thus, a quantum approach predicts a striking interaction in the final affective evaluation in the PN vs. NP conditions, depending on whether single ratings or double ratings are solicited, only on the basis of the role of measurement in QP theory.

Figure 2: An illustration of how the state for the mixed image is created in the NP condition.

\footnotetext{
\({ }^{1}\) A consistency consideration determines the direction of rotation. In the double rating PN condition, in transforming the state vector from the positive affect subspace to the state corresponding to the mixed image, an intermediate state cannot be aligned with the positive image subspace.
}

\section*{Method}

\section*{Participants}

Fifty-four Swansea University students participated in the experiment for course credit ( 45 women, 9 men, average age 21.74 years).

\section*{Stimuli}

Realistic-looking adverts were created, so that the positive and negative versions would make sense together. Different advertised products were used for the PN condition (insurance; see Figure 3 for example) and the NP one (smartphone), so as to avoid interference between conditions. For the PN set there were three positive images individually presented, and three mixed images with each of the positive images joined with a negative one, and analogously for the NP set. All images were piloted to confirm their intended affective response and their unrelatedness. The images were randomly presented with 24 adverts for a camera, which were included for a different study and acted as fillers in the current experiment.

Figure 3: Sample advert used in PN condition and procedure for presentation of single and double rated adverts.

\section*{Procedure}

Participants first completed a six-item current mood questionnaire. They were then told that they would see several adverts and that for each advert, when asked, they should answer the question 'how does this advert make you feel?', responding on a nine-point scale, with anchors "very unhappy/very happy". Each trial involved the presentation of a single image, followed by a request for rating (double rating condition) or not (single rating condition), followed by the mixed image and a final request for rating (Figure 3). Trials were organized into two blocks. One block contained the six single rating PN adverts and six double rating NP ones, together with 12 filler adverts (which were also rated). The other block contained the same adverts, but switching the requirement for single vs. double rating. Block order and trial order within blocks were randomized across participants.

\section*{Results}

As we had previously established the valence of the images (with the pilot study), we excluded four participants because their ratings for the single image adverts were over one standard deviation below (for positive adverts) or above (for negative adverts) the mean.

We conducted a two (advert type condition: PN vs. NP) \(\times\) two (rating condition: single vs. double) repeated measures ANOVA on the participants' ratings for the mixed adverts. There was a main effect of advert type \((F(1,49)=7.98\), \(p=.007\) ), but not of rating condition \((F(1,49)=0.04\), n.s. \()\). Crucially, the advert type x rating condition interaction was significant \((F(1,49)=10.96, \mathrm{p}=.002)\). Paired samples t-tests further showed that double rated PN adverts ( \(M=4.04\), \(S D=1.17\) ) were rated significantly lower (i.e. unhappier), compared to single rated adverts \((M=4.34, S D=1.43\); \(t(49)=2.18, p=.02\), two tailed; \(d=.31)\). For the NP adverts, double rated adverts ( \(M=4.94, S D=1.21\) ) were rated significantly higher (i.e. happier) than single rated adverts ( \(M=4.60, S D=1.22 ; t(49)=-2.39, p=.01\), two tailed; \(d=.34\) ).

Figure 4: Mean participant ratings of single and double rated PN and NP adverts (error bars represent standard deviations).

We also considered a plausible alternative explanation, that it is the availability of a rating after the first advert, rather than the act of measurement as such, drives the observed result, a possibility consistent with anchoring (Tversky \& Kahneman, 1974). In the double rating condition, the more readily accessible rating for the first advert is perhaps a reference point, against which the rating for the second advert is computed. However, there was no evidence for such an anchoring effect, as there were low, non-significant correlations between participant ratings for the first and second advert in the PN ( \(r=.26\), n.s.) and NP ( \(r=.18\), n.s) conditions.

\section*{Discussion}

The results of the experiment confirmed our predictions. For the NP mixed adverts, an intermediate rating led to a higher final evaluation and, for the PN mixed adverts, an intermediate rating led to a lower final evaluation. Such a finding is difficult to reconcile with a classical probability perspective, without additional assumptions, since an intermediate rating should simply read off an existing internal state. However, the QP approach can predict a change of the state of the system, as a result of a measurement, and so is able to predict how an intermediate evaluation could affect the final one. Our finding resonates with the uncertainty intensification hypothesis (Bar-Anan, Wilson \& Gilbert, 2009), according to which uncertainty about an event will prolong and intensify how people feel about it. In single rating trials the impact of the first image on the final evaluation is higher, than in the double rating ones (e.g., in PN trials with a single rating, the final evaluation is more positive than with double rating). Perhaps uncertainty about the internal state, after viewing the first image, intensifies its effect on the final rating, but in the double rating condition, reducing this uncertainty results in a greater impact on the final rating from the second image (that is, the component of the mixed image which is novel). The QP model can be seen as a formalization of such ideas.

We can elaborate on the intuition of why the QP approach works. The critical point concerns the state prior to the second, final rating. In, e.g., the PN condition, the single rating case, the state prior to the second rating reflects the impact of seeing the mixed image, that is, the original positive image, together with the new negative one. The impact of this mixed imaged would be slightly weighted in favor of the negative image, since this is shown last. In the double rating case, the intermediate evaluation (which produces a result of positive affect) can be understood as a process of abstracting away some information from the first image, but emphasizing its positive affective qualities. Therefore, this makes the introduction of the negative image produce a more contrasting affective impression. In other words, accepting that the first image is positive, creates a 'perspective' of positive affect for processing the subsequent negative image, which makes it look, well, more negative. The result of the intermediate rating is thus a larger negative final rating in the PN condition and exactly vice versa in the NP one.

The intuition that a measurement is not simply a record of an existing state, but rather it creates a state, is not alien to psychology. Notably, Shafer and Tversky (1985, p.337) proposed "A probability judgment depends not just on the evidence on which it is based, but also on the process of exploring that evidence." Quantum theory provides a formal framework within which to express this intuition.

There are plenty of possible extensions to the present work. First, it would be worth exploring more the putative role of reference points in such experiments, perhaps with the provision of an external rating. Second, we would like to explore this paradigm with changes in procedure and
materials, so as to establish its robustness. Finally, there have been recent interesting analyses on the putative constructive role of decisions (e.g. Sharot et al., 2010) and it would be worth exploring further the conceptual links between these ideas and the quantum approach.

\title{
Learning nonadjacent dependencies in thought, language, and action: Not so hard after all...
}

\author{
Jon A. Willits (jwillits@indiana.edu) \\ Indiana University, Department of Psychological and Brain Sciences, \(1101 \mathrm{E} .10^{\text {th }} \mathrm{St}\). Bloomington, IN 47405 USA

\begin{abstract}
Learning to represent hierarchical structure and its nonadjacent dependencies (NDs) is thought to be difficult. I present three simulations of ND learning using a simple recurrent network (SRN). In Simulation 1, I show that the model can learn distance-invariant representations of nonadjacent dependencies. In Simulation 2, I show that purely localist SRNs can learn abstract rule-like relationships. In Simulation 3, I show that SRNs exhibit facilitated learning when there are correlated perceptual and semantic cues to the structure (just as people do). Together, these simulations show that (contrary to previous claims) SRNs are capable of learning abstract and rule-like nonadjacent dependencies, and show critical perceptual- and semantics-syntax interactions during learning. The studies refute the claim that neural networks and other associative models are fundamentally incapable of representing hierarchical structure, and show how recurrent networks can provide insight about principles underlying human learning and the representation of hierarchical structure.
\end{abstract}

Keywords: hierarchical structure; recurrent connectionist networks; nonadjacent dependencies

\section*{Background}

Human concepts, languages, goals, and patterns of action are all describable in terms of complex hierarchical structures, but our experience of them as inputs, and our production of them as outputs, is often arranged in linear strings that unfold over time. A necessary consequence of this transformation of complex structure into linear strings is that most human knowledge involves many nonadjacent dependencies, where one element predicts another element, but at a distance. These nonadjacent dependencies, whether in thought, language, or action, enormously expand the computational complexity of representing the structure of the world.

In several subfields of cognitive science, difficulty learning and representing nonadjacent dependencies has generated considerable theoretical controversy. In linguistics, the limitation of simple associative structures has been a cornerstone of arguments for abstract syntactic structures (Chomsky, 1957). In cognitive psychology, researchers argued that associative mechanisms cannot learn the vast range of nonadjacent dependencies in the world, and thus rule-
based representations are necessary for human cognition (Bever et al., 1968). In early artificial intelligence, arguments about the limitations of associative systems led to a focus on symbolic, rulebased systems (Newell \& Simon, 1961).
However, recent research has questioned the need for rule-based representations of nonadjacent structure. A number of studies have demonstrated or modeled simple learning of nonadjacent structure in memory (Cleeremans \& McClelland, 1991), goals and event structure (Botvinick \& Plaut, 2004; visual sequences (Fiser \& Aslin, 2002), and artificial grammars using linguistic stimuli (Gomez, 2002; Newport \& Aslin, 2004). These results have changed the nature of the debate concerning the extent to which knowledge of nonadjacent dependencies requires a rule-based or an association-based explanation. Although there are many specific examples of learning or failing to learn in particular situations, what is lacking is a general account of nonadjacent dependency learning. As a result, the many subfields of cognitive science (such as linguistics, cognitive psychology, and artificial intelligence) continue working on the problem separately, without a clear theory or explanation for some of the most foundational human behaviors.
The current work aims to make progress toward a general account by examining whether a fairly simple neural network model, the simple recurrent network (SRN; Elman, 1990) can provide a general model of nonadjacent dependency learning. An SRN was used because previous research (Botvinick \& Plaut, 2006; Cleeremans \& McClelland, 1991; Elman, 1991) suggests that SRNs and other recurrent networks are capable of learning nonadjacent structure. However, there is controversy about whether they can serve as general solution for all cases, especially those involving abstract, rule-like relationships (Marcus, 2000) or complex interactions between structure and meaning (Fodor \& Pylyshyn, 1988).

In the service of testing the viability of SRNs, the current work had two distinct sub-goals. First, to be a general model of nonadjacent dependency learning, SRNs ought to be able to learn nonadjacent dependencies of the types that exist in the natural
world. This includes abstract, rule-like nonadjacent dependencies, such as learning "distance-invariant" representations (for example, learning the link between the and a noun, independent of how many adjectives come between them). Second, SRNs ought to capture behavioral phenomena observed in laboratory experiments, such as facilitated learning in the presence of perceptual (Newport \& Aslin, 2004) and semantic (Willits, Lany, \& Saffran, 2013) cues. Close analysis of model behavior can then shed light on the bases of the empirical effects. The following three studies test SRNs' abilities to satisfy these criteria.

\section*{General Methodology}

The three studies shared three core features common in connectionist-modeling approaches (Rumelhart \& McClelland, 1986). First, all simulations used sets of interconnected units and weights specifying how strongly each unit was connected to each other unit. The units in the model were divided into an input group, used to specify the input stimulus in each sequence; an output group, used to specify the output response (which also served as a prediction about the next item in the sequence); and a hidden group that mediated between the input and output groups. Second, the models featured recurrent connectivity, allowing the model to feed back information about its own previous internal state in ways critical to forming internal representations of sequential structure. Third, the models all made use of weight-based encoding, where the network's knowledge was encoded in the weighted connections between units.

The goal of the network was to learn a set of weights such that, for any given input, the model's weights led to activation in the output layer that was a correct prediction of the next item in the sequence. During training, a model was given an input, its output activation was treated as a prediction of what the next input would be. This prediction was compared to the target output, and divergence error was calculated across each unit and was used to adjust the weights of the model, using a version of recurrent backpropagation through time. For each simulation, 30 different randomly initialized models were trained. Each model was trained until it reached a predetermined level of overall error, corresponding to optimal prediction performance in the task. The critical test in each simulation was the relative rate of learning across the different conditions in that study.

\section*{Study 1: Distance Invariance}

In experiments on nonadjacent dependencies using artificial grammars, the distance between dependent
items is usually fixed, with one intervening item separating dependent items. However, in many realworld cases (such as the distance between nonadjacently related events in the world, or words in language) the distance between dependent items varies. In fact, learning a "distance-invariant" representation of a nonadjacent dependency has been considered a critical phenomenon, proving the need for a rule-based mechanism.

In Simulation 1, I attempted to train an SRN to learn distance-invariant representations of nonadjacent dependencies by exposing them to the same nonadjacent dependency at multiple spans of distance between the related items. A second issue of interest was whether SRNs would show facilitation in learning longer-distance dependencies if they also had experience with the dependency at a shorter distance, a learning effect that has been demonstrated in both infants and adults (Lany \& Gomez, 2008).

\section*{Stimuli and Design}

The models in Study 1 were trained on sequences where the first element (hereafter the \(A\) item) perfectly predicted the last element in each sequence (hereafter the \(B \mathrm{item}\) ), with the sequences having a number of items (hereafter the \(X\) items) intervening between them. The sequences were of lengths 2 to 5 , resulting in distances between the \(A\) and \(B\) items spanning from zero (adjacent dependencies) to three. There were two \(A B\) pairs ( \(\mathrm{A}_{1} \& \mathrm{~B}_{1}, \mathrm{~A}_{2} \& \mathrm{~B}_{2}\) ) and six possible intervening X -items \(\left(\mathrm{X}_{1} \ldots \mathrm{X}_{6}\right)\). The x -items were distributed across trials such that they provided zero predictive value for which \(B\) would occur. The only way to predict the correct \(B\left(\mathrm{~B}_{1}\right.\) or \(\left.\mathrm{B}_{2}\right)\) was to have stored which \(A\left(\mathrm{~A}_{1}\right.\) or \(\left.\mathrm{A}_{2}\right)\) initiated the sequence. The full set of stimuli used in Study 1 is shown in Table 1.

Thirty different networks (starting from different randomly initialized weights) were trained in each of six different training conditions: (1) only Span 0 trials; (2) only Span 1 trials; (3) only Span 2 trials; (4) only Span 3 trials; (5) a mixture of all Span trials; (6) a mixture of all Span trials except Span 3.

Over the course of training, networks from all six conditions were tested on stimuli from all Span conditions (without updating the network weights during those test trials), to assess the network's performance on strings of various spans. Networks were compared at points where they had experienced the same number of trials, controlling for the amount of experience the networks had with each \(A B\) pair.

\section*{Network Architecture}

The network had 10 input and output units (one for
each \(A, B\), and \(X\) ) and 25 hidden units. A simplification of the network architecture is shown in Figure 1.

Table 1. Stimulus inputs used in Study 1.

\hline
\end{tabular}

Figure 1. A simplified depiction of the network architecture used in Study 1. The actual model had \(8 X\)-units \(\left(\mathrm{X}_{1} \ldots \mathrm{X}_{8}\right)\) and 25 units in the hidden layer.

\section*{Hypotheses}

Three main hypotheses were under investigation. First, do networks trained on longer-distance dependencies (bigger Spans) take longer to learn the dependency, as people do? Second, do networks trained in more variable conditions (Conditions 5 \& 6) learn more slowly due to increased variability and noise? Or do they, like people (e.g. Lany \& Gomez, 2008) show facilitated learning of more distant dependencies due to experience with shorter dependencies? Third, are SRNs capable of learning a distance-invariant representation? Specifically, do the networks that are trained only on Spans of 0,1 , and 2, predict the correct B item on Span 3 trials, even though they have never before experienced the dependency at that distance?

\section*{Results \& Discussion}

Figure 2 shows the average SRN performance predicting the correct B (the network's activation level for the correct B output, on X trials) for networks
trained on only a single Span, when tested on the same Span. Networks showed strong effect of taking longer to learn, as the distance between the dependent items increased. Figure 3 shows the average performance on items of Span3 distance, for networks (1) trained on Span3, compared to (2) networks trained on a mixture of all the spans (SpanX) and (3) to networks trained on all the spans except Span3 (SpanX-3). At the earliest stages of training (trials \(0-1000\) ), the networks that experienced more variability showed slight decrements in performance on Span3 test items, relative to networks trained on Span3 alone. However, at later stages of training, both SpanX and SpanX-3 networks outperformed the Span3 network on Span3 items.

Figure 2. Average SRN performance for networks trained on a single span between nonadjacently dependent items, when tested on items of the same span. The \(y\)-axis is the network's softmax activation level of the correct B unit, when the network was presented with the preceding X item.

Figure 3. Average SRN performance for networks trained on Span 3, a mixture of all Span conditions (SpanX), or all Span conditions except Span3 (SpanX-3).
Thus, in Study 1 I show that SRNs display three critical features of human learning: (1) they show increased difficulty with longer dependencies; (2) they show facilitated learning when they have had experience with shorter-distance variations of that dependency; (3) they learn distance-invariant representations of nonadjacent dependencies, making
the correct prediction for Span3 items even in the SpanX-3 condition, where they had no training with dependencies of that span. This evidence that SRNs can learn a distance-invariant representations of nonadjacent dependencies is a critical finding, as it undercuts one of the fundamental arguments against association-based representations of knowledge, and in favor of rule-based explanations of cognition.

\section*{Study 2: Abstract Rules}

Marcus et al. (1999) performed a learning study with infants, where the infants where played sequences of syllables following either an ABB repetition pattern (e.g. "go-la-la") or an ABA alternation pattern (e.g. "go-la-go"). After hearing many examples repeated multiple times, infants then heard novel test sequences that either followed or violated that rule, and showed evidence of discriminating the legal and illegal sequences. Marcus argued that because no items were co-present at training and test, associative accounts were inadequate and only rule-based models could explain behavior. Marcus (2000) further argued that SRNs (like in Figure 4), could not in principle account for this finding. A number of researchers (Altmann \& Dienes, 1999; Christiansen \& Curtin, 1999) presented distributed SRN models of this phenomenon, where microfeatures (but not items) were co-present at training and test. Marcus, however, argued that resorting to such microfeatures was proof that SRNs and other network models are fundamentally incapable of learning abstract, algebraic rules, which some believe to be fundamental to human cognition.
In Study 2, I show that a simple, localist SRN without any distributed microfeature information learns to represent abstract, rule-like structure. Marcus's (2000) characterization of SRNs was correct; a localist SRN trained in the manner he described cannot show transfer of the rule-like knowledge. That is because the network learns (during the initial training) that the elements in the test items never occur, and thus their weights are set to zero, making them unable to make use of any information about the previous items' sequential structure that may have been learned and stored in the network's recurrent or output connections. However, there is no reason to restrict training in this way; one could instead allow the model to continue learning during the test phase, and again determine whether the model learns about the rule consistent test strings more quickly than the rule-violating ones.

\section*{Stimuli and Design}

The models in Study 2 (using the architecture in

Figure 4. A depiction of the architecture in Study 2. The actual model had 12 A - and B-units and 25 hidden units.

Figure 4) were trained on the exact design from Marcus et al., shown in Table 2. During the first training phase, models were trained in one of two conditions: (1) an ABA condition, where the first item perfectly predicted the last item, and predicted that it would be repetition of itself; (2) an ABB condition, where the middle item perfectly predicted the last item, again a repetition of itself. These ABA and ABB strings were composed of six possible A's and B's, which all occurred in all possible combinations, thus making all transition probabilities uninformative, and leaving the item-independent ABA or ABB rule as the only way to correctly predict whether the final element should be an A or B. The models were then given a second training phase, where they were trained on a new \(A B A\) or \(A B B\) sequences using new \(A\) and \(B\) items, and tested to see if they learned these sequences more quickly if the new rule was consistent with the rule on which they had been trained in phase 1.

\begin{tabular}{|c|c|c|c|}
\hline ABA1 & ABB1 & ABA2 & ABB2 \\
\hline \(\mathrm{A}_{1} \mathrm{~B}_{1} \mathrm{~A}_{1}\) & \(\mathrm{A}_{1} \mathrm{~B}_{1} \mathrm{~B}_{2}\) & \(\mathrm{A}_{7} \mathrm{~B}_{7} \mathrm{~A}_{7}\) & \(\mathrm{A}_{7} \mathrm{~B}_{7} \mathrm{~B}_{7}\) \\
\hline \(\mathrm{A}_{1} \mathrm{~B}_{2} \mathrm{~A}_{1}\) & \(\mathrm{A}_{1} \mathrm{~B}_{2} \mathrm{~B}_{2}\) & \(\mathrm{A}_{7} \mathrm{~B}_{8} \mathrm{~A}_{7}\) & \(\mathrm{A}_{7} \mathrm{~B}_{8} \mathrm{~B}_{8}\) \\
\hline \(\mathrm{A}_{1} \mathrm{~B}_{3} \mathrm{~A}_{1}\) & \(\mathrm{A}_{1} \mathrm{~B}_{3} \mathrm{~B}_{3}\) & \(\mathrm{A}_{7} \mathrm{~B}_{9} \mathrm{~A}_{7}\) & \(\mathrm{A}_{7} \mathrm{~B}_{9} \mathrm{~B}_{9}\) \\
\hline \(\ldots\) & \(\ldots\) & \(\cdots\) & \(\cdots\) \\
\hline \(\mathrm{A}_{1} \mathrm{~B}_{6} \mathrm{~A}_{1}\) & \(\mathrm{A}_{1} \mathrm{~B}_{6} \mathrm{~B}_{6}\) & \(\mathrm{A}_{7} \mathrm{~B}_{12} \mathrm{~A}_{7}\) & \(\mathrm{A}_{7} \mathrm{~B}_{12} \mathrm{~B}_{12}\) \\
\hline \(\ldots\) & ... & \(\ldots\) & \(\cdots\) \\
\hline \(\mathrm{A}_{6} \mathrm{~B}_{6} \mathrm{~A}_{6}\) & \(\mathrm{A}_{6} \mathrm{~B}_{6} \mathrm{~B}_{6}\) & \(\mathrm{A}_{12} \mathrm{~B}_{12} \mathrm{~A}_{12}\) & \(\mathrm{A}_{12} \mathrm{~B}_{12} \mathrm{~B}_{12}\) \\
\hline
\end{tabular}

\section*{Results \& Discussion}

The results from Study 2 are shown in Figure 5. When the model was allowed to continue learning during the second training phase, it shows facilitated learning if the new items follow the same structural sequence as the items in the first phase. Follow-up
analyses of the network's weight configurations show this is because the network's recurrent and output weights are effectively learning the abstract structural order of the sequence. Because of this, if the new set of items are following the same structural rule, all the network needs to do is learn to adjust the input weights for the new items so that they work well with the already-learned recurrent and output weights.

Figure 5. Average SRN performance during the second stage of learning in Study 2.

These findings have very significant implications, as they (along with the findings in Simulation 2), refute claims that associative models are not capable of learning the abstract and rule-like knowledge that seems fundamental to human cognition.

\section*{Study 3: Perceptual/Semantic Bootstrapping}

Previous research on nonadjacent dependencies has mainly focused on learning to represent sequences of events, actions, or words independent of other cues about those entities, such as perceptual or semantic features or similarity. Learning structure in such a purely symbolic way would be hard. However, there is no reason to limit attention to this type of impoverished input, which is uncharacteristic of naturalistic conditions.. Studies that have examined the use of correlated perceptual cues (Newport \& Aslin) or semantic cues Willits et al.), have found that under these circumstances nonadjacent dependencies are significantly easier to learn. For example, Willits et al. found that when the items to be learned are from the same category (e.g. nonadjacently related items both foods), both infants and adults learn the dependency more easily. Learners even learn the nonadjacent dependency if the two words form a consistent mapping between categories (e.g. across set of nonadjacent pairs, foods are always paired with an animals). These findings are critical, because many of the nonadjacent dependencies people need to learn have these kinds of correlated perceptual and semantic attributes.

The question, then, is whether SRNs also exhibit facilitated learning from correlated cues, thus broadening their appeal as a general model of dependency learning, and whether they provide any insights as to why learning might be easier under these circumstances. This was investigated in Study 3.

\section*{Stimuli and Design}

The models in Study 3 were trained using the architecture in Figure 4. This architecture allowed for tests of whether correlated similarity structure affected learning by allowing each input to activate two units: (1) one item-specific unit (either an \(\mathrm{A}_{\mathrm{N}}, \mathrm{X}_{\mathrm{N}}\), or \(\mathrm{B}_{\mathrm{N}}\) ), where the letter refers to which category the item is from); (2) a category-specific unit (either Category \({ }_{\mathrm{A}}\), Category \({ }^{2}\), or Category \({ }_{B}\) ), where the category unit turned on for all inputs that came from that category.

Output Layer

Figure 6. A depiction of the architecture used in Study 3. The actual model had 25 hidden units.

The models were trained in one of three conditions (shown in Table 3). In the Consistently Same condition, the nonadjacently dependent items were always from the same category (e.g. the first item in each sequence would activate the \(\mathrm{A}_{1}\) unit and the Category \(_{\mathrm{A}}\) unit, and third item would activate the \(\mathrm{A}_{3}\) unit and the Category \({ }_{A}\) unit). In the Consistently Different condition, the nonadjacently dependent items were consistently from opposite A \& B categories. In the Inconsistent condition, the dependent items'

\(\mathrm{~B}_{1} \mathrm{X}_{\mathrm{n}} \mathrm{B}_{3}\) & & \(\mathrm{~B}_{1} \mathrm{X}_{\mathrm{n}} \mathrm{A}_{3}\) & & \(\mathrm{~B}_{1} \mathrm{X}_{\mathrm{n}} \mathrm{B}_{3}\) \\
\(\mathrm{~B}_{2} \mathrm{X}_{\mathrm{n}} \mathrm{B}_{4}\) & & \(\mathrm{~B}_{2} \mathrm{X}_{\mathrm{n}} \mathrm{A}_{4}\) & & \(\mathrm{~B}_{2} \mathrm{X}_{\mathrm{n}} \mathrm{A}_{4}\)
\end{tabular}
categories were not predictable in terms of the other unit in the dependency. Across training trials, the
models were compared to see if any of the conditions showed facilitated learning.

\section*{Results \& Discussion}

The results for Study 3 are shown in Figure 7. SRNs showed facilitated learning in both consistent conditions, but not the inconsistent conditions, results similar to behavioral experiments with infants and adults. Follow-up analyses of network behavior show this is because the network has an easier time learning the category sequences, an intriguing hypothesis to test in future work with human learners.

Figure 7. Average SRN performance for the three training conditions in Study 3.

\section*{Conclusions}

Nonadjacent dependencies are a necessary consequence of experiencing a hierarchically structured world though a linear sequence of inputs and actions. The current studies support the notion that SRNs and other recurrent networks are viable models of the representation of hierarchical knowledge. They are capable of learning to represent abstract, rule-like structure (Study \(1 \& 2\) ), and they show critical learning effects that people exhibit, such as the interaction between structure and similarity (Study 3 ).

In addition, these simulations also provide evidence for the hypothesis that many learning situations that are thought to be especially difficult (of which the learning of nonadjacent dependencies is but one example) are only difficult because the problem has been underepresented. Many cues learners might use are stripped away in overly controlled experiments, making the problem harder than it is in the real world. Complexity is not the same thing as noise, if that complexity provides learners with useful cues to the structure of the world.

\title{
Acquisition of Phrase Structure in an Artificial Visual Grammar
}

\begin{abstract}
Recent studies showing learners can induce phrase structure from distributional patterns (Thompson \& Newport, 2007; Saffran, 2001) suggest that phrase structure need not be innate. Here, we ask if this learning ability is restricted to language. Specifically, we ask if phrase structure can be induced from non-linguistic visual arrays and further, whether learning is assisted by abstract category information. In an artificial visual grammar paradigm where co-occurrence relationships exist between categories of objects rather than individual items, participants preferred phrase-relevant pairs over frequency-matched non-phrase pairs. Additionally, participants generalized phrasal relationships to novel pairs, but only in the cued condition. Taken together these results show that learners can acquire phrase structure in a nonlinguistic system, and that cues improve learning.
\end{abstract}

Keywords: statistical learning, language learnability, syntax, modality independence

\section*{Introduction}

Theories of syntax differ, however, most contain two important elements: words are members of categories (traditionally nouns, verbs, determiners, etc.) and these categories are related to each other in higher-order patterns, e.g., phrases or sentences. To give an example in English take the sentence "The cat chased the dog." The word "cat" is a member of the word class, or category, noun and it has a relationship with "the" - its determiner - forming a noun phrase. A similar relationship exists between "the" and "dog." The verb phrase is comprised of "chased" plus "the dog." Thus, the sentence consists of several phrases defined over categories, arranged hierarchically.

In the traditional view, these elements of language are not learned, but rather considered to be innate by necessity (e.g. Crain, 1992; Wexler, 1991). A number of recent studies have begun to challenge the notion that these aspects of language are unlearnable, however, particularly with respect to categories (see, e.g., Mintz, 2002). The other basic properties of syntax, namely phrases (the property of interest in the current study) and their hierarchical organization have proved more challenging for a learning account. Saffran (2001) created a miniature artificial language, based on one used by Morgan, Meier, and Newport (1987), that was defined by a grammar over classes of words. Phrase structure in this language was defined by a number of rewrite rules over a basic or
canonical sentence type: \(\mathrm{S} \rightarrow \mathrm{AP}+\mathrm{BP}+(\mathrm{CP})\), where AP , BP , and CP are phrases, and CP is an optional phrase. The phrase rewrite rules were: \(\mathrm{AP} \rightarrow \mathrm{A}+(\mathrm{D}) ; \mathrm{BP} \rightarrow \mathrm{CP}+\mathrm{F}\) or \(\mathrm{BP} \rightarrow \mathrm{E}\); and \(\mathrm{CP} \rightarrow \mathrm{C}+(\mathrm{G})\). Learning of this grammar was statistically above chance; however, it was only marginally so, leaving open the question of whether phrase structure is an innate component of human knowledge.

More recently, Thompson and Newport (2007) used an adapted version of the same language with stronger cues to phrase boundaries - in particular, phrases tended to hang together in perfectly predictive relationships, while various language-like sentential manipulations created dips in predictive dependencies across phrase boundaries that were relatively low - and found greatly enhanced learning.

More specifically, the Thompson and Newport (2007) language had a phrase structure where phrases were composed of pairs of categories of words. There were 6 categories (labeled here, for simplicity: A, B, C, D, E, and F) which formed three phrases: AB, CD, and EF. Categories were distributionally defined. That is, the only way in which words were in the same category was that they occurred in the same locations both absolutely (their place in the sentence) and relatively (their adjacency to other elements). There were a total of 18 monosyllabic words in the language, 3 per category. Phrases could take part in a variety of operations: (1) movement, (2) repetition, (3) omission, and (4) insertion, thereby creating a set of sentences where the probability of a transition between categories within phrases was high (perfect 1.0) and the probability of a transition between categories that occurred across phrase boundaries was low. Importantly, the probability of a transition between individual words was also low, both within and across phrases. Therefore, the only indicator of structure was the transitional probabilities between categories of words - a higher-order relationship. At test, adult participants selected pairs of words which comprised a grammatical phrase more often than pairs of words which had co-occurred equally often in the input but which did not form a phrase, demonstrating they had acquired an understanding of category-level relationships. That is, they had learned categories as well as which categories formed phrases and which did not.

We investigate whether higher-order category relationships of this type are learnable in a non-linguistic system, something that might be expected if such learning is domain general. We exposed participants to visual stimuli constructed to have the same properties as the auditory language used by Thompson and Newport (2007). Simple
two-dimensional objects were organized into categories, then arranged into visual arrays according to a phrase structure grammar based on how categories of objects cooccurred. After exposure, participants were tested to see if they had learned the category-based grammar governing the combination of the items in the array.

We also assessed whether and how learning was affected by the presence and reliability of (nondistributional) cues to category membership. In previous work on larger versions of auditory languages (i.e., languages with a greater number of words per category than Thompson \& Newport, 2007) we found that phrase learning is affected by the presence and reliability of cues to category membership (Wilson \& Hudson Kam, 2009, 2013). Presumably, the cue makes it easier for people to identify the categories, thereby facilitating the tracking of probabilities over the categories necessary for phrase learning. We were interested in whether this would also be true of learning in the context of a non-linguistic visual system, and so included subtle visual cues to category membership in varying degrees in different conditions.

The visual array paradigm used here is based on that originally developed by Fiser and Aslin (2001). In their third and final experiment, Fiser and Aslin exposed adult participants to a set of visual arrays in which the adjacency relationships had a specific statistical structure irrespective of absolute spatial location. There were 12 uniquely-shaped black objects. Pairs of objects formed base pairs, always appearing together, in one of three possible alignment types: (1) vertical, (2) horizontal, or (3) oblique (diagonal). Additionally, the frequencies of some base pairs and crosspair, non-base pairs of items were equated. Therefore, the lower order, joint probability of these base pairs and cross pairs were equal (i.e., \(\mathrm{P}(\) object1, object2) \(=\mathrm{P}(\) object2, object3)), but the higher-order relative statistic, their conditional probabilities, differed (i.e., \(\mathrm{P}(\) object \(2 \mid\) object 1\()=\) 1.0 vs. \(\mathrm{P}(\) object2|object3) ~ low). At test, participants reliably chose the base pairs over cross pairs, suggesting they understood the higher order conditional probability relationship. (See Figure 1 for a schematic of a sample exposure scene.)

Figure 1. Schematic of example scene from Fiser and Aslin (2001), composed of three base pairs (one vertical, one horizontal, one oblique)

Their paradigm was modified here to investigate the acquisition of a phrase structure, where statistical relationships occur across pairs of categories, as opposed to pairs of individual items. To implement these ideas in the visual array paradigm, we expanded base pair relationships to include categories of objects which were adjacent in relevant configurations, while equating the co-occurrence of individual items within and across phrase boundaries. If our hypothesis is correct, that the learning processes that contribute to learning phrase structure are domain general, then we expect learning outcomes in the visual system to be commensurate with those found in previous auditory artificial language learning work, namely that it is possible to learn from dips in transitional probability that occur between categories of items in order to understand category relatedness (i.e. phrases) and that this learning is facilitated by non-distributional cues to category membership.

\section*{Methods}

\section*{Participants}

A total of 60 adults ( 20 per condition) participated in this study for course credit in Psychology courses at the University of California, Berkeley.

\section*{Stimuli}

Twenty-four unique objects were used, each with a unique color (properties of the color to be discussed later). Objects were assigned to one of eight categories (A, B, C, D, E, F, G, and H), with three objects per category. Pairs of categories were then grouped into phrases (much like the previous experiments), in one of two forms: vertical or horizontal. Phrases were then arranged into one of 16 distinct arrays in a five by five grid, with each array containing one example of each phrase. The 16 arrays, or category constructions, are much like sentence types. As such, the arrays constitute the 'grammar' of the visual system. Four distinct example arrays are shown in Figure 2.

Figure 2. Four examples of the 16 construction types or arrays with category placement labels.

This design resulted in conditional probabilities of adjacent co-occurrence of categories within phrases being perfect (1.0). Adjacent co-occurrence of pairs of categories that were possible but not necessary - i.e, which crossed a phrase boundary - had much lower conditional probabilities: each occurred exactly once over the exposure set, and therefore with \(p=.0625\). The complete set of adjacent cooccurrence relationships, for both the vertical and horizontal dimensions appear below in Tables 1 and 2.

Table 1. Adjacent co-occurrence conditional probabilities, vertical from top category to bottom category (phrase transitions in bold)
\begin{tabular}{ccccccccc} 
& A & B & C & D & E & F & G & H \\
A & - & \(\mathbf{1 . 0}\) & - & - & - & - & - & - \\
B & - & - & .06 & - & .06 & .06 & .06 & .06 \\
C & - & - & - & \(\mathbf{1 . 0}\) & - & - & - & - \\
D & .06 & - & - & - & .06 & .06 & .06 & .06 \\
E & .06 & - & .06 & - & - & - & .06 & .06 \\
F & .06 & - & .06 & - & - & - & .06 & .06 \\
G & .06 & - & .06 & - & .06 & .06 & - & - \\
H & .06 & - & .06 & - & .06 & .06 & - & -
\end{tabular}

Table 2. Adjacent co-occurrence conditional probabilities, horizontal from left category to right category (transitions in bold)
\begin{tabular}{ccccccccc} 
& A & B & C & D & E & F & G & H \\
A & - & - & .06 & .06 & .06 & - & .06 & - \\
B & - & - & .06 & .06 & .06 & - & .06 & - \\
C & .06 & .06 & - & - & .06 & - & .06 & - \\
D & .06 & .06 & - & - & .06 & - & .06 & - \\
E & - & - & - & - & - & \(\mathbf{1 . 0}\) & - & - \\
F & .06 & .06 & .06 & .06 & - & - & .06 & - \\
G & - & - & - & - & - & - & - & \(\mathbf{1 . 0}\) \\
H & .06 & .06 & .06 & .06 & .06 & - & - & -
\end{tabular}

The adjacent co-occurrence frequencies (or joint probabilities) of some within-phrase pairs and cross-phrase pairs of objects were equated. In order to accomplish this, some object pairs (pairing of particular objects either within or across phrases) were highly frequent (occurring 26 times) and some were less frequent (occurring 6 times). In this way, the less frequent within-category object pairs had equal joint probability as some cross-phrase object pairs (those that occurred adjacently in the 6 examples of any given scene) and served as test items. Additionally, some object pairs, both within phrase and across phrase boundaries, were
reserved from the exposure set also for test purposes.
The exposure set contained 96 unique scenes total, 6 of each construction type. (An example scene appears in Figure 3.) The exposure set was seen a total of four times, and so each scene appeared four times per session. All cross-phrase object pairs occurred 24 times per exposure session. Within-phrase object pairs occurred either 24 or 104 times per exposure session. Each individual object occurred exactly 32 times in the exposure set, and so occurred exactly 128 times per exposure session.

Each slide was seen for 2.5 seconds, and was interspersed with 1 second fixation slides. Additionally, there was a 2 minute break at the halfway point. The total exposure session lasted for approximately 25 minutes.

Figure 3. Example visual array (of construction type 1 from Figure 2), with phrases outlined

Note that the visual displays merely appear as complex designs; there is nothing in the visual arrays themselves that indicates the phrasal structure. If anything, Gestalt principles (Palmer, 1999) might lead participants to 'missegment' individual arrays into components larger than the phrases. In Figure 2 array 3, for example, participants might perceive two squares rather than four phrases, or in the display in Figure 3 participants might see an archway.

\section*{Experimental Manipulation}

This study also addressed the contribution of a subtle non-distributional cue to category membership in acquisition of the phrase structure. The visual cue to category was an aspect of the color of the objects irrespective of hue. Colors for objects were selected from levels of brightness and saturation available in Microsoft Powerpoint - three hues from each level. In the cuepresent version of the visual arrays, objects from the same category were of different hues from the same brightness and saturation level. In the without cue condition, objects were randomly assigned to categories, therefore, color could not serve as a cue to category membership. A third version of the arrays contained a partially predictive cue to category membership, where two of the three objects in the category were of the same brightness and saturation level.

Figure 4. All 24 objects, shown in respective color assignment, organized into 8 levels of brightness and saturation, (category shown at bottom of column).

\section*{Tests}

There were two types of tests in this experiment designed to test whether participants understood the phrases or units of the visual grammar - very much like the phrase tests from Thompson and Newport (2007). Both tests required participants to compare two pairs of objects: one with a high category-level conditional probability and one with a low category-level conditional probability. The two comparison pairs were displayed to the left and to the right of the center square of the \(5 \times 5\) grid, as shown in Figure 5 .

Phrase Test. Some pairs of objects in the exposure set were matched for frequency - that is, had the same joint probabilities of appearing together - either within or across a phrase boundary. However, the pairs differed in that some had high category-level conditional probability (i.e., they were within a phrase) while others had a category-level conditional probability that was low (i.e,, they were not within a phrase). The first test compared these two types of pairs. There were 12 such items total, six on the first day and six on the second day.

Generalization Test. The second test was a generalization test, in which participants were tested using pairs of objects that had been reserved from the exposure set. One test pair was a novel object pair with high category-level conditional probability. The comparison pair of objects was also novel, but with a low category transitional probability (but not zero or absent). There were 12 of these items, six on the first day and six on the second day.

Figure 5. Sample test item, within-phrase object versus frequency matched objects crossing a phrase boundary (vertical phrase).

\section*{Procedure}

Participation in this study spanned two days, with each day involving an exposure session and a test session. Unlike earlier experiments that tested strictly end-state performance outcomes, we also were interested in the trajectory of learning - whether we could capture an intermediary stage of having learned some aspects, but not all, of the grammar.

On each day, participants saw the exposure set a total of eight times: four times through, followed by a two-minute break, then another four times through, for a total exposure session of about 25 minutes. Across both days, participants saw the exposure set 16 times. After exposure on both days, participants were given the two-alternative, forced choice test.

The phrase test items were always given first, followed by the generalization test items. Prior to test, participants were shown a practice comparison that contained objects that had not appeared in the scenes, first in the vertical then the horizontal orientation. Participants were instructed that they were going to indicate which of the pairs of objects they thought more likely came from the scenes they had been learning about. Responses were recorded by the experimenter, who was also advancing the test-item slides. Participants were given as much time as they needed to make a response.

\section*{Results}

First, it is of interest to compare performance on the initial phrase test both across the two days and across conditions. This test compared pairs of objects with either high or low category-level conditional probability, with test pairs in the comparison having appeared with the same frequency in the exposure set. Importantly, successful performance on this test cannot be accounted for by simple adjacency since both pairs in the comparison had occurred an equal number of times in the exposure. Mean performance outcomes on this test appear in Figure 6.

An overall, 2 x 3 (day x cue-condition) ANOVA revealed a significant interaction between the two factors in the analysis \((F(5,119)=3.93, p=.022\). (An examination of main effects, day and cue condition, revealed that there were no significant differences \((\mathrm{F}(1,119)=.5452, \mathrm{p}=.463\) and \(\mathrm{F}(2,119)=.094, \mathrm{p}=.910\) respectively). This was also true for simple main effects of condition on both days ( \(\mathrm{F}(2\), 59) \(=1.640, \mathrm{p}=.203\) ) and \(\mathrm{F}(2,59)=1.936, \mathrm{p}=.154)\).) The interaction reflects the difference in performance patterns for the groups by day, which was, interestingly, not significant for either day. However, given that it was our expectation that all or some of the cue groups would demonstrate learning of the phrases, given results from previous work with auditory languages where this type of distinction was possible, while allowing for differences in performance, we did performance comparisons for each cue group against chance level performance. On Day 1, Without Cue participants performed significantly above chance, \(\mathrm{M}=\) \(63.3 \%, \mathrm{SD}=48.4 \%(\mathrm{t}(19)=2.707, \mathrm{p}=.014)\), while With

Figure 6. Mean percent correct on the first phrase test. Dashed line indicates chance level performance.

Cue participants performed at chance level, \(\mathrm{M}=52.5 \%\), \(\mathrm{SD}=50.1 \%(\mathrm{t}(19)=.529, \mathrm{p}=.603)\) as did Partially Predictive Cue participants, \(\mathrm{M}=53.3 \%, \mathrm{SD}=50.1 \%\) ( \(\mathrm{t}(19\) ) \(=.748, \mathrm{p}=.464\) ).

These means from the second day were also tested against chance performance. Without cue participants performed at chance level, \(\mathrm{M}=50.0 \%, \mathrm{SD}=50.2 \%(\mathrm{t}(19)=\) \(.000, \mathrm{p}=1.000\) ), while With Cue participants performed above chance, \(\mathrm{M}=65.0 \%\), \(\mathrm{SD}=47.9 \%(\mathrm{t}(19)=2.932, \mathrm{p}=\) .009) as did Partially Predictive Cue participants, \(\mathrm{M}=\) \(63.3 \%, \mathrm{SD}=48.4 \%(\mathrm{t}(19)=2.320, \mathrm{p}=.032)\).

We also tested participants' ability to generalize to novel phrases. This test asked participants to compare novel base pairs that had been reserved from the exposure set, but which again differed in that one had a high category-level conditional probability and one had a low category-level conditional probability. Mean performance scores on this test can be seen in Figure 7. An overall, \(2 \times 3\) (day x cuecondition) ANOVA did not reveal a significant interaction \((F(5,119)=.173, p=.841)\). Nor were there main effects of day
or cue-condition \((\mathrm{F}(1,119)=.640, \mathrm{p}=.425\) and \(F(2,119)=2.404, p=.095)\). Simple main effects of condition, additionally, were null for each day \((\mathrm{F}(2,59)=1.862, \mathrm{p}=.165\) and \(F(2,59)=.646, p=.528)\). Nonetheless, there were some intriguing patterns in the data that we pursued further with individual group analysis. As before, we performed planned comparisons to chance. With Cue participants performed significantly above chance on the first day ( \(M=62.5 \%\), SD \(=48.6 \%(\mathrm{t}(19)=2.380, \mathrm{p}=.028)\) ) while Without Cue performed at chance \(\mathrm{M}=49.2 \%, \mathrm{SD}=50.2 \%(\mathrm{t}(19)=-.188\), \(\mathrm{p}=.853\) ), as did the Partially Predictive Cue participants ( M \(=51.7 \%\), \(\mathrm{SD}=50.2 \%(\mathrm{t}(19)=.302, \mathrm{p}=.766))\).

We also compared performance on the generalization test for the second day. On this day, With Cue, Without Cue, and Partially Predictive Cue participants all scored at chance level \((\mathrm{M}=55.8 \%, \mathrm{SD}=49.9 \%(\mathrm{t}(19)=1.234, \mathrm{p}=\) \(.232) ; \mathrm{M}=48.3 \%, \mathrm{SD}=50.2 \%(\mathrm{t}(19)=-.302, \mathrm{p}=.766)\); and \(\mathrm{M}=49.2 \%, \mathrm{SD}=50.2 \%(\mathrm{t}(19)=-.165, \mathrm{p}=.871)\), respectively.

\section*{Discussion}

This experiment was designed to assess whether category relatedness or phrases can be inferred in a nonlinguistic system, or is instead a property only of linguistic systems. In addition, we asked whether cues to category membership would function similarly in the auditory and visual domains. Participants were exposed to visual arrays comprised of phrases defined over categories, arranged so that the within-phrase category-level conditional probabilities were higher than those of categories that co-occurred but did not form phrases. Participants were then tested to see if they had acquired the phrases of the visual grammar. The hypothesis was that general purpose learning processes would enable the acquisition of phrase structure in the visual system as in the auditory language, and that these learning processes would be improved by cues that facilitated the matching of items in categories. If this is the case, the relative statistics in the input should inform judgments about category relatedness that contrast pairs of objects that are a phrase-relevant pair to pairs that cross phrase boundaries.

We found some evidence of this. On the first day, Without Cue participants performed above chance on the first phrase test, demonstrating that they had learned something about the category-level co-occurrence probabilities. Surprisingly, performance in this group dropped on the second day - potentially the result of looking for further patterns in the stimuli that were not present. In contrast, With Cue and Partially Predictive Cue participants performed at chance level initially on Day 1 and went on to improve on the first phrase test on Day 2. These groups may have taken longer precisely because of the presence of distributional cues that were correlated with the color cue - they were figuring out that relationship first (as demonstrated by their above-chance performance on the second test), then having attained some (albeit shaky) knowledge of the color relationships, they went on to learn the relationships between categories. The With Cue participants were the only group to demonstrate above chance learning on the second test at all, on the first day -a result that may just be due to chance. However, since the relative pattern of performance (With Cue participants doing better) was consistent on this test across the two days we think that the fact that they performed better than the other two groups of participants on this test (even if not significantly so) is a real, if small, effect.

Given that the effects are sometimes present, sometimes absent, it may bring up the question as to whether there were particular aspects of our test stimuli that could have skewed the pattern of the data. There were a number of controls in place to minimize this possibility. While the particular test items were different for all three cueconditions, the number of pairings that incidentally paired objects of the same hue (albeit different brightness and saturation - as the cue dictated) were the same across all three conditions and all tests and were a very low number.

Additionally, each test had two versions: an A version as well as a B version, and those versions were randomized as to whether a particular participant received the A version on Day 1 or the B version. Thus, the pattern of results seems unlikely to have occurred due to particular test stimuli.

Ultimately, these general learning results should be replicated with different participants and stimuli if possible. The explanation for learning being sometimes present, sometimes absent should be explored and tested, possibly by looking at more individual learning trajectories. This project was intended to provide a visual analogue of both our previous work and work by Thompson and Newport (2007) - all of which provided a much longer input period. And so, this work may benefit from equivalent time on task to see if learning improves and generalization ability ever emerges and remains persistent in this paradigm.

\title{
The Role of Scene Gist and Spatial Dependency among Objects in the Semantic Guidance of Attention
}

\begin{abstract}
A previous study (Hwang et al., 2011) found evidence for semantic guidance of visual attention during the inspection of real-world scenes, i.e., an influence of semantic relationships among scene objects on overt shifts of attention. In particular, the results revealed an observer bias toward gaze transitions between semantically similar objects. However, these results are not necessarily indicative of semantic processing of individual objects but may be confounded by knowledge of the scene gist, which does not require object recognition (Torralba et al., 2006), or by known spatial dependency among objects (Oliva \& Torralba, 2007). To examine the mechanisms underlying semantic guidance, in the present study, subjects were asked to view a series of displays with the scene gist removed and spatial dependency varied. Our results confirm the previous finding of semantic guidance and show that it is not entirely due to either the effect of scene gist or the spatial dependency among objects. Even without scene gist or spatial dependency, subjects still retrieved semantic information to guide their attention. This strategy may facilitate scene understanding and object memorization.
\end{abstract}

Keywords: Attention, semantics, eye movements, visual guidance, real-world scenes.

\section*{Introduction}

Real-world scenes contain rich information, which usually is not thoroughly processed during natural viewing. Therefore, the way in which the visual system deploys the limited attention resources is crucial for effective vision and has drawn huge interest over the last two decades. The guidance of attention based on the features of stimuli in the visual environment has been well investigated in both its bottom-up (Itti \& Koch, 2001; Koch \& Ullman, 1985) and top-down aspects (Hayhoe et al, 2003; Hwang, Higgins \& Pomplun, 2009; Pomplun, 2006).

Visual attention is not only affected by factors based on the overt visual appearance, but also by inherent factors, such as meaning and semantic relations among objects. Hwang, Wang and Pomplun (2011) found that during natural scene viewing, humans tend to bring their gaze to the objects that are semantically similar either to the currently fixated one or to the specified search target. This result, however, may have been confounded by the observers' knowledge of the global scene context. That is, instead of considering the semantic relation between the currently fixated object and the objects located in the extrafoveal visual field, observers may simply use their knowledge about the scene type to decide where to look
next. For example, if observers are aware that the viewed image is a kitchen, they may only attend the regions nearby the counter or sink, where most of the kitchenware is likely located.

The ways in which people acquire such global contextual information is not well understood. Torralba, Oliva, Castelhano and Henderson (2006) found that observers could extract some global scene properties - referred to as scene gist - without recognizing individual objects and use this information to guide their attention and eye movements.

Even when the global context, which usually comes from visual background information, is missing, it is still possible to learn some context of the scene. Chun (2000) showed that some contextual information can be learned merely by the typical arrangement of elements and affect the deployment of attention. Oliva and Torralba (2007) also found that spatial dependency among objects could provide different contextual information about a scene. For example, a chair may be expected to be located behind a table, or a fork may be expected to be next to a spoon.

In summary, both the scene gist and the spatial dependency among scene objects may have caused a bias in observers' gaze patterns that could explain the results of Hwang et al. (2011) without the need for semantic analysis of extrafoveal scene objects. If gist, object dependency, or both were entirely responsible for the effect observed in that study, the concept of semantic guidance would not be a new phenomenon but rather a bias introduced by already known factors. The aim of the present study was to discern the contributions of scene gist, object dependency, and semantic object analysis to semantic guidance in order to address this problem.

To study the influence of spatial dependency among scene objects, we employed the LabelMe object annotated image data base (Russell, Torralba, Murphy, \& Freeman, 2008) in which scene images were manually segmented into annotated objects by volunteers. In addition, the locations of objects are provided as coordinates of polygon corner and all objects are labeled with English words or phrases. It provides an excellent opportunity for not only segregating each object from its scene, but also shifting the object's coordinates to any desired location in the image.

One way to eliminate potential influence of scene gist on attentional guidance is to remove all background information and only keep segregated objects in the scene. We used the resulting images in an experimental condition
referred to as 'fixed condition'. This procedure effectively removes the relation between scene and objects as defined by Torralba et al. (2006). For example, it is easier to predict where a plate is located in a scene when the plate is shown on a dining table than when it is shown by itself. The spatial dependency among objects, however, is still retained when the background information is excluded. For instance, it is possible to predict the likely location of a glass merely based on the location of a seen plate in a scene, even when no context is provided. To remove the spatial dependency among objects as well, we created another set of stimuli ('scrambled condition') by generating scenes without background as in the fixed condition and then randomly shifting the objects within the scene.

If the semantic guidance found in the previous study (Hwang et al., 2011) were due to the spatial dependency among objects, this effect should be eliminated once the background information and spatial arrangement are removed. On the other hand, if observers are able to use conceptual semantic information between objects to guide attention, their gaze transitions should still show an abovechance semantic relevance.

\section*{Method}

\section*{Subjects}

Ten subjects, aged between 19-40 years old, were tested. All had normal or corrected to normal vision and were naïve as to the purpose of the study. Each subject received a \(\$ 10\) honorarium.

\section*{Apparatus}

Eye movements were tracked and recorded using an SR Research EyeLink-2k system. Its sampling frequency was set to 1000 Hz . Stimuli were presented on a 22-inch ViewSonic LCD monitor. Its refresh rate was set to 75 Hz and its resolution was set to \(1024 \times 768\) pixels. Participant responses were entered using a keyboard.

\section*{Stimulus display}

A total of 60 images ( \(1024 \times 768\) pixels) were generated. Each image was composed of 13 to 15 objects selected from a real-world scene from the LabelMe database (http://labelme.csail.mit.edu). The selected scenes included home interiors, landscapes and city scenes. Objects of extreme size (small or large) were not chosen as scene objects. To remove the scene gist or other global regularity from the scene, all objects were segregated from the image and were pasted on a grey canvas. Each object was placed at either the same coordinates as in the original scene, which was referred to as 'fixed condition', or at randomly selected locations on the canvas, referred to as 'scrambled condition'. In the scrambled condition, different objects were placed manually to avoid overlap and clutter (see Figure 1 for an example).

Figure 1: Original scene (top) and a sample trial (bottom). The upper panel shows the original scene used to generate stimulus displays. The scene would be used to generate an image with objects at same coordinates (fixed condition) and an image with objects at randomly selected locations (scrambled condition). During each trial, the created image was presented for 5 seconds. After the stimulus image disappeared, a word was presented and subjects had to report whether the indicated object had been shown in the previous display.

\section*{Procedure}

Subjects were instructed to inspect the scenes and memorize them for the subsequent object recall test (see Figure 1, bottom panel). Each image was presented for 5 seconds. After the image had disappeared, an English word was shown and subjects were asked whether the object indicated by the word had been shown in the previous scene. Subjects responded by pressing one of two possible keys on a keyboard. If they believed the indicated object was shown in the previous image, they would press the left arrow key. Otherwise, they would press the right arrow key. The next trial would begin once subjects made a response. Subjects performed a total of 60 trials ( 30 trials each in the fixed and scrambled conditions). Each scene was only presented once to each subject, either in the fixed condition or in the scrambled condition.

\section*{Data Analysis}

\section*{Assigning fixations to objects}

Since all images excluded the global contextual information by only leaving the selected objects on a grey canvas, some fixations may land on the blank area rather than on any object in the image. When this happened, we assumed this fixation was aimed at the nearest object, i.e., the one whose center had the shortest Euclidean distance to the current fixation location.

\section*{Latent Semantic Analysis}

Similar to the original semantic guidance study (Hwang et al., 2011), we used Latent Semantic Analysis (referred to as LSA; Landauer \& Dumais, 1997) to serve as a quantitative measure of semantic similarity between objects. LSA is able to extract and represent the contextual usage-meaning of words by statistical computations applied to a large corpus of text. The basic premise in LSA is that the aggregate contexts in which a word does or does not appear provide a set of mutual constraints to deduce the word's meaning (Landauer, Foltz, \& Laham, 1998). The greater the cosine value, the higher is the semantic similarity. Since annotated objects in LabelMe have descriptive text labels, their semantic similarity can be estimated by calculating cosine values for the labels of object pairs.

LSA similarity computation can be described as follows: First, an occurrence matrix is constructed from a large corpus of text, where each row typically stands for a unique word, and each column stands for a document, which is typically a collection of words. Each cell contains the frequency with which the word occurred in the document. Subsequently, each cell frequency is normalized by an information-theoretic measure. However, it is computationally inefficient to operate with this very highdimensional matrix. Therefore, a form of factor analysis called Singular Value Decomposition (SVD; see Berry, Dumais, \& Obrien, 1995) is applied to reduce the matrix to a lower-dimensional vector space called 'semantic space'. LSA can still estimate the semantic similarity of two words even when they never co-occur in the same document (Jones \& Mewhort, 2007; Landauer \& Dumais, 1997).

Every term, every document, and every novel collection of terms has a vector representation in the semantic space. Thus, the pair-wise semantic similarity between any of them can be calculated as the cosine value of the angle between the two corresponding vectors, with greater cosine value indicating greater similarity. Table 1 shows examples of LSA cosine values for various object labels used in the LabelMe scene image "Child4" (see Figure 1) in terms of the reference object label "AIRPLANE". This label has, for instance, a higher cosine value (greater semantic similarity) with "HELICOPTER" (0.62) than with "PILLOW"' \((0.03)\). This difference indicates that in the text corpus, "AIRPLANE" and "HELICOPTER" occur in more similar contexts than "AIRPLANE" and "PILLOW". One of the nice features of LSA is that it can quantify
higher-level conceptual semantic similarity, regardless of any geometrical relation, functional relation or visual relation.

Table 1: Sample LSA cosine values
\begin{tabular}{lll}
\hline Label 1 & Label 2 & Cosine \\
\hline- & - & - \\
AIRPLANE & HELICOPTER & 0.62 \\
AIRPLANE & TOY TRAIN & 0.28 \\
AIRPLANE & PICTURE & 0.14 \\
AIRPLANE & PILLOW & 0.03 \\
- & - & - \\
\hline
\end{tabular}

To compute semantic similarity for each pair of object labels in our experiment, a web-based LSA tool, LSA@CU (http://lsa.colorado.edu), developed at the University of Colorado at Boulder, was used. This tool was set to create a semantic space from general readings up to 1st year college with 300 dimensions. Based on this space, we computed semantic similarity as the LSA cosine value, ranging between 0 and 1, for each object label compared to all other objects' labels for the same image.

\section*{Measuring semantic guidance}

In this study, the semantic guidance effect was defined as the extent to which the semantic relation/similarity between the currently fixated object and the other objects in the scene influences the choice of the next fixated object. In order to compute this effect quantitatively, the computation had to follow each subject's eye movements. Since we were interested in the effect of semantic similarity on gaze transitions, i.e., which object would be inspected next, only eye movements that transitioned between distinct objects were analyzed. For the starting point of each of these transitions, a semantic landscape was generated based on the LSA cosine value between the labels of the currently fixated object and each other object in the scene, as shown in Figure 2. The semantic landscapes, excluding the area occupied by the currently fixated object, were normalized so that the sum of all activation was one. With the normalized semantic landscape, the Receiver Operating Characteristic (ROC) value was computed in a similar way as it was done in previous studies (Hwang et al., 2009; Tatler, Baddeley \& Gilchrist, 2005). Overall, each fixation would build its own semantic landscape as a predictor of the target point of the next transition. All ROC values computed along scan paths were averaged across scenes to obtain the extent of semantic guidance during the inspection of a scene. If eye movements were exclusively guided by semantic information, this average ROC value should be close to one. If there were no semantic effect on eye movements at all, the average ROC value should be close to 0.5 , indicating prediction at chance level.

Figure 2: Example of semantic landscapes. The currently fixated object is marked with an orange square. (a) The original image that subjects inspected. (b) Semantic landscape during gaze fixation on the object labeled as "AIRPLANE". (c) Semantic landscape during gaze fixation on the object labeled as "GLOBE". (d) Semantic landscape during gaze fixation on the object labeled as "STORAGE BOX". As shown above, objects with conceptually higher relevance - measured as greater sematic similarity to the currently fixated object - receive higher activation (brightness), for example, the helicopter in (a) shows a higher activation due to the fixated object labeled as 'AIRPLANE'.

\section*{Excluding potential confounds by computing control analyses}

Following Hwang et al. (2011), to control for possible confounds in the measurements of semantic guidance, subjects' ROC values computed from their empirical gaze transition data were compared with two control data sets: (1) random fixations and (2) dissociated fixations. The random fixations were generated by replacing subjects' fixation positions with randomly positioned coordinates in the scene. This data set served as an unbiased test of ROC values. That is, since gaze transitions of the random data set were not affected by any other factor, we should always receive a chance level ROC value ( \(\mathrm{ROC}=0.5\) ).

Furthermore, it is likely that any above-chance ROC value was simply caused by the proximity effect. This effect is due to the previous finding (Hwang et al., 2011) that semantically similar objects tend to be located closer to each other and subjects' saccades tend to be shorter than gaze transitions in the random data set. To examine this possible confound, subjects' data were also compared with a "dissociated" data set. The dissociated data were analyzed using the eye movement data recorded in scene n against
object data from scene \(n+1\), and the eye movement data recorded from the last scene against the object data from the first scene. This mismatch conserved the spatial distribution of both the scene objects and the observers' fixations and therefore the proximity effect (at least in the fixed condition in which the coordinates of selected objects were not changed). This method allowed us to examine whether any observed above chance level ROC value for the empirical data was simply caused by proximity, which would be indicated by ROC values in the dissociated case being similar to the actual ROC values).

\section*{Experimental Results}

Results showed that subjects recall performances were above chance level in both the fixed and scrambled conditions (Recall performance in the fixed condition, 79\%, \(t(9)=21.50, p<0.05\); recall performance in the scrambled condition: \(70 \%, t(9)=4.36, p<0.05)\).
As mentioned earlier, in order to examine semantic guidance, we computed ROC values for the two experimental conditions (fixed vs. scrambled) for all three data sets (empirical, random and dissociated). Figure 3 shows that the transitional semantic guidance values of random fixations were close to 0.5 in both the fixed and scrambled conditions. This result shows that the ROC computation was applied properly and the normalized semantic landscapes used in our analysis were unbiased.

The ROC value in the fixed condition (ROC \(=0.704 \pm\) 0.14 ) was significantly higher than that in the scrambled condition ( \(\mathrm{ROC}=0.65 \pm 0.19\) ), \(t(9)=4.76, p<0.05\). ' \(\pm\) ' here indicates a mean value and its standard error.

This result suggests that the spatial dependency preserved in the fixed condition provided additional semantic information and facilitated semantic guidance. The ROC value decreased when this spatial dependency was eliminated by shuffling the locations of objects.

Interestingly, in the scrambled condition, where the spatial dependency among objects was destroyed, the ROC value of empirical transition between distinct objects was still substantially greater than both ROC values for the other two control cases. A one-way ANOVA showed that the effect was significant, \(F(2,27)=51.61, p<0.05\). A post hoc Tukey test indicated that there was no difference between the dissociated and random cases, \(p=0.53\). This finding shows that the proximity effect, at least in our experiment, had no impact on semantic guidance.

Overall, the results indicate that, even without scene gist and the spatial dependency among objects, subjects were still able to extract the semantic relevance between objects to guide their attention.

Figure 3: Transitional semantic guidance as measured by the ROC method in the fixed condition and the scrambled condition. The red dashed line represents the chance level \((\) ROC \(=0.5)\) and errors represent \(+/-1\) standard error of the mean.

\section*{Conclusions}

Hwang et al. (2011) found that, during scene inspection, observers tend to bring the line of sight to objects that are semantically relevant to the currently fixated object. Based on these previous data alone, it cannot be ruled out that the high semantic relevance of gaze transitions was contributed by scene gist information or by subjects' prediction of local scene context based on the spatial layout of objects. In other words, observers may not actually evaluate the semantics of peripheral objects for saccade target selection, and consequently, semantic guidance could not be considered a new phenomenon but rather an effect caused by other known mechanisms.

Our present results clarify the influence of these possible confounds in the previous findings. In the fixed condition in which the scene gist was removed, observers still showed strong semantic guidance. This result demonstrates that semantic guidance of visual attention in scene inspection is not entirely due to the scene gist. In fact, semantic guidance in the present study was even higher than that measured in Hwang et al. (2011), suggesting that scene gist only plays a marginal, if any, role in semantic guidance.

In the scrambled condition, in which both scene gist and possible spatial dependency among objects were removed, the effect of semantic guidance was slightly decreased but remained substantially higher than chance level. This finding shows that the spatial arrangement of objects only makes a small contribution to semantic guidance. Moreover, these data reveal that even when the scene gist was excluded and the spatial dependency was removed, subjects could still retrieve semantic information to guide their attention.

Moreover, Hwang et al. (2011) also found an even greater effect of semantic guidance in a visual search task. That is, observers tend to fixate on the objects which are semantically similar to the specified target. Instead of using any verbal probe and search paradigm as they did, the present study used a natural viewing and memory task which was less constrained by cognitive goal and we still found a substantial effect of semantic guidance.

Consequently, the question becomes how observers obtained this semantic information and how it influenced the guidance of attention. It is likely that extrafoveal visual processing may play a crucial role in enabling the semantic effect since observers had to recognize, at least partially, the objects in peripheral vision and processed the semantic relevance in the context of the currently fixated object. Kotowicz, Rutishauser and Koch (2010) found that, during visual search, observers already identified the extrafoveal target before fixating on it. We do not claim that in our task, observers were able to recognize the objects in the extrafoveal field. At the very least, extrafoveal perception may be used to increase the belief of what this object could be. Therefore, when contextual information was removed, people could still learn semantic information to help them determine where to fixate next by using the immediately acquired information from the current fixation and the information accumulated from extrafoveal vision. Such a strategy may facilitate scene understanding and memorization. It is also possible that, instead of using extrafoveal information, observers may construct their own scene representation merely based on the currently fixated object and update it during later fixations. This strategy may become useful when the extrafoveal information is not available or when the cost of processing it is too high.

Overall, the current study showed that semantic guidance of visual attention during the inspection of real-world scenes, as reported by Hwang et al. (2011), is a novel phenomenon that cannot be explained by effects of scene gist (e.g., Torralba et al., 2006) or spatial dependency among scene objects (e.g., Oliva \& Torralba, 2007) alone. It has been known that, in addition to the visual saliency from low-level features, attention could be also driven by other particular classes of objects, such as faces (Judd, Ehinger, Durand, \& Torralba, 2009) and texts (Wang \& Pomplun, 2012). Our result provides a new alternative class of features and suggests that the conceptual semantic effects may need to be considered in the present model of attentional guidance. Further research on semantic guidance, its underlying mechanisms, and its function is necessary before this concept can be integrated into existing models of visual attention.

\title{
Framing effects in evaluation of accuracy of others' predictions
}

\author{
Saiwing Yeung (saiwing.yeung@gmail.com) \\ Institute of Education, Beijing Institute of Technology, China
}

\begin{abstract}
Most predictions can be partitioned into two components: the predicted outcome, and the chance that one considers the outcome will happen. We studied how people evaluate predictions with binary outcomes. These predictions can be conveyed in two equivalent ways: one predicting an outcome with some probability, and the other predicting the other outcome with the probability of the complement of the first outcome. Although these two ways of stating the predictions are mathematically interchangeable, we hypothesized that people would judge the congruently stated prediction, one that has the same qualitative component as the actual outcome, as more accurate. We tested this hypothesis in four experiments. Results suggested that this effect is consistent across a number of domains; depends on the frame in which the prediction is stated; is robust regardless of whether the ratings were elicited in positive or negative terms; holds for both rating and choice tasks.
\end{abstract}

Keywords: framing effects; probabilistic judgment; decision making.

Probabilistic predictions are frequently encountered in everyday life. For example, weather forecasts are often made in probabilistic terms (e.g. "chance of rain is \(80 \%\) "). By comparing these statements against the actual outcomes, we can assess the predictors' skills at predicting these events. It is important to be able to accurately evaluate other people's predictions because it would then allow us to learn how good the predictors are in making predictions, to judge whether or to what degree should we trust the predictions, and to make decisions accordingly. For example, if a certain investment analyst predicts that there is a \(99 \%\) chance that Acme Company will declare bankruptcy, and that we consider this analyst to be a good predictor, then it would be advantageous to sell stocks of Acme Company that we are holding.

In this paper, we focus on one particular aspect of evaluating predictions - how framing of predictions affect people's evaluations. Framing effect is an extremely well-researched topic and has led to numerous scholarly work. It refers to a phenomenon in which people's judgment, decisions, and actions are influenced by frames, or presentation of information and its context.

Framing effects have been found to influence people in various ways in different contexts. Levin, Schneider, and Gaeth (1998) proposed a typology that categorized them into three main types. The first type, risky choice framing effect, induces a choice reversal effect between two logically equivalent gambles (Tversky \& Kahneman, 1981). In a prototypical setup, participants see one of the two gambles: either choosing between a sure gain and a risky gain, or choosing between a sure loss and a risky loss. Previous research has found that a majority of the people would prefer the sure gain choice in the gain condition, and risky loss choice in the loss condition.

The second type of framing effects was called attribute framing effects, as a single attribute within a given context presented in two logically equivalent frames has been shown
to change people's evaluations about the subject. For example, in Levin and Gaeth (1988), beef that was labeled as "75\% lean" was rated as better tasting and less greasy than beef that was labeled as " \(25 \%\) fat."

Goal framing effects is the third type in Levin et al.'s typology. Here negatively framed messages are found to be more persuasive than positively framed messages. Works by Meyerowitz and Chaiken (1987) demonstrated a typical setup of this problem. They found that women are more likely to perform breast self-examination (BSE) if they are told of the negative consequences of not performing BSE, compared to being told of the positive consequences of performing one.

In the present study we report a new type of framing effect, in which people's evaluation of a prediction with respect to the outcome is influenced by the frame in which the prediction is presented. We will focus on predictions in which there are clearly two possible outcomes (e.g. coin flips) and are stated with the subjective probability of said event happening (e.g. " \(80 \%\) "). Because there are exactly two outcomes, any predictions can be stated in two ways that are logically equivalent. For example, to say that there is a \(99 \%\) chance that the world will be destroyed at end of 2012 is equivalent to a \(1 \%\) chance that the world will not be destroyed at end of 2012.

We argue, however, that people evaluate these predictions differently. As demonstrated by the framing effects literature described earlier, people's judgments are often influenced by how information is presented. In the context of prediction evaluation, we suggest that people would overweight the qualitative component of the prediction (the stated outcome), relative to its quantitative component (the chance that one considers the outcome will happen). To differentiate this from previously discovered types of framing effects, we will call this probabilistic statement framing effect (PSFE). We will next describe four experiments that were carried out to investigate this hypothesized effect.

\section*{Pilot Experiment}

The main objective of the Pilot Experiment was to establish initial evidence about PSFE. To ensure the realism of the stimulus, we used a cover story about the 2012 U.S. presidential election which had just ended a few weeks prior.

\section*{Methods}

The participants were recruited using Amazon Mechanical Turk (MTurk). Only workers who were residing in the U.S., were at least 18 years old, and had a lifetime acceptance rate with MTurk of \(95 \%\) or over were allowed to participate \({ }^{1}\).

\footnotetext{
\({ }^{1}\) The same requirements applied to all experiments in this paper. Moreover, we disallowed participants from participating in more than one experiment in this paper (except for two participants who
}

In order to detect participants who might have been bored or inattentive during the experiment, an attention check (AC) was employed in the experiment (Oppenheimer, Meyvis, \& Davidenko, 2009). The AC took place before the actual experiment, and consisted of a paragraph of instruction followed by a question. The instruction began by asking participants to enter their favorite sports in the space below. However, at the end of the instruction we asked the participants to enter a different response: "To show that you have read this far, please enter candle below. To repeat, enter the word candle no matter what your favorite sports is." If participants had read the entire instruction, then they should have responded with the target word ("candle"). The other experiments in this paper employed AC's with exactly the same format with the exception of different target words.

The key content of the experiment would be next. The instructions were as follows, with the conditions marked by parentheses, and the differences between conditions marked by double brackets ( \(\llbracket\) and \(\rrbracket)\) and vertical lines \((\|\|)\) :

Acme inc. is a company that conducts public opinion polls about the 2012 presidential election between Barack Obama and Mitt Romney. Before the election it had predicted that \(\llbracket\) (congruent) Mitt Romney had a 20 percent chance of winning \(||\mid\) (incongruent) Barack Obama had an 80 percent chance of winning 】.
All participants were then asked "If Romney had won, was Acme inc. wrong?" in a forced-choice question. The two conditions in this experiment represented the different ways in which predictions were framed. In the congruent condition, the qualitative component of the prediction was the identical to the hypothetical result stated in the stimuli (Romney winning), whereas it was the opposite in the incongruent condition.

We then asked participants to rate the prediction using a 9point Likert scale on "How accurate was the prediction?" and "How useful was the prediction?" The participants then filled in a demographics survey, which included a question about their political orientation.

\section*{Results}

There was a total of 93 responses. Eleven of them failed the attention check question and their data were discarded. Out of the resulting 82 data points, \(56.1 \%\) were female, \(81.7 \%\) had at least some college education. We recorded age information in brackets. Almost half of the participants were in the youngest bracket of under 25 ( \(48.8 \%\) ), but there were also significant portion of the participants in older brackets ( \(22.0 \%\) between 26 and \(35 ; 18.3 \%\) between 36 and \(50 ; 11.0 \% 51\) or over).

We first examined the forced-choice question on whether the participants regarded the prediction as wrong. Relatively fewer participants in the congruent group rated the prediction as wrong \((16 / 40=40 \%)\) than in the incongruent group \((22 / 42=52.4 \%)\). However, the differences were not significant \(\left(\chi^{2}(1, N=82)=1.26, p=0.26, \phi=0.12\right)\).
participated in two experiments because of a programming error). This ensures a broader representativeness of our samples.

The congruent group rated prediction accuracy ( \(M=\) 4.58 , s.d. \(=2.21\) ) significantly higher than the incongruent \(\operatorname{group} \operatorname{did}(M=3.17\), s.d. \(=1.83 ; t(80)=3.15, p<0.01\), Cohen's \(d=0.71\) ). The congruent group also rated prediction usefulness \((M=4.30)\) higher than the incongruent group \(\operatorname{did}(M=3.45)\), although the difference was only marginally significant \((t(80)=1.75, p=0.09\), Cohen's \(d=0.39)\).

As the stimuli in this experiment involved a question in politics, we also tested whether subjects' political orientation influenced their responses. There were more self-reported Democrats than Republicans, with 22 (26.8\%) self-identified as strongly Democrat and 35 (42.7\%) as moderately Democrat. Nonetheless, the participants' political orientations had a low correlation with their evaluation of accuracy at \(r=\) 0.084 and was insignificant \((t(80)=0.75, p=0.45)\).

\section*{Discussion}

In this experiment we found initial evidence supporting PSFE: Participants in the congruent frame rated the prediction as more accurate, although they did not consider the prediction less wrong. Nonetheless, there remains a number of unresolved issues. The two conditions represent differences at multiple attributes, including the prediction frame (whether the prediction was described in terms congruent with the actual result), framing of the result (whether the results were described using the same agent as the prediction frame), and valence of the evaluation (whether the evaluation is elicited in positive or negative terms). It remains to be established which of these attributes underlie this phenomenon. Moreover, the scenario used was based on a real event and this might have interfered with people's reasoning, especially because most of our participants self-identified as liberal. Therefore, we conducted the next two experiments to tease apart the pathways involved in bringing about this phenomenon.

\section*{Experiment 1}

The first objective of Experiment 1 was to investigate PSFE using an artificial cover story in which the participants do not have a preference towards one of the two possible outcomes. The second objective was to investigate whether PSFE is driven by the prediction frame or result frame.

\section*{Methods}

Participants were again recruited from MTurk. The experiment used a between-subject \(2 \times 2\) design, crossing the prediction frame and the result frame. The stimuli in this experiment used the cover story of a college (American) football game. The stimuli were as follows:

Imagine that you have just arrived a little early for a new class on the first day of the semester. Another student was already there. The two of you started talking and the conversation turned to an upcoming college football game between universities A and B. The other student predicted that \(\llbracket\) (Prediction frame: congruent) University B has a \(30 \%\) chance of winning \(\| \mid\) (Prediction frame: incongruent) University A has a 70\% chance of winning \(\rrbracket\).

The game took place later that week and \(\llbracket\) (Result frame:
A) University A lost to University B \(\|\|\) (Result frame: B) University B defeated University A】.
The conditions in the two prediction frames are so named because if we ignore the confidence levels in the predictions, the prediction in the congruent prediction frame ( B winning) is congruent with the result ( B won in all conditions in this experiment), while the prediction in the incongruent prediction frame (A winning) is incongruent. The conditions in the result frames are simply named after the agent in the frame.

The participants were then asked to state whether the predictions wrong, and how accurate was the prediction ( 9 -point Likert scale). Finally the participants answered a demographics survey similar to that in the Pilot.

\section*{Results}

There were a total of 112 participants ( \(41.1 \%\) female), after discarding data from eight others for failing the attention check \((6.7 \%)\). Average age was \(28.62(\) s.d. \(=11.95)\) and \(84.8 \%\) had at least some college education.

The main objective of Experiment 1 was to investigate whether the prediction frame or the result frame is driving the PSFE, and whether there is interaction. To examine the effect of the prediction frame, we performed a \(t\)-test to compare the evaluation of prediction accuracy between the two prediction frames. The mean rating in the congruent prediction frame was 4.91 ( \(s . d .=1.79\) ), higher than that of the incongruent prediction frame at \(3.34(s . d .=1.47)\), and the difference was significant \((t(110)=5.08, p<0.01\), Cohen's \(d=0.97)\). This replicated the results from the Pilot.

In the Pilot, there was no significant difference between the two conditions in whether participants consider the predictions were wrong. Interestingly, this was significant in Experiment 1 , in which 12 of 56 ( \(21.4 \%\) ) participants in the congruent condition judged the prediction as wrong, compared to 29 of \(56(51.8 \%)\) of those in the incongruent condition did so \(\left(\chi^{2}(1, N=112)=11.12, p<0.01, \phi=0.32\right)\).

One alternative hypothesis is that the differences were caused by the different result frames. We found the mean accuracy ratings to be \(4.25(s . d .=1.96)\) for frame A and 4.00 \((s . d .=1.66)\) for frame B, respectively. There were no significant difference \((t(110)=0.74, p=0.46\), Cohen's \(d=0.14)\). For the question on prediction wrong-ness, there were no significant difference between different result frames either \(\left(\chi^{2}(1, N=112)=0.20, p=0.66, \phi=0.04\right)\). Moreover, there were no interaction between prediction framing and result framing \(\left(F(1)=0.32, p=0.57, \eta^{2}=0.00\right)\). Figure 1 plots the results from Experiment 1.

Another alternative hypothesis is that having the same agent in the prediction frame and result frame would lead to higher accuracy ratings. We found this to not be the case. Mean accuracy ratings for participants who had the same agent in both frames was lower (4.05, s.d. \(=1.69\) ) than those with different agents \((4.20\), s.d. \(=1.94)\), and the differences were not significant \((t(110)=0.43, p=0.67\),

Figure 1: Results of Experiment 1. Each graph plots a comparison of accuracy ratings for a different factor. Error bars represent s.e.

Cohen's \(d=0.08\) ). There were no significant differences in the forced-choice question either \(\left(\chi^{2}(1, N=112)=0.00\right.\), \(p=0.96, \phi=0.01\) ).

Self-reported football knowledge was evenly spread over the 4 -point scale. There were 32, 33, 23, and 24 responses, from the least knowledgeable to the most knowledgeable. To investigate whether there is an interaction between football knowledge and prediction frame, we carried out an ANCOVA analysis. The results indicated that there was no significant interaction \((F(1)=0.696, p=0.41)\).

\section*{Discussion}

Results of Experiment 1 suggested that framing of predictions significantly changes people's evaluation of predictions, whereas framing of results and whether the same agent is used in both frames has little effect. This not only replicated the results of the Pilot, but also suggested that prediction frame is what underlies the difference in how people evaluate how accurate predictions are. The results of this experiment correspond to the compatibility effects (Slovic, Griffin, \& Tversky, 1990), which states that stimuli attribute that is compatible with the response mode would be overweighted.

\section*{Experiment 2}

In both the Pilot and Experiment 1, the forced-choice question on evaluations were elicited in negative terms, i.e. we asked the participants whether the predictions were wrong. Therefore in Experiment 2 we tested whether PSFE also holds when the evaluations had a positive valence.

\section*{Methods}

Participants were again recruited from MTurk and the procedures were mostly the same as the previous two experiments. The instructions were:

Imagine that you have just arrived a little early for a new class on the first day of the semester. Another student was already there. The two of you started talking and the conversation turned to an upcoming college football game between universities \(A\) and \(B\). The other student predicted that \(\llbracket\) (congruent) University B has a 30\% \|| (incongruent) University A has a \(70 \%\) § chance of winning.

The game took place later that week and \(\llbracket\) (congruent) University B defeated University A ||| (incongruent) University A lost to University B \(\rrbracket\).

As can be seen from the instructions, there were two conditions: congruent and incongruent. The major departure of Experiment 2 from the previous two lies in how we elicited the forced-choice response on about the prediction: we asked "Was the prediction made by the other student right?"

Note that in both condition, the agent remains the same in both the prediction frame and the result frame.

\section*{Results}

Experiment 2 had a total of 78 participants ( \(34.6 \%\) female), after discarding data from nine of them for failing the attention check \((10.3 \%)\). Mean age was \(29.03(s . d .=12.73)\) and \(88.5 \%\) had at least some college education.

The main objective of this experiment was to test whether PSFE could be replicated when evaluations were elicited in positive terms. We first analyzed results of the forced-choice question in which the participants were asked whether the prediction was right. In the congruent condition, 22 of 40 ( \(55.0 \%\) ) responded affirmatively; whereas in the incongruent condition, 8 of 38 participants ( \(21.1 \%\) ) responded affirmatively. \(\chi^{2}\)-squared test showed that the difference was significant \(\left(\chi^{2}(1, N=78)=9.49, p<0.01, \phi=0.35\right)\). The quantitative accuracy ratings for the two conditions reflected a similar picture. The mean accuracy rating for the congruent condition was \(5.05(s . d .=2.06)\), compared to that of the incongruent condition of \(3.39(s . d .=1.72)\). The difference was significant \((t(76)=3.84, p<0.01\), Cohen's \(d=0.88)\).

\section*{Discussion}

Experiment 2 focused on whether PSFE holds when the people are asked to evaluate the predictions in positive terms. Results indicated that this is indeed the case, suggesting that PSFE to be robust regardless of the valence in which evaluations were elicited.

\section*{Experiment 3}

The first three experiments in this paper demonstrated that when people give accuracy ratings to predictions, predictions presented in a congruent frame as the actual result would be rated as more accurate. Experiment 3 investigated whether this phenomenon could be extended to choice tasks - when the two frames (congruent and incongruent) are presented at the same time as two choices and people are asked to judge which one is the more accurate one.

We also tested two factors that might shed light on the mechanism of PSFE. First, one potential reason that people rated predictions in the incongruent condition as less accurate might have been that the quantitative components of these predictions involve higher numerical probabilities (compared to those in the congruent condition), and this might have been perceived as being overconfident, which in turn led to participants down-adjusting their accuracy ratings. Second, many prior works have suggested that numeracy plays an important role in judgment and decision making. For example, Peters et al. (2006) found that participants who are higher in numeracy are less susceptible to attribute framing effects. To investigate
the influences of these two factors, we also assessed perception of overconfidence and participants' numeracy.

\section*{Methods}

Similar to the previous three experiments, all participants were recruited through MTurk. However, because this experiment is slightly longer than the previous three, we increased the reward from US \(\$ 0.15\) to US \(\$ 0.20\).

In the previous experiments, predictions in the two frames were given logically equivalent probability estimates (e.g. \(75 \%\) vs. \(100 \%-75 \%=25 \%\) ). However, in Experiment 3 the participants would see both frames side-by-side, and therefore such a setup might seem contrived. Moreover, we wanted to test whether the congruent frame would be favored even when it is logically inferior. Hence we parameterized the congruent frame with a probability estimate of \(15 \%\) (in the direction of the actual result), and the incongruent frame with \(80 \%\) (opposite the direction of the actual result). The congruent frame is now logically superior because it predicts the outcome that turns out to be correct with \(100 \%-80 \%=20 \%\) confidence, compared to \(15 \%\) in the congruent frame. Additionally, in order to make the scenarios more realistic, we added two detractor predictions to each option. The instruction for one of the conditions was as follows:

Imagine that you are an analyst at an investment firm. Currently you are evaluating predictions made a year ago by two of your subordinates concerning a technology company called Acme Corp.
Analyst A predicted that in the coming year:
- Acme would buy out their supplier SuperTech Company.
- Acme would expand into the European Union.
- There was an \(80 \%\) chance that Acme would become a public company.
Analyst B predicted that in the coming year:
- Acme would license crucial technology patents from their competitor CompX Company.
- Acme would build another manufacturing plant within the U.S.
- There was a \(15 \%\) chance that Acme would not become a public company.

The probabilistic prediction shared by both analysts was whether Acme would become public or not. Each of the two analysts also made two detractor predictions additionally.

The participants then read about what actually happened. There were five total predictions: two unique detractors from each analyst, plus the common prediction. In all conditions, Acme would not become public. However, one of the two detractors from each of the analysts would come true.

In this counter-balance condition shown above, Analyst A predicted that there was an \(80 \%\) chance of the target event (Acme became a public company) happening. Analyst B, in contrast, predicted that there was a \(15 \%\) chance of the target
event not happening. If probabilistic statements could be inverted algebraically, it would mean Analyst B predicted that there was an \(85 \%\) chance of the target event happening. As the target event did not happen, Analyst A should be evaluated as being more accurate, if prediction frames have no influence on people's judgment.

There were two counter-balancing conditions. First, the order of the congruent and incongruent options was randomized between subjects. Second, the detractors that came true were counter-balanced. For roughly half of the participants the supplier buy out and new U.S. manufacturing plant turned out to be true, while for the other half it was the opposite.

We then asked participants "Which analyst do you think made the better predictions?" and "Which analyst do you think was more confident about the predictions?" This was followed by a memory test. We asked the participants to indicate whether each of the five events happened in the actual outcome. Then to investigate the influence of participants' numeracy on their judgments, we added the 8 -item abbreviated numeracy scale from Weller et al. (2012). After the numeracy section, participants answered a few demographics questions, including two questions about their level of knowledge concerning stock trading and technology.

\section*{Results}

There were a total of 85 participants ( \(60 \%\) female; one declined to self-identify). We discarded data from 29 (25.4\%) participants: 27 for failing the AC and 2 for leaving over \(80 \%\) of the answers blank \({ }^{2}\). Mean age was \(33.1(s . d .=12.87)\) and \(87.1 \%\) had at least some college education.

The portion of workers who failed the AC was higher than the previous experiments. We ran a 4 (experiment) \(\times 2\) (number of AC pass/failure) \(\chi^{2}\)-squared test of independence and the results were significant \(\left(\chi^{2}(3, N=414)=19.33, p<0.01\right.\), \(\phi=0.22)\). However, there was no a priori reason to suspect that the workers in this experiment were different from those in the previous ones. In all four experiments, the AC was the second question in the entire experimental procedure, after only the question that elicited their MTurk ID. Therefore up to the AC , the experimental procedures of all four experiments were essentially the same. The monetary reward was the only difference between this experiment (US\$0.20) and the previous ones (all three at US\$0.15). However, Mason and Watts (2009) have found that financial incentives do not significantly impact the quality of MTurk experiments, even for amounts that differ by as much as 10 times. To further confirm the quality of the data, we checked the result of the memory test. The range of the memory score was from 0 to 5 (remembered perfectly). The mean memory score across all participants was 4.25 , indicating that the participants remembered the details of the experiment well. Hence, we attribute the high AC failure rate to coincidence.

The main objective of this experiment was to test whether the PSFE could be extended to a choice task. More partic-

\footnotetext{
\({ }^{2}\) No other participants left more than one of the nondemographic answers blank.
}
ipants ( \(56 ; 65.9 \%\) ) chose the analyst in the congruent condition \((15 \%)\) as more accurate, compared to the one in the incongruent \((80 \%)\) condition ( \(29 ; 34.1 \%\) ). A \(\chi^{2}\)-squared test indicated that it was significantly different from chance \(\left(\chi^{2}(1, N=85)=8.58, p<0.01, \phi=0.32\right)\).

We then examined whether perception of overconfidence was related to PSFE. There were 35 ( \(41.2 \%\) ) and 50 ( \(58.8 \%\) ) participants who judged the congruent and incongruent option, respectively, as more confident. The result was close to reaching significance \(\left(\chi^{2}(1, N=85)=2.65, p=0.10\right.\), \(\phi=0.18\) ). This suggests that perception of predictors' overconfidence might play a small part in this effect and deserves further investigation.

The order of presentation had a big effect on choice. In conditions where the incongruent option was presented first, there were about the same number of participants who chose the congruent option \((N=21)\) as those who chose the incongruent option \((N=20)\) as more accurate. However, if the congruent option was presented first, 35 (vs. 9) participants judged the congruent option as more accurate. The interaction was significant \(\left(\chi^{2}(1, N=85)=7.58, p<0.01\right.\), \(\phi=0.30\) ). This suggests that order of presentation significantly influenced evaluation of accuracy. However, order of presentation did not have a significant effect on evaluation of confidence \(\left(\chi^{2}(1, N=85)=0.24, p=0.62, \phi=0.05\right)\). The other counter-balancing condition - which pair of distractors turned out to be correct - had no significant effect on evaluation of accuracy ( \(p=0.37\) ) nor confidence ( \(p=0.79\) ).

We also investigated the effect of numeracy on people's judgments. As there are eight questions in Weller et al.'s numeracy scale, the range of the numeracy scores is from 0 to 8. No participant answered the mammogram question correctly. In fact, no answer came within 3 percentage point of the correct answer. This is not surprising because this question has been found to be a very difficult question (see Weller et al., 2012). The percentage of participants who answered each question correctly (Table 1) was in fact quite close to the result obtained by Weller et al. (2012). This suggests that the numeracy and motivation of the participants in this experiment were comparable to those in their experiment. This result also partly mitigated the concern raised by the high percentage of participants failing the AC.

The mean (and s.d.) of the numeracy score for participants who chose the congruent or incongruent options as more accurate were 4.43 (1.45) and 5.41 (1.45), respectively. We fitted a logistic model using the numeracy score as the independent variable, and participants' choices as dependent variable. Results indicated that the influence of numeracy was significant ( \(\beta=0.75, z=2.74, p<0.01\) ). This suggested that participants who were lower on numeracy are more likely to consider the analyst in the congruent option - the normatively less accurate of the two - the more accurate predictor.

The effect of self-reported knowledge about stock trading and technology on choice of more accurate prediction was not significant in either case ( \(p=0.80\) and \(p=0.56\) ).

Table 1: Percentage of participants correctly answering each item of the numeracy scale in Experiment 3 (E3), compared to the results from Weller et al. (2012).
\begin{tabular}{rrrrrrrrr}
\hline & Q1 & Q2 & Q3 & Q4 & Q5 & Q6 & Q7 & Q8 \\
\hline E3 & 0.0 & 27.1 & 45.9 & 57.6 & 80.0 & 81.2 & 96.5 & 88.2 \\
W & 11.0 & 26.5 & 39.8 & 42.1 & 60.4 & 70.2 & 73.8 & 84.8 \\
\hline
\end{tabular}

\section*{Discussion}

The key objective of this experiment was to investigate whether PSFE would hold in a choice task. We also put PSFE to a stronger test because the congruent option was presented vis-à-vis a logically superior option. Our results found that significantly more participants would choose the congruent option, suggesting the robustness of PSFE. We also found that perception of overconfidence did not explain PSFE. However, numeracy was found to be a moderating factor. Like Peters et al. (2006), we found that people who are higher in numeracy to be less susceptible to framing effects.

\section*{General Discussion}

We proposed a new phenomenon, probabilistic statement framing effect (PSFE), that occurs when predictions made in congruent frames (relative to eventual outcomes) are judged as more accurate, compared to logically equivalent or even superior predictions made in incongruent frames. Across four experiments, we found that this effect holds regardless of real world based event (Pilot Experiment) or hypothetical events (Experiments 1 to 3), and rating (Pilot and Experiment \(1 \&\) 2) or choice (Experiment 3) task. The effect held even when the congruent option was logically inferior (Experiment 3). Finally, we found numeracy to be a moderating factor.

The results from these experiments suggest that a majority of people do not evaluate the goodness of predictions in a normative manner. They overweight the qualitative component of a prediction while underweighting its quantitative component. This is especially true for people who are low in numeracy. The findings in this paper might have important implications in domains such as personal finance, medical decision making, and corporate strategic planning.

Among the three major types of framing effects, PSFE might be most closely related to the attribute framing effects. However, we argue that it is distinct for one major reason. Levin et al. (1998) demonstrated that attribute framing effects occurs because positive frames evoke favorable associations in memory; and vice versa for negative frames. However, PSFE can favor evaluations of negative frames (e.g. losing a game in sports), as long as the predictions are congruent to the outcome. This cannot be explained using the above framework and therefore we suggest that PSFE should be regarded as a separate phenomenon.

Although the effect seems to be robust across a broad range of conditions, its causal mechanism and cognitive processes are not well understood. Moreover, prior research has suggested that important personal decisions are less influenced by frames (Marteau, 1989). We are currently examining what
roles information leakage (Sher \& McKenzie, 2006), selective attention (Levin, 1987), and encoding of information (Levin \& Gaeth, 1988), might play in relation to this effect.

All experiments here have been carried out through MTurk. This enabled us to collect data from a subject pool more diversified than one that of a university sample. Moreover, MTurk has been found to be able to yield high quality data (Buhrmester, Kwang, \& Gosling, 2011), and be able to replicate a number of classical findings (Crump, McDonnell, \& Gureckis, 2013). However, it might be interesting in the future to study this phenomenon in lab-based and field studies.

The findings in this paper demonstrate the psychological impact of prediction frames on how people evaluate predictions with respect to outcomes. When predictions are described in congruent frames as the eventual result, people consider them as more accurate than if they were described in incongruent frames. This observation is not captured by the previous literature on framing effects and highlights the need for a better understanding of the processes that underlies this phenomenon.
Acknowledgments. We thank the very helpful comments from four anonymous reviewers.

\begin{abstract}
Aesthetics and the arts have garnered more attention within cognitive science in recent years. Despite this increasing interest, "scientists of art" often focus on one of two areas: the formal properties of artworks themselves, or the mental processes involved in perceiving these works in an isolated, one-on-one encounter. In this paper, I review some representative examples of such work before suggesting some alternative ways that cognitive science might approach aesthetics and the arts-ways that would complement the isolationist approaches that have predominated to this point. In doing so, I draw on the observations and arguments of various philosophers of art, highlighting some of the socially and culturally situated factors that are important in shaping the development of our taste and sensibilities.
\end{abstract}

Keywords: Aesthetics; Culture; Social Cognition; Art.

\section*{Introduction}

What can cognitive science tell us about aesthetic experience? Given the putative aims of cognitive scienceroughly, "to provide a cogent scientific account of how human beings achieve their most remarkable symbolic products" (Gardner, 1987, p. 391)—artistic and aesthetic phenomena fit within the scope of the field. While they have long been fringe topics within the field, they have been garnering increasing attention in recent years. This work ranges from so-called neuroaesthetics (Ramachandran \& Hirstein, 1999), which seeks to uncover the evolved neural underpinnings of our aesthetic responses, to computational aesthetics (Hoenig 2005), which employs sophisticated mathematical tools to analyze the formal properties of various aesthetic objects. Meanwhile, others have focused more on the representational and/or computational processes involved in perceiving and appreciating works of art

Despite this recent interest, there remains a deep-seated tension between the aims of science, which prizes generality, laws, and quantification; and the arts, which we experience qualitatively through encounters with particular works (songs, paintings, films, etc.). Furthermore, these experiences take place amid a complex background of social, cultural, and historical influences. Thus, one could argue that the goals of science are simply incompatible with the kind of understanding we seek when it comes to aesthetics and the arts. Such misgivings have been voiced by many philosophers (Dickie, 1962; Morgan, 1950; Wittgenstein, 1967) and even some psychologists (e.g., Arnheim, 1991). Others view these misgivings as stubbornly anti-science, insisting that the problems faced by
"scientists of art" are merely very difficult, not fundamentally intractable or ill-conceived. If the results of their efforts have been meager, they argue, it is because of this difficulty, together with the fact that it's still early-and after all, one must start somewhere (cf. Berlyne, 1971; Birkhoff, 1932; Meyer, 1957; Rigau, Feixas \& Spert, 2008).

Instead of trying to resolve this longstanding debate, I want to focus on the picture of aesthetic experience that has tended to emerge from cognitive science's encounters with the arts. According to this picture, the artwork (or other aesthetic object) is treated as an isolated stimulus, while the viewer or listener is treated as a sort of idealized receiver of the information encoded in the work. With this picture in mind, researchers typically either focus on (a) the intrinsic properties of artworks (or other aesthetic objects), as with much of computational aesthetics; or (b) on the mental processing involved in perceiving and appreciating art (Kintsch, 2012; Leder, Belke, Oeberst \& Augustin, 2004).

In this paper, I want to look more closely at some of this research, with the dual aim of showing what we can learn from it as well as what its limitations are. In keeping with the theme of the conference ("Cooperative Minds: Social Interaction and Group Dynamics"), I also want to suggest some alternative ways of approaching aesthetics and the arts-ways that would complement the isolationist approaches that have predominated to this point. In doing so, I draw on the observations and arguments of various philosophers of art and aesthetics, highlighting some of the socially and culturally situated factors that are important in shaping the development of our taste and sensibilities.

There are three main sections in this paper. The first looks at research (both recent and not-so-recent) on the perception, appreciation, and value of visual art; the second looks at some parallel work on music (in particular, on musical meaning); and the third focuses on outstanding questions and possible future directions for research.

\section*{Order, Complexity, and Value in Visual Art}

The scientific study of aesthetics date back to at least the 1870s and Gustav Fechner (cf. Arnheim 1985). However, the work of mathematician George Birkhoff's Aesthetic Measure (1933) remains an important landmark in this pursuit. Birkhoff's quest to formalize beauty yielded a succinct mathematical equation, \(M=O / C\), where \(M\) is the aesthetic measure (or value) of the stimulus in question, \(O\) is the order, and \(C\) is the complexity. This equation was thought to crystallize Fechner's notion of "unity in variety" while providing a "logical tool in order to answer aesthetic
questions by purely mathematical (logical) reasoning" (p. 46). Birkhoff asked, and sought to answer, questions such as, "Which is the most beautiful of all polygonal forms?"

Birkhoff's approach was grounded in two key assumptions. First, it is assumed that the formal properties of the aesthetic object (e.g., symmetry, equilibrium, number of components, etc.) can be isolated from its connotative (i.e., referential or associative) properties. Second, he believed that the same kinds of methods employed in simplified domains (e.g., geometric forms) could be applied to other, more complex domains such as visual art, poetry, and music. The difference between the two was thought to be merely one of degree, not of kind.

\section*{Optimal Complexity, Pleasure, and Arousal}

Birkhoff's conception of aesthetic measure influenced subsequent efforts by psychologists (e.g., Eysenck 1942) and information theorists (e.g., Moles 1966). The latter would recast Birkhoff's order and complexity as redundancy and entropy, respectively. The informational and psychological approaches were brought together by Berlyne (1971). Berlyne conceptualized the link between the two in terms of the Wundt curve (Fig. 1). The idea was that people prefer stimuli of moderate-but not excessivenovelty and complexity. The greater the stimulus complexity, the greater the arousal potential, which in turn correlated with a more pleasurable aesthetic experience, so long as the subject was not overwhelmed by the stimulus. Berlyne acknowledged that "what constituted novelty and complexity would vary from person to person" (Margulis \& Beatty, 2008, p. 66), but maintained "that his adapted Wundt curve could apply to both of them; it would simply shift along the x -axis to reflect the experience level" of the perceiver (ibid.).

Figure 1: The Wundt curve. From Margulis and Beatty (2008); adapted from Berlyne (1971).

Surely, there is some truth to this sort of "Goldilocks theory" of complexity and optimal arousal. However, there is also a clear tradeoff between (1) the level of generality sought in such a theory and (2) the degree of fidelity one
would hope for in a genuinely enlightening account of musical experience. In order to achieve the latter, it becomes necessary to reincorporate just those factors-listener background, experience, personality, mood, et cetera-that must be subtracted out in order for the information-theoretic approach to get off the ground. What I want to suggest is that the factors influencing this "shift along the x -axis" are where much of the interest lies. (I will return to this point below.)

\section*{From Aesthetic Measure to Computational Aesthetics}

Computational aesthetics (Hoenig, 2005) is the most recent offspring of Birkhoff's aesthetic measure and its subsequent reformulations in terms of information theory. Various researchers have picked up on these threads, including Koshelev, Kreinovich, and Yam (1998), who recast aesthetic measure as a joint function of (a) the length of the shortest program required to generate a given visual design and (b) the running time of this program; and Machado and Cardoso (1998), who recast it as0020the ratio between image complexity and processing complexity.

More recently, Rigau, Feixas, and Sbert (2008) created several reformulations of Birkhoff's aesthetic measuremost notably, as the ratio between algorithmic reduction of uncertainty and initial information content, which correspond, respectively, to order and complexity. Essentially, this ratio measures "the degree of order created from a given palette" (2008, p. 131), with the "palette" construed as "the range of colors selected by the artist with a given probability distribution" (p. 128). This and other measures are applied to paintings by Mondrian, Pollock, and van Gogh, resulting in is a series of rank-orderings that, not surprisingly, show Mondrian's works to possess a higher degree of order than those of the other two painters.

These proposed metrics are intended to "help us ... quantify the aesthetic experience" (p. 124), but it is questionable what we are to make of them. Are these formulas being proposed as measures of aesthetic value (in which case Mondrian trumps van Gogh and Pollock)? Would these metrics be able to discern the difference between a genuine Pollock and an imitation, or between a Mondrian painting and some generic arrangement of primary-colored geometric forms? Do the authors themselves draw a distinction between artistic value and mere pleasantness? It is not quite clear what lessons we are to take from this work.

\section*{Meaning, Information, and Entropy in Music}

The quest to formalize aesthetic value in the visual arts has parallels in the attempt to quantify meaning in music. The work of Leonard Meyer (1957) is a touchstone here. Meyer linked musical meaning to expectation, uncertainty, probability, observing that "the rules of musical grammar and syntax found in textbooks on harmony, counterpoint, and theory in general" are "almost invariably stated in terms of probability" (p. 414). Conceived of in this light, the
"meaning" of a musical event-a note, a chord, or a phrase-is inversely proportional to its probability: low probability events (such as the sounding of a \(D b\) in the key of C ) are more surprising and thus more meaningful. Meyer summarized, "Both meaning and information are thus related through probability to uncertainty" (p. 416). The greater the probability, the lower the information, or entropy.

By operationalizing musical meaning in terms of information theory, Meyer lent the former a newfound precision. However, the tradeoff is that this precise characterization does not intuitively capture what we typically mean when we talk about "meaning," whether in music or in more general terms. "So much for intuitions," one might reply-except that Shannon and Weaver themselves warned against conflating information (in the information-theoretic sense of the term) with meaning. For example, Weaver (1949) stressed that "the rather strange way in which, in this theory, the word 'information' is used ... must not be confused at all with meaning" (p. 12). He added, "It is surprising but true that, from the present viewpoint, two messages, one heavily loaded with meaning and the other pure nonsense, can be equivalent as regards information" (ibid.).

Similar objections were raised by Vermazen (1971) and Sherburne (1966) in direct response to Meyer. One objection, later referred to as the "Information Theory Paradox" (cf. Titchener \& Broyles, 1973), holds that if meaning were tied to uncertainty, then repeated listening to the same piece would yield less and less "meaning" each time-which surely runs counter to experience. The second objection is that the most meaningful music would be that in which all of the musical events within the piece were equally likely to occur at any moment.

\section*{Cultural Noise and Distance}

Meyer anticipated some of the aforementioned objections in his 1957 paper. In order to circumvent them, he appealed to the related notions of cultural distance and cultural noise. Writing during the heyday of serialism, Meyer acknowledged the general public's disdain for modern classical music: "Here 'noise' is the result of a time-lag between the habit responses which the audience actually possesses and those which the more adventurous composer envisages for it" (p. 420). He added that "in their zeal to 'pack' music full of meaning some contemporary composers have perhaps so over-loaded the channel capacity of the audience that one meaning obscures another in the ensuing overflow" (p. 420). Thus, too much meaning (in the information-theoretic sense) can essentially render a work meaningless (in the pre-theoretic sense), at least to lay audiences.
Cultural noise and distance are also invoked to explain why audiences struggle to make sense of music from unfamiliar cultures. In a nutshell, "[T]he more distant a culture is from our present set of habit responses, the greater the amount of cultural noise involved in communication" ( p .
420). While there is truth to this statement, it overlooks that (a) the listener always brings something to the table, even if it is simply a lack of familiarity with the musical style in question; and (b) there is always some degree of distance between listener and work. Meyer's way of factoring out this distance was to take for granted the notion of an "Ideal Auditor"-that is, someone who "knows the style of the piece and the styles of the period and thus has an experiential basis for the expectations which Meyer's theory requires" (Titchener \& Broyles 1973, p. 17). But how do we come to know the style of a piece or the style of a period? As with the confounding factors that caused Berlyne's modified Wundt curve to shift along the x -axis, these factors are worthy of exploration in their own right.

\section*{Meyer Rehabilitated? Huron's Sweet Anticipation}

The most thorough and ambitious attempt to bring Meyer's work up to date can be found in Huron (2006). Huron maintains Meyer's emphasis on listener expectations-and the ways in which they are "exploited" by composers-as the key to a systematic understanding of how music works on the mind/brain. One could debate the "composer as manipulator" characterization that emerges throughout this work, along with the idea that the chief aim of music is to evoke specific emotions in listeners. However, I will instead look briefly at Huron's effort to incorporate cultural context into an account that is otherwise rooted in evolutionary psychology, statistical learning, and information theory.

A specific example comes from a study that compared Balinese and American musicians' predictions of successive notes in a melodic line. The melody was composed in a \(10-\) tone Balinese scale but was unfamiliar to participants in each group. Huron and his associates found that while the Americans performed better than chance, they were outpaced by their Balinese counterparts in terms of both predictive accuracy and confidence (as opposed to uncertainty) in their guesses.
Thus, in contrast to Meyer, Huron does try to account for "cultural noise," or at least one aspect of it. However, we should keep in mind that cultural background plays a more significant role in musical understanding and experience than merely imparting a set of statistical expectations for melodic or harmonic development. For example, what does it really mean to be an "American musician" (or "American listener")? Of course, there are certain melodic, harmonic, and rhythmic norms that most American (and, more generally, Western) listeners are accustomed to. However, underneath the broad umbrella of "Western music," there is a vast array of musical subcultures-pop, jazz, punk, classical, rap, electronic, noise, drone, Tin Pan Alley-most of which can be further subdivided into sub-subcultures. Each subculture (or subgenre) has its own norms, its own aesthetic values. To know a genre (or subgenre, or artist) extends far beyond possessing a matrix of transition probabilities of the sort used to model melodic expectation.

Another way to put it is this: Huron's emphasis on generalities-transition probability matrices, statistical
learning tendencies, and our (mostly) shared evolutionary heritage as human beings-lends itself to a study of what is universal about music cognition (or at least "universal" within a particular culture). This is fine as far as it goes, but this sort of account is not going to supplant the kind of understanding that comes from engaging with particular works and understanding them in particular contextswhether that's the context of a genre, a historical period, an individual artist's work, or whatever else. There is value in the sort of research documented in Huron's book. It's just that the gains made in understanding the psychology of expectation through the study of music are likely to far exceed the gains made in understanding music via the psychology of expectation.

\section*{Sketching an Alternative Approach}

In this section, I highlight some important points and arguments from philosophers of art and aesthetics, with the goal of suggesting alternative ways for cognitive science to engage with aesthetics and the art.

\section*{Aesthetic sensibility and personal development}

Despite David Hume's (1757) ingenious arguments to the contrary, the notion of a fixed "standard of taste" is unrealistic. This is true whether we seek this standard in the form of a group of ideal critics or judges, as Hume suggested, or whether we follow the Birkhoffs of the world in searching for quantifiable measures of aesthetic value. Regardless, the lack of a fixed or objective standard doesn't stop us from seeking to improve our taste and encounter more rewarding aesthetic experiences. The development of taste and aesthetic sensibility is an ongoing process. But how do we know where to look for these more rewarding experiences as we undertake this process of developing our taste? Herwitz (2008) offers some useful suggestions, arguing that "taste is a circular and constructivist enterprise. We are led by others because they elevate our taste to their level, and this because we already have taste" (p. 52). Even so, we are left to ask how we are able to gain an initial foothold in this process.

One suggestion comes from neuroaesthetics (Ramachandran \& Hirstein, 1999), which seeks to uncover the evolutionarily hardwired tendencies that shape our preferences. Certainly, our preferences and tastes are constrained by our biological makeup, but they are not rigidly determined by them. What we know about an artwork or other aesthetic object affects our appreciation of it. This seems like a truism, but it poses problems for nativist accounts of aesthetic preference.

A vivid example comes from Saito (2010), in which the author discusses the example of a lavishly kept green lawn in Arizona. Superficially, the lawn might be visually appealing-the kind of lawn that would make any suburban homeowner jealous. Yet once we come to understand what goes into maintaining such a lawn in the middle of the desert-in particular, the burden it places on the local environment-it is likely to lose some of its appeal. It might
even be perceived as garish or tacky, in much the same way that a previously admired painting loses its luster when it turns out to be a forgery. In other words, we do not just respond automatically and passively to aesthetic stimuli. Furthermore, our differential responses to artworks and other aesthetic objects cannot be simply a matter of differences in processing fluency (think back to Berlyne's modified Wundt curve). How can we better understand the effects of such background knowledge on our aesthetic responses? This is another underexplored question for cognitive science to consider.

\section*{Getting Outside the Frame}

It is a given that scientific research must make certain simplifying assumptions in order to get off the ground. This is especially true when the subject matter is as complex as human aesthetic and artistic experience. That said, many of the assumptions taken for granted by Birkhoff, Berlyne, and their followers have been (indirectly) called into question by the work of philosophers of art, on issues ranging from originality and forgery (Dutton, 1979) to the very distinction between works of art and "mere real things" (Danto, 1992). A unifying thread among these arguments is that neither artistic value nor even an object's status as an artwork can be predicated on mere appearances-that is, by an exclusive concern with what lies "inside the frame." Here we find a basic difference between works of art and psychological stimuli such as Birkhoff's geometric forms. The latter are designed to be context-invariant, perceived and experienced in isolation; the former are not and, in fact, cannot be if they are to be genuinely understood and appreciated. As philosopher Garry Hagberg (2011) recently put it, "Art that we see or hear or read is to a large part constituted by relational interconnections." These connections involve not just other works of art, but the art world itself (Danto, 1992), as well as the broader culture in which art works (and worlds) exist.

Take the case of Mondrian, who has long been a favorite of aesthetic formalists, since his work might initially appear to consist of nothing but pure form. Even here, though, there is more to the story. Kieran (2005) describes a visit to a Mondrian exhibit in which the artist's work was presented in chronological order, allowing for an understanding of the way his style and approach evolved over the years, become increasingly abstract but always "trying to get at the underlying structure of the naturalistic world of appearances" (p. 38). Kieran adds that "unless one is concerned with what Mondrian was striving to capture and express in his artistic development, one will fail to understand and properly appreciate his art" (p. 40). Danto (1992), in his discussion of the work of avant-garde sculptor Eva Hesse, makes a similar point about the role of arthistorical (or "art world") context in criticism.

\section*{Expertise and the "Feeling for the Rules"}

In addition to knowledge about artworks, aesthetic appreciation also draws on less explicit, more tacit forms of
knowledge. This tacit knowledge can be likened to the kind of know-how that Dreyfus and Dreyfus (1988) emphasize in their five-stage model of skill acquisition, the last stage of which is expertise. It makes sense to think of the development of aesthetic sensibility within a given field or genre as tracing a similar arc of development.

In discussing Huron's research on melodic expectation, I suggested that there is more to learning a style of music than, say, internalizing a frequency distribution matrix. But I also raised the question of how we come to know a novel genre or style of music in the first place. Yes, listening is important, but trying to grasp a foreign style of music can be as bewildering as trying to learn a new language without so much as a dictionary. Wittgenstein (1967) offers some illuminating, if occasionally cryptic, hints on this process. As he argues, coming to know a style amounts to developing a "feeling for the rules"-rules that are largely social and cultural in character. This feeling for the rules, when fully "internalized," constitutes a kind of expertise. Novitz (2004) helpfully elaborates on Wittgenstein's terse remarks that "to have a 'feeling for the rules' that are embodied or instantiated in a work or a category of art is to understand the role that they play within the 'culture of a period.' It is to understand their cultural or their social significance" (p. 61). Developing this feeling for the rules goes hand in hand with overcoming the barriers Meyer spoke of in his discussion of cultural noise and cultural distance.

But why should we bother trying to overcome such barriers? One kind of argument suggests that we should try because doing so is intrinsically valuable. As Cooper (2010) puts it, "[A]ppreciation of new beauty is educative, for it requires initiation into traditions, practices and cultural contexts that allow for beauty of a certain kind to become visible" (pp. 63-64). He adds, "[T]his appreciation is an achievement or acquirement that, typically, calls for effort, imagination, and intelligence. Finally, the appreciation is, typically, edifying or improving" (p. 64). In other words, aesthetic appreciation-especially when it comes to "new beauty"-is not an automatic, facile accomplishment, but is often the product of much cognitive "work."

If, as Cooper suggests, this sort of achievement is intrinsically valuable, it seems that it is worth trying to understanding it better. What kinds of imagination and intelligence are involved? Why are some people more open to pursuing such experiences than others? What kinds of barriers-social, cultural, biological, or otherwise-prevent those others from pursuing the kind of "initiation" Cooper describes? At this point, there are more questions than answers, but I believe they are worthwhile questions for us to ask, even if doing so is bound to raise further difficult questions about the scope and methods of cognitive science.

\section*{Conclusion}

The drive to bring aesthetics and the arts under the umbrella of cognitive science is understandable. They are important aspects of our (mental) lives, so to simply ignore them
would be to limit the scope of the field to a perhaps depressing extent. On the other hand, it is still unclear how best to go about studying them. However, as I have emphasized in this paper, there are limits to what can be understood via many of the tried-and-true methods of the past. Artworks differ from garden-variety psychological stimuli in important ways, such that many of the "complicating," noise-like factors-social, cultural, and otherwise - that have traditionally been removed from the equation are actually quite important, and possibly even essential to accurately understanding the phenomena in question.

\title{
An Embodied Perspective of Early Language Exposure
}

\begin{abstract}
Advances in developmental research has made it clear that word learning has a long beginning. Recent work has demonstrated that infants learn words at 6 months of age - that is, before the traditional "first word" milestone in productive language - which is a full year before the usual "naming explosion" in productive vocabulary. Before infants talk, walk, or even point, how can the earliest stage of word learning take place at all? We used recent technology that allowed us to zoom in on the point of view of infants and also the traditional roomview observations to document how infants' visual input is dynamically synchronized with their own participation, as well as from social input in the context of parent-child word learning play. The parents' task was to play with the child with a set of toys as they taught the toys to them. To specifically document the child's dominant view and their participation, we coded the size of the toy object on which the child was focused and who was manipulating the toy at the moment. The results reveal systematic and dynamic links between infants' view and their level of participation.
\end{abstract}

Keywords: embodied perception; word learning context; child-centered view

\section*{Introduction}

Recent advances have made it clear that word learning has an early beginning. A new study has demonstrated that infants comprehend at least some words at 6 months of age - that is, before the traditional "first word" milestone in productive language (Bergelson \& Swingley, 2012) and a full year before the usual "naming explosion" in productive vocabulary (Goldfield \& Reznick, 1990). What is the nature of this very early stage of word learning? What are the experiences when such infants hear words, and are they fundamentally different from the experiences of older infants? During the first 2 years of life, infants learn and refine a whole set of new motor skills that dramatically change the ways in which the body moves and interacts with the environment, and their social interactions consequently also change. Six-month-old infants are relative novices at reaching for objects and do not sit steadily, and so for the most part, objects are brought to them or perceived from a distance; 12-month-olds, in contrast, walk and bring themselves to objects, and 18-month-olds are mobile, socially skilled, and capable of physically achieving their own desires. Do these changes in the ways infants physically interact in the world also change the way they socially interact, and determine the nature of their visual experiences that support word learning?

Needless to say, there are a number of factors that contribute to the process of later word learning, including
social cues such as eye gaze and gesture, prosody, language structure, input frequency, pragmatics, and many others. Yet recent evidence demonstrating effective word learning at a much earlier stage than previously thought suggests the need for investigation of the language learning environment at the earliest stage. Moreover, learners, even very young babies, actively engage in the world by contingently responding to the social gestures of others. In doing so, infants-and perhaps in different ways at different ages - distort regularities and carve up the input in systematic ways. This means that one cannot really consider the input separately from the learners' own actions, because the learner selects and creates the input. Importantly, word learning takes place at any stage of early parent-child interactions, and most often co-occurs with infants' active exploration of objects where their head, hands, or body, and eyes coordinate and shape "input" and possibly optimize their view for initial learning of labels.

Recent work that motivated this present study investigated how early learners create their own visual input by observing the first-person-view during toy play (Smith, Yu, \& Pereira, 2011; Yoshida \& Smith, 2008; Yu, Smith, Shen, Pereira, \& Smith, 2009). These studies typically used a small camera attached to young children's foreheads and documented how this child-centered view provides insight into factors relevant for early word learning. In the work presented here, we sought to study developmental changes in this child-centered view by longitudinally following children from 6 to 18 months in order to detail the quality of their visual input, how it changes over time, and the potential dynamic relation to their rapidly growing physical capacities in the context of parent-child play. Documentation of precise changes in visual experiences mediated through children's own physical growth is essential to studying how infants' changing motor skills serve as strong filters of their early learning experiences, because effective visual attention determines effective learning.

\section*{Emergence of Language Learning}

One crucial question in language learning is how children overcome referential ambiguity - that is, how children selectively extract the referents to map the corresponding words. Effective learning of such a complex skill requires a highly selective process of sampling information from the environment; observing infants' eye gaze reveals a great deal about what they are processing and learn-
ing. Infants' language learning, however, takes place in a dynamically changing context-that of physical growth and motor development. Indeed, acting and knowing are inseparable aspects of human life, and early learning heavily depends on a person's physical capacities and environment. The potential link between language learning and bodily constraints may be uniquely different for different developmental stages. Yet, there are few studies looking directly at the how early bodily experiences influence language learning in relation to an individual's task involvement. As a first step, we document how the early visual input in a language learning tasks relates to the physical constraints of the child's sensory-motor engagement during the task.

\section*{Object Size and Language Learning}

If infants shape the effective view of objects through their own physical growth, consequential actions, and mature social partners' participation, the degree of referential ambiguity or perceptual accessibility may be partially addressed at the level of sensory motor coordination. In a recent study of 18-month-old infants (even some as young as 17 months) in a naturalistic parent-child play context, both parent and infant physically participated in the play (holding objects) at the same level, but objects dominated the child's view (much bigger, thus occluding other objects) when the object was held by the child (Pereira, Smith, \& Yu, under revision; Yu \& Smith, 2012). Infants of this age (18 months) are capable of producing smooth head turnings and can manage a stable posture, suggesting that their own body coordination may help optimize their focus, and bodily movements having a relatively stronger role for the optimal view at this age. This quality of visual experiences was also related to learning object names (Yu \& Smith, 2012), suggesting that how well 18-month-olds can zoom in on objects has important implications for their successful word learning. What happens if younger infants, who seem capable of learning words (Bergelson \& Swingley, 2012), do not yet have the physical capacity to coordinate their bodies to support their optimal view? We specifically targeted younger infants to further our understanding of the role of physical development in the organization of early visual input. We looked at the size of the object in the infants' view at the moment of it being held by the infant or parent.

\section*{Visual Attention, Motor Skills, and Social Development}

Infants and young children's ability to follow eye gaze and pointing directed toward objects is considered a major milestone in the development of joint attention. This type of attention emerges in infants as young as 3 months. It helps early learners identify word meaning and serves a potential communicative function. For infants to develop this ability, they have to coordinate their head and
body so that they can capture the adult's head and eyes as well as the target. As they become more efficient at coordinating their view, they can produce head turnings to follow the adult's movement to maximize the input (Butterworth \& Grover, 1990; D'Entremont, Hains, \& Muir, 1997). If a stable view containing all the important elements for effective attention and learning is important, then one might think that 6 -month-olds, whose head movements are less active (thus much more stable) and views more distal, would be in a better position to capture all the relevant components than more advanced infants who are capable of producing more movements. However, there is one study using a peripheral distracter to measure the focus of 7 - to 10 -month-olds' attention which found infants were more attentive - and showed potentially more effective attentional shifts-when engaged in active play than when receptively observing the task stimuli (Oakes, 1994). Another previous observation points to an interesting potential role of a social partner, suggesting that caregivers naturally respond to children's motor skill changes in order to support the transformation (e.g. Zumbahlen, 1997). These studies raise the question of how, exactly, an infant's own physical participation shapes the development of visual experiences and possibly influences the social partner's physical participation. If infants are not capable of bringing toys to their view, does this motivate the parent to help the infant gain a better view by bringing and holding the objects themselves? Or is the quality of the infants' view tightly linked to their own physical growth (with minimal parental support), thus emerging poorly yet dramatically improving as a function of their physical growth and advances in body coordination?

In the present study, we investigated two components that together influence an infant's visual focus: (a) who brought the object to the child's view (parent/social partner or the child), and (b) how parents' participation reflects their child's physical constraints. Studying how visual and bodily experiences support language learning reveals what contributes to effective visual attention, such as joint attention, and how such effective attention may emerge through both the child's own experiences and parental participation.

Figure 1: Snapshots showing the first-person (right) and third- person (left) view from Yoshida and Smith (2008).

Figure 2: Snapshot of third-person views of the same child across five sessions.

\section*{Child-centered View}

In a head camera study of parent-child play, Yoshida and Smith (2008) recorded 18 -month-old infants' perspective in the context of a parent teaching a set of early learned words while the parent and child sat naturally at a table. The results revealed that the child's view was much more constrained (captured fewer items) compared to the room view (see Figure 1) and provided evidence of the coupling of head and eye movements. Yoshida and Smith (2008) independently measured eye gaze direction (frame by frame via a camera fixated on the infant's eyes) and head direction and found that eye and head directions were highly correlated, such that \(87 \%\) of head camera frames coincided with independently coded directions of eye gaze.

In this study, we used the same procedure to capture younger infants' point of view. We monitored the development of their view by following a set of infants from 6 months to 18 months, testing them every 3 months to document how their focus changes over time, and how their own object exploration and parent's support (in bringing objects) relates to their view (demonstrated by Figures 2 and 3).

Because of the current focus on much younger children than have been studied in the past, we used a slightly different setup - the infant was supported in a child's chair and the parent sat diagonal to the infant-yet we maintained the relational position between the infant and parent used in the previous study. Moreover, a previous head camera study (Smith et al., 2011) evaluating head camera images from different seating arrangements (sitting naturally in a chair or on the floor) found no differences in any aspect of infant or parent behavior as a function of the task geometry, suggesting minimal impact from the current modification to the sitting arrangement. Another modification is that we used the head-mounted portable eye-tracking device (Figure 4) instead of a head camera to ease the difficulty of calibrations. With the head-mounted eye-tracking device, eye gaze can be directly measured and calibration issues can be better addressed without having the infants point to the object of their fixation (typically camera adjustments are made by asking infants to point to or touch what they are looking at).

To run the experiment, we placed an infant in the chair, and then one experimenter put a light weight headmounted eye-tracking device on the infant's forehead while another experimenter distracted the infant by intro-

Figure 3: Images corresponding to a distinct developmental time point, which demonstrates the changes in object size over time and parent-child interactions.
ducing him or her to a set of attractive toys (which made noise and had colorful moving lights). A standard camera recorded the play scene from a corner of the room, so that we collected synchronized third- and first-person-views, as in Yoshida and Smith (2008). In the present study we used naturalistic word learning in the context of playing with toys. The parent was instructed to teach the infant a set of words by selecting the toys the parent thought were most appropriate to play with from a collection of available toys.

Figure 4: Snapshot of an infant (at 6 months) with a headmounted eye-tracking device.

\section*{Study}

With a setup similar to that of Yoshida and Smith (2008), we observed seven infants, starting when they were 6 months old and ending when they were 18 months old, in the context of a parent-child word-learning play session (see Figs. 2 and 3). We specifically investigated the infants' moment-to-moment quality of object view by measuring the size of the focal object (as percentage of image pixels), that is, the image size of the largest object in the infant's view, and determining if the optimal visual moments for an object relate to who is holding it (the infant or parent), and whether this contributes to the infants' development of visual experiences.

\section*{Method}

Participants Seven parent-infant dyads were brought to the laboratory five times (3-month intervals). There were three male and four female infants. Three additional infants began the study but did not contribute to the data because of refusal to wear the measuring equipment. The mean age of the infants was 6.4 months (first visit), 9.2 months (second visit), 12.4 months (third visit), 15.3 months (fourth visit), and 18 months (fifth visit), with each range less than 13 days.

Stimulus and Materials There were eight unique toy objects in a box, located on the floor beside the parent's chair for easy access to them by the parent. Each toy was a naturalistic toy whose name is listed on a developmental vocabulary inventory, McArthur Child Development Inventory (Fenson et al., 1993). Figure 5 shows eight toy objects that were used for parents to teach the typical early-learned words (open, bunny, car, bottle, cookie, eat, drink, put). The order and the duration of playing with them were controlled by the instructions given through the experimenter.

Figure 5: Toy objects used for the word-teaching play sessions.

Procedure Prior to entering the experimental room, the parents were presented with a set of instructions on their type of interaction. Parent and infant then entered the experimental room and were asked to sit in the designated chairs. The experimenter started one camera attached to the wall ( 5 meters away from the chairs) for recording the third-person view, and then put the headmounted eye-tracking device on the child's forehead. The calibration procedure took place to adjust synchronization between camera placement and eye position. The experimenter left the room as she instructed the parents to pace their play and teaching according to the guidance from the audio prompt, which said the name of one of the objects every 40 seconds. The entire session took approximately 6 minutes.

\section*{Results}

The results suggest that a child's view changes dramatically over the course of 12 months of development. At 6 months, the child's view was moderately selective. The focus of the object is then reduced in size at 12 months, then becomes most selective with a sharp increase in object size by 18 months. These changes may be the development of optimal focus, and the results from the room view suggest that the infant's frequency of reaching and holding of objects has a systematic influence on the infant's own view. Furthermore, the parent's participation level also reflected the development of this optimal view.

We first focus on two variables for the present study in order to address the nature of developmental growth in visual experiences. These variables of interest are the
quality of the focused object (how the object looks to the child in terms of the size of the object from their perspective) and also the participation level of the parent and child interacting with the object, determined by the frequency in which either manipulates, holds, or touches the object within a given trial. Eye gaze was measured and tracking data was overlayed onto the video to capture the infant's central view. This was used to aid the coding process and to help determine to which object the child was currently attending.

The coding process involved evaluating individual frames of video to determine the size of the object in view and whether or not the parent and child were interacting with the object. For every 5 seconds of video at 30 fps , multiple data entry fields were randomly generated, giving a total of 250 rows of data per video. Each video corresponds to a single subject and experimental session at a specified developmental time period. Research assistant coders were thoroughly trained to identify the object in view based on the tracking data, and to determine the area of the object in pixels as a proportion of the entire child-centered view. The mean and standard errors of the size proportions are based on sampled frame evaluations and then averaged across all the frames for each 320 second session. A separate set of coders were trained to enter information about the individual that was manipulating the object at each of the sampled frames (if any). Coders made judgments about who was interacting with the object and the type of object seen on screen. The frequency in which parent or child manipulated the object throughout the session was calculated as a proportion based on the total number of cells randomly generated for that session.

The first result, which is evident in Figure 6, shows that objects within an infant's view during the first session take up a moderately sized proportion of their view, yet at 12 months (their 3rd visit), the average size of objects focused within their view is reduced dramatically, and reaches its lowest point during this age. The proportion of all objects in terms of pixel area was greatest at 18 months of age (5th and final visit). There were significant developmental differences in object size between 6 months and 9 months, \((t=2.56 ; p<.01)\), and between 15 months and 18 months, \((t=2.28 ; p<.05)\). There were no significant differences found between ages 9 and 12 months, nor between 12 and 15 months.

The developmental shifts in focus is interesting and suggests that these optimal visual experiences do not come as easy, and do not appear to be a straight linear growth. At the 6,9 , and 12 month points, the size of objects in their visual field seem to fluctuate, and the dip at 12 months may be of developmental significance and contain important information about their physical growth and parental involvement. Initial parental interactions with the infant may help set the stage for determining

Figure 6: The average size of all objects as a proportion of the camera view at each longitudinal time point.
optimal visual experiences while infants learn to properly handle and manipulate objects later on their own.

An infant's optimal view has been characterized by very few objects being focused upon and dominating the infant's visual field (Smith et al., 2011; Yoshida \& Smith, 2008; Yu, Smith, et al., 2009). But, the magnitude of this type of focus appears to change dramatically in one year (see Figure 3), where at least by 6 months, infants show initial steps toward the development of language learning based on both physical growth and environmental interactions. To address this question, we analyzed the variable where coders made a judgment about who was interacting with the object. In absence of a longitudinal perspective, results might suggest that across all developmental time points ( 6 to 18 months) objects were held equally frequent between infants and parents. Yet, as can be seen in Figure 7, as early as 6 months, parents held the object of focus reliably more than infants \(\left(\chi^{2}=6.25 ; p<.05\right)\). This contrasts with later periods, in which children are interacting with objects much more frequently than adults. At 15 months, infants began to reliably hold the objects more often than adults ( \(\chi^{2}=4.9 ; p<.05\) ), and by 18 months, the magnitude of this difference in object interaction was most dramatic ( \(\chi^{2}=7.79 ; p<.01\) ). There were no significantly reliable differences found in object manipulation during the 9 month and 12 month time periods.

During the early stages of development, parental involvement seems to account for a majority of the visual experiences gained by infants, while at later stages, infants are responsible for their own experiences as they hold and manipulate objects with greater frequency. At the 12 month time point, there was no reliable difference in who was holding the object. Interestingly, this is the point where their center view quality drops to as small as \(12.1 \%\). This may be the point at which the parent begins to demonstrate less involvement in shaping the child's visual experiences-and thus a drop in object

Figure 7: Frequency in which participants interact with objects over the course of 5 longitudinal sessions shown as a proportion of the number of coded frames.
focus-which allows for the infant to independently start shaping what comes into their view and determine their own optimal focus, an ability that they apparently are not immediately successful in controlling during the early months.

\section*{General Discussion}

The present findings suggest the contexts for early and later word learning are quite different, and that they shift from greater parental control to greater infant control, with parents ensuring early on that the named object is visually dominant, and the infant plays a more active role later in development. Clearly these findings are just a first step toward understanding the possible, developmentally changing pathways through which infants learn words. Recent advances make clear that infants start learning words much earlier than previously thought (as young as 6 months), before the traditional "first word" milestone in productive language (Bergelson \& Swingley, 2012). The present results suggest that parents may isolate objectsfocusing on objects one at a time, zooming in on a single object-to help this learning. Later, this isolation may be most effectively done when the child actively engages in object manipulation (holding and bringing objects) as suggested by the Yu and Smith (2012) results.

The inflexion point in the visual size of the named object at 12 -months is intriguing, and suggests a possible transition from more parent control toward more infant controlled learning, and the parent following of the child's interests when naming. The 12 -month mark has been noted by others as a period of change in social interactions. For example, whereas very young infants appear to automatically follow the eye-gaze of another (Farroni, Massaccesi, Pividori, \& Johnson, 2004; Hood, Willen, \& Driver, 1998) and follow head movement-not eye-gaze - when head and eye direction are in competition (Brooks \& Meltzoff, 2005; Gergely, Nádasdy, Csibra,
\& Bíró, 1995), 12-month olds appear to require more coherent cues as well as contingent interactions to follow these cues (Tomasello, Hare, Lehmann, \& Call, 2007; Moore \& Corkum, 1998; Johnson, Ok, \& Luo, 2007). In brief, as infants' motor and cognitive skills make them more independent, social interactions and the structure of word learning may change in systematic ways.

The present finding that 12-month-old infants do not seem to experience this optimal view suggests that both parents and infants may be working out this transition. This finding does not mean that the infant and parent are not involved with each other or have no interest in playing. Rather, infants and parents appeared to participate relatively equally. This leads to new insight into how action coordinated through dominant participation (one agent or the other, but not both) maximizes support for the development of optimal view, and it raises a number of novel developmental predictions about the role of action coordination such as emergence of join attention and social contingencies in learning.

Linking word learning to the changing sensory-motor skills of infants may also be key to understanding the co-morbidity of language delay and motor deficits in developmental disorders such as autism (Iverson, 2010). Studying changes in visual experiences mediated through a child's own physical growth and experiences is a way to gain new perspectives on the nature of embodied language learning.

\begin{abstract}
Although word learning unfolds over days, weeks, and months, individual naming events are over in a matter of seconds. To benefit from a naming event, children must at least hear the label and see the referent. We tested 1 -, 2- , 3-, and 4 -year old children in a naturalistic word learning task with two conditions: one that taxed both speech processing and rapid gazefollowing, and one in which a social cue-to-reference was available for an extended time. The development of wordlearning in the extended condition paralleled the development of speech processing, but learning in the brief condition lagged behind. However, learning from both the brief and extended cues was predicted by individual differences in speech processing and cue-following together. Thus, even through the 4th year, real-time processing of social and linguistic information are a critical bottleneck for word learning.
\end{abstract}

Keywords: Language acquisition, word learning, attention, social cues, development

\section*{Introduction}

Language learning is a fundamentally social endeavor - it relies critically on input from social partners. This is because many aspects of natural languages, like the mappings between words and their referents, are conventions that can vary from community to community (Chater \& Christiansen, 2010). To learn their first words, children must track the relationship between the sounds that speakers produce and the things in their world (Pinker, 1984; Siskind, 1996).

Not everything about a word and its referents needs to be learned in a single shot. Instead, it is likely that this relationship is refined over multiple exposures, over a period of days, weeks or months (Carey \& Bartlett, 1978; Smith \& Yu, 2008; McMurray, Horst, \& Samuelson, 2012). Nonetheless, each individual naming event occurs in real-space and realtime (Samuelson, Smith, Perry, \& Spencer, 2011; Spencer, Perone, Smith, \& Samuelson, 2011). If a child does not hear the label, or does not see the target referent, the information "available" in the naming event is effectively unavailable to the child (Yu \& Smith, 2012; Yurovsky, Smith, \& Yu, in press). Thus, a critical bottleneck in language acquisition is the ability to process the right information at the right time (Fernald \& Marchman, 2012).

Young children are slow processors of both speech and visual input (Kail, 1991; Fernald, Pinto, Swingley, Weinberg, \& McRoberts, 1998). They are also slow to re-deploy their attention in response to changing visual information (Colombo, 2001). Thus, it is perhaps unsurprising that the properties of child-directed speech and child-directed actions seem welldesigned to scaffold slow processors. Child-directed utterances are slower, shorter, and have larger pitch contours than do utterances spoken to adults. Repetition is common in
child-directed speech, and key words are made more salient through minor local variations (Onnis, Waterfall, \& Edelman, 2008). In addition, new labels are often introduced through a small set of common naming phrases that facilitate attention tom and learning of, new words (Fernald \& Hurtado, 2006; Yurovsky, Yu, \& Smith, 2012). Exposure to these kind of structure makes a real difference, predicting individual differences in vocabulary development (Hoff, 2003). Childdirected actions are similarly exaggerated, marked by bigger, simpler, and more repetitive movements (Brand, Baldwin, \& Ashburn, 2002). Indeed, multi-modal synchrony between these exaggerated visual and auditory inputs may be precisely the the information that young children use to to learn their first words (Gogate, Bahrick, \& Watson, 2000).

However, while social partners may sometimes scaffold young language learners, simplifying their speech and timing their naming events so that labels coincide with the focus of children's visual attention, this kind of pedagogical naming likely accounts for a minority of the relevant input from which words and their referents could be learned. For instance, while isolated words facilitate speech processing and word learning, they make up less than \(10 \%\) of all speech to children (Brent \& Siskind, 2001). Similarly, referential expressions produced while children are already looking at the target object facilitate word learning, but make up only a portion of the naming events produced to young children (Tomasello \& Farrar, 1986; Frank, Tenenbaum, \& Fernald, 2013). In the remaining naming events, successful learning requires the child to check with the speaker to determine the target of her reference (Baldwin, 1991). Consequently, the ability to quickly process speech, and to quickly follow a speaker's social cues, should both give learners access to more and more useful information.

Over the first two years, children make rapid gains in the rate at which they process auditory input, picking referential words out of continuous speech (Fernald et al., 1998). During this time, individual differences in rate of spoken language processing predict individual differences in vocabulary size (Fernald, Perfors, \& Marchman, 2006). Over the same two year period, children also improve in their abilities to attend to and use social cues indicating the target of a speaker's reference (Scaife \& Bruner, 1975; Hollich, Hirsh-Pasek, \& Golinkoff, 2000). As with speech processing, individual differences in children's gaze- and point-following predict their language development over these two years (Brooks \& Meltzoff, 2006).

But, while the second year is marked by an increase in the rate at which children learn new words, this acceleration in

Figure 1: Example training and test trials from the Experiment. On Extended Cue trials (a), the speaker picked up and interacted with the target toy over the course of \(10-20\) seconds, providing consistent social information about her target reference. On Brief Cue trials (b), the speaker made a quick glance at the target toy, and then looked forward into the camera for the remainder of the trial. Determining her target of reference on these trials thus required rapid social-cue following. On test trials (c), children saw two of the toys from training and heard the speaker's voice ask them to find the target toy.
vocabulary growth continues into the third and fourth years and beyond (Bloom, 2000). Do these same skills in spoken language processing and rapid social-cue following continue to develop and continue to predict word learning over this extended period of vocabulary acceleration?

To determine how speech processing, social-cue following, and word learning co-develop over the first four years, we tested a large cross-sectional sample of children in age from \(1-5\) years in a short, naturalistic word-learning task. Over the course of approximately four minutes, we measured each child's ability to process speech containing a known referent, learn a new word when an Extended social-cue continuously provided disambiguating information about the target referent, and learn a new word the speaker gave only a Brief social-cue to indicate her target referent, requiring rapid gazefollowing. We subsequently fit a linear mixed-effects model to children's looking times to determine how speech processing and social-cue following predicted word learning in both conditions over the course of development.

\section*{Method}

Children's eye movements were tracked while they watched a series of naturalistic word-learning videos. In each, children saw a speaker seated at a table between two novel toys. She introduced them to one of the toys, providing a label and several interesting facts about it. Crucially, on some of the trials she provided an Extended Cue indicating the target of her reference - picking up the object and interacting with it over the course of the video. On other trials, she provided Brief Cue - only a quick glance to the target object when she first labeled it. After each learning trial, children were tested for their knowledge of the referent for the new word using the Looking While Listening procedure (Fernald et al., 1998). In addition, similar test trials were administered for known objects to measure children's processing of familiar words. Because eye movements were recorded during both learning and test, we were able to analyze the relationship between children's behavior during learning and test trials.

\section*{Participants}

Parents and their 1-5 year-old children were invited to participate in a short language learning study while they visited the San Jose Children's Discovery museum. All-together, we collected demographic and experimental data from 114 children, 39 of whom were excluded for one or more of the following reasons: abnormal developmental issues \((N=7)\), failure to calibrate ( \(N=26\) ), less than \(75 \%\) exposure to English ( \(N=13\) ), and fussiness or inattention \((N=22)\). The final sample consisted of \(181-2\) year olds ( \(M_{\text {age }}=1 \mathrm{yr}\).; 7 mo., 9 girls), 25 2-3 year olds ( \(M_{\text {age }}=2\) yr.; 6 mo., 9 girls), \(213-4\) year olds ( \(M_{\text {age }}=3 \mathrm{yr}\).; 6 mo., 8 girls ), and 11 children over the age of 4 ( \(M_{\text {age }}=4\) yr.; 8 mo., 5 girls).

\section*{Stimuli}

The experiment consisted of two kinds of trials: learning and test. Learning trials were \(10-20\) second video clips in which a speaker first introduced herself to the child, and then produced a short monologue about one of the two toys on the screen, labeling it three times. The script for the first learning trial, for example, was "Hey there, can I show you my friend's toys? This is a manu. I really like the manu. The manu is fun to play with." The exact script varied from trial, but always followed this general format. On Extended Cue trials, the speaker picked up the target toy and engaged with it over the course of labeling (Figure 1a). In contrast, on the Brief Cue trials, the speaker indicated her target of reference only with a quick glance to the toy when she first produced it's label. She looked straight into the camera for the rest of the trial (Figure 1b). Thus, learning from Brief Cue trials required children to rapidly follow her gaze.

Test trials followed the standard Looking While Listening protocol (Fernald et al., 1998). On each test trial, children saw two objects - one on each side of the screen - heard a short audio clip of the speaker from the learning trials asking them to find a target object (Figure 1c). Each test trials was 7.5 seconds long. On Familiar test trials, both the target and distractor were common objects familiar to young children (e.g. book vs. dog). On Novel test trials, both the target and distractor were novel objects from the previous learning trial.

Finally, the experiment ended with a calibration check: a short video in which small dancing stars appeared in four places on the screen. Because eye-tracker calibration can be imprecise, especially with younger children (Morgante, Zolfaghari, \& Johnson, 2011), this check allowed us to adjust initial calibration settings to minimize the discrepancy between the behavior children produced and the behavior we analyzed (for details, see Frank, Vul, \& Saxe, 2012).

\section*{Design and Procedure}

The experiment began with a 4-point calibration and then proceeded into a series of learning/test blocks. In each block, children first watched a learning trial in which a speaker labeled one of two on-screen toys. Following this learning trial, children were given a Looking While Listening test trial in which they saw both of these toys and were asked to find the toy labeled on the previous learning trial (e.g. "Can you find the manu?"). Each block consisted to two such learning/test combinations: one for a toy indicated by an Extended Cue, and one for a toy indicated by a Brief Cue (Figure 1a and b). The same toys and the same label (тапи) were used for all Extended Cue trials, and a different set of toys and a different label (bosa) were used for all Brief Cue trials. The entire experiment consisted of three such blocks, and two Familiar test trials were inserted between each block. Thus, in total, each child participated in three learning and test trials in each Cue condition, and four Familiar test trials.

\section*{Data Analysis}

Children's eye movements during both learning and testing were analyzed using a Regions of Interest (ROI) approach. On learning trials, bounding-box ROIs were drawn by a human coder frame-by-frame for the speaker's face and for the two objects. On test trials, a bound-box ROI was drawn for each of the two static images. To ensure that recorded eye movements were mapped to the correct ROIs, children's calibrations were first adjusted by fitting a robust linear regression for their fixations during the calibration check video and using this model to transform eye movements during the rest of the experiment (Frank et al., 2012).

Children's learning and test behaviors were quantified by measuring their proportion of looking to each ROI on each trial. To ensure that proportions were representative, individual test trials were excluded from analysis if eye gaze data was missing for more than half of their duration. To compute age-group looking proportions, proportions were computed first for each individual trial, averaged at the individual-child level, and then averaged across children.

Window-of-analysis selection began by coding the point of disambiguation for each trial. This was the onset of the target label for test trials, and the rotation of the speaker's head for learning trials (marked ' 0 ' in the graphs in the Results section). The window for each trial began 500 ms after this point of disambiguation to allow children of all ages enough time to process. The window ended at the end of test trials, and

Figure 2: Children's probabilities of fixating the correct target of each label over the course of each test trial. The point labeled 0 indicates the onset of the label, and different colors indicate different age groups. Each line indicates the mean proportion of looking for one age group, and shaded areas repent \(\pm 1 \mathrm{SE}\). A proportion of .5 indicates chance performance.
the point at which the label was heard for a second time on learning trials: 2.5 seconds after the point of disambiguation.

\section*{Results and Discussion}

Children's patterns of fixation provide a continuous record of their moment-by-moment visual attention over the course of both learning and test trials. We first present an analysis of word learning and familiar word recognition over development. We then connect test behavior to children's patterns of looking during learning. Figure 2 shows gaze trajectories over the course of both Familiar and Novel test trials for each age group. To quantify children's learning with standard analyses, we aggregated these patterns of looking over time to compute the aggregate proportion of looking at the target object on each test trial.

\section*{Test Trials}

Overall, children in each age range showed evidence of recognizing familiar words - looking at the correct target on Familiar trials for a greater proportion of time than expected by chance \(\left(M_{1-2}=.60, t(16)=2.27, p<.05 ; M_{2-3}=.76\right.\), \(t(22)=10.31, p<.001 ; M_{3-4}=.78, t(20)=7.95, p<.001\); \(\left.M_{4+}=.82, t(9)=8.46, p<.001\right)\). A linear model showed that familiar word recognition improved significantly across development ( \(\beta_{\text {age }}=.07, t(67)=4.12, p<.001 ; r=.46\) ).

When tested for their knowledge of the word from Extended Cue trials, children in the youngest age group did not show evidence of learning \(\left(M_{1-2}=.48, t(17)=-.41, p=\right.\) .68), but children in the older age groups did \(\left(M_{2-3}=.64\right.\), \(t(20)=3.14, p<.01 ; M_{3-4}=.71, t(20)=5.22, p<.001\); \(\left.M_{4+}=.75, t(8)=8.46, p<.001\right)\). Learning from Extended Cue trials also improved significantly across development ( \(\beta_{\text {age }}=.09, t(69)=4.28, p<.001 ; r=.45\) ).

Finally, when tested for knowledge of the word from Brief Cue trials, 1-2 year olds did not show evidence of learning ( \(M_{1-2}=.48, t(17)=-.44, p=.67\) ), 2-3 year olds showed marginal evidence of learning \(\left(M_{2-3}=.59, t(21)=1.96\right.\), \(p=.06\) ), and the older two age groups showed significant evidence of learning; \(M_{3-4}=.60, t(20)=2.41, p<.05 ; M_{4+}=\) \(.74, t(9)=6.57, p<.001)\). As with the other conditions, learning from Brief Cue trials improved significantly across development \(\left(\beta_{\text {age }}=.08, t(69)=3.64, p<.01 ; r=.40\right)\).

Together, these results provide clear evidence of a developmental trajectory in both word learning and word recognition (Figure 3). Word recognition and learning from the Extended Cue improved particularly rapidly over early development, consonant with previous work examining the link between speech recognition and early word learning (Fernald et al., 2006; Fernald \& Marchman, 2012). Because the speaker in the Extended Cue condition continued to provide a social cue-to-reference over the course of labeling, the primary hurdle to learning in this condition was speech processing rather than referential ambiguity. The Brief Cue condition, however, presented an additional challenge: children needed to rapidly follow the speaker's social gaze to determine her target of reference. In this condition, the biggest jump in performance came much later in development. While 2-3 year olds showed marginal evidence of learning from the Brief Cue, and learning in 3-4 year olds was statistically significant, only the oldest children showed robust evidence of learning. Because children in the middle age groups are well into the stage of development at which they attend to and learn from social cues, it is likely that Brief Cue condition was difficult for them precisely because it required rapid processing of referential information (Baldwin, 1991; Hollich et al., 2000).

These results suggest that a critical bottleneck in early word learning may be attention in-the-moment: children need to process speech and social information quickly enough to determine the label and target of reference.

Figure 3: Children improved in their abilities to recognize familiar words, and to learn from both the Extended and Brief Cues over the course of development. Individual lines indicate different age groups and error bars indicate \(\pm 1\) SE.

Table 1: Predicting Learning of Novel Words.
\begin{tabular}{lrrr}
\hline Predictor & Estimate (SE) & \(t\) Value & Significance \\
\hline Intercept & \(.34(.09)\) & 4.04 & \(p<.001\) \\
Age (yrs) & \(.06(.02)\) & 3.18 & \(p<.001\) \\
Brief Cue & \(.04(.04)\) & 1.00 & \(p=.34\) \\
Familiar Test & \(.25(.12)\) & 2.09 & \(p<.05\) \\
Face Prop. & \(-.23(.08)\) & -2.91 & \(p<.01\) \\
\hline
\end{tabular}

\section*{Connecting Learning and Test}

In addition to recording children's patterns of looking on test trials, we also captured their looking behavior during learning. This allowed us to chart the developmental trajectories of looking at the caregiver's face and at the target of reference. Figure 4 shows the time course of looking for each age group in both Cue conditions around the point of disambiguation.

In the Extended cue condition, looking patterns were qualitatively similar across development. At all ages, children oriented to the speaker's face as she began speaking, and then switched their attention to her target of reference between 500 ms and 1.5 s after she produced the label. They continued to look predominantly at this target object for the next several seconds. There were apparent quantitative differences for instance the youngest children were slowest to disengage form the face, but the Extended cue scaffolded children at all ages into finding the target of reference and sustained their attention on it.

In contrast, looking patterns in the Brief cue condition changed qualitatively across development. Children in the youngest two age groups generally maintained fixation on the speaker's face long after the point of disambiguation, and were relatively unlikely to attend to the target referent. Thus, they were not able to process the speaker's social gaze quickly enough to use it for disambiguation. In contrast, the 3-4 year olds, and especially children over the age of four, showed evidence of disengaging from the face and following the speaker's gaze to find her intended referent. These data provide evidence of children's developing abilities to track and use social information in real-time at a rapid rate.

To determine whether these developing abilities to process speech and social cues contribute to word learning, we fit a linear mixed-effects model to the data (Baayen, Davidson, \& Bates, 2008). This model used children's age, their accuracy on Familiar test trials, and their looking during learning trials to predict their test accuracy for both Extended and Brief cue trials. Table 1 shows coefficient estimates and their significance for each of these predictors. While Cue type was not a significant predictor, age and Familiar test accuracy were both significant positive predictors of test accuracy, and looking to the speaker's face was a significant negative predictor. No interaction terms approached significance. \({ }^{1}\)

\footnotetext{
\({ }^{1}\) When looking to the target was included instead of looking to the face, this term was a significant positive predictor \((\beta=.18, t=\)
}

Figure 4: Children's looking patterns during learning for both Extended Cue and Brief Cue trials. The top row shows looking to the target referent and the bottom row shows looking to the speaker's face. Dotted lines at ' 0 ' indicate the point of disambiguation. Looking patterns were qualitatively similar in the Extended Cue condition across development, but diverged significantly in the Brief Cue condition. Only the oldest two groups of children were able to rapidly follow the speaker's social cue.

Thus, children who were fast at picking the label out of the speaker's utterance, and fast to follow her social cue in both Cue conditions were the most likely to learn the mapping between the word and its target referent. Because age was also a significant predictor, even after accounting for speech processing and cue-following, there must be additional changes in cognitive processing across development that moderate to the connection between real-time attention and ultimate word learning (e.g. working memory). Nonetheless, these data provide strong evidence that children's abilities to process both speech and social signals change over the course of the first four years, and that changes in these skills are important contributors to word learning.

\section*{Conclusion}

Although children may learn words by aggregating information across a number of naming events (Pinker, 1984; Smith \& Yu, 2008), their success must ultimately be constructed from the information they acquire in each individual event. Because both speech and social cues to reference are rapid, serial channels, getting the most out of each naming event requires processing words and identifying social referents quickly and accurately. Our data suggest that the ability to do both of these things develops significantly over the course of childhood, and that both of these abilities are related to the ability to learn novel labels for novel objects.

While a large body of work has established the relationship between children's language processing speed and their later language outcomes (Fernald et al., 1998, 2006), our study

\footnotetext{
\(1.996, p<.05)\). However, this model gave a slightly poor fit to the data, so we report the version including looking to the face.
}
adds to this literature by suggesting that processing speed is important in social understanding as well. Much of the early social input that children receive from their caregivers is the social equivalent of child-directed speech: slow, clear, and focused on accessible referents. But as children develop and begin to interact with others, they may encounter an increasing proportion of situations in which they need to track a fleeting glance or a subtle reference. Being able to apprehend these brief social signals may play an important role in allowing children to learn across a range of environments.

More generally, becoming a better word learner is about getting more information out of less input. Many developments that are linked to better word learning - the emergence of mutual exclusivity, the shape bias, and increased speed in language processing (Yurovsky, Bion, Smith, \& Fernald, 2012; Smith, Jones, Landau, Gershkoff-Stowe, \& Samuelson, 2002; Fernald \& Hurtado, 2006) - have their effects because they allow children to glean information about word meanings from their environment more effectively. The work in this paper suggests that children's developing understanding of the social environment may have a similar role in early word learning.

\begin{abstract}
How people achieve long-term goals in an imperfectly known environment, via repeated tries and noisy outcomes, is an important problem in cognitive science. There are two interrelated questions: how humans represent information, both what has been learned and what can still be learned, and how they choose actions, in particular how they negotiate the tension between exploration and exploitation. In this work, we examine human behavioral data in a multi-armed bandit setting, in which the subject choose one of four "arms" to pull on each trial and receives a binary outcome (win/lose). We implement both the Bayes-optimal policy, which maximizes the expected cumulative reward in this finite-horizon bandit environment, as well as a variety of heuristic policies that vary in their complexity of information representation and decision policy. We find that the knowledge gradient algorithm, which combines exact Bayesian learning with a decision policy that maximizes a combination of immediate reward gain and longterm knowledge gain, captures subjects' trial-by-trial choice best among all the models considered; it also provides the best approximation to the computationally intense optimal policy among all the heuristic policies.
\end{abstract}

Keywords: Bandit problems; human decision making; human active learning; knowledge gradient

\section*{Introduction}

How humans achieve long-term goals in an imperfectly known environment, via repeated tries and noisy outcomes, is an important problem in cognitive science. The computational challenges consist of the learning component, whereby the observer updates his/her representation of knowledge and uncertainty based on continual observations, and the control component, whereby the observer chooses an action that somehow balances between the need to obtain immediate reward and to obtain information that assists long-term reward accumulation.

A classical task setting used to study sequential decisionmaking under uncertainty is the multi-armed bandit problem (Robbins, 1952). The bandit problems are a family of reinforcement-learning problems where the decision maker must choose among a set of arms on each trial: the reward gained on each trial both has intrinsic value and informs the decision maker about the relative desirability of the arms, which can help with future decisions. In the basic bandit setting, each arm has an unknown probability of generating a reward on each trial. The problem is called finite horizon if the total number of trials is finite; it is called infinite horizon if the number of trials is infinite, in which case one either discounts future rewards or tries to maximize average reward per unit time. In this work, we focus on stationary, non-discounted, finite-horizon bandit problems, where the underlying reward rates are independent and identically (iid) distributed across the arms.

Bandit problems elegantly capture the tension between exploration (selecting an arm about which one is ignorant) and exploitation (selecting an arm that is known to have relatively high expected reward), which is manifest in many real-world decision-making situations involving noise or uncertainty. Bandit problems have been well studied in many fields, including statistics (Gittins, 1979), reinforcement learning (Kaebling, Littman, \& Moore, 1996; Sutton \& Barto, 1998), economics (Banks, Olson, \& Porter, 2013, e.g.), psychology and neuroscience (Daw, O'Doherty, Dayan, Seymour, \& Dolan, 2006; Cohen, McClure, \& Yu, 2007; Steyvers, Lee, \& Wagenmakers, 2009; Lee, Zhang, Munro, \& Steyvers, 2011). There is no analytical solution to the general bandit problem, though properties about the optimal solution of special cases are known (Gittins, 1979). For relatively simple, finite-horizon problems, the optimal solution can be computed numerically via dynamic programming (Kaebling et al., 1996), but its computational complexity grows exponentially with the number of arms and with the time horizon. In the psychology literature, a number of heuristic policies, with varying levels of complexity in the learning and control processes, have been proposed as possible strategies used by human subjects (Daw et al., 2006; Cohen et al., 2007; Steyvers et al., 2009; Lee et al., 2011). Most models assume that humans either adopt simplistic policies that retain little information about the past and sidestep longterm optimization (e.g. win-stay-lose-shift and \(\varepsilon\)-greedy), or switch between an exploration and exploitation mode either randomly (Daw et al., 2006) or discretely over time as more is learned about the environment (Steyvers et al., 2009).

Here, we analyze a new model for human bandit choice behavior, based on the knowledge gradient (KG) algorithm, which has been developed by Frazier, Powell, and Dayanik (2008) to solve problems in operations research. At each time step, the KG policy chooses, conditioned on previous observations, the option that maximizes future cumulative reward gain. It is based on the myopic assumption that the next observation is the last exploratory choice, used to learn about the environment, and all remaining choices will be exploitative, choosing the option with the highest expected reward by the end of the next trial. Note that this myopic assumption is only used in reducing the complexity of computing the predicted value of each option, and not actually implemented in practice - the algorithm may end up executing arbitrarily many non-exploitative choices. Despite a certain greedy aspect to the KG control policy, it is not completely short-sighted. In particular, it tends to explore more when the number of trials left is large, because finding an
arm with even a slightly better reward rate than the currently best known one can lead to a large cumulative advantage in future gain; on the other hand, when the number of trials left is small, KG tends to exploit and stay with the currently best known option, because it knows that finding a slightly better option will not lead to large improvement, while the risk of wasting time on a bad option is high. KG is also known to be exactly optimal in certain special cases (Frazier et al., 2008), such as when there are only two arms.
KG has several advantages over previously proposed algorithms. Unlike the simple heuristic algorithms such as win-stay-lose-shift and \(\varepsilon\)-greedy, and in common with the other Bayesian learning algorithms (Daw et al., 2006; Steyvers et al., 2009; Lee et al., 2011), KG uses a sophisticated Bayesian posterior distribution as its belief state at each time step. Unlike the other Bayesian learning algorithms, KG gracefully and gradually transitions from primarily exploring to primarily exploiting over the course of a finite-horizon bandit experiment. Also unlike previously proposed algorithms, which typically assumes that the stochastic component of action selection is random or arbitrary, KG also provides a more sophisticated and discriminating way to explore, by normatively combining immediate reward expectation and long-term knowledge gain. On the other hand, in contrast to the optimal algorithm, which scales exponentially in computational complexity with respect to the number of remaining timesteps, KG is computationally much simpler, incurring a constant cost regardless of the number of timesteps left.
In the following, we first describe the experiment, then describe all the learning and control models that we consider. We then compare the performance of the models both in terms of agreement with human behavior on a trial-to-trial basis, and in terms of computational optimality.

\section*{Data}

\section*{Participants}

A total of 451 participants completed a series of bandit problems as part of 'testweek' at the University of Amsterdam.

\section*{Experimental procedure}

Each participant completed 20 bandit problems in sequence, all problems had 4 arms and 15 trials. The reward rates for all games were generated independently from a \(\operatorname{Beta}(2,2)\) distribution, and were all done prior to data collection. All participants thus played games with the same sets of reward rates, but the order of the games was randomized. Participants were aware that the reward rates in all games were drawn from the same environment, but they were not told its form, i.e. Beta(2,2). A representation of the basic experimental interface is shown in Fig 1.

\section*{Modeling Methods}

There exist multiple levels of complexity and optimality in both the learning and the decision components of decision making models of bandit problems. For the learning component, we examine whether people learn any abstract representation of the environment at all, and if they do, whether

Figure 1: Experiment interface. The four panels correspond to the four arms, each of which can be chosen by pressing the corresponding button. In each panel, successes from previous trials are shown as green bars, and failures as red bars. At the top of each panel, the ratio of successes to failures, if defined, is shown. The top of the interface provides the count of the total number of successes to the current trial, index of the current trial and index of the current game.
they only keep a mean estimate (running average) of the reward rate of the different options, or also uncertainty about those estimates, or indeed more complex meta-information, such as the general abundance/scarcity of rewards. The decision component can also differ in complexity in at least two respects: the objective the decision policy tries to optimize (e.g. reward versus information), and the time-horizon over which the decision policy optimizes its objective (e.g. greedy versus long-term). In this section, we introduce models that encompass different combinations of learning and decision policies.

\section*{Bayesian Learning in Beta Environments}

The observations are generated independently and identically (iid) from an unknown Bernoulli distribution for each arm. We consider two Bayesian learning scenarios, either subjects have a fixed belief about the distribution from which the Bernoulli rates are drawn ("basic learning"), or they do meta-learning about the parameters of that distribution over time ("meta learning"). We explore the two scenarios below. In either case, we assume the distribution that generates the Bernoulli rates is a Beta distribution, Beta \((\alpha, \beta)\), which is a conjugate prior, and whose two hyper-parameters, \(\alpha\) and \(\beta\) are determined by the total number of rewards and failures experienced so far, plus any pseudo-counts associated with the prior.

Basic Learning Suppose we have \(K\) arms with reward rates, \(\theta_{k}^{g}, k=1, \cdots, K\), which are independent and identically drawn from \(\operatorname{Beta}(\alpha, \beta)\) for the \(g\) th game. On the \(t\) th trial, if the \(k\) th arm is chosen, a reward is attained with a

Bernoulli distribution, \(R_{k}^{t, g} \sim \operatorname{Bernoulli}\left(\theta_{k}^{g}\right)\). Let \(\mathbf{S}^{t, g}\) and \(\mathbf{F}^{t, g}\) be vectors of the number of successes and failures attained from each arm at the \(t\) th trial of the \(g\) th game. The model learns the individual reward rates using Bayes' Rule:
\[
\begin{aligned}
\operatorname{Pr}\left(\theta^{g} \mid \alpha, \beta, \mathbf{S}^{t, g}, \mathbf{F}^{t, g}\right) & \propto \operatorname{Pr}\left(\mathbf{S}^{t, g}, \mathbf{F}^{t, g} \mid \theta^{g}\right) \operatorname{Pr}\left(\theta^{g} \mid \alpha, \beta\right) \\
\theta^{g} & \sim \operatorname{Beta}(\alpha, \beta) \\
S_{k}^{t, g} & \sim \operatorname{Binomial}\left(S_{k}^{t, g}+F_{k}^{t, g}, \theta_{k}^{g}\right)
\end{aligned}
\]

The learner's belief state at the trial \(t\) of the game \(g, \mathrm{~B}^{t, g}\), is the set of posterior Beta distributions for each arm, and the mean reward on each arm, based on the observed sequence, is \(\hat{\theta}^{t, g}=\left(\alpha+S_{k}^{t, g}\right) /\left(\alpha+\beta+S_{k}^{t, g}+F_{K}^{t, g}\right)\).
Meta Learning We also consider the case that subjects may use observations to learn about the true environmental reward distribution (the true Beta distribution), corresponding to the general abundance/scarcity of resources in the environment. In this case, observing an outcome on any arm will affect the posterior distribution on all arms because of the correlation induced by shared hyper-parameters of the environment (Gelman, Carlin, Stern, \& Rubin, 2004):
\(\operatorname{Pr}\left(\theta^{g}, \alpha, \beta \mid \mathbf{S}^{t, g}, \mathbf{F}^{t, g}\right) \propto \operatorname{Pr}\left(\mathbf{S}^{t, g}, \mathbf{F}^{t, g} \mid \theta^{g}\right) \operatorname{Pr}\left(\boldsymbol{\theta}^{g} \mid \alpha, \beta\right) \operatorname{Pr}(\alpha, \beta)\)
The belief state on trial \(t\) of game \(g, \mathrm{~B}^{t, g}\), is a joint posterior distribution over the reward rates and environmental parameters, conditioned on the observed sequence.

\section*{Decision Policies}

We consider five different decision policies. We first describe the optimal model, and then the four heuristic models with increasing levels of complexity.
The Optimal Model The learning and decision problem for bandit problems can be instantiated as a Markov Decision Process with a finite horizon (Kaebling et al., 1996). Due to the low dimensionality of the bandit problem here (i.e. small number of arms and number of trials per game), the optimal policy, up to a discretization of the belief state, can be computed numerically according to Bellman's dynamic programming principle. Let \(V^{t}\left(\mathbf{S}^{t}, \mathbf{F}^{t}\right)\) be the expected total future reward on trial \(t\). The optimal policy should satisfy the following iterative property:
\[
V^{t, g}\left(\mathbf{S}^{t, g}, \mathbf{F}^{t, g}\right)=\max _{k} \mathbb{E}\left[V^{t+1, g}\left(\mathbf{S}^{t+1, g}, \mathbf{F}^{t+1, g}\right)\right]+\hat{\theta}_{k}^{t, g}
\]
and the optimal decision, \(D^{t, g}\), is decided by
\[
D^{t, g}\left(\mathbf{S}^{t, g}, \mathbf{F}^{t, g}\right)=\operatorname{argmax}_{k} \mathbb{E}\left[V^{t+1, g}\left(\mathbf{S}^{t+1, g}, \mathbf{F}^{t+1, g}\right)\right]+\hat{\theta}_{k}^{t, g}
\]

We solve the equation using dynamically programming, backward in time from the last time step, whose value function and optimal policy are known for any belief state, i.e. any setting of posterior Beta distribution for each of the arms: it always choose the arm with the highest expected reward, \(\hat{\theta}^{T, g}\), and the value function is just that expected reward. In the simulations, we compute the optimal policy offline, for any conceivable setting of belief state on each trial
(up to a fine discretization of the belief state space), and then apply the computed policy for each sequence of choice and observations that each subject experiences. We use the term "the optimal solution" to refer to the specific solution under \(\alpha=2\) and \(\beta=2\), which is the true experimental design.

Win-Stay-Lose-Shift WSLS does not learn any abstract representation of the environment, and has a very simple decision policy. It assumes that the decision-maker continues to choose an arm following a reward, but shifts to other arms (with equal probabilities) following a failure to gain reward.
\(\varepsilon\)-Greedy The \(\varepsilon\)-greedy model assumes that decisionmaking is driven by a parameter \(\varepsilon\) that controls the balance between random exploration and exploitation inherent in bandit problems. On each trial, with probability \(\varepsilon\), the decision-maker chooses randomly (exploration), otherwise chooses the arm with the greatest estimated reward rate (exploitation). \(\varepsilon\)-Greedy keeps simple estimates of the reward rates, but does not track the uncertainty of the estimates. It is not sensitive to the horizon, maximizing the immediate gain with a constant rate, otherwise searching for information by random selection \({ }^{1}\).
We call the situation \(k \in \operatorname{argmax}_{k^{\prime}} \hat{\theta}_{k}^{t, g}\) 'case 1 ', and the \(\varepsilon\)-greedy model is implemented as
\[
\operatorname{Pr}\left(D^{t, g}=k \mid \varepsilon, \hat{\theta}^{t, g}\right)= \begin{cases}(1-\varepsilon) / M^{t, g} & \text { if case 1 } \\ \varepsilon /\left(K-M^{t, g}\right) & \text { otherwise }\end{cases}
\]
where \(M^{t, g}\) is the number of arms with the greatest estimated value at the \(t\) th trial of the \(g\) th game.
\(\varepsilon\)-Infomax The \(\varepsilon\)-infomax model is similar to the \(\varepsilon\)-greedy model in that it chooses the arm with the greatest estimated reward rate with probability \(1-\varepsilon\), and explores with probability \(\varepsilon\). The difference is that, instead of random selection for exploration, it selects the arm that results in the largest reduction in the expected total entropy. In our study, the arms are independent given the same environmental distribution, and the policy reduces to choose the arm with the largest uncertainty. We use \(S_{k}^{t, g}+F_{k}^{t, g}\) as an approximate, simple measure of the uncertainty associated with arm \(k\) given the state of the game. In this model, an arm may be chosen when one of the two cases applies: in case 1 , it has the greatest estimated reward rate; in case 2 , it does not have the greatest estimated reward rate, but has the least number of times being chosen. We implement \(\varepsilon\)-infomax as
\[
\operatorname{Pr}\left(D^{t, g}=k \mid \varepsilon, \hat{\theta}^{t, g}\right)= \begin{cases}(1-\varepsilon) / M^{t, g} & \text { if case 1 } \\ \varepsilon / N^{t, g} & \text { if case 2 } \\ 0 & \text { otherwise }\end{cases}
\]
where \(M^{t, g}\) and \(N^{t, g}\) are the number of arms that satisfy case 1 and 2 , respectively, at the \(t\) th trial of the \(g\) th game.
The \(\varepsilon\)-infomax model uses both the mean estimates and measure of uncertainty as criteria for action selection. It is a

\footnotetext{
\({ }^{1}\) The \(\varepsilon\)-Greedy model has a variant, \(\varepsilon\)-decreasing, where the probability of random selection decreases over trials. However, previous studies found that \(\varepsilon\)-decreasing had a poor fit to the same data when compared with the \(\varepsilon\)-greedy model (Zhang \& Lee, 2010), so we only consider the \(\varepsilon\)-greedy model in this study.
}
greedy heuristic, maximizing the immediate reward gain at a constant rate.

Knowledge Gradient The knowledge gradient (KG) algorithm (Ryzhov, Powell, \& Frazier, 2012) is an approximation to the optimal policy, by pretending only one more exploratory measurement is allowed, and assuming all remaining choices will exploit what is known after the next measurement. It evaluates the expected change in each estimated reward rate, if a certain arm were to be chosen, based on the current belief state. Its mathematical expression is
\[
v_{k}^{\mathrm{KG}, t}=\mathbb{E}\left[\max _{k^{\prime}} \hat{\theta}_{k^{\prime}}^{t+1} \mid D^{t}=k, B^{t}\right]-\max _{k^{\prime}} \hat{\boldsymbol{\theta}}_{k^{\prime}}^{t}
\]

The first term is the expected largest reward rate on the next step if the \(k\) th arm were to be chosen, with the expectation taken over all possible outcomes of choosing \(k\). The KG decision rule is
\[
\begin{equation*}
D^{\mathrm{KG}, t, g}=\underset{k}{\arg \max _{k}} \hat{\theta}_{k}^{t, g}+(T-t-1) v_{k}^{\mathrm{KG}, t, g} \tag{1}
\end{equation*}
\]

The first term of Equation 1 denotes the expected immediate reward by choosing the \(k\) th arm at \(t\) of the \(g\) th game, whereas the second term reflects the expected gain of total remaining reward from \(t+1\) to the last trial of the current game. The formula for calculating \(v_{k}^{\mathrm{KG}, t, g}\) for the binary bandit problems can be found in Chapter 5 of Powell and Ryzhov (2012).

\section*{Model Implementation and Agreement Calculation}

We used model agreement as a measure of how well it captures experimental data, which was calculated as the average per-trial likelihood, conditioned on the observed game states. We fit the models and calculated model agreement across all participants.
WSLS is a fully deterministic paradigm, so the per-trial likelihood is 1 for a win-stay decision, \(1 / 3\) for a lose-shift decision, and 0 otherwise. All other models have at least two free parameters, \(\alpha\) and \(\beta\), and the \(\varepsilon\)-greedy and the \(\varepsilon\)-infomax models have one additional parameter, \(\varepsilon\). We implemented the \(\mathrm{KG}, \varepsilon\)-greedy and \(\varepsilon\)-infomax models as Bayesian graphical models under both learning frameworks. We used a vague prior for the environmental parameters, \(\operatorname{Pr}(\alpha, \beta)=(\alpha+\beta)^{5 / 2}\), as suggested by Gelman et al. (2004), because it is uniform on the psychologically interpretable reparameterization, \(\alpha /(\alpha+\beta)\) and \((\alpha+\beta)^{-1 / 2}\). We used uniform prior for \(\varepsilon\). Model inference used combined sampling algorithm, with Gibbs sampling of \(\varepsilon\), and Metropolis sampling of \(\alpha\) and \(\beta\). All chains contained 3000 steps, with a burn-in size of 1000. All chains converged according the R-hat measure (Gelman et al., 2004). We calculated the model agreement as the proportion of same choices between the model and the data, based on the full posterior predictive distribution of choices given each observed state of the game. For this study, we implemented the optimal model only with basic learning because of the heavy computational load.

Figure 2: Model agreement with data simulated by the optimal solution under the correct prior of the environment. Each bar shows the agreement of a model combining the corresponding decision policy and the learning framework. For the \(\varepsilon\)-greedy (eG), \(\varepsilon\)-infomax (eINFO) and the KG models, the error bars show the standard errors of the average agreement based on a 4 -fold cross-validation. WSLS has no parameters to fit and does not rely on any learning framework.

Figure 3: Model agreement with human data. The figure is generated in the same way as for Figure 2, except for that the optimal model was only implemented with basic learning for this study.

\section*{Results}

\section*{Model Agreement with the Optimal Solution}

As shown in Figure 2, the KG algorithm, under either learning framework, is able to approximate the optimal solution well in terms of the average number of correct predictions. In this sense, the KG policy is 'process optimal'. \(\varepsilon\)-infomax outperforms the \(\varepsilon\)-greedy model, which implies that smarter exploration for information gain increases the optimality of the heuristic. The simple WSLS model achieves model agreement well above \(60 \%\). In fact, both WSLS and the optimal model do win-stay with probability 1 . The only situation that WSLS does not resemble the optimal behavior is when it shifts away from an arm that the optimal solution would otherwise stay with.

Figure 4: Behavioral patterns in the human data and the simulated data from a selection of the best- and worst-performing models. The four panels show the trial-wise probability of win-stay, lose-shift, choosing the greatest estimated value, and choosing the least known when it is an exploration trial, respectively. Probabilities are calculated based on simulated data from each model at their MAP estimate, and are averaged across all games and all participants. The optimal solution shown here uses the correct prior \(\operatorname{Beta}(2,2)\).

\section*{Model Agreement with the Human Data}

Figure 3 shows the average model agreement with human data. Overall, the type of decision policy, other than the learning framework, makes significant differences in the model agreement. However, a decision policy tends to do better under the meta learning framework - the \(\varepsilon\)-greedy model and the KG model have significantly greater model agreement with meta learning.

We next break down the overall behavioral performance into four finer measures: how often people adopt win-stay and lose-shift, how often they exploit, and whether they use random selection or search for the greatest amount of information during exploration. We compare three of our models that have the highest agreement with human data on these additional behavioral criteria. Figure 4 shows the model analysis results. We show the patterns of the human subjects, the optimal solution, the best performing decision policy (KG) under both learning frameworks, and the simplest WSLS.

The first panel probably contains the most interesting results. It shows the trialwise probability of staying with the same arm following a previous success. People show clear sub-optimality by not staying with the same arm after an immediate reward. In fact, obtaining a reward from any arm should always increase the estimated value of the chosen arm. Under the basic learning framework where unchosen arms do not change in value, this means the optimal decision process should always do win-stay. This is consistent with the curve of the optimal solution. As implied by Equation \(1, \mathrm{KG}\) considers the likelihood of an arm surpassing the known best value upon chosen, and weights this knowledge gain more heavily in the early stage of the game. In general, during the early trials, it chooses the second-best arm with a certain probability, not necessarily depending on the previous outcome. This explains the drop of the win-stay probability of KG during the early trials. When the learner is also updating its knowledge of the environment, a previous suc-
cess will cause the environment to appear more rewarding, making other arms more likely to surpass the current best arm.

The second panel shows the trialwise probability of shifting away following a previous failure. People, the optimal solution, and KG show a decline in this probability over trial. When the horizon is approaching, it becomes increasingly important to stay with the arm that is known to be reasonably good, even if it may occasionally yield in a failure, because it is increasingly important to maximize the reward on the current trial.

In general, the KG model with meta learning matches the second-order trend of human data. However, there still exists a big difference on the absolute scale, especially regarding the probability of staying with 'good' arms - in fact, the KG policy does win-stay and exploitation more often, and resembles the optimal solution more than the human data.

\section*{Model Performance in Cumulative Reward Collection}

Fig 5 shows a comparison of the distribution of average reward per trial achieved by the participants, the optimal solution, and the knowledge gradient model. When playing at their best fit parameterization based on the human data, KG with meta learning and WSLS achieve nearly identical reward distributions as the participants. Moreover, if we let KG with meta learning forward play under the correct prior knowledge of the environment, i.e. Beta \((2,2)\), it is able to achieve a nearly identical distribution as the optimal solution.

\section*{Discussion}

Our analysis supports the KG decision policy under the meta learning framework as a good fit to human data in bandit problems. Our result implies that people might learn the individual reward rates as well as the general environment,

Figure 5: Average reward achieved by the KG model forward playing the bandit problems with the same reward rates. KG achieves similar reward distribution as the human performance, with KG playing at its maximum a posteriori probability (MAP) estimate, \(\alpha=.1\) and \(\beta=.8\). KG achieves the same reward distribution as the optimal solution when playing with the correct prior knowledge of the environment.
and the shared, latent environment induces a special type of correlation among the bandit arms. The meta learning framework is a psychologically sensible improvement to basic learning, because correct knowledge of the environment can be critical for achieving the best performance, especially when the environment can change over time or contexts. For the decision component, our results support the KG policy, which optimizes the semi-myopic goal of maximizing future cumulative reward while assuming only one more time step of exploration and strict exploitation thereafter (but does not actually ever carry out that policy). The KG model under the more general learning framework has the largest proportion of correct predictions of human data, and can capture the trial-wise dynamics of human behavioral reasonably well. KG achieves similar behavioral patterns as the optimal model, and is computationally tractable, making it a plausible algorithm for human learning and decision-making

One remaining puzzle why human subjects tend to explore more often than policies that optimize the specific utility of the bandit problems. One possibility is that people believe the task environment can undergo stochastic changesand exhibit sequential effects due to recent trial history, as in many other psychological task contexts (Yu \& Cohen, 2009) . This would be an interesting line of future inquiry.

\section*{Acknowledgments}

We thank Mark Steyvers and Eric-Jan Wagenmakers for sharing the data on bandit problems for our analysis, and three anonymous reviewers for their valuable comments that helped improve the paper.

\begin{abstract}
This paper introduces a cognitive tutor designed for second language grammar instruction. The tutor adopted Corbett and Anderson's (1995) Bayesian knowledge tracing model and provided adaptive training on the English article system. We followed the Competition Model (MacWhinney, 1997) and understood the article system as a galaxy of cues determining article usage on the basis of form-function mapping. Cues are in competition during language acquisition; hence cue contrast is predicted to be an effective instructional method. Seventy-eight students were randomly assigned to four article training conditions (to learn 33 cues) and a control condition (to write essays). We found that article-training groups significantly outperformed the control group in an immediate posttest and a delayed posttest. Specifically, our result also suggested that there was a significant interaction between cue contrast and cue type (definite vs. indefinite). Cue contrast promoted more learning on the indefinite cues (more difficult for learners). Knowledge tracing did not demonstrate such an interactional effect with cue types. Instead, it boosted the instructional effect promoted by cue contrast.
\end{abstract}

Keywords: knowledge tracing; cue contrast; cognitive tutor; second language acquisition; English article.

\section*{Introduction}

Since the mid-1990s Corbett \& Anderson's (1995) Bayesian knowledge tracing model has been widely used to model student knowledge in learning systems of various domains, including tutors for mathematics, computer programming, and reading skills (Baker et al., 2010). In recent years, there has been an emergence of tutoring systems designed to facilitate second language learning (MacWhinney, 1995; Pavlik \& Anderson, 2005). Among them we rarely find learning systems adopting Bayesian knowledge tracing to promote robust language learning (Koedinger, Corbett \& Perfetti, 2012).

This paper introduces a Bayesian tutorial system of grammar instruction applied in an English as a Foreign Language (EFL) context. The primary goal of this research has been to develop an adaptive vehicle for testing the efficacy of Bayesian Knowledge Tracing in this domain. Another feature of the tutor, which presents grammatical cues in contrast, is informed by the cognitive linguistic
theories of the Competition Model (MacWhinney, 1997). This paper discusses how these two areas of thought are blended to shape the design of the tutor and how they interact to influence learning effects. Specifically, the tutor targets the English article system, a difficult grammatical category for second language learners (Butler, 2002; CelceMurcia \& Larsen-Freeman, 1999).

\section*{Bayesian Knowledge Tracing}

Corbett and Anderson's (1995) Bayesian knowledge tracing assumes that at any given opportunity to use a rule within the software, there exists a probability that a student knows the rule and may either give a correct or incorrect response. A student who does not know a skill generally will give an incorrect response, but there is a certain probability (called \(p(G)\), the Guess parameter) that the student will give a correct response. Correspondingly, a student who does know a skill generally will give a correct response, but there is a certain probability (called \(p(S)\), the Slip parameter) that the student will give an incorrect response. Each rule has an initial probability \(\left(p\left(L_{0}\right)\right)\) of being known by the student, and at each opportunity to practice a skill, the student has a certain probability \((p(T))\) of learning the skill. Once these four parameters are set, the model can be used to predict student performance. Figure 1 illustrates the relationship between the four parameters in the Bayesian Knowledge Tracing Model.

Figure 1: Bayesian Knowledge Tracing Model (Corbett and Anderson, 1995)

The system's estimate that a student knows a rule at time \(\mathrm{n}\left(\mathrm{P}\left(L_{n}\right)\right)\) is continually updated every time the student responds (correctly or incorrectly) to a problem step. First,
the system calculates the probability that the student knew the rule before making the attempt, using the evidence from the current step. Then, taking this into account, it computes the probability that the student learned the rule during the problem step. The equations for these calculations are:
\[
\begin{aligned}
& P\left(L_{n-1} / \text { Correct }_{n}\right)=\frac{P\left(L_{n-1}\right) *(1-P(S))}{P\left(L_{n-1}\right) *(1-P(S))+\left(1-P\left(L_{n-1}\right) *(P(G))\right.} \\
& P\left(L_{n-1} / \text { Incorrect }_{n}\right)=\frac{P\left(L_{n-1}\right) * P(S)}{P\left(L_{n-1}\right) * P(S)+\left(1-P\left(L_{n-1}\right)\right) *(1-P(G))} \\
& P\left(L_{n} / \text { Action }_{n}\right)=P\left(L_{n-1} / \text { Action }_{n}\right)+\left(\left(1-P\left(L_{n-1} / \text { Action }_{n}\right)\right) * P(T)\right)
\end{aligned}
\]

To set the initial \(\mathrm{P}(\mathrm{S}), \mathrm{P}(\mathrm{G}), \mathrm{P}(\mathrm{T})\), and \(\mathrm{P}\left(L_{0}\right)\) parameters for each skill, we used data from a previous English article study to train each model (Zhao, 2012). During this previous study, we collected 10,523 student attempts at choosing the correct article, with each attempt labeled with the article rule applied. We used the "brute force" method (Baker et al, 2010) to utilize this data and arrive at the most likely parameter values. This method tries every possible combination of the four parameters in the grain size of 0.01 and for each combination, computes the sum of squared residuals (SSR). The parameter value combination that gives the best SSR for that rule are the ones we use to model the rule in the tutor.

\section*{The Competition Model}

An important feature of the tutorial system in this paper is its theoretical ground in cognitive linguistics. We adopted the Competition Model (MacWhinney, 1997) and integrated one of its fundamental principles (cue competition) into the design of grammar instruction.

The model presents a functionalist rather than nativist view of language acquisition and understands the linguistic sign as a set of mappings between forms and functions. Forms are the external phonological and word order patterns that are used in words and syntactic constructions. Functions are the communicative intentions or meanings that underlie language usage. Each lexical item or syntactic construction can be understood as a form-to-function mapping.

In the context of discussion of the English article system, there are four forms: the, \(a, a n\), and the zero article (0). The form the specifies the definite article; the forms \(a\) and an encode the indefinite article ( \(a\) is followed by noun phrases starting with consonants; an is followed by noun phrases starting with vowels); the form 0 is commonly known as the zero article or null article.

How about functions in the English article system? Adopting the model, we carried out a functional linguistic analysis and found that the four article forms are mapped with approximately 90 different functions or usages (more information see Zhao, 2012). Some functions are syntactic and semantic properties (e.g., countability, singularity, plurality); some functions are discourse-based properties
(e.g., first mention, second mention, immediate situation); many functions are idiosyncratic surface features whose usage is highly conventional (e.g., names of rivers, lakes, malls, parks, bridges, theatres); and some functions combine both syntactic and idiosyncratic properties (e.g., names of singular mountains or plural mountains). So many functions are mapped with only four forms. This complex formfunction mapping is one of the critical reasons why English articles are difficult to acquire.

The Competition Model understands one form-function mapping as a unit or a cue. E.g., the tag "the - river names" represents a cue since it maps the association between the form the and the semantic property of names of rivers. But the tag "the - river names and second mention in the discourse" is not a valid cue because one form is mapped with two functions. In this case, the form-function mapping needs to be broken down to the smallest unit.

The basic claim of the Competition Model is cue competition. It considers cue competition as vital for language acquisition. Sentences (1-2) illustrate how cues compete and one gains dominance over another. In sentence (1), the zero article is required because "wealth" is a noncountable mass noun and is used alone with no modifiers. When this noncountable noun is modified by the prepositional phrase (PP) "of her parents" in sentence (2), the noun "wealth" becomes concrete and identifiable. Hence, the PP structure (strongly associated with the) overrides noncountability (strongly associated with 0 ) in sentence (2).
(1) Alice is interested in \(\underline{0}\) wealth.
(2) Alice is interested in the wealth of her parents.

Early stages of language acquisition focus on obtaining input on individual cues from the learning environments. Learners may not know when a cue can or cannot override another cue. As their language proficiencies increase, learners develop their skills of interpreting cue conflict. Some cue competitions are easier to interpret than others. For example, the competition between the cue " \(a\) - first mention" and the cue "the - second mention" is relatively easier to interpret and are among the earliest acquired cues in the article system. But the competition between the two cues in Sentence (1-2) is relatively harder to interpret. Learners need to know the grammatical properties of a PP structure, its strong association with the definite article, and how a PP structure typically interacts with mass nouns.

This paper proposes an instructional invention of cue contrast that originates from the basic claim of the Competition Model. There are two theoretical justifications for the proposal. First, regularities, and heuristics are always good for learning a complex problem space (Reber et al., 1980; Ellis, 2011). Instead of understanding the article system as a space with almost 90 unrelated usages, learners formulate a more organized mental space with more than 40 contrasting pairs of usages. That leads to the most important advantage of cue contrast: it significantly reduces learners'
memory load and storage cost, and consequently increases their learning capacity. One major theoretical commitment made in the Competition Model is to a capacity-limited model of language processing. This account treats sentence interpretation as a constraint satisfaction process that balances the limitations imposed by verbal memory against the requirements of conceptual interpretation. Our raw memory for strings of nonsense words is not more than about four. However, when words come in meaningful groups, we can remember dozens of words, even when the message is unfamiliar. The most likely candidate for this additional storage is some form of conceptual representation. By presenting article usages to learners as meaningful groups, we help learners form the conceptual representation of the article system. In turn, storage cost is reduced.

\section*{Method}

\section*{Participants}

The participants of the current experiment were 78 (31 males, 47 females) Chinese intermediate-advanced learners at a public university in Beijing that specialized in foreign language education and research. Their average years spent learning English was 7.8 years.

\section*{Materials and Design}

A 2 (Contrast: yes vs. no) \(\times 2\) (Knowledge tracing: yes vs. no) \(\times 2\) (Cue type: the vs. \(0 / a / a n)^{1}\) mixed model design was used in this experiment. Cue contrast and knowledge tracing are two between-subject variables, whereas cue type is a within-subject variable.

There were five conditions in the experiment (Table 1): four experimental groups who received article training; one control group who did not receive article training. The four experimental conditions were manipulated based on the two between-subject variables. The control group spent roughly the same amount of training time as the four experimental groups. Instead of learning articles, they were asked to write four English essays during the training sessions and weren't given feedback.

Table 1: Experiment conditions.
\begin{tabular}{ccc|c}

group
\end{tabular} \\
\hline
\end{tabular}

Article training was provided as a sentence-level cloze task. Figure 2 exemplifies training received by the two cue contrast groups. Students were given a prompt question and two sentence items that belonged to a pair of contrasting cues. They used a pull down menu to make choices and

\footnotetext{
\({ }^{1}\) We grouped indefinite article cues with zero article cues due to the small number of \(a / a n\) cues.
}
were given immediate feedback. The feedback included correct/wrong, cue name, explicit cue explanations, and examples. Training pages in the two no-cue-contrast conditions also included two sentences. But they cannot belong to a contrasting pair.

Figure 2: A training page of cue contrast conditions.
This experiment trained 33 article cues that were grouped into 18 pairs of contrasting cues. Definite article cues were paired with indefinite article or zero article cues primarily based on structural distinction. Table 2 exemplifies five representative cue pairs. In the first and second pairs, article choices are distinguished based on the existence of a relative clause as a post-modifier. The distinction in the third pair is due to the "of ..." prepositional phrase as a post-modifier. The contrast in the four pair originates from the singular vs. plural distinction of mountain names. When we could not rely on structural distinction to create cue pairs, we relied on semantic distinction. The 'hall' and 'building' cues in the fifth pair, for example, are idiosyncratic cues whose article choices can only be explained by historical conventions. Hence, we relied on their semantic distinction to manipulate the contrast.

Table 2: Exemplar Cue Pairs (With Examples)
\(\left.\begin{array}{ccc}\hline 1 & a-\text { singular countable } \\ (a \text { store })\end{array} \begin{array}{c}\text { the }- \text { singular countable }+ \text { clause } \\ \text { (the store she bought the dress) }\end{array}\right]\)

\section*{Implementing Bayesian Knowledge Tracing}

We adopted Corbett and Anderson's (1995) Bayesian knowledge tracing algorithm and used Baker et al.'s (2010) approach to train the model parameters using learner data from a previous but similar article tutor study (Zhao, 2012).

With the models for each article skill trained this way, the tutor updates \(\mathrm{P}\left(L_{n}\right)\) after observing correct/incorrect attempts at each skill and uses \(\mathrm{P}\left(L_{n}\right)\) for the item selection criteria. If we simply chose the next item to present with the lowest \(\mathrm{P}\left(L_{n}\right)\), the tutor would frequently show the same item back-to-back. To introduce some variety while still giving more practice on the items least learned, we use \(\mathrm{P}\left(L_{n}\right)\) to set the selection criteria of training items as: random selection in proportion to percent unlearned. Percent unlearned for a rule is calculated by taking the probability the rule is "unlearned": \(\left(1-\mathrm{P}\left(L_{n}\right)\right)\), divided by the sum of the probabilities each other rule is "unlearned". A difficult cue will have a higher percent unlearned compared to other cues and will thus be more likely to be chosen next. But it is still possible (but less likely) that a better-acquired cue will be chosen next. This selection criterion avoids over-training of unlearned cues and under-training of better-acquired cues.

\section*{Procedure}

The study was composed of three sessions. Session I included a pretest ( \(25-\mathrm{min}\) ) and the first training session (1 hour). Session II (2 days later) included the second training session ( 1 hour) and an immediate posttest ( \(25-\mathrm{min}\) ). Session III (2 weeks after Session 2) included a delayed posttest ( \(25-\mathrm{min}\) ). All sessions were administered online. The tests were also in the format of a sentence-level cloze.

\section*{Results}

\section*{Instructional Effects}

A univariate analysis indicates that there was no significant difference of mean accuracy between the article training groups and the control group in the pretest ( \(F=.207, p=\) .651). These two groups showed a significant difference of mean accuracy in the immediate posttest ( \(F=37.836, p<\) .001). The article training groups gained a mean accuracy of \(.154(\mathrm{SD}=.071)\), whereas the control group only gained a mean accuracy of \(.026(\mathrm{SD}=.076)\). Figure 2 illustrates the learning trajectories of the above conditions.

A paired samples \(t\)-test shows that the article training groups significantly improved mean accuracy from pretest to immediate posttest ( \(T=17.156, p<.001\) ). Though they had a significant drop of accuracy from immediate-posttest to delayed-posttest ( \(T=-3.774, p<.001\) ), their mean accuracy in the delayed posttest was significantly higher than their pretest level ( \(T=13.374, \mathrm{p}<.001\) ). This suggested that the article training groups retained learning two weeks after training.

A paired samples t-test suggests that the control group did not show improvement from pretest to immediate posttest ( \(T=1.359, p=.196\) ). Neither did they improve mean
accuracy from immediate-posttest to delayed-posttest ( \(T=\) 1.361, \(p=.195\) ).

Figure 2: Mean test accuracies of conditions.

\section*{Cue Contrast, Knowledge Tracing, Cue Type}

Figure 3 compares the four article training conditions (KTCC, KT-noCC, noKT-CC, noKT-noCC) in terms of mean accuracies of all the cues in the pretest, posttest, and delayed posttest. In the pretest, univariate analysis indicates no significant difference of mean accuracy among the four conditions when all the cues are examined ( \(F=.468, p=\) \(.759, \eta 2=.025\) ). Meanwhile, univariate analyses of pretest accuracy also show no significant difference among the four conditions regarding the acquisition of the-cues \((F=1.083\), \(p=.371\) ) and \(0 / a / a n\)-cues ( \(F=.441, p=.778\) ).

Figure 3: Mean accuracies of three tests of four conditions
In the immediate posttest, univariate analyses suggest no significant difference between contrast and no-contrast ( \(F=\) \(.110, p=.741, \eta 2=.002\) ) and between knowledge-tracing and no-knowledge-tracing ( \(F=2.435, p=.124, \eta 2=.038\) ), when all the article cues are examined. The same pattern was found in the delayed posttest. We then delved into four conditions and looked for variations. Again, when all article cues were considered, we could not find significant differences among the four conditions in the immediate
posttest ( \(F=2.165, p=.102, \eta 2=.099\) ) and in the delayed posttest ( \(F=1.464, p=.234, \eta 2=.069\) ).

Our next step was to explore interaction between the two primary variables (KT, CC) and cue type (the vs. 0/a/an). A repeated measure ANOVA suggested that there was a significant interaction (Figure 4) between cue contrast and cue type ( \(F=9.744, p<.001, \eta 2=.138\) ). Bonferroni pairwise comparisons indicated that within each cue type, the differences between cue contrast and non-cue contrast were significant: the-cues ( \(p<.001\) ) and 0/a/an-cues ( \(p<\) .001 ). Cue contrast promoted significantly more learning ( \(p<.001\) ) of 0/a/an cues than of the cues. In contrast, noncue contrast created a more balanced instructional effect. Its instructional effect on the cues and \(0 / a / a n\) cues were not significantly different ( \(p=.844\) ).

Figure 4: Contrast versus non-contrast
Yet, we did not find significant interaction between knowledge tracing and cue type. Bonferroni pairwise comparisons suggested no significant differences between knowledge tracing and non-knowledge tracing within the cues ( \(p=.557\) ) or \(0 / a / a n\) cues ( \(p=.385\) ).

\end{tabular}

Figure 5: Gained accuracy (immediate posttest - pretest) of the-cues and \(0 / a / a n\)-cues in four training conditions

Figure 5 illustrates an interaction between cue types (the vs. O/a/an) and the four training conditions. The Y-axis is gained mean accuracy (immediate posttest-pretest). As we can see, the cue contrast conditions (KT-CC, noKT-CC) pushed for more learning of the \(0 / a / a n\) cues. In particular, KT-CC had a more tilted slope leaning towards more learning on \(0 / a / a n\), which sharpened the interactional effect between cue contrast and article forms. Meanwhile, the noncue contrast conditions (KT-noCC, noKT-noCC) were suggested to promote more learning on the cues. This trend appears to be more obvious in the KT-noCC condition than in the noKT-noCC condition.

The above findings indicated that cue contrast played the primary role of determining patterns of results. Knowledge tracing did not change the interactional effects between cue contrast and article type. It gave the interactional effects a boost and made the patterns sharper.

\section*{Discussion and Conclusion}

The intermediate-advanced students in this study were given a difficult task of learning 33 article cues within two hours of training. The article training groups managed to show significant learning in the immediate posttest and retained learning two weeks later. This positive instructional effect confirms two principles that MacWhinney (1995) suggested to be important in designing and evaluating foreign language tutoring systems: 1) practice makes perfect and 2) feedback promotes learning (p. 318-319). Our study clearly demonstrated that given a difficult learning task, students would learn when they are given enough practice trials, accurate and digestible feedback, and an effective instructional method that helped to reduce memory and learning loads. The study implications for a third principle of MacWhinney (1995), that 3) cue conflicts are crucial for learning, are less clear.

As indicated by the interaction with type of item ('the' vs. \(0 / \mathrm{a} / \mathrm{an}\) ), the cue contrast manipulation had a clear impact, raising performance on 0/a/an-cues but lowering performance on the-cues. By analyzing contrasting cue pairs, it was hypothesized that learners in the cue contrast condition would formulate a new understanding of the article system and develop a more systematic knowledge space. Knowledge tracing effects, in comparison, would be less visible. Indeed, KT did not change how learners conceptualized the article system. It mainly functioned to escalate learning.

Why did only cue contrast show interaction with cue type (the vs. O/a/an)? Because that was the way the tutor was designed. Contrasting pairs were created because they shared similar features (e.g., mountain names) but required different article forms (e.g., 0-single mountain names, theplural mountain names). But knowledge tracing was not manipulated based on article type.

And why did cue contrast promote more learning on O/a/an cues than the cues? At first we suspected an ordering effect behind this interactional effect, i.e., cue contrast made learners pay more attention to the first item on a training
screen and consequently paid less attention to the second item. But in fact there were more the items than O/a/an items at the top of the training screen. Meanwhile, a repeated measure ANOVA also suggested no significant interaction between cue contrast and item sequence ( \(F=\) 2.427, \(p=.124\) ) and no main effects of item sequence ( \(F=\) 1.311, \(p=.991\) ) or of cue contrast ( \(F=.049, p=.825\) ). Also we suspected that cue contrast groups got a higher frequency of exposure to \(0 / \mathrm{a} / \mathrm{an}\) items. Yet this was not confirmed either. Frequency of exposure to the-items and \(0 / a /\) an-items was balanced between contrast and no-contrast conditions.

Then the most plausible account was that cue contrast illuminated weak areas of learning. 0/a/an cues were poorly acquired by learners. Their pretest mean accuracy of \(0 / a / a n\) cues ( \(M=.472\) ) was significantly lower ( \(p<.001\) ) than the cues \((M=.761)\). We found that a particular problem associated with the zero article acquisition was due to a misunderstanding made by students \({ }^{2}\). They thought that all the so-called "proper nouns" (e.g., Lake Michigan, the Colorado River, Baker Hall, the Tepper Building) were unique and therefore had to be used with the definite article. They did not know that some of such noun phrases required the zero article. Therefore, it became enlightening moments for students to see two proper nouns being contrasted in one screen. They allocated more time and attention to the zero article proper noun. As we can see, the mechanism behind cue contrast was cue focusing that directed students' attention to the right areas.

Due to the interaction between contrast and cue type, there was a trade-off that cancelled the overall instructional effect of cue contrast when all cues were considered.

The last question to discuss is the reason why knowledgetracing groups did not outperform non-knowledge-tracing groups. The most plausible reason was the relatively short duration of instruction. Two hours might not be enough for knowledge tracing to demonstrate its full advantages. Learners in the knowledge tracing conditions were in the middle of tackling the most difficult cues when training ended. They did not have enough time to work on the less difficult cues. The posttest mean accuracy (.744) of the article training groups was far from the mastery level (.950). This sent us a stronger signal that a longer training time was needed for knowledge tracing to be more effective.

In short, this study demonstrated a successful application of cognitive psychology and human-computer interaction theories in second language grammar instruction. We found that cue contrast was an effective method in teaching English article usages to adult second language learners. In particular, contrast allowed learners to become aware of and shift focus to problematic knowledge domains. Knowledge tracing boosted instructional effects of cue contrast. More research is needed to further specify duration of instruction so that we can make the best use of knowledge tracing in second language grammar instruction.

\begin{abstract}
Stroop interference is often explained by an automaticity account, according to which it arises due to more extensive practice in reading than in color naming. Here we investigated the effect on interference of isolated practice in color naming (of incongruent and neutral stimuli) and in word reading (of color names) in adults and children in Grades 4-5. In both groups interference was reduced after practicing color naming of incongruent stimuli. For children, interference was also reduced after practice in word reading of color names. In neither group was interference diminished after practice in color naming of neutral stimuli. These findings are consistent with a negative relationship between reading ability and interference and challenge the automaticity account.
\end{abstract}

Keywords: Stroop Interference; Reading; Color Naming; Training; Automaticity

\section*{Stroop Interference and Reading Ability}

One of the most familiar, most studied and most cited phenomena in cognitive psychology is Stroop interference. It is a robust finding that it takes longer to name the color of the ink in which a word is printed when the stimulus is a word denoting a different color (e.g. the word "red" printed in green ink) than when the stimulus is a string of colored letters (e.g. XXX) or a plain rectangular patch. MacLeod (1991) reviewed the evidence for variants of this task and addressed three issues that are crucial for understanding the causes of the Stroop effect: practice, integration, and the relation between facilitation and interference.

For the purposes of our analysis the concepts of practice and automaticity are of major importance. The notion of automaticity has been central for understanding and explaining the Stroop effect, since it is generally considered obligatory to read the word but not to name the color. This imbalance is thought to arise from our extensive practice in reading but not in color naming. The automaticity account considers Stroop interference as a consequence of a betterpracticed skill, namely reading, that dominates color naming without regard of attention (Logan, 1997; MacLeod, 1991). Cohen, Dunbar, and McClelland (1990) proposed a connectionist model whereby practice in a task such as
reading strengthens its connections and allows it to interfere with other tasks that have weaker connections, like color naming. Practice is seen as influencing the relative level of automaticity of two dimensions, resulting in interference. From this point of view reading and color naming differ along a continuum of practice and the degree of interference in the Stroop task may reflect the degree of word reading automaticity (Logan, 1997; Samuels, 1999).

Consequently, the degree of interference is often taken as a marker of word reading automaticity. This has significant practical implications, taking into account that word reading automaticity is been considered a fundamental element of reading development and as an essential background for more complex processes like reading comprehension (Kuhn \& Stahl, 2003; Wolf \& Katzir-Cohen, 2001).

One prediction that derives from the automaticity account is that poorer and less skilled readers will exhibit less interference in the standard Stroop task than good readers as a result of less practiced and therefore less automatized reading. This prediction stands in contrast to empirically observed data. A number of studies have showed that poor readers produce robust interference (Alwitt, 1966; Everatt, Warner, \& Miles, 1997; Helland \& Asbjørnsen, 2000; Kelly, Best, \& Kirk, 1989; van der Schoot, Licht, Jorsley, \& Sergeant, 2000). Everatt et al. (1997) found that children with dyslexia exhibit more interference than age-matched controls. More recently, Protopapas, Archonti, and Skaloumbakas (2007) showed that reading ability is negatively related to Stroop interference. In a first study they compared children with dyslexia to age-matched controls in the Stroop task and reported greater interference for the children with dyslexia. In a second study they examined the relationship between interference and reading skills in the general school population and found that poorer reading skills were associated with more interference. Furthermore, interference was found to be primarily associated with reading speed. Protopapas et al. suggested that reading ability and interference are directly linked, without mediation from executive functions such as attention and inhibition.

In line with these observations, Faccioli et al. (2008) also found that 7 - to 12 -year-old Italian children with dyslexia exhibited larger interference than a control group. The same pattern of results was reported by Kapoula et al. (2010) for French teenagers with dyslexia. These findings run counter to the automaticity account and challenge the notion that interference can be used to assay word reading automaticity.

In place of automaticity, a blocking mechanism, as implemented in the computational model WEAVER++ (Roelofs, 2003), may account for the empirical findings. According to this model, word reading can directly activate lemma retrieval and word-form encoding, whereas colornaming must pass through conceptual identification before activating lemma retrieval and word-form encoding. Stroop interference is assumed to occur because color naming must wait until the incorrect response (from word reading) is suppressed. As a consequence of the basic assumptions of the model, greater reading speed leads to less Stroop interference, consistent with the data.

\section*{Training}

Although the effects of practice on the Stroop task have been of concern since the very beginning, only a small number of studies have examined this relationship. Stroop (1935) himself tried to examine the development of interference through practice in color naming and found that interference can be present even after 8 days of practice.

MacLeod and Dunbar (1988) trained participants to respond to shapes with familiar color names. Prior to practice, "shape naming" suffered from interference from incompatible colors, an effect that was reversed 20 days later. After training, participants showed interference in naming the colors but not in naming the shapes.

Other studies have used mixed or inconguent-only stimuli and have succeeded to reduce but not eliminate interference (Davidson, Zacks, \& Williams, 2003; Dulaney \& Rogers, 1994; MacLeod, 1998). However, so far no study has examined the effects of practice on the individual task dimensions involved in Stroop interference, namely plain color word reading and color naming of neutral stimuli.

\section*{Rationale of the Present Study}

In light of the aforementioned findings the aim of the present study was to examine how interference is affected by practice not only in color naming but also in word reading. According to the automaticity account, practice in color naming should make this otherwise unpracticed dimension more competitive and thereby decrease interference, while practice in word reading might strengthen an already practiced dimension and thereby further increase interference, at least when reading skill has not yet reached ceiling performance. However, if the relationship between reading ability and interference is negative, as proposed by Protopapas et al. (2007), practice in color naming should have little effect on interference, because the bottleneck causing interference does not involve the processing of color but the delay in rejecting the word.

In contrast, practice in word reading could lead to a reduction of interference insofar as there is any potential for increase in the speed of reading the color words.

Adults are skilled readers and are considered to have achieved a high level of word reading automaticity. Therefore training in word reading should not affect interference in this population. In contrast, word reading automaticity has only partially developed in children and can improve further through practice, leading us to the prediction of a reduction in Stroop interference through practice in word reading.

\section*{Method}

\section*{Participants}

The study included adults and children from the general school population. The adult sample comprised 92 volunteers 18-40 years old, including 25 in the incongruent color group, 23 in the neutral color group, 22 in the word group, and 22 in the control (no-training) group. The school sample consisted of 105 children attending Grades 4-5, including 22 in the incongruent color group, 26 in the neutral color group, 31 in the word group, and 26 in the control group.

\section*{Materials}

The Greek words for red (ко́ккıvo /kocino/), green ( \(\pi \rho \alpha ́ \sigma\) vo /prasino/), and yellow (кít \(\rho \imath v o /\) citrino/) were used, because they have the same number of letters and syllables, comparable written frequency, and begin with voiceless stops, which facilitate response time triggering. The corresponding colors are familiar and easily distinguishable. The color word condition included these three words in white font.

Stimuli for the neutral color condition were made up of 7 repetitions of the letter X (no spaces) in red, green, and yellow color (RGB \#FF0000, \#00FF00, and \#FFFF00, respectively). For the incongruent condition the Greek words for red, green and yellow appeared in a non-matching color. All stimuli were presented on a black background.

\section*{Procedure}

Testing. On Day 1 the first interference measurement was taken. Participants were asked to name the color of the ink as quickly as possible and to try to avoid errors. A blocked design was implemented to minimize errors. The neutral condition was administered first (24 stimuli, including 8 in each color), followed by the incongruent condition (24 stimuli, including 4 in each mismatching word-color combination). The number of test trials was determined in a pilot study, to minimize learning due to testing. Each stimulus appeared on the screen for up to 2 s . Responses were recorded via a headset under the control of DMDX (Foster \& Foster, 2003). Four practice trials preceded data collection. The entire testing session lasted about 3 minutes. An identical measurement was made on Day 5, following practice.

Figure 1: Response times in milliseconds (left) and proportions of incorrect responses (right) for each sample (adults and children) in each condition (neutral and incongruent) and time point (pre- and post-practice). Each row of panels displays data for one experimental group (top to bottom: D , no practice; A , incongruent; B , color naming; C , reading). Each colored box contains the middle two quartiles of individual participant logarithmic means; the thick horizontal line marks the median; error bars extend to the full range.

Practice. Participants were assigned randomly into one of four conditions to practice for three consecutive days. Group A practiced color naming of incongruent stimuli (e.g. red), Group B color naming of neutral stimuli (e.g. XXXXXXX), and Group C practiced word reading of neutral stimuli (e.g. "red"). Children were required to complete one block of 144 trials per day. Adults completed one block of 192 trials per day. A fourth group (D) of control participants included no practice, to serve as a reference baseline.

\section*{Results}

Responses were examined with CheckVocal (Protopapas, 2007) to determine accuracy and placement of the timing marks. Response times were subsequently logarithmically transformed to bring their distribution closer to normal.

To examine the differential effects of practice on interference between groups we tested a triple interaction between group, time, and condition using function lmer of
the lme4 package (Bates, Maechler, \& Bolker, 2012) in R ( R Core Team, 2012). Each training group was thus compared for effects of practice against the no-practice group. We employed linear mixed-effects models with maximal random structures (Barr, Levy, Scheepers, \& Tily, 2013), that is, including random intercepts for participants as well as random slopes for time, condition, and their interaction. For response time, in R notation the model formula was specified as:
```

logRT~time*cond*group+(time*cond|subject)

```

Here, "time" refers to before vs. after practice and "cond" refers to neutral vs. incongruent (condition coding). Models were estimated with full maximum likelihood. The significance of the critical triple interaction was then tested via likelihood ratio test against a simpler model excluding the interaction from the fixed effects.

For children, as expected, the group practicing color naming in the incongruent condition significantly reduced
their time interference relative to the no-practice group ( \(\hat{\beta}=\) \(-.14, t=-3.83 ; \chi^{2}=12.84, d f=1, p<.0005\) ). The group practicing color naming in the neutral condition did not differ from the no-practice group ( \(\hat{\beta}=-.03, t=-.04 ; \chi^{2}=\) \(.49, d f=1, p=.482\) ). In contrast, the group practicing color word reading significantly reduced their time interference ( \(\hat{\beta}=-.07, t=-2.05 ; \chi^{2}=4.05, d f=1, p=.044\) ).

For adults, the group practicing color naming in the incongruent condition significantly reduced their interference relative to the no-practice group ( \(\hat{\beta}=-.13, t=\) -3.44; \(\chi^{2}=10.56, d f=1, p=.001\) ). However, there was no significant change in interference either for the group practicing color naming in the neutral condition ( \(\hat{\beta}=-.03\), \(t\) \(=-.83 ; \chi^{2}=.69, d f=1, p=.408\) ) or for the group practicing word reading \(\left(\hat{\beta}=-.02, t=-.45 ; \chi^{2}=.20, d f=1, p=.652\right.\) ).

To analyze error rates, we employed generalized linear mixed-effects models with binomial responses modeled via a logit link. Again, a maximal random structure was used.

For children, the group practicing color naming in the incongruent condition significantly reduced their accuracy interference relative to the no-practice group ( \(\hat{\beta}=-1.89, z=\) \(-2.34, p=.019\) ). The group practicing color naming in the neutral condition did not differ from the no-practice group ( \(\hat{\beta}=-.43, z=-.68, p=.494\) ), in contrast the group practicing color word reading significantly reduced their accuracy interference ( \(\hat{\beta}=1.46, z=2.04, p=.041\) ).

For adults, there were no significant effects in the accuracy analyses (all \(p>.5\) ).

\section*{Discussion}

The results of the present study show that just three days of practice in word reading suffice to produce a reduction in Stroop interference in children. In contrast, interference did not diminish with practice in color naming of neutral stimuli in either population. Even though color naming is considered to be insufficiently automatized (indeed this is the usual explanation for the interference) and therefore presumably amenable to improvement through practice, this dimension of performance did not seem to have much effect on interference. In contrast, we found that interference can be reduced in children through practice in word reading of color names, a highly counterintuitive finding from the point of view of automaticity but a predicted outcome on the basis of the blocking hypothesis. It is strengthened by the fact that it was not replicated in adults, whose reading is skilled and presumably not amenable to improvement.

Our findings cannot be explained by the automaticity account. If Stroop interference derives from the imbalance between reading and color naming due to extensive practice in reading, then we should have observed the opposite pattern of results. Specifically, practice in color naming of neutral stimuli should strengthen the unpracticed dimension and thereby decrease interference, while practice in word reading should have made reading even more dominant and further increase interference. Both of these predictions were contradicted by the results.

Our main finding that word reading practice led to a reduction of Stroop interference is consistent with a negative relationship between reading ability and Stroop interference, as proposed by Protopapas et al. (2007). This relationship is due to the dependence of interference primarily on the speed of processing of the irrelevant stimulus, that is, of reading the word. The time needed to retrieve the irrelevant word response is a crucial factor in the process of interference because it sets a lower limit on the time taken to reject (inhibit) this response. Therefore the speed of reading puts severe constraints on interference. In contrast, neutral color naming may be related to incongruent color naming, because they are both color naming tasks (cf. di Filippo \& Zoccolotti, 2012), but it is not specifically predictive of interference because there is ample time for the color naming response to build up while the inappropriate one (word reading) is retrieved and subsequently inhibited. This suggestion links word reading and neutral color naming, the two component tasks involved in Stroop interference, with the phenomenon of interference directly, via a blocking mechanism as proposed by Roelofs (2003).

Specifically, according to the computational model WEAVER++ (Roefols, 2003) a blocking mechanism prevents obligatory responses from being produced while allowing their processing speed to determine the nondominant response latency. In this theoretical context, interference does not occur because of the relative processing strength of reading and color naming but because a fundamental architectural distinction forces color naming responses to wait until word reading responses are activated and then suppressed. This approach can explain our results in children, assuming that word lemma activation can benefit through reading practice by strengthening the direct connections between visual word stimuli and phonological word forms. This leads to a faster suppression of the word and ultimately to a faster color naming response.

Interference was also reduced in both groups with practice in color naming of incongruent stimuli. Presumably, in this condition participants learned to apply cognitive control more effectively and suppress the irrelevant response faster.

As our data were not constrained by any participant selection criteria and the participants were randomly assigned to the experimental conditions, there is no factor to attribute the differential development of interference other than the experimental manipulation, namely practice. Moreover, our implementation of an individual-item computerized version of the Stroop task, instead of the oftemployed sheet form, alleviates concerns related to task demands and spatial context that might impose consideration of attentional allocation factors (Lachter, Forster, \& Ruthru, 2004; Risko, Stolz, \& Besner, 2005). Without diminishing the significance of executive functions and attentional processes in interference, our data are consistent with the idea of a direct link between reading ability and Stroop interference.

One objection that may be raised against our interpretation is that three days of practice in color naming
of neutral stimuli may not have been enough to counterbalance years of experience in word reading in children, and especially in adults, so that a reduction of interference can be observed. However, if we take into account the effect of word reading practice in children, we see that three days of practice were enough to reduce interference despite years of previous experience with words. Thus it seems that a few hundred trials may be sufficient for these kinds of effects to emerge. Certainly, it cannot be precluded that additional factors modulate color and word processing and act differentially in the naming and reading tasks, but this is an issue beyond the scope of our current analysis, to be addressed in future study. However, from the point of view of a graded automaticity account, it still cannot be explained why practice in word reading did not increase Stroop interference but, instead, decreased it.

Close examination of the raw response times for children (Figure 1, left) reveals that post-training performance tended to be slower than pre-training performance, a trend visible also in the no-training group. This is an additional reason to use a control group rather than directly comparing pre- to post-training times. As it turned out, significant reduction of interference was associated with a lack of increase in posttraining incongruent color naming times. So, in comparison with the control group, this amounts to faster responses.

To the best of our knowledge, this is the first training study of the simple skills involved in Stroop interference, namely reading and color naming, carried out with children. Therefore there is no closely related literature to compare our findings to. Because of the theoretical importance of these results and the implications for cognitive theories of conflict resolution processing, further research will be required to confirm and extend these findings to additional populations and tasks.

\begin{abstract}
A series of papers have appeared investigating the ability of various species to learn context-free languages. From a computational point of view, the experiments in this tradition suffer from a number of problems concerning the stimuli used in the training phase of the experiments, the controls presented in the test phase of the experiments, and the motivation for and the conclusions drawn from the experiments. This paper discusses in some detail the problems with the existing work in this domain before presenting a new design for this type of experiments that avoids the problems identified in existing studies. Finally, the paper presents results from a small study demonstrating the benefits of the new design.
\end{abstract}

Keywords: Context-free languages, formal language theory, artificial language learning, animal experiments

\section*{Introduction}

Since the publication of (Fitch \& Hauser, 2004), a small but highly visible literature has emerged investigating the ability of various species to learn and process a context-free language (e.g., Friederici, 2004; Perruchet \& Rey, 2004; Gentner, Fenn, Margoliash, \& Nusbaum, 2006; Hochmann, Azadpour, \& Mehler, 2008; van Heijningen, de Visser, Zuidema, \& ten Cate, 2009; Abe \& Watanabe, 2011; ten Cate \& Okanoya, 2012). It is not difficult to see why the questions addressed in this literature appeal to a wide audience: the grammars generating context-free languages are context-free by virtue of their ability to generate hierarchical structures and to implement center-embedding. Hierarchy and centerembedding are, since (Chomsky, 1957), widely recognized to be hallmark features of human language. Hence, experimentally establishing whether non-human animals can handle a context-free language \({ }^{1}\) seems to address a prime candidate in the search for uniquely human, and perhaps uniquely linguistic, cognitive skills.

However, on a closer look, there are many problems with this literature, and almost a decade of investigation and debates have not brought the clarity about this issue that we might have hoped for. In this paper I will first discuss in some detail the problems with the existing work in this domain before presenting a new design for this type of experiments. I will present results of a small experiment with this design, that show it is workable. For lack of space, I will not review elementary formal language theory here; see (O'Donnell, Hauser, \& Fitch, 2005) for an introductory and (Jäger \& Rogers, 2012) for a more advanced discussion of the formal background of the experiments discussed here.

\footnotetext{
\({ }^{1}\) Throughout this paper I will use the phrase "a context-free language" as denoting a member of the subset of the context-free languages that is not also in the set of regular languages.
}

\section*{Problems with the experimental record}

From a computational point of view, the experimental record suffers from a number of problems concerning the stimuli used in the training phase of the experiments, the controls presented in the test phase of the experiments, and the motivation for and the conclusions drawn from the experiments.

The first major problem is a lack of clarity about which ability is really investigated: the ability to implement a context-free language, the ability to learn a context-free language, or a preference for selecting a context-free strategy from the set of strategies adequate for solving the task. Much of the rhetoric seems to be about the ability to implement, but all existing experiments that I am aware of really at best address the weaker hypothesis that non-human animals lack the human preference.

This problem is exacerbated as all existing studies allow a great deal of ambiguity in the training phase about which strategies are adequate. Some ambiguity is unavoidable: all real-world experiments can only present a subset of the infinite stringsets that make up context-free languages, leaving the learner fundamentally uncertain about whether or not sub- or supersets of the intended context-free language are the target (see figure 4). Moreover, studies using familiarization/habituation paradigms can only present positive stimuli in the training phase. However, in a reinforcement paradigm some ambiguity is avoidable, but existing studies using such a paradigm fail to provide learners with the information that some plausible alternatives are not intended. For instance, (Gentner et al., 2006) presented their starlings with in the order of 300000 stimuli with positive and negative feedback to learn to distinguish \(A^{n} B^{n}\) from \((A B)^{n}\), but not with a single stimulus that would help the birds exclude \(A^{n} B^{m}\). If the question we want to ask is whether these birds can learn the context-free language at all, it would be better to avoid unnecessary ambiguity about the task (desideratum 1).

A second unclarity in existing work comes from unnecessary variation in the syllables of (song) elements used to compose the stimuli. Thus, when testing whether subjects can learn \(A^{n} B^{n}\), all studies I am aware off use multiple instances of \(A\) 's and \(B\) 's. This means the subjects are really confronted with two tasks at the same time: the task to categorize \(a_{1}, a_{2}, \ldots\) as instances of class \(A\), and the task to learn sequencing rules. While the interaction between categorization and sequence learning is certainly interesting, this interaction has in fact not been explicitly addressed in this paradigm. In most studies the categorization task is made rather trivial because \(A\) 's and \(B\) 's are carefully selected to be acoustically very similar within one category and very dissimilar between categories. In these studies the variation in stimuli probably has
little impact on the results and just makes describing the experiments unnecessarily complicated; in other cases, it introduces confounds. It would be better, therefore, to avoid these complications and start with experiments using an alphabet with just 2 items: \(a\) and \(b\) (desideratum 2).

A third major problem with the existing literature concerns inadequate controls (see also Beckers, Bolhuis, Okanoya, \& Berwick, 2012). (Fitch \& Hauser, 2004) present no data on controls for alternative strategies (although the supplementary material states - without presenting details - that various alternative explanations have been controlled for). Unlike many other experiments, (Gentner et al., 2006) did test a number of these alternative strategies, and presented results that seemed to exclude all except for the most "heavily contrived" finite-state grammar hypotheses. It turns out that even their quite elaborate efforts to control for various alternative strategies are insufficient, as I will discuss below. It would seem necessary, therefore, to work out better ways to evaluate the plausibility of alternative explanations for the results (desideratum 3).

\section*{A case-study: Gentner et al. 2006}

To make these problems concrete, I will here discuss them in the context of (Gentner et al., 2006). This is not because this paper has more methodological problems than others; on the contrary, in fact, this paper probably represents one of the most serious efforts to control for alternative explanations among the experimental papers in this domain. As I will show below, however, the results from this study have nevertheless little to say about the ability or inability of song birds to learn a context-free language.

Training Gentner et al. studied whether starlings (Sturnus vulgaris) are able to learn a context-free language. As in many other studies, the stimuli in this experiment were strings of elements that fall into two easily distinguishable categories, \(A\) and \(B\), each with a small number of members, i.e. \(A=\left\{a_{1}, a_{2}, a_{3}, \ldots, a_{8}\right\}\) and \(B=\left\{b_{1}, b_{2}, b_{3}, \ldots, b_{8}\right\}\). Gentner et al. extracted these stimuli from the starling's own song, where the \(A\) 's were "rattle" motifs and the \(B\) 's were "warble" motifs. Stimuli in the training phase consisted of strings of length 4 from two patterns \({ }^{2}\) : (i) \((A B)^{n}\) and (ii) \(A^{n} B^{n}\). I will refer to string sets defined by these patterns as the FINITE-STATE-0 and the CONTEXT-FREE language (the 0 indicating that this is just the first of many finite-state languages that I will consider).

The birds were trained in a go-nogo operant conditioning procedure to respond selectively to stimuli from one or the other pattern. In the experiment, birds did indeed learn to distinguish the stimuli sets, at levels far exceeding chance, also when new \(A\) - and \(B\)-category elements were used. This in

\footnotetext{
\({ }^{2}\) I use a conventional shorthand notation for sets of strings of a given pattern, where \(A\) 's and \(B\) 's indicate any elements from these classes, \(X^{n}\) indicates \(n\) repetitions of \(X\), and brackets are used to disambiguate the scope.
}
itself is not enough to prove context-freeness, as Gentner et al note. For instance, the two groups of birds could have internalized +FINITE-STATE-0 and -FINITE-STATE-0 instead \({ }^{3}\). I.e., they could do with a model for the finite-state stimuli set, and only accept/reject stimuli that do not/do conform to it. Or, because the string length is set to \(4, A^{n} B^{n}\) is indistinguishable from \(A^{2} B^{2}\) (which, again, doesn't need context-free power to be recognized). Worse even: there are many other alternative strategies to distinguish the training stimuli-sets, the simplest of which are based on detecting specific element-to-element transitions, or memorizing the beginning or end of strings. For instance, the \(B A\) transition, and the \(A B\) beginning, are diagnostic, because they both only occur in the +FINITE-state-0 set.

If one could show, in the test phase, that the birds have learned a context-free language, this ambiguity in the training phase is not a problem. However, if the birds turn out to choose one of the simpler strategies that also suffice to distinguish the two classes, we are left almost empty-handed. We cannot make plausible, then, that birds cannot learn contextfree language, because we haven't tried very hard to force them to.

Testing In the test phase, Gentner et al did consider a relevant set of alternative strategies.

The first test is whether subjects generalize from \(A^{2} B^{2}\) to a larger subset of \(A^{n} B^{n}\). Of course, in formal language theory the language \(A^{n} B^{n}\) contains an infinite number of strings, where \(n\) can be any integer. Gentner et al. argue, quite reasonably, that in an experimental setting we should be concerned about whether subjects generalize to unseen \(n\). (This is completely analogous to the use of formal language theory in the study of natural language: if we can demonstrate the right generalization mechanisms on necessarily finite data, we can reason about an infinite competence under a hypothetical lifting of performance constraints.) Gentner et al. report, for birds trained with \(A^{2} B^{2}\), a strong preference for \(A^{3} B^{3}\) and \(A^{4} B^{4}\) strings over \((A B)^{3}\) and \((A B)^{4}\) respectively (and an inverse preference for birds trained on \(\left.(A B)^{2}\right)\). This rules out the -FINITE-STATE-0 (or +FINITE-STATE-0) strategy.

There remain, however, still many alternative hypotheses that predict successful discrimination of \(A^{n} B^{n}\) and \((A B)^{n}\) strings. It is useful to define the following simple, but effective strategies for positively responding to the +CONTEXTFREE stimuli \({ }^{4}\) :
+ AnBn: \(A^{n} B^{n}\), with \(n \geq 1\)
+ AnBm: \(A^{+} B^{+}\), the set of strings that consist of 1 or more \(A\) 's followed by 1 or more \(B\) 's;
-BIGRAM-BA: . \({ }^{*} B A \cdot{ }^{*}\), strings containing transition \(B A\);

\footnotetext{
\({ }^{3}\) A strategy is defined by a PATTERN, written in smallcaps, and a + or \(\mathrm{a}-\) in front of it; the + indicates that strings that conform to the pattern are treated as positive stimuli; the - indicates that strings that conform to the pattern are treated a negative stimuli.
\({ }^{4}\) I will use more or less standard regular expression notation, where a dot \(\cdot\) means any symbol, \({ }^{*}\) means repeated any number \((\geq 0)\) of times, and \({ }^{+}\)means repeated any number \((\geq 1)\) of times.
}
\begin{tabular}{|c|c|c|c|c|c|c|c|c|c|c|c|c|c|c|}

\hline
\end{tabular}

Table 1: Predicted response of various hypothesized pure strategies to probe stimuli. See the main text for descriptions of the top 9 strategies; the bottom two strategies check the length of a string, and accept strings up to length 4 and 6 respectively.
+BIGRAM-AA: \(\cdot{ }^{*} A A \cdot^{*}\), strings containing transition \(A A\);
+BIGRAM-BB: . \({ }^{*} B B \cdot^{*}\), strings containing transition \(B B\);
-PRIMACY-AB: \(A B \cdot^{*}\), the set of strings that start with \(A B\);
+PRIMACY-AA: \(A A \cdot^{*}\), the set of strings that start with \(A A\);
-RECENCY-AB: \(\cdot{ }^{*} A B\), the set of strings that end with \(A B\);
+RECENCY-BB: . \({ }^{*} B B\), the set of strings that end with \(B B\);
Any of these strategies (together with their complements when considering the birds that should NOT respond to \(A^{n} B^{n}\) ) suffices to distinguish positive from negative samples in the experimental set-up (and all listed alternative strategies are in the finite-state class). But these nine hypotheses do make different predictions on the behavior of the subjects for previously unseen patterns. For instance, the +PRIMACY-AA strategy classifies all of the +CONTEXT-FREE stimuli as positive, but in addition, for string length 4 , also includes AAAA, AAAB, AABA. Table 1 gives for (the + variety of) each of these strategies the predicted response ( 1 is a GO-response, 0 is a NOGO-response).

There are, in fact, still many other alternative strategies that we could consider, such as memorizing non-adjacent pairs (e.g., \(A \cdot B \cdot^{*}\) ), or requiring a specific number of a particular transition (e.g., requiring two \(A B\) transitions, as in \(B^{*} A^{+} B^{+} A^{+} B^{+}\), or exactly one, as in \(A^{+} B^{+} A^{*}\) ). Gentner et al. appeal, quite reasonably again, to considerations of parsimony to ignore such alternatives.

To rule out the 9 remaining alternative explanations, Gentner et al. presented birds with a number of diagnostic strings. For instance:
- AAAB, which is incorrectly predicted to give a positive response by -FINITE-STATE-0, -BIGRAM-BA, +BIGRAMAA, and +PRIMACY-AA;
- BBBB, which is incorrectly predicted to give a positive response by -FINITE-STATE-0, -BIGRAM-BA, +BIGRAMBB, -PRIMACY-AB, -RECENCY-AB and +RECENCY-BB.

In an experimental setup, however, checking these predictions needs to be buffered to unavoidable noise in the data. (It would be unreasonable to reject an hypothesis based on a single unexpected classification by a bird.) Hence, we need
to use statistics, but how statistical methods for data analysis are combined with formal language theory is a non-trivial issue that both theoreticians and experimentalists have so far largely ignored. (Even the review by (Jäger \& Rogers, 2012), which presents a major effort to bridge formal language theory and artificial language learning experiments, ignores this issue).

Gentner et al. chose to use the \(d^{\prime}\)-statistic, which is a measure for discrimination between stimuli classes that corrects for response bias (the tendency to prefer a GO or a NOGOresponse regardless of the stimulus). They show that the \(d\) ' between AAAA and ABBA is significantly lower than the \(d\) ' between A2B2 and AB2, and argue this rules out the +AAPRIMACY strategy. Similarly, they find lower \(d\) ' for BBBB vs BAAB , and for \(\mathrm{BAAB} / \mathrm{ABBA}\) vs. \(\mathrm{AAAA} / \mathrm{BBBB}\), and argue this rules out + BB-RECENCY and -BA-BIGRAM. Similar analyses can be given for the remaining alternative strategies.

However, it turns out that this approach for ruling out alternatives is only valid if the population is homogeneous all members follow the same strategy - and if each individual follows a pure strategy. If individuals or populations can mix multiple strategies, Gentner et al.'s method leads to invalid conclusions. The data of Gentner et al., reproduced as the blue bars in figure 2, clearly show that the assumption of pure strategies is false: the \(d^{\prime}\)-statistic for the \(A^{n} B^{n}\) vs. \(A B^{n}\) constrast decreases with increasing \(n\), and the \(d^{\prime}\) 's for the primacy and recency strategies differ significantly. A study on zebra finches, by (van Heijningen et al., 2009), reported major individual differences between birds, further strengthening the case against the pure strategy assumption.

Simulated Data To show how the \(d\) '-statistic can lead to wrong conclusions, I will now present some artificial data that shows a qualitatively similar pattern of \(d^{\prime}\)-scores for both a model that involves an underlying context-free grammar (model I: CFG) and a model that is just a mix of finite-state strategies (model II: MIX).

To generate the CFG data, I assume a population where \(70 \%\) of the individuals have internalized the +ANBNstrategy, \(10 \%\) follow a strategy to reject long strings

Figure 1: Simulated data, generated from the CFG-model (left) and the MIX-model (right). In both graphs, the first group of 3 bars represent the number of go-responses to \(A^{n} B^{n}\)-stimuli (out of 100); the second to \((A B)^{n}\)-stimuli; the third group to \(A^{n} B^{m \neq n}\)-stimuli; the fourth to the remaining control-stimuli.

Figure 2: The \(d^{\prime}\)-statistic calculated for the \(A^{n} B^{n}\) vs. \((A B)^{n}\) distinction (left) and for various controls (right). Blue: Gentner et al, Red: CFG, Yellow: MIX.
\((+.\{1,6\}), 10 \%\) reject medium and long strings (+. \(\{1,4\}\) ), and \(10 \%\) randomly choose GO or NOGO. This is equivalent to assuming a mixed strategy with the same proportion, or a combination of intra- and interindividual variation.

To generate the MIX data, I assume a mix of finite-state strategies in the following proportions (roughly based on the findings of (van Heijningen et al., 2009)): \(25 \%\) +AAPRIMACY, \(15 \%\) +BB-RECENCY, and \(10 \%\) for each of the other strategies in table \(1+\) RANDOM.

A given mix of strategies defines for each stimulus a specific number \(f\) of GO-responses, from a fixed number of 100 presentations. To generate some randomness, I assume each of the \(f\) stimuli that should be classified as a GO-response has a fixed probability \(p=0.03\) to receive a NOGO-response, and similarly, that each of the \(100-f\) remaining stimuli have a probability \(p\) of receiving a GO-response.

Hence, the final number of GO-responses is \(g=x+y\), where both \(x\) and \(y\) are sampled from a binomial distribution:
\[
x \sim B(f, p), y \sim B(100-f, 1-p)
\]

This generates a dataset as in figure 1 (left) for the CFG model, and (right) for the MIX model (note that the datasets
are the result of a single run of the model).
I subsequently calculate the \(d^{\prime}\)-statistic in the same way as (Gentner et al., 2006). This statistic is simply the difference between the z-transform of the counts: \(d^{\prime}(x, y)=z(x)-z(y)\) where the z -transform in turn is a way to express the magnitude of the score in terms of how many standard deviations it is away from the mean: \(z(x)=(\bar{d}-x) / \sigma_{d}\) where \(d\) is the complete data vector from which \(x\) is one value (or the average of several values), and \(\sigma_{d}\) is the standard deviation over that vector.

Applying these formulas to the contrasts between \(A^{n} B^{n}\) and \((A B)^{n}\) for \(n \in\{2,3,4\}\) we obtain, in figure 2(left) qualitatively similar results to Gentner et al: significant discrimination for all, but a decrease in discriminability with increasing \(n\). Although unsurprising, this result points to a problem with existing studies that fail to show generalization: this could be due to length effects. It would be better if tests for generalization do not only test on longer strings in the test phase than were offered in the training phase (desideratum 4).

Applying these formulas to the contrasts between AAAA and ABBA (labeled "primacy" in (Gentner et al., 2006)), BBBB vs BAAB (labeled "recency"), and BAAB/ABBA vs. AAAA/BBBB (labeled "bigram B/A") we observe, in figure 2(right) the exact same pattern of results as Gentner et al reported: overall much lower \(d^{\prime}\)-values than for the baseline, with primacy receiving the second highest score and recency the lowest.

Hence, for both the context-free (CFG) and mix of finitestate strategies (MIX) we see the same pattern of \(d^{\prime}\)-values, showing that when mixed strategies are possible, these values are uninformative about whether or not a context-free language is learned by any individual in the population. Hence, we need better tools to assess which strategies individuals are using and whether there is significant individual variation in a population (desideratum 5).

\section*{A new design}

The problems I discussed with the Gentner et al. study are symptomatic for many studies in this domain. Confusion
about exact goals and methodology are of course typical for the early phase of a new research field. It is now time, however, for an experimental design to emerge that is both methodologically sound and capable of generating useful results. In the following I will present an attempt to give such a design and a first experiment to assess its usefulness. The design follows desiderata 1-4 discussed above:
1. The goal of the design is to test whether or not the subjects can learn the context-free language \(A^{n} B^{n}\) from the type of data that can be used with animals as well as human infants and adults; i.e., not too long strings, possibly with positive and negative feedback. Some strings are reserved for the test phase only, to assess generalization, but otherwise any training regime is allowed within these constraints. In practice, I choose for a two-stage training phase: a familiarization phase where only positive stimuli are presented, and a feedback phase where positive and negative stimuli are presented with positive and negative feedback. The negative stimuli are not just from \((A B)^{n}\), but also from other plausible, but incorrect, alternative languages.
2. To make the task as simple and unambiguous as possible, I define the patterns over an alphabet of just two different sounds: \(a\) and \(b\), selected to be short and acoustically clearly distinct.
3. To be able to test for generalization, I reserve 2 values of \(n\) for strings from \(A^{n} B^{n}\) and \(A^{n} B^{n}\) for the test phase only. I further reserve a number of \(n, m\) combinations for strings in \(A^{n} B^{m \neq n}\) for the test phase, to be able to exclude primacy, recency and ANBM-strategies.
4. To make sure the test strings are not much longer than the strings seen at training, I use \(n \in\{2,3,5,6\}\) for \(A^{n} B^{n}\) and \((A B)^{n}\) strings at training, and \(n \in\{3,4,6,7\}\) at test.

The stimuli presented to subjects in the various phases are thus as follows:
\begin{tabular}{l|l} 
Phase & Stimuli \\
\hline Familiarization & \(\mathrm{a} 2 \mathrm{~b} 2, \mathrm{a} 3 \mathrm{~b} 3, \mathrm{a} 5 \mathrm{~b} 5, \mathrm{a} 6 \mathrm{~b} 6\) \\
\hline Feedback & \begin{tabular}{l} 
Positive: \(\mathrm{a} 2 \mathrm{~b} 2, \mathrm{a} 3 \mathrm{~b} 3, \mathrm{a} 5 \mathrm{~b} 5, \mathrm{a} 6 \mathrm{~b} 6\) \\
Negative: \(\mathrm{ab} 2, \mathrm{ab} 3, \mathrm{ab5}, \mathrm{ab} 6, \mathrm{a} 3 \mathrm{~b} 2, \mathrm{a} 5 \mathrm{~b} 4\)
\end{tabular} \\
\hline Test & \begin{tabular}{l} 
Positive: \(\mathrm{a} 3 \mathrm{~b} 3, \mathrm{a} 4 \mathrm{~b} 4, \mathrm{a} 6 \mathrm{~b} 6, \mathrm{a} 7 \mathrm{~b} 7\) \\
Negative: \(\mathrm{ab} 3, \mathrm{ab} 4, \mathrm{ab} 7, \mathrm{a} 3 \mathrm{~b} 2, \mathrm{a} 4 \mathrm{~b} 3, \mathrm{a} 2 \mathrm{~b} 3\)
\end{tabular}
\end{tabular}

Experimental data Ultimately we need a lot of data and new analysis tools to meet desideratum 5 and exclude mixed strategies between and within individuals. However, a first important check on the design is to evaluate whether we can replicate the findings (Hochmann et al., 2008) that humans adults can, at the population level, (i) learn to distinguish strings from \(A^{n} B^{n}\) from several finite-state alternatives, and (ii) generalize to unseen \(n\). We therefore carried out a small experiment with the design above, to test whether its new features 1-4 stand in the way of successful learning.

The experiment was implemented as a simple internetbased applet. Subjects were instructed that they were going to do an experiment that looked a bit like a computer game, where they would have learn an alien language. At the computer screen, subjects were presented with written instructions, and, once they started the game, presented with a space background and UFO's moving over the screen. Subjects were asked to click on disks and listen to the sounds produced. After hearing the sounds they would decide to either shoot the UFO or save the aliens inside. In the familiarization phase (4 exposures to each stimulus), they were told all aliens were 'good aliens' and shooting was disabled. In the feedback phase ( 1 exposure to each stimulus) feedback was provided in the form of happy or sad face on the screen. In the test phase ( 2 exposures to each stimulus) no feedback was given.

54 subjects were recruited in the Amsterdam Science Museum (Nemo) in August 2012, and volunteered for the experiment without payment. The experiment last only about 5 minutes per subject. Subject ages ranged from around 10 to around 80; native languages included several major European languages. We thus worked with a very heterogeneous group of subjects and obtained very little data per person. Hence, the experiment was not useful (nor intended) for settling the question of whether human adults can learn a context-free language in such a setup, but to assess whether the experimental design defined above is able to generate useful data.

Figure 3 (left) gives the overall response rates for each of the stimuli presented in the test phase. As can be seen, the response rates for the \(A^{n} B^{n}\) stimuli on the left are higher than for the \(A^{n} B^{n}\) stimuli on the right, which in turn are higher than the \(A B^{n}\) stimuli in the middle. All three pairwise between-group difference are highly significant ( \(p<0.01\), Kolmogorov-Smirnov test). Crucially, responses to a4b4 are indistiguishable from other positive stimuli, indicating subjects have, at the population level, generalized to unseen \(n\).

These data thus, roughly, replicate earlier results. But can we check for all relevant alternative explanations, including a mix of finite-state strategies, as I argued above would be necessary? Unfortunately, with so little data per subject, we cannot sensibly estimate individual strategies. To get some idea about individual variation I split the data in two based on performance during the feedback phase. 20 subjects were classified as low-performers, with an accuracy in the feedback phase of less than \(70 \%\) (similar to the criterion used in van Heijningen et al., 2009). The other 34 subjects were classified as high-performers. Figure 3 (right) shows the \(d^{\prime}\) statistic for the three pairwise contrasts. One striking value is a \(d^{\prime}\) of approximately zero for the low performers on the \(A^{n} B^{n}\) vs. \(A^{n} B^{m}\) contrast, showing that they did not distinguish between the two classes and clearly had not learned a context-free language.

These data thus suggest that the experimental design presented above is very workable and can be used to obtain useful data to address the question of whether subjects can

Figure 3: Experimental results.
learn \(A^{n} B^{n}\), provided it is applied in more controlled circumstances and more data per person is gathered. With enough data per subject, we can apply the model selection approach of (van Heijningen et al., 2009) to estimate the most likely strategy for each individual subject.

\section*{Conclusions}

I have discussed some major problems with existing studies attempting to show that nonhuman animals can or cannot learn a context-free language. In that discussion, I identified four desiderata for a new design of an experiment, and a fifth desideratum for data analysis, to properly address that question. I have shown that these desiderata for the design can be satisfied, and presented some experimental results that suggest there are no major obstacles to apply the new design in animal experiments. I hope the interdisciplinary community that tries to bring formal language theory, artificial language learning and animal cognition experiments together will apply this new design in future experiments, such that the search for uniquely human cognitive skills can be based on a more sound foundation. I have not, in this paper, discussed the difficult question of whether context-freeness is really the most important property to investigate in the search for a biological basis for language (Zuidema, 2013). Even if it is not - and I suspect it isn't - it is essential that the methodological errors in the experimental record on context-freeness get corrected.

Acknowledgments I thank Vanessa Ferdinand, Richard Kunert and Sander Latour for their help in designing the experiment and creating the software for stimulus presentation and data gathering, and the team at Nemo for running the experiment.

\begin{abstract}
Vertical and horizontal head movements (universally associated with nodding and shaking, respectively) have frequently been demonstrated to affect cognitive processes. Two experiments were conducted to test the hypothesis that overt head movements can influence memory for valenced images. In the first experiment, participants were instructed to perform either vertical or horizontal head movements while viewing a slideshow of 76 randomized positive and negative images, which they later had to recognize from a set containing \(50 \%\) of the same target images and \(50 \%\) distractor images. No interaction between head movement type and image valence was obtained. In the second experiment, participants were told to remember as many images as possible from a slideshow of 60 randomized valenced images, which they were later asked to freely recall. A significant interaction was obtained, with a higher rate of recall for positive images when vertical head movements (VHM) were performed and a higher rate of recall for negative images when horizontal head movements (HHM) were performed.
\end{abstract}

Keywords: overt head movements; image recall and recognition; embodiment.

\section*{Introduction}

Previous work has demonstrated that inducing overt head movements can influence certain cognitive processes due to their positive or negative association with a given cognitive activity. For example, Wells \& Petty (1980) showed that the manipulation can have an effect on persuasion. Participants in their study performed either vertical or horizontal head movements while listening to a simulated radio broadcast, containing either a message in agreement or disagreement with participants’ attitudes (proattitudinal or counterattitudinal messages). Those participants who performed VHM agreed with the content of the broadcast more than those who performed HHM, regardless of the content of the message. Participants also found it more difficult to perform head movements that were incompatible with the message (VHH during a counterattitudinal broadcast vs. HHM during a proattitudinal broadcast). Consistent results were obtained by Briñol \& Petty (2003).

This manipulation has produced similar effects in various other domains. Tom et. al. (1991) showed that VHM led to an increased preference for neutral objects, while HHM led
to a decline in preference for the same. In another study, it was demonstrated that overt head movements can affect product choice and price perception (Tom et. al., 2006). Eppley \& Gilovich (2002) examined the effects of the same manipulation on the anchoring and adjustment heuristic, demonstrating that participants induced to accept values by nodding adjusted to self-generated anchors less than those induced to deny values by shaking their heads.

Apart from attitudinal effects, overt head movements have also been demonstrated to influence memory. Förster \& Strack (1996) induced overt head movements in participants while they listened to valenced adjectives and found that VHM led to better recognition for positive adjective and HHM led to better recognition for negative adjectives in a surprise recognition task. They refer to this as a motor-compatibility effect, suggesting that the process of learning valenced words was more effective when accompanied by compatible head movements during the encoding phase, which led to better recognition during the test phase. They point to natural and socially-learned cooccurrences of overt and covert responses as a possible explanation of this effect. An example of the former is the co-occurrence of basic emotions with specific facial expressions, while learned nonverbal responses like nodding and shaking our heads to indicate agreement and disagreement, respectively, are an example of a sociallylearned co-occurrence of overt and covert responses.

Following Förster \& Strack's methodology, in this study we explore the influence of overt head movements on the recognition and free recall of valenced images. We performed two experiments in order to investigate whether a similar motor-compatibility effect would be obtained, by inducing either HHM or VHM while participants viewed positive and negative images, which they later had to recognize among distractor images (Experiment 1) or freely recall (Experiment 2).

There were two main motivations behind this study. First and foremost, we wanted to see if the manipulation extends to memory for images. It is well known that people's memory capacity for images is far superior to that for words (Shepard, 1967; for an old but good review of the literature, see Landauer, 1986). Hence, observing the same effect

\footnotetext{
* This paper was accepted for CogSci 2012 in Sapporo but not included in those proceedings by accident.
}
would be a non-trivial finding, further confirming the validity of the effect. Second, Bulgaria is a unique place to test this manipulation, given that nodding and shaking mean the exact opposite to what they mean in the rest of the world - shaking denotes agreement, whereas nodding indicates disagreement. If the mechanism of this effect is social in nature, as Förster \& Strack suggest, we should expect the exact opposite results: facilitation for encoding negative images while performing VHM and facilitation for encoding positive images while performing HHM. Thus, the results would give insight into the extent to which culture mediates this effect.

\section*{Experiment 1}

\section*{Method}

\section*{Participants}

Nineteen New Bulgarian University students (11 men and 8 women) were given course credit for participation in what they were told was a marketing study to test the comfort and quality of a headphone set.

\section*{Stimulus Material and Apparatus}

Seventy six target images (38 positive and 38 negative) were selected from The International Affective Picture System (IAPS; Lang, Bradley, \& Cuthbert, 2008) for the encoding part of the procedure, along with half as many positive and negative distractor images (closely resembling half of the target images thematically) for the recognition part of the procedure. The reason why such distractor images were used for the retrieval procedure is that people have a naturally high memory capacity for images (Brady, 2008; Schacter, Israel, \& Racine, 1999; Shepard, 1967), which can lead to ceiling effects. One of the most impressive demonstrations of this is a study by Standing (1973), who, using a single-trial learning task with a delayed recognition test, tested subjects' memory capacity for groups of pictures ranging from 20 to 10,000 and found that, even though percentage of retention gradually declined, the absolute number of stimuli retained increased as the set of learning material increased. In an attempt to avoid losing the effect of the head movement manipulation because of such a ceiling effect, we increased the difficulty of the recognition task by introducing interference with distractor images thematically related to half of the target images (the presentation of similar distractor images has been shown to reduce accuracy in image recognition; Goldstein \& Chance, 1970). These distractor images were presented in the recognition task instead of the target images that they resembled in order to confused participants and prevent them from getting perfect accuracy scores. For samples of positive and negative target-distractor pairs, see Figure 2.

Images were selected for similar levels of arousal (approx. 5 on a 1-9 scale). The average valences of the negative and positive stimuli were approximately 3 and 7, respectively, also on a 1-9 scale. For the first part of the procedure, images were presented on a 17 " monitor
(1024×760) in Microsoft PowerPoint© and then in EPrime \({ }^{\circledR} 2.0\) during the recognition task.

Figure 1. A visualization of the procedure in Experiment 1. On the left: Encoding phase, consisting of 76 positive (+) and negative (-) target images (top left and bottom left blocks). On the right: Recognition task, in which half (38) of the original (=) targets (top right block) are presented
with 38 distractor images (bottom right block), corresponding ( \(\cong\) ) to 38 of the original targets excluded from the retrieval phase.

\section*{Design and Procedure}

The experimental design was a \(2 \times 2\) mixed-model factorial comparing head movement type (horizontal vs. vertical) between subjects and image valence (positive vs. negative) within subjects. The dependent measure was the accuracy of recognition during the test phase.

Participants were introduced to the experiment by signing a consent form and being told that they were participating in a marketing study to test the comfort and quality of a headphone set (this is the same cover story as the one used by Wells \& Petty, 1980). The entire session consisted of an encoding phase, a distractor task, and a recognition task (see Fig. 1 for a visualization of the procedure). Each of the 76 positive and negative images appeared on screen for 3 seconds as Astor Piazolla's tango "Adios Nonino" played in the background (the same type of music used by Förster \& Strack, 1996). Stimulus order was pseudo-randomized (same order for each participant). The set of images was preceded and followed by a 6 second long blank slide and the entire slideshow lasted for 4 minutes. Ten of the participants were instructed to perform HHM while listening to the music and viewing the images (presumably to test the sound quality of the headphones under more realistic conditions, namely, during movement), while the remaining nine performed VHM. The experimenters would demonstrate the movement and instruct participants to
maintain one head movement per second for the entire duration of the slideshow.

After the encoding procedure was over, participants were asked to fill out a feedback form regarding comfort of the headphones, sound quality, difficulty of the head movements, and likability of the music as part of the cover story. They were then given a distractor task for 15 minutes, during which they had to assemble two different wooden puzzle cubes (similar to the classic Soma puzzle cube).

Once those 15 minutes were up, the experiment proceeded to a surprise recognition task. Participants were presented with only half (38) of the target images from the original slideshow mixed with 38 distractor images. For each image that appeared on the screen, participants had to press an "old" button to indicate that they had seen the image before or a "new" button if they hadn't seen it. The images remained on the screen until both responses were given. Once done, participants were thanked for their participation and dismissed. All were debriefed via e-mail once the study was over.

Figure 2. Sample target and distractor images. Target images (top and bottom left) were presented during the encoding procedure and replaced by their matching distractors (top and bottom right) in the recognition procedure.

\section*{Results and Discussion}

We performed a repeated measures ANOVA with valence as a within-subject and head movement as a betweensubject factor. There was a main effect of valence, \(F(1,17)\) \(=8.253, p<0.05\), with better discrimination for negative images, \(\operatorname{Pr}=0.53\), as opposed to positive images, \(\operatorname{Pr}=\) 0.43 . \({ }^{1}\) There was no main effect of head movement type,

\footnotetext{
\({ }^{1}\) Due to the fact that several participants made no false alarms during the recognition task, our first preference, \(d^{\prime}\), could not be calculated and \(\operatorname{Pr}\) was used instead. \(\operatorname{Pr}\) is a coefficient that describes participants' discrimination performance; the higher its value, the better participants' discrimination between targets and
}
\(F(1,18)=0.59, p=0.812\). Contrary to what was hypothesized, there was no significant interaction between head movement type and image valence: \(F(1,17)=0.001, p\) \(=0.975\). Average accuracy for participants performing HHM was \(\operatorname{Pr}=0.4\) for positive images and \(\operatorname{Pr}=0.5\) for negative ones, while participants performing VHM had an average accuracy score of \(\operatorname{Pr}=0.46\) and \(\operatorname{Pr}=0.56\) for positive and negative images, respectively (see Fig. 3).

Figure 3. The average discriminability of images as a function of head movement type and image valence.

Due to the fact that accuracy scores are generally high on image recognition tasks because participants rely on their implicit memory, we tried to deliberately deteriorate their performance by presenting them with distractor images closely resembling half of target images from the encoding procedure, which explains why they made errors in the first place. However, even though it prevented a ceiling effect, this manipulation could have caused other problems. By increasing the difficulty of the task with thematically similar distractor images, we may have suppressed an existing HMimage valence interaction due to the strong interference between the similar target-distractor pairs. A reason for this suspicion is that some studies have demonstrated constructive memory effects in image recognition (e.g., Foley \& Foy, 2008 and Miller \& Gazzaniga, 1998 demonstrated this using the DRM paradigm). \({ }^{2}\)
We decided to conduct a second experiment, but instead of increasing the memory task's difficulty by introducing interference, we replaced the recognition task with a free recall task, which requires participants to rely on their explicit memory. We expected this manipulation to prevent a ceiling effect without introducing additional strong memory effects, as in Experiment 1.
distractors, and vice versa. It is calculated using the following formula: \(\operatorname{Pr}=\mathrm{H}-\mathrm{FA}\), where H (hits) is the proportion of correct identifications of targets, and FA (false alarms) is the proportion of incorrect identifications of distractors (Snodgrass \& Corwin, 1988).
\({ }^{2}\) For more on the DRM paradigm, see Roediger \& McDermott (1995).

\section*{Experiment 2}

\section*{Method}

\section*{Participants}

Twenty-six volunteers and New Bulgarian University students ( 6 men and 20 women), took part in Experiment 2, the latter of whom were given course credit for participation. The cover story from Experiment 1 was maintained.

\section*{Stimulus Material and Apparatus}

Thirty positive and 30 negative images were selected from IAPS (Lang et. al., 2008). They were selected according to the same criteria used in Experiment 1.

\section*{Design and Procedure}

The experimental design and stimulus presentation were the same as in Experiment 1. The changes made in this experiment's procedure were as follows: Participants were explicitly told to try to remember as many of the images from the slideshow as possible, as they would be asked to recall them later, after filling out the feedback form. Following the learning phase, participants were asked to write down all the images they could remember, listing each one on paper (free recall test phase) and using the minimum number of words to accurately describe them. They were given 20 minutes to describe as many images as they could remember. Upon completion of this task, they were thanked for participating and dismissed.

\section*{Results and Discussion}

Two independent experts were used to evaluate the correspondence between the descriptions of recalled images given by participants and the images used in the slideshow. Only answers which gained unanimous consent by the experts were counted as correctly recalled images. Overall agreement between them was \(98 \%\).

The average number of correctly recalled images was 20.04. Similar to Experiment 1, on average, more negative (10.73) than positive (9.31) images were recalled for a main effect of valence, \(F(1,24)=5.03, p<0.05\). There was no significant main effect of head movement type, \(F(1,24)=\) \(0.207, p=0.653\). Contrary to Experiment 1, the crucial interaction between head movement type and valence was significant, \(F(1,24)=4.5, p<0.05\). That is, more positive images were recalled by participants who performed VHM (9.69), compared to participants who performed HHM (8.92). In contrast, more negative images were recalled by participants who performed HHM (11.7), compared to those performing vertical ones (9.77; see Fig. 4). It is evident that the difference between vertical and horizontal head movements is greater for negative \((d=1.14)\) than for positive ( \(d=0.4\) ) images. It is curious to note that this is the opposite of what Förster \& Strack (1996) observed for valenced adjectives and may be due to some type of negativity bias. Many previous studies have failed to demonstrate memory effects for images as a function of
valence, but according to Ochsner (2000), this may have been a result of using memory measures that lack sensitivity to differences in the experience of past events. Using the remember/know paradigm, the author obtained more remember responses for negative images compared to positive ones, whereas positive images evoked more know responses (i.e. they were just familiar, rather than remembered). Kensinger et. al. (2007) have similarly shown a general recognition advantage for negative stimuli.

Figure 4. The average number of recalled images as a function of head movement type and image valence.

\section*{General Discussion}

Despite the positive results obtained in Experiment 2, the findings of Experiment 1 did not show a significant interaction between head movement type and image valence. We hypothesized that our attempt to prevent a ceiling effect during the recognition task by introducing strong interference between target and distractor images may have concealed an otherwise existing effect of the head movement manipulation. In Experiment 2, we employed a different method for eliminating the possible ceiling effect by changing the recognition task to a free recall task, which proved successful in finding the significant interaction.

A finding consistent across both experiments was that more negative images were remembered than positive images, even though they were specifically selected for equal arousal ratings. One possible explanation for this is that negative events leave stronger memory traces compared to positive events. Studies on memory have tended to focus more on arousal levels of stimuli than on valence, but recent research has shown it to be an important factor in encoding and retrieval processes. Multiple studies show that negative information is remembered more vividly than positive information, that it is remembered in more detail, and that people are better at remembering whether they saw or only imagined negative stimuli, whereas with positive stimuli, they are more likely to be confused (for a review, see Kensinger, 2009). This body of research and the results of our experiments are in line with the general trend observed in various domains in psychology (e.g. impression
formation, learning, judgments, information processing, memory, etc.) that bad is stronger than good (for an extensive review of the converging evidence across research domains, see Baumeister, 2001).

Our study extends the overt head movement paradigm to the domain of memory for images. The significant interaction found between head movement type and image valence in Experiment 2 is consistent with the results of Förster \& Strack (1996), who found the same interaction between head movement type and adjective valence. Obtaining a significant interaction between head movement type and image valence despite people's exceptional memory capacity for images offers further support for the motor-compatibility effect. The main idea that information is better encoded while compatible head movements are performed, as opposed to when incompatible head movements are performed, is in line with the findings of other researchers in many other domains (see the Introduction of this paper for a brief review) and is also consistent with findings of other research on stimulusresponse compatibility (Romaiguere et. al., 1993; Solarz, 1960).

Interestingly, the reversed meaning of head movements in Bulgarian culture seems to have no influence on the effect observed in previous studies. We found that upon asking how they gave nonverbal responses for "yes" and "no", oftentimes participants demonstrated nodding and shaking, respectively, whereas when implicitly tested about this right after the explicit test (the experimenter would informally ask the participant a yes/no question, the answer to which was known in advance), they would often respond in the traditional Bulgarian way (shaking for "yes" and nodding for "no"). Our findings may suggest that the motorcompatibility effect is independent of culture, but it may also be due to the strong influence of Western culture (e.g., through media, mass communication, globalization, etc.). The discrepancy suggests that the issue of which nonverbal head gestures Bulgarians perform to denote agreement/disagreement is not clear cut and is an interesting empirical question on its own.

\section*{Summary}

We conducted two experiments to test the effect of overt head movements on the encoding of positive and negative images. The main findings of our study are the following:
1) Negative images were remembered more than positive images, despite equal levels of arousal;
2) Head movement type interacted significantly with image valence during the free recall task, but not during the recognition task;
3) Contrary to what was expected, the direction of the interaction was the same with Bulgarian participants as has been reported in previous studies with nonBulgarians, despite the cultural difference in meaning of vertical and horizontal head movements.

Although interesting, these results require further investigation in future studies.

\section*{Acknowledgments}

We would like to thank the people who volunteered to participate in our experiment and Oksana Itkes for her assistance in finding some of the references.

\title{
Sequential Structure Suffices to Solve Nativist Puzzles
}

\author{
Rens Bod (rens.bod@uva.nl) \\ ILLC, University of Amsterdam \\ Science Park 107, Amsterdam, Netherlands
}

Keywords: language modeling; computational models of language learning.

\section*{Nativism versus Empiricism}

The debate between hierarchical versus sequential structure in language acquisition has recently flared up again (cf. Frank, Bod \& Christiansen 2012; Pesetsky 2013). Roughly, the nativist view on language endorses that human language acquisition is guided by innate rules that operate on hierarchical structures. The empiricist view assumes that language acquisition is the product of abstractions from empirical input but leaves it as an open question whether sequential or hierarchical structure is needed. Some empirical models use sequential structure (e.g. Reali \& Christiansen 2005) while other models are based on hierarchical structure (Bod 2009; Bod \& Smets 2012).

Much work in empirical language acquisition has focused on a relatively small set of phenomena such as auxiliary fronting. For example, Reali \& Christiansen (2005) argued that auxiliary fronting could be learned by linear models based on sequential structure, though Kam et al. (2008) showed that the success of these models depend on accidental English facts. Other empiricist approaches have taken the notion of structural dependency together with a combination operation as minimal requirements (e.g. Bod 2009), which overcomes the problems raised by Kam et al. (2008).

In Bod and Smets (2012) it was shown that a much larger set of phenomena can be learned by an empiricist computational model. These phenomena are well-known in the generativist literature (Ross 1967; Adger 2003) and are related to wh-questions, relative clause formation, topicalization, extraposition and left dislocation. It turned out that these hard cases can be learned by an unsupervised tree-substitution grammar induction algorithm that returns the sentence with the best-ranked derivation for a particular phenomenon, using only a very small fraction of the input a child receives.

However, Bod and Smets (2012) also observed that these nativist cases were learned by using relatively shallow structures with little or no hierarchy. This raised the question as to how much structure is actually needed to learn these syntactic constraints. In the current paper, we present a very simple model that reduces all syntactic structuring to concatenations of substrings without any hierarchy. We show that almost all results obtained by the hierarchical grammar in Bod \& Smets (2012) can also be learned by means of a sequential grammar using substringconcatenation only.

It should be stressed that the essence of the debate between nativism and empiricism lies often in the relative contribution of prior knowledge and linguistic experience (cf. Lidz et al. 2003; Ambridge \& Lieven 2011; Clark and Lappin 2011). Following the nativist view, the linguistic evidence is so hopelessly underdetermined that innate components are necessary. This Argument from the Poverty of the Stimulus can be phrased as follows (see Pullum \& Scholz 2002 for a detailed discussion):
(i) Children acquire a certain linguistic phenomenon
(ii) The linguistic input does not give enough evidence for acquiring the phenomenon
(iii) There has to be an innate component for the phenomenon

In this paper we falsify step (ii) for a number of linguistic phenomena that have been considered "parade cases" of innate constraints (Crain 1991; Crain and Thornton 2006). We will show that even if a linguistic phenomenon is not in a child's input, it can be learned by a sequential model using only a tiny fraction of child-directed utterances, i.e. the Adam corpus in Childes (MacWhinney 2000).

\section*{Methodology}

Our methodology is very simple: by means of concatenations of substrings (of parts of speech) of any length from the Adam corpus, we compute from the alternative sentences of a syntactic phenomenon (reported in the generativist literature) the sentence with the most probable shortest concatenation. Next, we check whether this sentence corresponds with the grammatical sentence. The shortest concatenation is defined as consisting of the minimal number of substrings (smoothed by the n-shortest concatenations, similar as in Bod and Smets 2012). In case there is more than one shortest concatenation, the most probable one is computed by multiplying the (smoothed) relative frequencies of these substrings in the corpus. For example, given a typical nativist problem like auxiliary fronting, the question is: how do we choose the correct sentence from among the alternatives (0) to (2):
(0) is the boy who is eating hungry?
(1) \(*\) is the boy who eating is hungry?
(2) \(*\) is the boy who is eating is hungry?

According to Adger (2003), Crain (1991) and others, this phenomenon is regulated by an innate principle. In our approach, instead, we produce all concatenations of
substrings that generate (the pos-sequences corresponding to) those sentences. Next, the sentence generated by the most probable shortest concatenation is compared with the grammatical expression.

\section*{An Example and Overvie w of the Results}

As an example we will look into the Left Branch Condition (Ross 1967; Adger 2003). This condition has to do with the difference in grammaticality between (3) and (4):
(3) which book did you read?
(4) *which did you read book?

When we let our model generate these two sentences by the shortest combinations of substrings from Adam, we get the respective concatenations ( \(3^{\prime}\) ) and (4'), where for reasons of readability we substituted the pos-tags with the words:
(3') [which book] + [did you read]
(4') [which] + [did you] + [read book]
In this case the shortest concatenation already breaks ties, thus we do not have to compute the most probable shortest concatenation (the latter actually being the typical case).

Table 1 gives an overview of the syntactic constraints/phenomena we have tested so far, and whether these can be successfully explained by the most probable shortest concatenation. The table shows that with only a tiny fraction of a child's input (i.e. just the sentences from the Adam corpus) the correct sentence can be predicted by our simple model for all but two of the phenomena. Our result approaches Bod and Smets (2012) which missed only one phenomenon rather than two, but which relied on a much more complex hierarchical model that induced full-fledged probabilistic tree-substitution grammars. In the future we will therefore also test with larger corpora in Childes.

Table 1: overview of phenomena tested
\begin{tabular}{lc} 
Phenomenon & Succesful? \\

\title{
Whorf for the \(21^{\text {st }}\) century: From interactive processing to linguistic relativity
}

\author{
Gary Lupyan (lupyan@wisc.edu) \\ Department of Psychology \\ University of Wisconsin-Madison \\ Madison, WI 53706
}

The crux of the Whorfian thesis is that our thought and behavior are influenced in deep ways by the language we use. In recent years we have seen a wave of rigorous and creative investigations of this thesis (Boroditsky, 2010; Wolff \& Holmes, 2011 for reviews). Yet, many researchers remain highly skeptical of findings purporting to support Whorfian claims (Gleitman \& Papafragou, 2005), and much confusion remains about how to integrate these findings into existing theories of cognition. A major barrier to understanding the degree to which various aspects of human cognition may be affected by speaking different languages is understanding the relationship between language-any language - and the rest of cognition. To remove this barrier we need to address a fundamental question: To what degree is normal human cognition actually language-augmented cognition? I will argue that a surprising variety of behavior previously assumed to be "nonverbal" shows signs of being influenced by linguistic factors and I will outline a theory of language-augmented thought that offers a mechanistic account of where we might expect to find effects of language on "nonverbal" cognition (Lupyan, 2012a, 2012b, for reviews).

One of the core features of language is using words to denote categories, e.g., using the word "dog" to refer to dogs. Words are commonly seen as a kind of "pointer" to concepts, the content of which is independent of language. In recent work, we have argued for an alternative: verbal labels do not simply point or refer to nonlinguistic concepts, but rather actively modulate conceptual representations that are brought online during "nonverbal" tasks. For example, Lupyan \& Thompson-Schill (2012) showed that hearing referential labels such as "dog" consistently enhanced picture recognition compared to equally familiar, predictive, and unambiguous nonverbal cues such as a barking sound. This label advantage extended to newly learned labels and sounds. Despite participants' equivalent facility in learning what a novel object is called and what sound it makes, newly learned verbal labels were subsequently more effective in activating the concept than nonverbal sounds. In particular, hearing a label appeared to activate more category-typical information than hearing equally predictive nonverbal cues. This and related findings that verbal labels selectively activate category-typical features is hypothesized to underlie detrimental effects of labeling on visual memory such as the ability to remember not just that one saw a chair, but what kind of chair it was (Lupyan, 2008a).

As a further example of the kinds of powerful and surprising effects that category labels have on putatively nonverbal tasks, consider the following results (summarized in Lupyan, 2012a): When asked to draw a figure with three
sides, all participants predictably drew triangles: \(50 \%\) were isosceles/equilateral and \(50 \%\) were parallel to the bottom of the page. When a separate group was asked to draw a "triangle," \(91 \%\) drew isosceles or equilateral triangles and \(82 \%\) drew triangles with bases parallel to the bottom of the page (the canonical horizontal orientation). These differences do not stem solely from pragmatics. In a speeded recognition task, participants were faster to verify isosceles than scalene triangles, and horizontally-oriented than oblique triangles, but only on trials on which they actually heard the word "triangle" and not on trials on which they viewed the same shapes after hearing "three-sided" (all factors withinsubjects). Finally, in an untimed visual-reasoning task, participants were asked to estimate the angle of the base of various three-sided polygons. These shapes were referred to as "triangle" or a "three-sided shape" (between subjects). As shown in Fig. 1, when the shape was referred to as a "triangle," its tilt was perceived as deviating more from the canonical (horizontal) as steeper than when the category name was omitted. On one interpretation, these results support the hypothesis that the representation activated by the word "triangle" are a better match to more "canonical" triangles than a formally equivalent cue. Despite denotative equivalence between "triangles" and "three-sided polygons" the category label "triangle" seems to reliably activate a more "canonical" triangle as measured by both explicit and implicit tasks_prima facie evidence of category labels augmenting underlying representations in systematic ways.

Figure 1: Left: Perceived orientation of shapes is systematically affected by whether they are called "triangles" or "three-sided". Right: Participants take longer to look at scalene (atypical) triangles when they hear the word "triangle."

Thus, referring to an object by its name appears to activate a different representation than when ostensibly the same concept is activated without using the name (Lupyan \& Thompson-Schill, 2012; Lupyan, 2008b).

Why do labels have these effects? On the present account these effects are a product of (1) the association history of the discrete label with numerous category exemplars and (2) the feedback of the label on conceptual/perceptual representations. Under the influence of this feedback, the representations of various entities (objects, relations, etc.) become more categorical. This account can explain, for example, findings of pervasive effects of language on color perception (e.g., Regier \& Kay, 2009; Lupyan, 2012a for discussion). Stated simply: the association of a label such as "green" with a range of colors means that when one sees a greenish color, the label is rapidly activated, temporarily warping the perceptual space. Viewing a green object becomes a hybrid visuo-linguistic experience.

To better understand this account, a simulation of how feedback label-feedback can augment conceptual and perceptual representations will be presented. Fig 2A shows a schematic of an interactive neural network trained on a bidirectional mapping between bit-vectors (representing featurebased object representations) and category labels (i.e., learning to label chairs as "chairs" and learning to activate a likely visual representation of a chair given the label). After training, when the network is presented with a perceptual input, the label becomes automatically activated, and then feeds back to affect representations as they unfold

Labels prevented from feeding back

Labels allowed to feed back
Figure 2. (A) Schematic of a neural network for studying the role of label feedback on object representations. (B) Activation dynamics in the "conceptual" layer. Each line represents an activation of a category exemplar over the course of a single trial. Color represents category membership.
in time in the "perceptual" and "conceptual" layers. We can then examine what role the label is playing in the activation and maintenance of the representation of a particular category exemplar by directly perturbing the activation of the label or its feedback onto these layers. Feedback from labels (whether activated by the network on its own, or provided externally) provides much more categorical (clustered) representations (Fig. 2b), leading to improved categorizationa prediction confirmed by overt categorization tasks (Lupyan, 2009; Lupyan, Rakison, \& McClelland, 2007; Lupyan \& Thompson-Schill, 2012). Additional evidence for verbal labels augmenting "nonverbal" representations comes from their apparent effects on basic visual perception. Visual rep-
resentations activated by verbal means appear to be differ-ent-specifically, more categorical-than ostensibly the same representations activated by nonverbal means (Lupyan \& Spivey, 2008, 2010; Lupyan, 2008b).

Given that small linguistic manipulations affect how perceptual and conceptual information is brought online even within the same language community, we may expect that the substantial cross-linguistic differences in human languages should have substantially larger consequences on "thought," but there seems to be fewer such differences than expected. I will argue that this curious absence of evidence is due to a dichotomy made by researchers between verbal and nonverbal processes (e.g., "thinking for speaking") with the consequence that investigators may of linguistic relativity may have been looking in the wrong places.

\section*{Introduction}

In the 1970s and 80s Cognitive Science and Cognitive Linguistics and Computational Psycholinguistics emerged as the boxes around our disciplines started to become straight-jackets, and research out of one discipline would start to make waves in others. The toy systems of Artificial Intelligence were reaching limits, and introspection by programmers and engineers was reinventing square wheels without any biological plausibility and in ignorance of relevant work across the cognitive sciences, while conversely, work in other fields often lacked the understanding of computability and complexity necessary to ensure that models were realistic and computationally plausible.

This is the starting point for the research program I have been undertaking for the last 35 years, seeking to build intelligent computer systems and computational cognitive models. The idea has been to try to build an intelligent system modelled on the way a baby learns about the world, culture, society and language. Conversely, the idea has been to explore theories from psychology, linguistics and neuroscience through the medium of computational models. The primary focus and agenda of our research program are summed up in Powers and Turk (1989): language and ontology are learned together through multimodal association.

\section*{Language \& Ontology}

Over the years, the breadth of the both the "Language" and "Ontology" learning aspect of the research has grown to include audio-visual speech, gesture and emotion recognition and synthesis, as well as robots both simulated and physical. The earliest models (Powers, 1983; 1984) selforganized with a clear dependency on closed class lexemes as the basic for syntactic structuring, and later work extended this to the levels of phonology and morphology (Powers, 1991;1997abc). In parallel, the same learning models, including both statistical and neurally based coclustering models, were also used to learn noun, verb and preposition semantics in the context of a robot world simulation, and remain of major importance in our research (Pfitzner et al. 2009; Leibbrandt \& Powers, 2010;2012).

The physical models ranged from a robot baby that turned and looked at you if your talked to it or touched it
(Powers, 2002), whilst wheeled robots took on a life of their own (Powers et al., 2012) with simulated Teaching Head applications becoming a major focus (e.g. Milne et al., 2011-12) as an outcome of a major ARC/NHMRC Thinking Systems initiative that not only funded our "Thinking Head" project, but our colleagues' "Thinking Hand" and "Thinking Feet" projects. \({ }^{1}\) Whereas we concentrated on hands and feet and wheels for locomotion, with fairly conventional path planners for navigation, and made use of conventional robotic grippers for grasping, or much safer simulated grasping for our Hybrid World (Newman et al., 2010), this Thinking Hand team concentrated on such matters as how to hold a glass or a light bulb without breaking it, whilst the Thinking Feet team looked at spiking models for navigation.

One of the core driving forces for our work at this point is the realization that our "five senses" actually hide a multitude of specific sensors and percepts each. For example the fingerprints on the hand distinguish the transverse motion of slip vs the normal force of pressure, in ensuring we neither drop nor crush the light bulb. Our two eyes and four types of visual transducer, and the different afferents and efferents involved in controling convergence and focus and aperture, combine with our inner and outer ears to direct our gaze and focus sound, with two different Nyquist tradeoffs of time vs frequency, with 3D balance and inertial sensing. Much of our focus is combining together different senses or subsenses, or discriminating out the different features from our combined senses that have particular value in the tasks we attempt.

This combination of multiple sensory or feedback inputs is called fusion (Lewis and Powers, 2000;2003) and complements processes of signal deconvolution (Li et al., 2003) and feature selection (Atyabi et al., 2012). Computationally it is not effective to learn by throwing all the mass of sensory input together into one big vector and trying to make sense of it ('early fusion'), but nor is it effective to try to deal with each sense or sensor on its own to do the task, and at the last minute vote to fuse sources or models ('late fusion'). Rather we need to look at the similarities and correlations (e.g. whose lips are moving to know who is talking to us) and dissimilarity and independence (viz. we don't want a committee of yes-men, but of independent thinkers, so we search a large space of potential solutions). The first step is often to figure out how many independent components, or clusters or features there are - or we can use algorithms that decide on the fly.

Keywords: joint action; wisdom of crowds; group behaviour, situated cognition; decision making; public goods games

We present results from a new paradigm: mass participation games. In our experiments, hundreds of people can play a computer game simultaneously using audience response handsets. We can collect responses from a lecture hall full of people with the precision of a laboratory cubicle. We have studied two games: continuous, action games where participants cooperate to achieve a goal; and decisionmaking paradigms in which participants make repeated choices to maximise their own or the group's rewards. We address a range of theoretical questions with experimental manipulations and computer modelling. Do participants play as if they were alone, or as a group? If so, do they represent the group as a single entity, or a collection of other agents? What are the dynamics of these behaviours, with learning across many trials? Lastly, what does it feel like to act in concert, or in competition, with a room full of people?

There is wisdom in a crowd. The averaged response of a crowd usually betters any of the individual guesses, whether they are guessing the weight of a cow (Galton, 1907), predicting the stock market or making bets about geopolitical events (Surowiecki, 2004). But is the superiority of crowds restricted to single, static decisions? There may be wisdom in a crowd but what happens when they have to act together? What happens when they have to make decisions - pervasive in society - that trade off their own interests with those of the group? For these actions and decisions to be made, how do they learn to predict the behaviour of the group? We addressed these questions by developing mass participation games, in which participants cooperate or compete, maximising their own rewards or those of the group \({ }^{1}\).

\section*{Tightrope walking: a cooperative action game}

In our first, action-based game participants saw on a projection screen a picture of a man holding a pole, balanced on rope (Figure 1). Each participant held a handset and pressed one of two buttons. A laptop computer collected the responses and controlled the movements of the tightrope walker. Each time one of the participants pressed a button, it sent a small nudge to the tightrope walker, sending him left or right. A game ended when the tightrope walker fell.

Analysing the time he stayed aloft and tracking individual responses, we found that on successful games participants were able to anticipate and compensate for the behaviour of the group. This conclusion was supported by agent based simulations. In later conditions we instructed the participants to vocalise their button presses as they made them. The evidence is that they made use of this information, and were better able to predict and compensate for each others' actions.

Figure 1. The tightrope walker game, the participants and the correlation between performance and anticipations

\footnotetext{
\({ }^{1}\) If this paper is presented as a talk at the Cognitive Science conference, then the audience will of course be invited to play these games
}

\section*{Zombie attack: A public goods game}

Our second mass participation game studied decisionmaking in a public goods game. A contribution tin in an office kitchen is a public goods game. If everyone contributes money each week, it will pay for everyone's coffee. But a single person could chose not to contribute: they would get free coffee. If everyone followed this strategy, then the whole system would collapse and there would be no coffee. The trade-off between private and public gain is at the heart of public goods games. They are a standard tool in economic theories, used as a model for a huge range of activity from traffic patterns to tax returns.

Most empirical studies of public goods games use a small number of participants or have a small number of trials. We believe these miss the essential character of decisions made outside of the laboratory. People make these choices continuously throughout their lives, within the context of a social interaction. To understand how they learn to anticipate the actions of others, to see how social forces sway the choice to be selfish or cooperative, we argue it is vital to study the behaviour of a large group of people, present in a room together, playing repeated trials over time.

In our Zombie attack game, participants made a binary choice on each trial (Figure 2). They pressed one button to hide from the zombies, and another to fight. Rewards for the individual and the group decreased as more people chose to hide, but increased as more people chose to fight. Feedback on groups' decisions and rewards were shown. In one condition, they were told how many people had changed their choice from the previous game. Over the course of 25 games, we found that the switching feedback influenced strategies: without it, more people chose to fight. Though fighters always score less than hiders individually, group scores increased across the no feedback group. This was because the higher number of fighters increased the scores of those who chose to hide too. This pattern of results shows that participants are not just making a rational decision about the relative rewards, but also making a social decision that is shaped by the perceived actions of others.

\section*{Future Directions}

We continue to collect data with these paradigms to answer a range of questions. Does the size of the group influence the group dynamics? How are participants learning about each others' behaviour and shaping their actions? We are answering these question by manipulating the information participants have about each other, and by developing computer models of the process. Lastly, we are interested in the social phenomenology of group dynamics. What social forces might shape group cohesion? How does it feel to be part of a successful, coordinated group? Anecdotal evidence suggest that there are complex issues at play. During one zombie game, a small group stood up and shouted, 'Everyone fight! Stand up if you are fighting!'. But later, in debriefing, members of the group admitted they were all choosing to hide and maximise their individual rewards. Clearly, though the games themselves are simple, more research is required to understand the choices made when they are played in the context of mass participation.

Figure 2. The zombie feedback screen, participants playing the game, and the relationship between feedback on switching behaviour and group decisions.

\title{
Mental Simulation for Grounding Object Cognition
}

\author{

\begin{abstract}
Grounded (embodied) theories of cognition propose that memory, including knowledge and meaning, is grounded in sensorimotor and mental state processes. The main proposed mechanism for how memory is grounded is mental simulation. Simulation occurs when neural activity in modal association cortex triggers time-locked, recurrent and feedback activity across multiple lower-level modal processing areas from which the memory was initially constructed. Through this distributed multi-regional activity, seeing an object or reading its name (e.g., "dog") re-enacts associated features that were stored during earlier learning experiences (e.g. its shape, color, motion, actions with it), thereby constructing cognition, memory, and meaning. This paper reviews convergent evidence from cognitive neuroscience of mental imagery, object cognition, and memory that supports a multi-state interactive (MUSI) account of automatic and strategic mental simulation mechanisms that can ground memory, including the meaning, of objects in modal processing of visual features.
\end{abstract}

Keywords: Embodiment, grounded cognition; category; concept; meaning, memory; shape; object; vision; brain.

The MUSI account of the brain dynamics of visual object cognition proposes that posterior object processing areas activate at different times in at least 3 states performing distinct functions (Schendan \& Ganis, 2012; Schendan \& Kutas, 2007). In state 1 , initial activation of object processing cortex feeds forward from occipital to anterior temporal cortex. In this state, from \(\sim 120\) to 200 ms , an object is perceptually categorized coarsely for the first time (Ganis \& Schendan, 2008; Ganis, Smith, \& Schendan, 2012; Schendan \& Ganis, 2013; Schendan, Ganis, \& Kutas, 1998). An event-related potential (ERP) that localizes to occipitotemporal cortex, the N170/VPP, shows the first clear object-sensitivity (i.e., greater for intact objects than scrambled versions depicting no figure), which is a hallmark of this cortex using functional magnetic resonance imaging (fMRI) (Schendan \& Lucia, 2010; Schendan \& Stern, 2007). However, cognitive factors (e.g., mental imagery, category decision success, meaning, semantic context) modulate this cortex sensitively in fMRI studies but do not likewise affect the N170/VPP (e.g., Ganis \& Kutas, 2003; Schendan \& Lucia, 2009; Schendan \& Lucia, 2010; Schendan \& Maher, 2009). Thus object information activated in state 1 supports categorical perception, but cognition that enables complex behavior (e.g., deciding the object is a member of the dog category) does not start until later, in a second state.

State 2 operates from \(\sim 200\) to 500 ms when occipitotemporal cortex is activated again but in a sustained, interactive manner dominated by feedback and recurrent
processing among these areas and with ventrolateral prefrontal cortex (VLPFC). The frontal N3(00) complex is the first ERP to reflect activity in occipitotemporal cortex related to the success of visual object cognition. Like the N170/VPP (state 1) and fMRI activation, the N3 is objectsensitive, category-specific, and shows adaptation effects (Ganis \& Schendan, 2008; Schendan \& Ganis, 2012; Schendan \& Lucia, 2010). However, unlike state 1 but like occipitotemporal and VLPFC activity in fMRI, the N3 varies dramatically with mental imagery and factors affecting category decision success, such as stimulus typicality and impoverishment, implicit memory, knowledge, and meaning (Ganis \& Kutas, 2003; Philiastides \& Sajda, 2007; Schendan \& Ganis, 2012; Schendan \& Kutas, 2002, 2003, 2007; Schendan \& Lucia, 2009, 2010; Schendan \& Maher, 2009; Schendan \& Stern, 2008; Voss, Schendan, \& Paller, 2010). Later from 300 to 500 ms , the centroparietal N400 reflects semantic memory activation related to processing word-related information in anterior temporal cortex and VLPFC (Kutas \& Federmeier, 2011). Intriguingly, N3 effects start and peak before those on the N400, placing the N3 in a temporal position to reflect processes supporting mental simulation of object information that constructs the meaning analyses indexed by the N400. State 2 reflects decision, implicit memory, knowledge, and meaning processes distinct from earlier state 1 and later state 3 processes.

State 3 operates from \(\sim 400\) to 900 ms during complex cognitive tasks and evaluates internally the accuracy of earlier and ongoing decision processes and executes verification processes, including effortful, strategic, conscious mental simulations. These brain dynamics are reflected in a centroparietal late positive complex (LPC) that distinguishes between correct and wrong decisions but does not vary with how well the stimulus matches memory, which, by contrast, sensitively modulates the N3 (Schendan \& Kutas, 2002; Schendan \& Maher, 2009). The LPC varies with episodic recollection, as when recalling details of the learning experience during recognition and mental imagery tasks (Rugg \& Curran, 2007; Schendan \& Ganis, 2012), as does a default mode network that connects strongly with the mediotemporal system for episodic memory and is associated with episodic simulation and strategic, conscious mental imagery (Ganis \& Schendan, 2011; Schacter, Addis, \& Buckner, 2008). Such late processes, however, may also support complex semantic analysis (e.g., Sitnikova, Goff, \& Kuperberg, 2009). Thus the LPC reflects internal evaluation and verification processes that also support strategic, conscious, goal-driven mental simulation that can contribute
to grounding cognition in more abstract and complex ways than earlier automatic mental simulation.

The MUSI account can explain object cognition as well as the brain mechanisms of mental simulation to ground cognition in visual object processing, positing two functionally-distinct states of mental simulation: Earlier automatic simulation and later strategic simulation (Schendan \& Ganis, 2012). Crucially for grounded cognition theory, the pattern of mental imagery findings on the N3, N400, and LPC resembles that for repetition priming of perceived pictures, implicating these ERPs as markers of mental simulation. Following initial categorical perception of objects in state 1 , interactive, top-down and reflexive feedback, and recurrent processes in state 2 support automatic mental simulation to ground knowledge and meaning (Barsalou, 2009) in modal processing of visual features in occipitotemporal cortex (N3) and word-related semantic processes in anterior temporal cortex (N400). The second type of mental simulation is strategic, goal-directed, and conscious and recruited when the task demands internal evaluation of cognition, as in mental imagery and episodic memory tasks. This simulation reflects intentional top-down processes directed by lateral prefrontal and posterior parietal networks for attention, cognitive control, and working memory (LPC). These neural markers of automatic and strategic mental simulation should be the focus of needed research into the brain mechanisms for how modal information processing grounds cognition.

\begin{abstract}
Probabilistic models of cognition have enjoyed recent success in explaining how people make inductive inferences. Yet, the difficult computations over structured representations that are often required by these models seem incompatible with the continuous and distributed nature of human minds. To reconcile this issue, and to understand the implications of constraints on probabilistic models, we take the approach of formalizing the mechanisms by which cognitive and neural processes could approximate Bayesian inference. Specifically, we show that an associative memory system using sparse, distributed representations can be reinterpreted as an importance sampler, a Monte Carlo method of approximating Bayesian inference. This capacity is illustrated through two case studies: a simple letter reconstruction task, and the classic problem of property induction. Broadly, our work demonstrates that probabilistic models can be implemented in a practical, distributed manner, and helps bridge the gap between algorithmic- and computationallevel models of cognition.
\end{abstract}

Keywords: Bayesian inference, importance sampling, rational process models, associative memory models, sparse distributed memory

\section*{Introduction}

Probabilistic models of cognition can be used to explain the complex inductive inferences people make every day, such as identifying the content of images or learning new concepts from limited evidence (Griffiths, Chater, Kemp, Perfors, \& Tenenbaum, 2010; Tenenbaum, Kemp, Griffiths, \& Goodman, 2011). However, these models are typically formulated at what Marr (1982) called the computational level, focusing on the abstract problems people have to solve and their ideal solutions. As a result, they explain why people behave the way they do, rather than how cognitive and neural processes support these behaviors. This approach is thus quite different from previous work on modeling human cognition, which focused on Marr's algorithmic and implementation levels, and has been criticized because it seems to imply that human minds and brains need to solve intractable computational problems and use structured representations (Gigerenzer \& Todd, 1999; McClelland et al., 2010).

Understanding the actual commitments that computational-level accounts of human cognition based on probabilistic models make at the algorithmic and implementation level requires considering how these levels of analysis could be bridged (Griffiths, Vul, \& Sanborn, 2012). Identifying specific cognitive algorithms and neural architectures that can approximate Bayesian inference is a key step towards knowing whether it really poses an intractable problem for human minds, or whether structured representations need to be used to implement models that involve structured probability distributions. In this paper,
we take on this challenge by showing that an associative memory using sparse distributed representations can be used to approximate Bayesian inference, producing behavior consistent with a structured statistical model while using distributed representations of the kind normally associated with artificial neural networks.

The associative memory that we use to approximate Bayesian inference implements a Monte Carlo algorithm known as importance sampling. Previous work has shown that this algorithm can be implemented in a common psychological process model - an exemplar model (Shi, Griffiths, Feldman, \& Sanborn, 2010). Shi and Griffiths (2009) further demonstrated that importance sampling can be implemented with a radial basis function neural network. However, this neural network used a localist representation, in which each hypothesis considered by the model had to be represented with a single neuron - a "grandmother cell." While this might be plausible for modeling aspects of perception in which a wide range of neurons prefer specific stimuli, it becomes less plausible for modeling complex cognitive tasks in which hypotheses correspond to structured representations. For example, having separate neurons for each concept or causal structure we consider seems implausible.

We demonstrate that an associative memory that uses distributed representations - specifically, sparse distributed memory (SDM) (Kanerva, 1988, 1993) - can be used to approximate Bayesian inference through importance sampling. The underlying idea is simple: we use the associative memory to store and retrieve exemplars, allowing us to build on the equivalence between exemplar models and importance sampling. The critical advance is that this is done using distributed representations, meaning that arbitrary hypotheses can be represented, and arbitrary distributions of exemplars encoded by a single architecture. We show that the SDM naturally implements one class of Bayesian models, and explain how to generalize it to implement a broader range of models.

The plan of the paper is as follows. First, we give a brief overview of performing Bayesian inference with importance sampling and summarize how the sparse distributed memory system is implemented. Next, we formalize how importance sampling can be performed using a SDM. We provide two case studies drawn from existing literature in which we use the SDM to approximate existing Bayesian models. The first case study is a simple example involving reconstructing English letters from noisy inputs, and the second is a more sophisticated model of property induction. We conclude the paper with a discussion of implications and future directions.

\section*{Background}

Our results depend on two important sets of mathematical ideas: approximating Bayesian inference by importance sampling, and sparse distributed memories. We introduce these ideas in turn.

\section*{Bayesian inference and importance sampling}

Probabilistic models of cognition provide rational solutions to problems of inductive inference, where probability distributions represent degrees of belief and are updated as more data becomes available. Beliefs are updated by applying Bayes' rule, which says that the posterior probability of a hypothesis, \(h\), given observed data, \(d\), is proportional to the probability of observing \(d\) if \(h\) were the correct hypothesis (known as the likelihood) multiplied by the prior probability of that hypothesis:
\[
\begin{equation*}
p(h \mid d)=\frac{p(d \mid h) p(h)}{\int_{\mathcal{H}} p(d \mid h) p(h) d h} \tag{1}
\end{equation*}
\]

Unfortunately, computing the integral in the denominator is computationally expensive and often intractable. This has resulted in the development of many algorithms for approximating Bayesian inference.

For the sake of illustration, consider the case in which we have noisy observations \(x\) of a stimulus \(x^{*}\). To recover the value of \(x^{*}\), we use Bayes' rule to compute the posterior distribution over \(x^{*}\) :
\[
\begin{equation*}
p\left(x^{*} \mid x\right)=\frac{p\left(x \mid x^{*}\right) p\left(x^{*}\right)}{\int_{x^{*}} p\left(x \mid x^{*}\right) p\left(x^{*}\right) d x^{*}} \tag{2}
\end{equation*}
\]

It is often desirable to compute the expectation of the posterior distribution over some function \(f\left(x^{*}\right)\) :
\[
\begin{equation*}
E\left[f\left(x^{*}\right) \mid x\right]=\int f\left(x^{*}\right) p\left(x^{*} \mid x\right) d x^{*} \tag{3}
\end{equation*}
\]
where the choice of \(f\left(x^{*}\right)\) depends on the task. However, evaluating this expectation still requires computing the full posterior distribution.

To approximate expectations over posterior distributions, we can use a Monte Carlo method known as importance sampling (see, e.g., Neal, 1993), in which a finite set of samples are used to represent the posterior. These samples are drawn from a surrogate distribution \(q\left(x^{*}\right)\) and assigned weights proportional to the ratio \(p\left(x^{*} \mid x\right) / q\left(x^{*}\right)\) :
\[
\begin{equation*}
E\left[f\left(x^{*}\right) \mid x\right]=\int f\left(x^{*}\right) \frac{p\left(x^{*} \mid x\right)}{q\left(x^{*}\right)} q\left(x^{*}\right) d x^{*} \tag{4}
\end{equation*}
\]

Given a set of \(K\) samples \(\left\{x_{k}^{*}\right\}\) distributed according to \(q\left(x^{*}\right)\), this integral can be approximated by:
\[
\begin{equation*}
E\left[f\left(x^{*}\right) \mid x\right] \approx \frac{1}{K} \sum_{k=1}^{K} f\left(x_{k}^{*}\right) \frac{p\left(x_{k}^{*} \mid x\right)}{q\left(x_{k}^{*}\right)} \tag{5}
\end{equation*}
\]
with the approximation becoming more precise as \(K\) becomes larger.

Figure 1: An illustration of the basic read and write operations over SDMs. The outer dotted line represents the space of \(2^{N}\) possible addresses while the squares with labels \(\mathbf{A}_{\mathbf{m}}\) represent the \(M\) sampled hard addresses used for storage. The address being requested for operation is the \(\mathbf{x}\) in the center of the blue circle of radius \(D\). The hard addresses selected for operating correspond to the blue squares within the Hamming radius of \(\mathbf{x}\).

One possible choice for \(q\left(x^{*}\right)\) is the prior, \(p\left(x^{*}\right)\), which yields importance weights proportional to the likelihood, \(p\left(x \mid x^{*}\right)\). Formally,
\[
\begin{align*}
E\left[f\left(x^{*}\right) \mid x\right] & \approx \frac{1}{K} \sum_{k=1}^{K} f\left(x_{k}^{*}\right) \frac{p\left(x_{k}^{*} \mid x\right)}{p\left(x_{k}^{*}\right)} \\
& =\frac{1}{K} \sum_{k=1}^{K} f\left(x_{k}^{*}\right) \frac{p\left(x \mid x_{k}^{*}\right) p\left(x_{k}^{*}\right)}{p\left(x_{k}^{*}\right) p(x)} \\
& =\alpha(x) \sum_{k=1}^{K} f\left(x_{k}^{*}\right) p\left(x \mid x_{k}^{*}\right) \tag{6}
\end{align*}
\]
where we assume \(x_{k}^{*}\) is drawn from the prior, \(p\left(x^{*}\right)\), and \(\alpha(x)\) is a constant of proportionality that depends only on \(x\). Returning to the general case of data \(d\) and hypotheses \(h\), we can use the same approximation to compute the expectation of a function \(f(h)\) given observed data, with
\[
\begin{equation*}
E[f(h) \mid d] \approx \alpha(d) \sum_{k=1}^{K} f\left(h_{k}\right) p\left(d \mid h_{k}\right) \tag{7}
\end{equation*}
\]
where \(h_{k}\) is drawn from the prior \(p(h)\), and \(\alpha(d)\) is a constant of proportionality that depends only on \(d\).

\section*{Sparse distributed memory}

Sparse distributed memory (SDM) was developed as an algorithmic-level model of human memory, designed to encapsulate the notion that distances between concepts in memory correspond to distances between points in highdimensional space (Kanerva, 1988, 1993). In particular, it has a natural interpretation as an artificial neural network that uses distributed representations.

SDMs preserve distances between items in memory by storing them in a distributed manner. Assume that items enter memory as two strings of bits, with \(N\) bits indicating a
location and \(L\) bits indicating its content. A conventional approach would be to sequentially enumerate the set of \(2^{N}\) locations (more technically, addresses), storing items by setting the content bits at the appropriate address in turn. In contrast, a SDM samples \(M \gg N\) addresses \(\mathbf{a}_{j}\) to use as registers from the space of \(2^{N}\) possible addresses. Items are then stored by changing the bits that encode the content associated with multiple addresses, according to how close those addresses are to the target location. The algorithms for writing to and reading from a SDM are given below and are illustrated in Figure 1.

Writing A SDM stores an \(L\)-bit vector, z, associated with an \(N\)-bit location \(\mathbf{x}^{*}\) by storing the pattern at multiple addresses \(\mathbf{a}_{j}\) near \(\mathbf{x}^{*}\). Since the set of \(M\) available addresses does not enumerate the total space of \(2^{N}\), there may be very few addresses near \(\mathbf{x}^{*}\). Consequently, \(\mathbf{z}\) is written to all addresses \(\mathbf{a}_{j}\) that are within a Hamming distance \(D\) of \(\mathbf{x}^{*}\) (i.e. those \(\mathbf{a}_{j}\) that differ from \(\mathbf{x}^{*}\) in \(D\) or fewer bits). The contents of these selected addresses are modified to store the pattern \(\mathbf{z}\) such that each bit in the contents is increased or decreased by 1 depending on whether or not that bit in \(\mathbf{z}\) is a 1 or 0 , respectively.

A SDM can be constructed as a neural network with \(N\) units in the input layer, a hidden layer with \(M\) units for each sampled address, and an output layer with \(L\) units. The weights between the input and hidden layer correspond to the \(M \times N\) matrix \(\mathbf{A}=\left[\mathbf{a}_{1} ; \mathbf{a}_{2} ; \ldots ; \mathbf{a}_{M}\right]\) of hard addresses, and the weights between the hidden and output layer correspond to the \(M \times L\) matrix \(\mathbf{C}\) of contents stored at each address. The rule for writing \(\mathbf{z}\) to memory address \(\mathbf{x}^{*}\) is expressed as:
\[
\begin{align*}
\mathbf{y} & =\Theta_{D}\left(\mathbf{A} \mathbf{x}^{*}\right)  \tag{8}\\
\mathbf{C} & =\mathbf{C}+\mathbf{z y} \tag{9}
\end{align*}
\]
where \(\Theta_{D}\) is a function that converts its argument zeros and ones, with \(\Theta_{D}(w)=1\) if \(\frac{1}{2}(w-N) \leq D\) and 0 otherwise. \(\mathbf{y}\) is thus a selection vector that picks out a particular set of addresses. The expected number of addresses selected in \(\mathbf{y}\) is a function of \(N, M\), and \(D\) :
\[
\begin{equation*}
E\left[\mathbf{y}^{T} \mathbf{y}\right]=\frac{M}{2^{N}} \sum_{d=1}^{D}\binom{N}{d} \tag{10}
\end{equation*}
\]

Reading To read a pattern out of memory from address \(\mathbf{x}\), the SDM again computes a \(M\)-bit selection vector \(\mathbf{y}\) of addresses within Hamming distance \(D\) of \(\mathbf{x}\). The contents of each address selected by this vector are summed, resulting in a vector \(\widehat{\mathbf{z}}\) of length \(L\). The rule for reading \(\widehat{\mathbf{z}}\) from memory address \(\mathbf{x}\) is expressed as:
\[
\begin{align*}
& \mathbf{y}=\Theta_{D}(\mathbf{A} \mathbf{x})  \tag{11}\\
& \widehat{\mathbf{z}}=\mathbf{C}^{T} \mathbf{y} \tag{12}
\end{align*}
\]

The output \(\widehat{\mathbf{z}}\) can then be passed through a non-linearity to return a binary vector if desired.

\section*{SDMs as importance samplers}

Previous work formalizing a probabilistic interpretation of SDMs (Anderson, 1989) lays the groundwork for using

SDMs to perform Bayesian inference. Here, we show that the output of SDMs approximates the expectation of a function \(f\left(\mathbf{x}^{*}\right)\) over the posterior distribution \(p\left(\mathbf{x}^{*} \mid \mathbf{x}\right)\) by linking its behavior to that of the importance sampler in Equation 6.

Writing Let \(w\left(\mathbf{a}_{j}, \mathbf{x}^{*}\right)\) be the probability of writing to address \(\mathbf{a}_{j}\) given an input address \(\mathbf{x}^{*}\). In the standard SDM, this is 1 if the Hamming distance between \(\mathbf{a}_{j}\) and \(\mathbf{x}^{*}\) is less than or equal to \(D\) and 0 otherwise. In the limit, the number of addresses increases to the point where we will always be able to write to exactly \(\mathbf{x}^{*}\) (i.e., to set \(D=0\) ). Thus, this writing probability must satisfy the following constraint:
\[
\begin{equation*}
\lim _{M \rightarrow 2^{N}} w\left(\mathbf{a}_{j}, \mathbf{x}^{*}\right)=\prod_{i=1}^{N} \delta\left(x_{i}^{*}-a_{j i}\right) \tag{13}
\end{equation*}
\]

After writing \(K\) (address, data) pairs \(\left(\mathbf{x}_{k}^{*}, \mathbf{z}_{k}\right)\), the value of the counter associated with bit \(i\) of address \(\mathbf{a}_{j}\) will be:
\[
\begin{equation*}
\mathbf{c}_{j}=\sum_{k=1}^{K} w\left(\mathbf{a}_{j}, \mathbf{x}_{k}^{*}\right) \mathbf{z}_{k} \tag{14}
\end{equation*}
\]

Reading We are given a location \(\mathbf{x}\), which as before is a corrupted version of \(\mathbf{x}^{*}\). Let \(r\left(\mathbf{x}, \mathbf{a}_{j}\right)\) be the probability that we read from address \(\mathbf{a}_{j}\) given input \(\mathbf{x}\). In the standard SDM, this is 1 if the Hamming distance between \(\mathbf{a}_{j}\) and \(\mathbf{x}\) is less than or equal to \(D\) and 0 otherwise. Then, the output of the SDM for a particular set of addresses \(\mathbf{A}\) is:
\[
\begin{equation*}
\widehat{\mathbf{z}}=\sum_{j=1}^{M} \mathbf{c}_{j} r\left(\mathbf{x}, \mathbf{a}_{j}\right) \tag{15}
\end{equation*}
\]
where \(\mathbf{c}_{j}\) is defined in Equation 14.
To see how this output behaves for any SDM, we consider the expected value of \(\widehat{\mathbf{z}}\) over sampled sets of addresses \(\mathbf{A}\). We first substitute Equation 14 into Equation 15 and simplify according to linearity of expectation:
\[
\begin{align*}
E_{\mathbf{A}}[\widehat{\mathbf{z}} \mid \mathbf{x}] & =E_{\mathbf{A}}\left[\sum_{j=1}^{M}\left(\sum_{k=1}^{K} w\left(\mathbf{a}_{j}, \mathbf{x}_{k}^{*}\right) \mathbf{z}_{k}\right) r\left(\mathbf{x}, \mathbf{a}_{j}\right)\right]  \tag{16}\\
& =\sum_{k=1}^{K} \mathbf{z}_{k} \cdot E_{\mathbf{A}}\left[\sum_{j=1}^{M} w\left(\mathbf{a}_{j}, \mathbf{x}_{k}^{*}\right) r\left(\mathbf{x}, \mathbf{a}_{j}\right)\right] \tag{17}
\end{align*}
\]

As our address space grows larger (as in Equation 13), this approaches:
\[
\begin{equation*}
\lim _{M \rightarrow 2^{N}} E_{\mathbf{A}}[\widehat{\mathbf{z}} \mid \mathbf{x}]=\sum_{k=1}^{K} \mathbf{z}_{k} \int_{\mathbf{a}_{j}} \delta\left(\mathbf{x}_{k}^{*}-\mathbf{a}_{j}\right) r\left(\mathbf{x}, \mathbf{a}_{j}\right) \mathrm{d} \mathbf{a}_{j} \tag{18}
\end{equation*}
\]

Thus, in the limit, the expected value of \(\widehat{\mathbf{z}}\) read from the SDM will be:
\[
\begin{equation*}
E_{\mathbf{A}}[\widehat{\mathbf{z}} \mid \mathbf{x}]=\sum_{k=1}^{K} \mathbf{z}_{k} r\left(\mathbf{x}, \mathbf{x}_{k}^{*}\right) \tag{19}
\end{equation*}
\]

Comparing Equation 19 to Equation 6 yields our main result: SDMs can perform importance sampling by defining a
reading density proportional to a likelihood function, approximating the posterior expectation of the items stored in memory. More formally, the expectation of \(\widehat{\mathbf{z}}\) given \(\mathbf{x}\) is proportional to the output of the importance sampling approximation of the expectation of \(f\left(\mathbf{x}^{*}\right)\) with respect to \(p\left(\mathbf{x} \mid \mathbf{x}^{*}\right)\) :
\[
\begin{equation*}
E_{\mathbf{A}}[\widehat{\mathbf{z}} \mid \mathbf{x}] \propto \sum_{k=1}^{K} f\left(\mathbf{x}_{k}^{*}\right) p\left(\mathbf{x} \mid \mathbf{x}^{*}\right) \tag{20}
\end{equation*}
\]
provided \(\mathbf{z}_{k} \propto f\left(\mathbf{x}_{k}^{*}\right)\) and \(r\left(\mathbf{x}, \mathbf{x}_{k}^{*}\right) \propto p\left(\mathbf{x} \mid \mathbf{x}^{*}\right)\).
The utility of this result is limited with the standard formulation of the SDM, as it only holds in the limit where the address size becomes large and \(D\) becomes small, meaning that \(r\left(\mathbf{x}, \mathbf{x}^{*}\right)\) becomes a delta function. Instead, we can consider generalizations in which we use different values of \(D\) for reading and writing ( \(D_{r}\) and \(D_{w}\), respectively), or where we choose \(r\left(\mathbf{x}, \mathbf{x}^{*}\right)\) more freely. These modifications allow us to approximate a variety of Bayesian models using SDMs.

We make a further note, which is that in most practical applications, the address space will not approach the limit (i.e. \(M \ll 2^{N}\) ). For any sampled set of addresses, we would still expect the value of \(\widehat{\mathbf{z}}\) to be near the posterior mean \(E_{k}\left[f\left(\mathbf{x}^{*}\right) \mid \mathbf{x}\right]\), but we cannot make any statement about how close. We leave it as an area for future work to place analytic bounds on the accuracy of the SDM's approximation. For the case studies we present here, we estimate the variance of the SDM using Monte Carlo approximations.

In the following two sections, we evaluate SDMs as a scheme for approximating Bayesian inference in two tasks: one where the Bayesian likelihood matches the standard SDM read rule, and one where the SDM read rule is adjusted to match the Bayesian likelihood. The second case further illustrates how SDMs can be applied to more general problems of Bayesian inference that go beyond simply removing noise from a stimulus.

\section*{Letter reconstruction}

As a simple illustration of approximating Bayesian inference with a SDM, we consider the task of recovering images of English letters, \(\mathbf{x}^{*}\), from noisy observations \(\mathbf{x}\). To solve this problem, we set up a Bayesian model loosely based on that presented in Rumelhart and Siple (1974). Each letter of the alphabet is encoded as a binary feature vector of length \(N=\) 14 based on the Rumelhart-Siple font template (Figure 2).

\section*{SDM approximation}

In the Bayesian model, we wish to reconstruct the original letters \(\mathbf{x}^{*}\) from the exemplars \(\mathbf{x}\) by computing the mean of the posterior distribution over original letters, \(p\left(\mathbf{x}^{*} \mid \mathbf{x}\right)\), i.e. \(f\left(\mathbf{x}^{*}\right)=\mathbf{x}^{*}\). Each of the original letters is associated with a prior probability, \(p\left(\mathbf{x}^{*}\right)\), set to be the relative letter frequency of English text (Lewand, 2000). Following the generative model, a noisy image \(\mathbf{x}\) is produced from the original letter \(\mathbf{x}^{*}\) via a noise process in which at most \(B\) bits are flipped (uniformly). Given a noisy image vector \(\mathbf{x}\), we define the likelihood \(p\left(\mathbf{x} \mid \mathbf{x}^{*}\right)\) to be uniformly distributed over the number of possible bit strings in a hypersphere of radius \(D_{r}\).

Figure 2: The Rumelhart-Siple font feature map and the Rumelhart-Siple representation for the letter " \(A\) " along with its binary feature pattern.

In the SDM, we sample exemplars \(\mathbf{x}^{*}\) of the original letters from the prior \(p\left(\mathbf{x}^{*}\right)\) and write them to the SDM at inputs \(\mathbf{x}^{*}\) (i.e., \(\mathbf{z}=\mathbf{x}^{*}\) ). The likelihood defined for the Bayesian model is naturally compatible with the standard read rule of a SDM, where we only consider hypotheses \(\mathbf{x}^{*}\) which are within Hamming distance \(D_{r}\) of \(\mathbf{x}\). Thus, we can set the read function \(r\left(\mathbf{x}^{*}, \mathbf{x}\right)\) of the SDM to be a variation of this likelihood:
\[
p\left(\mathbf{x} \mid \mathbf{x}^{*}\right) \approx r\left(\mathbf{x}, \mathbf{x}^{*}\right)= \begin{cases}{\left[\sum_{d=1}^{D_{r}}\binom{N-d+1}{d}\right]^{-1}} & \left|\mathbf{x}-\mathbf{x}^{*}\right| \leq D_{r} \\ 0 & \text { otherwise }\end{cases}
\]

The corrupted images \(\mathbf{x}\) are the inputs that we attempt to read from and \(D_{r}\) is the SDM's read radius; we additionally define \(D_{w}\) to be the write radius. The intuition is that we write the original letters \(\mathbf{z}=\mathbf{x}^{*}\) to input \(\mathbf{x}^{*}\), and read from \(\mathbf{x}\) outputs \(\widehat{\mathbf{z}}\) which are similar to the mean of the Bayesian posterior.

\section*{Analysis}

To evaluate how well the SDM approximates the posterior mean, we sampled 1000 exemplars from the prior distribution \(p\left(\mathbf{x}^{*}\right)\). We then created three images \(\mathbf{x}\) for each letter in the alphabet, each with two bits of corruption, yielding a total of 72 test images. We repeated this simulation - sampling from the prior and generating test images - 20 times for each SDM with parameters \(D_{r}, D_{w}\), and \(M\), where each simulation used a different set of sampled addresses \(A\).

We determined the appropriate settings of the read and write radii, \(D_{r}\) and \(D_{w}\), by considering the constraints imposed by the SDM and the specific problem of letter reconstruction. The mean Hamming distance between pairs of letters was 5.4615 , indicating that the read radius must lie somewhere between 2 (the amount of corruption) and 5. Choosing a radius outside these bounds would have the effect of returning an inaccurate expectation, either because the noise was greater than the signal \(\left(D_{r}<2\right)\) or because too many hypotheses were considered \(\left(D_{r}>5\right)\). So, we chose \(D_{r}=2\), thus ensuring that the true \(\mathbf{x}^{*}\) would always fall within this radius, and also minimizing the number of incorrect hypotheses considered. For the write radius, we considered three different values, \(D_{w}=\{0,1,2\}\).

We stored all 1000 letters in each SDM, varying the number of hard addresses, \(M\), among eight evenly spaced values

Figure 3: The average correlations between the Bayesian posterior mean and pre-thresholded SDM outputs for the task of recovering a Rumelhart-Siple letter from a noisy observation. \(D_{r}=2\) for each of the 4 values of \(D_{w}\) presented.
between 2048 and \(2^{N}=16384\). We then read the value \(\widehat{\mathbf{z}}\) for each corrupted input \(\mathbf{x}\), for different address spaces \(A\). For the Bayesian model, we analytically calculated the posterior mean by evaluating the full posterior for each \(\mathbf{x}^{*}\) and then calculating the average \(\mathbf{x}^{*}\) weighed by its posterior probability. We then computed the average correlation between the SDM values of \(\widehat{\mathbf{z}}\) and the Bayesian posterior mean across sampled addresses \(A\). These results are displayed in Figure 3.

The SDMs with \(D_{w}=0\) performed similarly to the Bayesian model only when \(M=2^{N} \quad(\rho=0.9628\), se \(=\) 0.0058 ), reflecting the intuition that it's highly unlikely to find an exact address from a random sample of \(2^{N}\). Conversely, the SDMs with \(D_{w}=2\) and \(D_{w}=3\) had near-constant correlations with the Bayesian model ( \(\rho \approx 0.88\) for \(D_{w}=2\) and \(\rho \approx 0.79\) for \(D_{w}=3\) ), regardless of the size of the hard address space. This behavior was also in line with our expectations: with \(D_{w}=2\) and \(D_{w}=3\), the probability of having no hard addresses within \(D_{w}\) of \(\mathbf{x}^{*}\) is extremely low for \(M=2048\); this probability only decreases as \(M\) increases.

In summary, these results show SDMs can naturally approximate Bayesian models of noisy stimulus reconstruction. Here, we set the likelihood function to follow the standard SDM read rule. In the next section we consider a more general example of Bayesian inference and explore the consequences of adjusting the SDM read rule to match the likelihood in question.

\section*{Property induction}

If you are told that a horse has a particular property, protein \(K\), what other animals do you think share this protein? Questions of this type are considered problems of property induction, where one or more categories in a domain are observed to have some novel property and the task is to determine how the property is distributed over the domain. For our analyses we explore the category-based induction task introduced by

Osherson, Smith, Wilkie, Lopez, and Shafir (1990), where judgments are made as to whether certain animals can get a disease knowing other animals that can catch it.

\section*{SDM approximation}

We solve this problem with a Bayesian model of property induction based on Kemp and Tenenbaum (2009). Here, we observe a set of examples \(d\) of a concept \(C\) (known to have property \(K\) ) and we aim to calculate \(p(y \in C \mid d)\), the probability that object \(y\) is also a member of \(C\). Thus, averaging over all possible concepts, we compute:
\[
\begin{equation*}
p(y \in C \mid d)=\sum_{h \in \mathcal{H}} p(y \in C \mid h) p(h \mid d) \tag{21}
\end{equation*}
\]
where the hypothesis space \(\mathcal{H}\) is the set of all possible concepts in a domain, \(p(y \in C \mid h)=1\) if \(y\) is in hypothesis \(h\), and 0 otherwise. The posterior probability \(p(h \mid d)\) can be computed via Bayes' rule from Equation 1.

We explore two variations of likelihood functions based on assumptions of how the data were generated. If the data are generated uniformly at random, the likelihood follows from weak sampling: \(p(d \mid h)=1\) if all examples in \(d\) are in \(h\) and \(p(d \mid h)=0\) otherwise. If the data are generated at random from the true concept \(C\), the likelihood follows from strong sampling, where \(p(d \mid h)=1 /|h|^{n}\) if all \(n\) examples in \(d\) belong to \(h\), and \(p(d \mid h)=0\) otherwise. This likelihood function incorporates the size principle, where hypotheses with fewer items are given more weight than hypotheses with more items for the same set of data (Tenenbaum \& Griffiths, 2001).

In the SDM, the location \(\mathbf{x}^{*}\) corresponds to a hypothesis \(h\), and the content \(\mathbf{z}\) corresponds to data \(d\). For both weak and strong sampling assumptions, we set the read function of the SDM, \(r(d, h)\), to be proportional to the Bayesian likelihood by weighting the selection vector \(\mathbf{y}\) by \(p(d \mid h)\).

\section*{Analysis}

To evaluate the performance of this modified SDM, we used the category-based induction dataset from Osherson et al. (1990), consisting of 36 two-premise arguments and 45 threepremise arguments ( e.g., "Cat, Dog, Horse can get disease X ") for a domain of 10 animals. Thus, each observation \(d\) is encoded as a binary feature vector of length \(N=10\). We used a taxonomic hypothesis space following Kemp and Tenenbaum (2009), constructed from human similarity judgments for each possible pairing of animals. As before, we stored 1000 exemplars sampled from \(p(h)\) in the SDM, and varied the number of hard addresses among eight evenly spaced values between 128 and \(2^{N}=1024\). We evaluated this modified SDM against the Bayesian model of property induction for 3 values of \(D_{w}\) over a constant reading radius \(D_{r}=0\). The results are presented in Figure \(4^{1}\).

We find the SDM approximates Bayesian inference for a variety of write radii and, as predicted, matches Bayes when

\footnotetext{
\({ }^{1}\) We note that these correlations are not strictly monotonic as one might intuit, due to sampling error in the address space (most notable in the case when \(D_{w}=0\).)
}

Figure 4: The average correlations between the Bayesian posterior and pre-thresholded SDM outputs assuming weak sampling (left panel), and assuming strong sampling (right panel) for the property induction task. \(D_{r}=0\) for each of the 3 values of \(D_{w}\) presented.
\(D_{w}=0\) and \(M=2^{N}\). Furthermore, the SDMs that use a weak or strong sampling read rule correlate equally well with the Bayesian models that use weak or strong sampling likelihoods, respectively. This nicely illustrates the correspondence between the SDM's read rule and a Bayesian likelihood, and implies that SDMs can approximate a broad range of Bayesian models by adjusting the read rule to match the likelihood function.

\section*{Conclusion}

What constraints do the algorithmic and implementation levels impose on probabilistic models of cognition? We explored this question by considering whether the computations employed by a distributed representation of associative memory could approximate Bayesian inference. By choosing the SDM read rule to appropriately match the the likelihood function, we showed in two separate scenarios that SDMs can accurately implement a specific form of Bayesian inference called importance sampling.

Future work will take our analyses one step further and investigate whether SDMs can approximate Bayesian inference without modifying their read rule. Specifically, can we encode the data in a manner such that reading it from a standard SDM is still proportional to the likelihood? If so, it would make SDMs an even more general and appealing approach to performing Bayesian inference. Regardless, the results presented in this paper are an important step towards an explanation of how the structured representations assumed by probabilistic models of cognition could be expressed in the distributed, continuous representations commonly used in algorithmic-level models such as neural networks.

\title{
The Effect of Physical Load on the Cognitive Process of Estimation
}

\begin{abstract}
The purpose of this study was to examine the process of embodied cognition in distance estimation. According to recent cognitive science studies, our intelligent behavior that ranges from perception to inference is not accomplished in only a closed mental process, but is affected by body and action. However, previous studies do not clarify whether these effects were derived from physical load or subjective heaviness. In order to examine the question, two experiments were conducted using the "size-weight illusion". Performance on the distance estimation task was not affected by subjective heaviness but by physical load.
\end{abstract}

Keywords: embodied cognition; size-weight illusion; distance estimation

\section*{Introduction}

We examined the contribution of the physical body on higher-order cognitive processing. Recently, in cognitive science, studies have reported that a wide range of intellectual behavior, from perception to inference, is not only a closed mental process but is also subject to influences of the physical body and its actions/motions(Wilson, 2002; Gibbs, 2005; Proffitt, 2006). Since physical loading is known to exert effects on mental processes, Narukawa, et al. (2010) reported changes in gustatory sensation that accompany the degree of fatigue. Krishna \& Morrin (2008) showed that the sense of hardness of the bottle affected the evaluation of mineral water. Bhalla \& Profitt (1999) demonstrated experimentally that different estimates are made of the inclination of a sloped path under the conditions of carrying a load on the back versus being empty-handed. In addition, in the study by Ackerman, Nocera \& Bargh (2010), the curriculum vitae of a fictitious person bound to two types of clipboards that differed in heaviness were handed to the subjects, who were asked to make evaluations of the person. The evaluations made by those of the group handed the heavier clipboard were higher than that of the group handed the lighter clipboard. The results of these prior studies suggest that mental processes are influenced by loading and fatigue of the physical body of the subject. However, it has not been clarified whether these effects were due to the amount of actual physical load or due to the amount of the subjective load. In this study, this issue was examined using a distance estimation task adopted from a prior study. If the effects were due to the amount of the physical load, then physical/non-overt processes, which are separate from the subjective view of the subject, are
expected exert an effect on the inference. Conversely, if they are due to the amount of the subjective load, it may be considered that the subjective view of the subject and overt processes exert the effects on the inference.

To examine these physical and subjective loads separately, the "size-weight illusion" (Charpentier, 1891) was used in this study. This illusion occurs when if the weights of two objects are the same, the larger object is sensed as being lighter. Utilizing this illusion, distance estimation tasks under conditions of being subject to different subjective loads while being subject to the same physical load (Experiment 1) and distance estimation tasks under conditions of being subject to different physical loads while being subject to the same subjective load (Experiment 2) were conducted to examine the effect of the physical and subjective amount of the physical load.

\section*{Experiment 1}

In Experiment 1, experimental manipulations were conducted to generate the subjective view that loads with different weights were being exerted while the same weight physically was exerted, and distance estimation tasks were conducted under conditions of a divergence between the amount of subjective and physical load. This was used to examine how the perceived load of the weight exerted on the body is processed.

\section*{Method}

Subjects Ninety-two college students participated in the experiment. Of them, 24 were assigned to the 10 L group, in which the subject held a 5 kg tank with capacity of 10 L as the number of steps of a stairway was estimated; 33 were assigned to the 20 L group, in which the subject held a 5 kg tank with a capacity of 20 L as the estimation was made; and 35 were assigned to the control group, in which they made the estimation without holding any weight. A singlefactor between-subjects design was used in this experiment.

Task A revised form of the distance estimation task published by Bhalla \& Profitt (1999) was employed. In the revised form, a picture of the up-bound steps of the Atago Shrine (Fig. 1) was presented for 5 s , and the subject was

Figure 1. The up-bound steps of the Atago Shrine
instructed to estimate the number of the steps. The picture was displayed on a 17-in XGA display placed at a height of 160 cm . With regard to the physical loads to be exerted on the subjects, we prepared a reference weight with 5 kg of water in a polyethylene tank with a capacity of 5 L , and the weights for those assigned to the groups other than the control group ( 5 kg with a size of 10 L , or 5 kg with a size of 20 L ).

Procedure For each group, the subject was first handed the reference weight and was told that its weight was 5 kg . Next, the weight assigned to each group for the distance estimation task was given, and the task of estimating the number of steps was performed with subject holding the reference weight with both hands. The up-bound steps of the Atago Shrine were present to the subject for 5 s ; then the estimation was given orally while holding the weight. The subjects were told to respond immediately without thinking deeply when providing their oral response. Following this, they were asked to estimate the weight of the tanks.

\section*{Results}

First, the values of the weight of the tanks used for the estimation task predicted by the 10 L group and by the 20 L group are discussed. The value was 5.94 kg for the 10 L group and 4.06 kg for the 20 L group. A significant difference was found between the two groups \((t(26)=2.74\), \(p<0.05, r=0.470\), Fig. 2). This result confirmed that a size-weight illusion effect had occurred for members of the 10 L and 20 L groups. he estimates of the distance of the steps was 52.79 steps for the 10 L group and 49.88 steps for the 20 L group.

Figure 2: The values of the weight of the weights used in Experiment 1

Figure 3: The estimated distance of the steps in Experiment 1

A one-way ANOVA revealed a main effect for the weight factor \(\left(F(2,89)=14.82, p<0.01, \eta^{2}=0.25\right.\), Fig. 3). Multiple comparisons (Bonferroni's method) revealed significant differences between the control group and the other two groups ( \(p<0.01\) ) but not between the 10 L and the 20 L groups.

\section*{Experiment 2}

The results of Experiment 1 suggested that a difference in perceived weight did not affect the estimate of the number of steps but instead the physical loading affected the distance estimations. However, the conclusion that the subjective amount did not affect the estimates, runs contrary to the finding that no significant difference was observed between the 10 L and 20 L groups. Therefore, in Experiment 2, the self-adjustment of the amount of loading by the subject was performed using the point of subjective equality(PSE) measurement procedure, and comparisons were made for cases in which physically different loads were exerted whereas the subjective load was the same.

Figure 3: The values of the weight of the tanks used in Experiment 2

Figure 4: The subjective weight of the tanks in Experiment 2

As in Experiment 1, if the effects on the estimates were due to the physical load and not due to the subjective load, significant differences should be observed between the estimates.

As, in Experiment 1, the subjects were asked to estimate the number of steps, but it was difficult to predict whether the number is over-estimated or under-estimated by the physical loading in comparison to the previous studies since the correlations between the number of steps and the distances and inclinations reported by those studies cannot be guaranteed. Thus, in Experiment 2, they were instructed to estimate the distance, and not the number, of the steps.

\section*{Method}

Subjects Twenty-seven college students participated in the experiment. Of them, 14 were assigned to the experimental group and 13 were assigned to the control group. A singlefactor between-subjects design was used for the experiment.

Figure 5: The estimated distance of the steps in Experiment 2

Task The same distance estimation task was employed as in Experiment 1. With regard to the physical loads to be exerted on the subjects, after having the reference stimulus of a polyethylene tank with a capacity of 5 L containing 5 kg of water presented to them, they were asked to, by themselves, adjust the amount of physical loading by using the PSE measurement procedure. In accord with this procedure, the subjects put water into a polyethylene tank with a capacity of 20 L for the stimulus weight until they thought it to be identical in weight as that of the reference stimulus. The average weight of the stimulus weights set by the subjects was 6.36 kg , which was more than 1 kg heavier than the reference weight (Fig. 3). The subjects were not informed that the reference weight was 5 kg , and were only aware that the adjusted weights have the same weight as the reference weight.

Procedure In each group, the subject was first asked to perform the adjustment of the weight in accordance with the PSE procedure. Subsequently, tasks of estimating the length of the steps were performed with the self-adjusted weight, in the case of the experimental group, and with the reference weight, in the case of the control group, held in both hands. As in Experiment 1, the up-bound steps of the Atago Shrine were presented to the subject for 5 s . Next, each of the subjects provided their estimates orally while still holding the weight. Following this, the weight used for the distance estimation task was also estimated.

\section*{Results}

First, the predicted values of the weight of the reference weight are discussed. The mean value was 4.11 kg for the control group and 4.25 kg for the experimental group. No significant difference was found between the two groups \((t(25)=0.26, p=0.79\), n.s., \(r=0.05\), Fig. 4).
Based on this result, the possibility that the sense of weight was significantly different between those in the control group and those in the experimental group was rejected.

The estimate of the distance of the steps was 31.79 m for the control group and 70.77 m for the experimental group. A significant difference was found between the two groups \((t(25)=2.65, p<0.05, r=0.47\), Fig. 5).

\section*{Discussion}

In the present study, the result of experiments using distance estimation tasks accompanied by physical loading using the size-weight illusion showed that the effects of physical loading on mentation are due to physical load rather than subjective load. The subjects in the control group in Experiment 2 estimated the length of the steps while holding a 5 kg weight that they thought weighted 4 kg , and the subjects in the experimental group while holding a 6 kg weight that they thought was 4 kg . The difference between their length estimates of the two groups suggests that their estimations were being influenced, not by how heavy they thought the weights were, but rather by the actual physical load exerted on the body. This also suggests that a load that is exerted on the body may play an implicit role in making inferences and judgments.

Unlike previous studies, a picture of stairs was used in the present study instead of an actual environment. Nevertheless, physical loading affected the participants' distance estimation. This shows robustness of the previous studies, and suggests that participants mentally simulate action with reference to physical load.

\section*{Future Issues}

Although physical loading exerted effects in a manner that did not reach the subjective level, it is not possible to conclude that the amount of subjective load did not exert any effect at all. Further, many aspects of the process by which physical loading influenced the estimation have yet to be elucidated. It is necessary to consider the mutual relationship of and processing between the subjective load and the physical load.

In the present study, the estimates were made when the individuals were subjected to a physical load, but it is not known to what extent the effects were sustained. As indicated by previous studies, fatigue influences inference. The degree of fatigue and the extent of recovery are expected to also influence the duration for which the effects are sustained.

In addition, the duration of the presentation of the object to be estimated warrants some discussion. In this study, the stimulus was presented for a limited duration of 5 s . The subjective level could become dominant in processing when the object of the estimation is presented for longer duration. Moreover, many issues remain with regard to the mutual relationship between the top-down processing of the subjective view and the bottom-up processing from the physical body.

In the literature of the cognitive process of metaphor, it is thought that metaphors enable us to think about concepts on the basis of concrete sensorimotor experiences. Previous
studies suggested that a conceptual representation was linked to some somatic and physical state by some metaphorical concept (Clark, 1973; Lakoff \& Johnson, 1980). Researchers who investigated the haptic priming effect found evidence to support that idea (Williams \& Bargh, 2008; Ackerman, Nocera \& Bargh, 2010). In future studies, the effects of physical load on conceptual representation should be examined.

\begin{abstract}
This study attempts to advance corpus-based exploration of sound iconicity, i.e. the existence of a non-arbitrary relationship between forms and meanings in language. We examine a number of phonesthemes, phonetic groupings proposed to be meaningful in the literature, with the aim of developing ways to validate their existence and their semantic content. Our first experiment is a replication of Otis and Sagi (2008), who showed that sets of words containing phonesthemes are more semantically related to each other than sets of random words. We augment their results using the British National Corpus and the Semantic Vectors package for building a distributional semantic model. Our second experiment shows how the semantic content of at least some phonesthemes can be identified automatically using WordNet, thereby further reducing the room for intuitive judgments in this controversial field.
\end{abstract}

Keywords: Iconicity; Phonesthemes; Corpus analysis; Distributional Semantics; WordNet.

\section*{Introduction}

The claim that the relationship between forms and meanings in language is not always arbitrary is controversial. However, evidence for non-arbitrary relationships comes at multiple levels of language, from phonology to syntax (Perniss, Thompson, \& Vigliocco, 2010). Here we focus on the phonetic level and investigate the association of particular sounds with aspects of word meaning. Such sound iconicity has been described in a variety of non-Indo-European languages (see the studies in Hinton, Nichols and Ohala Hinton, Nichols, \& Ohala, 2006b) and its existence in English suggested by a number of authors (Firth, 1930; Marchand, 1969), and exploited in commercial settings (Shrum \& Lowrey, 2007).

Phonesthemes (a technical term for meaningful sound patterns) are sub-morphemic units that play a role of morphemes but have been traditionally distinguished from them by being non-compositional (but see Rhodes Rhodes, 2006 for an opposite view). The most oft-cited example is the English phonestheme \(g l\) which occurs in a large number of words related to light or vision (glitter, glisten, glow, gleam, glare, glint, etc.). Once the phonestheme is taken out, the remainder of the word is not a morpheme (-itter, -isten, -ow etc.) and one does not attach \(g l\) to other words to make them light-related. Still, the extent and the nature of this phenomenon is not clear.

Traditionally, the evidence for the existence of phonesthemes and their proposed meaning consisted in listing a number of words that share a given sound and attempting to find the semantic core that unites them. Popular expla-
nations for the phenomenon would rest on the intuited association between sound production and meaning. For example, Reid (1967) states that "The explosive nature of the letter \(b\) is intensified when it is combined with \(l\) before the breath is released. Consequently words beginning with \(b l\) are found generally to indicate a 'bursting-out' or the resultant swelling or expansion" (p. 10). More recent accounts view them rather as a matter of statistical clustering. According to such "snowballing effect" theory, a group of phonemes in related words (for example, by common etymology) becomes over time associated with the meaning of these words and given the right conditions starts to attract other words with the same phoneme into a cluster, through semantic change or influencing the creation of new words (Blust, 2003; Hinton, Nichols, \& Ohala, 2006a). \({ }^{1}\)

Dissociating these competing explanations would require a combination of historical and cross-linguistic research but, arguably, there is a wealth of more basic questions that need to be addressed first. The nature of iconicity is such that it is easy to see the connection between form and meaning once we are aware of both elements but such intuition is not always a reliable guide for discovering the connections. Just as it is difficult to interpret an iconic sign from American Sign Language when its meaning is unknown (Bellugi \& Klima, 1976), we might miss the connection that is in fact present. On the other hand, we might over-estimate the connection by listing only the light-related \(g l\)-words and forgetting the amount of \(g l\)-words that have nothing to do with light (glide, glucose, globe, glove, etc.). In other words, if we want to validate the existence of phonesthemes or explain their origin, we need to apply more falsifiable and unbiased methods in all stages of investigation: identifying them in a given language, quantifying their scope and establishing their meaning.

So far, the reality of phonesthemes has been demonstrated in behavioral experiments (Bergen, 2004; Hutchins, 1998) and corpus studies (Drellishak, 2006; Otis \& Sagi, 2008). Our aim is to contribute to the second current of this research. We believe that this is a valuable way of objectively addressing large-scale linguistic phenomena that can refine our understanding of sound iconicity and lead to further testable hy-

\footnotetext{
\({ }^{1}\) This is not to say that there are no universal sound features underlying certain cases of sound iconicity, such as words for small and large objects usually associated with high and low acoustic frequency respectively (Ohala, 1994).
}
potheses with respect to its cognitive underpinnings.
Otis and Sagi (2008) conducted the first corpus-based analysis of phonesthemes. They examined 47 groups of words containing phonesthemes using Project Gutenberg texts and a method for calculating word similarity based on Latent Semantic Analysis (LSA), in particular its Infomap \({ }^{2}\) variety (Schütze, 1997). The analysis performed by Otis and Sagi showed that semantic relatedness of clusters of words that share a phonestheme is higher than that of clusters composed of randomly chosen words. This method, therefore, can be used to examine the validity of conjectured phonesthemes. However, as the authors admit, it "does not identify what specific semantic content is carried by the identified phonestheme" (p. 68). Our first aim is replicating the study of Otis and Sagi using (1) a more recent and balanced corpus - the British National Corpus (BNC), and (2) a newer and more versatile and efficient tool for calculating semantic relatedness, Semantic Vectors \({ }^{3}\) (Widdows \& Cohen, 2010).

Our second aim is attempting to develop a method for automatically identifying the semantic content associated with a particular phonestheme-a task that, to our knowledge, has not previously been addressed in the literature. Otis and Sagi (2008) suggest that methods designed to identify the topic of a given text could be used to that end. We think, however, that a more straightforward method lies in analogy with the task of unsupervised ontology acquisition: placing a word within a hierarchy of concepts based on its semantic relationship with the rest of the words in the hierarchy: for example, pear being placed close to apple and banana under fruit. In the case of phonesthemes, it is conceivable that a group of \(g l\) words would be assigned a vision-related higher class. Whether this can be done automatically and applied to a variety of phonesthemes is one of the questions we pose in this study.

In sum, our hypotheses are the following:
Hypothesis 1: Words that share a phonestheme are on average more semantically related than random words.

Hypothesis 2: The core semantic import conjectured in the literature for a phonestheme can be derived automatically from a set of phonestheme-bearing words.

\section*{Experiment 1: Semantic Relatedness}

\section*{Methods}

To explore our Hypothesis 1, we used the British National Corpus (Burnard, 2007), a 100 million word collection of written and spoken English language compiled from a wide variety of sources and genres. We pre-processed the entire corpus using the Natural Language Toolkit (NLTK) (Bird, Klein, \& Loper, 2009). In particular, we used NLTK to extract the content words in the corpus (nouns, adjectives, and lexical verbs) and to lemmatize them, i.e. to reduce a family of inflected words (such as walk, walks, walked, walking) to a single word type or lemma (e.g. walk). This resulted in a subcorpus of about 43 million words, which we used as input to

\footnotetext{
\({ }^{2}\) Freely available at http://infomap-nlp.sourceforge.net.
\({ }^{3}\) Freely available at http://code.google.com/p/semanticvectors/.
}
construct a distributional semantic model with the Semantic Vectors package (Widdows \& Cohen, 2010).

Semantic Vectors allows us to use a corpus to build a high-dimensional vector space where words are represented as vectors that record their frequency of co-occurrence with other words or other documents in the corpus. We can then use well-defined methods to measure how similar the meanings of two words are, such as computing the cosine of the angle formed by their corresponding vectors. As Otis and Sagi (2008) indicated in their pioneering corpus study, this methodology can be of great value to investigate the claims behind phonesthemes in an objective, data-driven way, since we can use the distributional model to test whether words sharing a hypothesized phonestheme exhibit higher semantic similarity than random words.

Like Otis and Sagi, we built a term-term model where each word vector records the co-occurrence of that word with other words in the context (rather than recording occurrence in particular documents like LSA), but unlike them, who used the traditional singular value decomposition method for reducing the dimensions in the matrix, we used Random Projection, a more computationally efficient algorithm. \({ }^{4}\) We experimented with the settings of two parameters in the Semantic Vectors package: the minimum frequency of the word types considered for building the model (as we may not be able to construct reliable distributional semantic representations for low frequency words) and the window size, i.e. the context window of \(n\) words to left and right of the target word where the model looks for co-occurrences of other words. McDonald and Ramscar (2001) claim that "the best fit to psychological data is typically achieved with word vectors constructed using context window sizes between \(\pm 2\) and \(\pm 10\) words." Otis and Sagi used \(n=15\), which is the default setting in Infomap.

We focused on the 22 prefix phonesthemes conjectured by Hutchins (1998). Our statistical analysis followed the procedure proposed by Otis and Sagi (2008). For each phonestheme, we first extracted all the vectors of the phonesthemebearing word types in our distributional semantic model. \({ }^{5}\) We shall refer to the resulting set of words (and vectors) as a phonestheme cluster. We then performed two Monte Carlo analyses. In the first analysis, we computed the average semantic similarity of each phonestheme cluster by forming 1000 random pairs and averaging the semantic distance obtained. In addition, we did the same for similarly-sized clusters of random words and performed an independent samples \(t\)-test for the resulting two groups of values. In the second analysis we took 50 random pairs within each phonestheme cluster and a corresponding group of pairs of random words and run 100 independent sample \(t\)-tests noting whether the mean of phonestheme cluster distances was significantly higher than the distances obtained for pairs of random words (with \(\alpha=0.05\) ). Based on the binomial distribution, we

\footnotetext{
\({ }^{4}\) See Sahlgren (2005) and Widdows and Cohen (2010) for a comparison of these methods.
\({ }^{5}\) Since we are dealing with a written corpus, this is done on the basis of an orthographic match with the phonetic grouping.
}
judged the number of significant t -tests as higher than 15 to lend statistical support to our Hypothesis 1. We performed the procedure 5 times and took the mean to be the final result.

We used the results obtained with the \(g l\) phonestheme cluster (which obtained the highest statistical support in the Otis and Sagi study) to optimize the minimum frequency and the window size parameters of our distributional semantic model. The model produced the most qualitatively sensible and most statistically stable results when setting the minimum frequency to 100 and the window size to 10 . This resulted in a model containing a set of 22292 vectors. This vector space was used in all subsequent parts of our study.

\section*{Results}

The results obtained with our parameter optimizing test on the \(g l\) phonestheme showed that the semantic relatedness of the words in the \(g l\) cluster was significantly higher than that of clusters of random words, as measured by our t-test procedure. On average, 26.4 t -tests produced a significant result (recall that the threshold of significance of the binomial test was for at least 15 out 100 t -tests to turn out as significant).

We used the same vector space (with the parameters fixed) to analyze the remaining 21 prefix phonesthemes. The results obtained are reported in Table 1. For each phonestheme, the table shows the number of word types in the phonestheme cluster (\# Tokens), the average degree of semantic relatedness amongst those words (Sim) calculated according to our first Monte Carlo analysis, the number of significant t-tests (\# Sig) calculated according to our second Monte Carlo analysis, and the mean effect size (Effect) of these t-tests. As can be seen, the model did not only confirm the semantic similarity of the words in the \(g l\) phonestheme (for which it had been optimized), but produced significant results for 16 different prefix phonesthemes out of the 22 considered. The

Table 1: Phonestheme semantic relatedness results
\begin{tabular}{|l|rccc|}
\hline Prefix & \#Tokens & Sim & \#Sig & Effect \\
\hline \hline\(b l-\) & 105 & 0.4607 & 56.8 & 0.2845 \\
\hline\(c l-\) & 156 & 0.4295 & 29.4 & 0.2570 \\

\hline\(d r-\) & 99 & 0.4504 & 63.6 & 0.2849 \\
\hline\(f l-\) & 137 & 0.4340 & 34.2 & 0.2536 \\
\hline\(g r-\) & 197 & 0.4050 & 25.2 & 0.2617 \\
\hline\(s c-/ s k-\) & 167 & 0.4031 & 10.2 & 0.2443 \\
\hline\(s c r-\) & 32 & 0.5174 & 68.4 & 0.3093 \\
\hline\(s l-\) & 83 & 0.4275 & 42.4 & 0.2734 \\
\hline\(s m-\) & 42 & 0.4803 & 51.4 & 0.2817 \\
\hline\(s n-\) & 40 & 0.4650 & 52.2 & 0.2909 \\
\hline\(s p-\) & 161 & 0.4127 & 14.4 & 0.2392 \\
\hline\(s p l-\) & 11 & 0.5224 & 59.0 & 0.2723 \\
\hline\(s p r-\) & 24 & 0.3950 & 4.80 & 0.2373 \\
\hline\(s q u-\) & 24 & 0.4916 & 67.0 & 0.3205 \\
\hline\(s t-\) & 298 & 0.4307 & 25.0 & 0.2465 \\
\hline\(s t r-\) & 89 & 0.4525 & 61.8 & 0.2899 \\
\hline\(s w-\) & 67 & 0.5138 & 91.2 & 0.3396 \\
\hline\(t r-\) & 249 & 0.3912 & 5.80 & 0.2318 \\
\hline\(t w-\) & 22 & 0.4304 & 17.4 & 0.2408 \\
\hline\(w r-\) & 38 & 0.5155 & 90.6 & 0.3915 \\
\hline
\end{tabular}
average semantic relatedness of phonestheme clusters ( \(M=\) \(0.446, S D=0.044\) ) was highly correlated with the number of significant t-tests ( \(r=0.95, p<0.0001\) ) and was furthermore significantly higher than the average semantic relatedness of random words clusters ( \(M=0.397, S D=0.018\) ), as shown by an independent samples t-test \((t(42)=4.83, p<0.0001)\).

In line with the findings of Otis and Sagi (2008), we were thus able to obtain support for Hypothesis 1 for 16 conjectured phonestheme prefixes. Using the BNC - a more general, balanced, and modern corpus of English than Project Gutenberg - our study yielded higher support for the hypothesis than Otis and Sagi's previous study, which had found only 12 phonestheme prefixes as reaching statistical significance.

\section*{Experiment 2: Phonestheme Cluster Labeling}

\section*{Methods}

After establishing significant differences between the semantic relatedness scores for phonestheme word clusters and clusters of random words, we turned to our second experiment, whose aim is to investigate possible methods to automatically detect the core semantic content carried by a phonestheme. To our knowledge, this is the first attempt to address this issue by objective means. To test our Hypothesis 2 , we selected a number of prefix phonesthemes based on the amount of statistical support obtained in our first experiment and on how unambiguous and generally agreed upon were the sense definitions proposed in the literature. We selected 10 phonesthemes with high semantic relatedness scores and compiled a list of definitions based on the descriptions given by Hutchins (1998), Marchand (1969) and Reid (1967). The resulting list of phonesthemes together with their conjectured semantic import is presented in Table 2.

Table 2: Phonesthemic senses
\begin{tabular}{|l|l|l|}
\hline Prefix & Definition & Example \\
\hline \hline\(b l-\) & swelling, explosion, extension, broadness & bloating \\
\hline\(g l-\) & light, vision, look, brightness, shine & glitter \\
\hline\(g r-\) & threatening noise, anger, grip & growl \\
\hline scr- & unpleasant sound, irregular movement & screech \\
\hline sn- & nose, mouth, smell, snobbish person & sneeze \\
\hline spl- & divergence, spread, splash & splash \\
\hline squ- & discordant sound, softness, compression & squeeze \\
\hline str- & linear, forceful action, effort & strike \\
\hline\(s w-\) & rhythmical movement & swing \\
\hline\(w r-\) & irregular motion, twist & wring \\
\hline
\end{tabular}

In order to automatically assign a semantic class label to a phonestheme cluster, we used WordNet (Fellbaum, 2005), a cognitively motivated ontology of words and concepts linked by different semantic relations commonly used in computational linguistics. The main semantic relation connecting words that express different concepts in WordNet is the super/subordinate relation (also called hypernymy/hyponymy), which establishes a hierarchy of concepts from more general concepts like animal to increasingly specific ones like mammal or whale. Since hypernymy is a transitive relation, for
each word we can construct its hypernymy chain: the set of all its superordinate concepts or hypernyms connecting the word in question to the root node in the hierarchy (entity in the case of WordNet), ordered by their level of specificity.

WordNet is made up of independent hierarchies for different parts of speech: nouns, verbs, and adjectives. Given this (which prevents the possibility of assigning a crosscategorical semantic label) and the fact that the hierarchies for verbs and adjectives are far less complete than the noun hierarchy, we focused on the common nouns \({ }^{6}\) within each phonesthemic cluster amongst those listed in Table 2. This resulted in eliminating \(37 \%\) of words over all clusters.

For each common noun \(w\) in a phonesthemic cluster, we computed a set \(H(w)\) containing all superordinate concepts in the hypernym chain of \(w\), and derived a set \(\mathcal{H}\) of potential class labels for that cluster by taking the union of all sets \(H(w)\) for each noun \(w\) in the cluster. We then considered several methods for selecting the most optimal semantic class labels from \(\mathcal{H}\). Our methods were inspired by the approach to unsupervised ontology acquisition proposed by Widdows (2003) according to which "the most appropriate class-label for the set [of words] \(S\) is the hypernym \(h \in \mathcal{H}\) which subsumes as many as possible of the members of \(S\) as closely as possible in the hierarchy" (p. 278). Widdows offers a general scheme for defining an affinity score function \(\alpha(w, h)\) between a word \(w\) and a candidate label \(h\), which generates a ranking of all the potential class labels for a cluster of words:
\[
\alpha(w, h)= \begin{cases}f(\operatorname{dist}(w, h)) & \text { if } h \in H(w) \\ -g(w, h) & \text { if } h \notin H(w)\end{cases}
\]
where \(\operatorname{dist}(w, h)\) is a distance measure between a given word and a hypernym, \(f\) is a reward function that gives points to \(h\) if it subsumes \(w\) and the more points the closer this relationship, while \(g\) is a penalty function that subtracts points if \(h\) does not subsume \(w\). The best class-label is the hypernym \(h \in \mathcal{H}\) that has the highest affinity score summed over all the elements in the cluster.

Following Widdows, we chose as our distance measure the number of intervening levels in the WordNet hierarchy and set the rewarding function to \(f=1 / \operatorname{dist}(w, h)^{2}\). As for the penalty function \(g\), we tested constant values of \(0.25,0.1\) and 0.01. This particular variant of the scoring function thus magnifies the credit given to classes that are close to the words they subsume while giving a very small penalty to potential labels that miss out words in the cluster. The expected result is thus a ranking of class labels with a strong preference for specificity. This seems congruent with the nature of phonestheme clusters, which may contain a relatively large number of words that due to, for example, etymological factors are unlikely to be all related to the phonesthemic meaning. In fact, it is acknowledged in the literature that the soundmeaning associations are likely to be probabilistic (Hutchins,

\footnotetext{
\({ }^{6}\) We discarded proper nouns, which in WordNet are always terminal leaf nodes representing concrete instances rather than types.
}
1998) and that phonesthemic meaning can fall into related but separate groups. For example, \(g r\) is taken to be related to both angry noises (growl, grunt) and grabbing actions (grab, grasp). Given this, we also considered an approach whereby we first run a Gaussian Expectation-Maximization clustering algorithm on each phonestheme cluster to obtain more refined subsets of words and then run our scoring function algorithm on each of the resulting sub-clusters.

Finally, to counterbalance the preference for high specificity but potentially low coverage of the words in the phonesthemic clusters, we experimented with a different labeling algorithm that fixed a minimum coverage threshold. The algorithm examines all hypernyms \(h \in \mathcal{H}\), selects those that subsume a minimum percentage \(\theta\) of words in the cluster and then ranks them according to their specificity (the number of intervening levels to the root node entity). We tested the percentage values \(\theta=10\) and \(\theta=20\) and run the algorithm both on complete cluster phonesthemes and on the unsupervisedly derived sub-clusters. \({ }^{7}\)

\section*{Results}

Our results show that successful labeling of phonesthemic clusters can be performed but success depends on a number of factors. First, it is necessary to clarify what we mean by successful labeling. A labeling outcome of phonesthemic senses was deemed successful when the top 10 labels fulfilled the following criteria:
1. the topmost label is not the WordNet root node (entity);
2. the top 5 labels do not all have specificity score \(m \leq 2\);
3. at least \(50 \%\) of the top 10 labels carry meaning predicted for a given phonestheme;
4. the top 10 labels together subsume at least \(50 \%\) of the words in the cluster.
These heuristics mean that if it is possible to establish the semantic core of a phonesthemic cluster using WordNet hypernym trees, the top labels will be both specific and in the direction predicted by the literature. It is always possible to subsume all the words in the cluster, independently of their semantic relationship, under the root, just due to the WordNet structure. Such a label, however, would not be very informative. By the same reasoning, we excluded the next two levels of the hierarchy which contain concepts such as physical entity, abstraction, matter or relation. On the other hand, specificity needs to be balanced out by coverage, i.e. it is possible to have very specific labels as top results but covering only a small portion of words in the cluster. Finally, the labels need to at least intuitively relate to the domain specified in the literature for a given phonestheme.

Given these criteria, we obtained clear positive results for one phonestheme \((g l)\) out of 10 examined; moderately successful results for two phonesthemes ( \(s n\) and \(s t r\) ); and negative results for the remaining 7 phonesthemes. We present

\footnotetext{
\({ }^{7}\) Assigning a higher value to \(g\) would also increase coverage. However, for consistency \(g\) would have to be dependent on the size of the cluster. We instead choose a simple approach here which resorts to a percentage.
}

Table 3: Top 5 WordNet labels for \(g l-\), \(s n-\), and \(s t r\) -
\begin{tabular}{|c|c|ccc|}
\hline Prefix & Label & Score & Spec & Cov \\
\hline \hline \multirow{4}{*}{\begin{tabular}{c} 
gl- \\
\((N=56)\)
\end{tabular}} & brightness & 4.82 & 6 & \(23.7 \%\) \\
\cline { 2 - 5 } & flash & 4.67 & 5 & \(13.2 \%\) \\
\cline { 2 - 5 } & radiance & 3.92 & 7 & \(13.1 \%\) \\
\cline { 2 - 5 } & light & 2.23 & 5 & \(26.3 \%\) \\
\cline { 2 - 5 } & look & 2.16 & 8 & \(10.5 \%\) \\

\end{tabular}
the top labels for the 3 successfully labeled phonesthemes in Table 3, together with the scores calculated by the affinity score function with penalty set to a constant \(g=0.01\) (Score), specificity of each label (Spec) and the proportion of words in the cluster subsumed (Cov).

The \(g l\) phonestheme received light- and vision-related labels in all labeling algorithms that we tested. As can be seen in Table 3, they are clearly specific, cover a large proportion of words and all carry the predicted meaning. Similar results are obtained using other two settings of the \(g\) function and the coverage-based algorithm, although a small percentage of high-level labels like entity does appear in these lists.

Our moderately supported phonesthemes sn and str obtain labels in the predicted direction only with algorithms that reward specificity over coverage. For \(s n\) (related to nose, mouth and snobbism according to the literature), the best result is obtained with the distance measure and penalty function \(g=0.01\), while for the str phonestheme, related to forceful action - with the coverage-based algorithm of \(\theta=10\).

Similar conclusions can be drawn from phonesthemes that did not lead to clear tendencies in their labels or to specific enough labeling. Such lack of success is evident in either only one label out of the top 10 being relevant to the predicted meaning or all of the labels being very general. In the first case, for example, both \(g r\) and \(s c r\) words are subsumed under noise. In fact, this label appears in all instances of scr scores as a top label, covering \(26.9 \%\) of words in the cluster. However, the rest of the top labels are either of a general kind (entity, change) or not related to sound or movement (handwriting, wound) and therefore we cannot consider the labeling result to be very strong. In other cases, the words are primarily subsumed by labels like entity and abstraction.

As explained in the Methods, we considered the possibility that clusters might be composed of several groups of words that do not all share the same semantic content. This is especially likely for numerous clusters (e.g. \(g r\) cluster even with proper nouns removed contained 158 words). To counteract this problem we examined how prior sub-clustering affects the labeling results. The EM algorithm we used detected the
presence of two clusters for 4 out of 10 phonesthemes we considered (bl, gl, gr and str). \({ }^{8}\) Again, however, the most interesting result was obtained for the \(g l\) phonestheme. According to the labels we obtained for its two sub-clusters, only one of them was light-related. The second sub-cluster contained words like gluten, glucose and glycoprotein, which were placed under labels such as protein, macromolecule and organic compound, indicating a clear presence of chemistryrelated words. No clear patterns were obtained for the other 3 phonesthemes with two sub-clusters. We do not exclude the possibility that this result was due to the quality of the vectors given to our clustering algorithm or to the algorithm itself. For example, the presence of a large proportion of kinship concepts in one of the \(g r\) sub-clusters (grandfather, grandchildren etc.) led to it being assigned labels such as grandparent and ancestor, while the same sub-cluster contained words such as growl and grunt. Therefore, whether the sub-clustering step is theoretically sound and if so how it should be accomplished requires further study.

\section*{Discussion}

The results of our first experiment are largely in line with those of Otis and Sagi (2008), but we also see a number of differences. On the one hand, we obtain higher support for phonestheme clusters overall and show statistical significance for several phonesthemes previously unsupported. On the other hand, our support for the strongest phonesthemes in the original study ( \(g l\) and \(s p r\) ) is weaker. These differences can be due to several factors. First, we use a different, more modern and balanced, BNC corpus and our resulting phonestheme clusters are larger. Second, we use a different method for building our distributional model - both a different algorithm (Random Projection) and a smaller window size.

It is worth noting that our tuning experiments with the \(g l\) phonestheme show that the kind of pre-processing that we apply to the corpus and the window size parameter do make a difference to the statistical results that can be obtained from the model. However, while pre-processing could be viewed as merely a methodological challenge common to all types of corpus analyses, there might be a theoretical significance behind the impact of the window size. Sahlgren (2008), for example, suggests that a small window size is preferable for detecting paradigmatic relationships between words (those that hold between words that do not co-occur themselves but occur in similar contexts, e.g. dog and cat) and at the same time there is evidence (Peirsman, Heylen, \& Geeraerts, 2008) that larger context is beneficial for picking out syntagmatic relationships that hold between words that often occur together (e.g. "crystal clear"). To our knowledge, the kinds of relationships that hold between phonesthemic words (in general or depending on a given phonestheme) have not been systematically investigated using such distinctions and further work on the influence of the kind of context useful for detecting phonesthemic relatedness, in conjunction with experimental

\footnotetext{
\({ }^{8}\) For the other phonesthemes, no sub-clusters were detected.
}
work on similarity, could offer clues on this issue.
Our labeling results are somewhat disappointing but, given the novelty of our approach, still highly informative. The fact that we obtain better results for \(s n\) and \(s t r\) phonesthemes with algorithms that favor specificity over coverage and that labeling is not fully successful with the remaining phonesthemes are puzzling given the high support that we obtain for these phonesthemes in our first experiment. We believe that there are two possibilities that can explain this.

The first possibility is that our WordNet-based methodology is not fully suited to discover the common semantic content that is present. WordNet does not allow for integrating hypernymy tree chains across different parts of speech, which might be vital for phonesthemes, a large proportion of which are verbs. In addition, it does not make all the distinctions that would be useful for phonesthemic studies, e.g. both \(s c r\) and \(g r\) are associated with kinds of sound but one is "unpleasant" and the other one "threatening" - a distinction which is not part of the WordNet taxonomy. On a more general note, hypernymy might not be the most appropriate relation for all phonesthemes, e.g. snout and sneezing are not similar because they are both a type of nose. Therefore, perhaps better labeling results could be achieved using a different semantic network, such as ConceptNet \({ }^{9}\), which allows for exploiting other than merely "is a" relations.

The second possibility, which we cannot reject, is that there is in fact no semantic core that unites phonestheme clusters and that the statistical support obtained by Otis and Sagi and in our first experiment is a result of a particular methodology. This interpretation is suggested by the fact that in our second experiment the overall coverage of phonesthemic words by the semantic labels is relatively low. Qualitative examination of the clusters also seems to show that they contain a lot of variability. In the future, we plan to design stricter tests for example, comparing phonestheme clusters to clusters that share a particular (non-phonesthemic) sub-string rather than simply to a group of random words.

Ultimately, the aim of automatically detecting phonesthemes and their semantic content in a more objective, falsifiable way is, on the one hand, to help researchers interested in iconicity to validate the existence of phonesthemes previously reported in the literature, to possibly discover new phonesthemes, and to settle disputes over their particular meaning; and on the other hand, to open the door to investigating further the cognitive nature of the semantic relationships that unite phonestheme clusters. This study constitutes a step in this research programme.

\title{
Can Playing Portal Affect Spatial Thinking and Increase Learning in a STEM Area?
}

\author{

}

\begin{abstract}
Spatial skills have been associated with learning in STEM areas and some research has shown that playing video games could facilitate the development of spatial skills. This study examines whether playing a game that uses a realistic physics engine and places spatial demands on the players could facilitate learning a subsequent physics lesson. Fifty-eight participants viewed a brief lesson on Newton's laws of motion after either playing the puzzle game Tetris or the firstperson perspective puzzle game Portal, which incorporates aspects of physics such as momentum. The groups did not differ on subsequent tests of learning outcomes involving physics, but the Portal group scored significantly higher on a perspective taking test \((d=0.57)\). This study shows that playing a commercial game that incorporates Newtonian physics does not prepare students to learn physics but does improve an important spatial cognition skill related to physics.
\end{abstract}

Keywords: video games; physics learning; spatial orientation

\section*{Objectives}

The goal of this study is to examine whether playing an off-the-shelf first-person perspective puzzle game based on physics principles (i.e., Portal) can help prepare students to learn physics concepts and improve their spatial skills as measured by the perspective taking task. In the present study, students studied a brief lesson on Newton's laws of motion after spending an hour playing Portal or the puzzle game Tetris. Examining the effects of playing an off-the shelf computer game can be called cognitive consequences research and constitutes one of three major experimental methodologies for game research (Mayer, 2011). In short, the goal is to determine the cognitive consequences of playing Portal on (a) improving a spatial skill that is related to learning in physics and (b) enabling students to learn physics concepts on a subsequent physics lesson.

\section*{Learning Physics and Video Games}

Learning physics can often be difficult because many learners already have misconceptions about how the physical world works. White (1993) argued that one of the problems with physics education is the top-down approach in which abstract formulas are taught first, which students later have trouble applying to every-day phenomenon. Instead White (1993) argued that physics should be taught using an approach in which students are presented with concrete versions of these models in the form of computer
simulations. While the real world can be overly complex with multiple forces acting simultaneously, a simulation can control for these factors and allow for students to make predictions, then test them, and to try to explain the results. White (1993) used a group of microworlds called "ThinkerTools" with 6th graders. The curriculum was developed so that the initial microworlds had simple situations (no friction and only one dimension of motion) so that learners could develop intuitive knowledge before dealing with more sophisticated causal relationships. White (1993) found that, compared to high school students who were taught using traditional methods, \(6^{\text {th }}\) graders who received the "ThinkerTools" curriculum performed better on simple force and motion problems, better retained what they learned, and transferred what they learned to new contexts.

Similar to White's (1993) computer simulation, some off-the-shelf video games have been developed to depict realistic movement based on Newtonian physics and provide simplified environments to make game play easier. In a study by Masson, Bub, and Lalonde (2011) participants completed 6 one-hour game training sessions playing the video game Enigmo or the control game Railroad Tycoon 3. During Enigmo the player must alter the trajectories of falling droplets so that the drops land in target receptacles. The authors proposed that the Enigmo group would benefit from game play because the game gives repeated exposure to the movement of falling objects and this may benefit students by priming them to learn from formal physics instruction. The pretest/posttest consisted of a test of knowledge about the motion of objects with 15 items involving objects moving freely through space based on physics. Participants in the Enigmo group increased their ability to produce realistic trajectories but only in terms of the general parabolic shapes of those trajectories. After the posttest, participants then completed a PowerPoint tutorial on physics after which they completed 13 test problems based on the tutorial. Masson et al. (2011) found that students in the Enigmo group did not show a higher improvement after viewing the tutorial compared to the Railroad Tycoon 3 group.

Masson et al. (2011) were not able to show that experience playing a game that uses realistic physics motion prepares students to benefit from direct instruction in physics, but video games may benefit science learning through improvements in visuospatial ability. Previous research has shown that playing video games such as firstperson shooters (Feng, Spence, \& Pratt, 2007), and spatial puzzle games (Okagaki \& Frensch,1994; Subrahmanyam \&,

Greenfield,1994; Terlecki et al., 2008) can increase different spatial cognition skills, such as mental rotation. Work by Kozhevnikov and colleagues has shown a relationship between spatial ability and physics problem solving (Kozhevnikov, Hegarty and Mayer, 2002; Kozhevnikov, Motes, and Hegarty, 2007). When looking at a factor analysis of spatial ability tests and different types of kinematic problems, Kozhevnikov, Hegarty, and Mayer (2002) found that spatial ability loaded on the same factor as problems which involved determining an object's trajectory based on combining two motion vectors and using a different frame of reference to determine the characteristics of an object's motion. In an additional study in which participants were classified as being either high or low spatial, students classified as having high spatial ability were: (1) more successful at integrating several motion parameters versus only considering one at a time; (2) could interpret a object's motion based on kinematic graphs versus seeing the graphs as picture-like representations; and (3) understood the connection between different representations of spatial problems versus using multiple uncoordinated representations of the same problem (Kozhevnikov et al. 2007). Kozhevnikov et al.’s (2007) results with eye movements also suggest that high spatials actually visualize the movement of objects based on integrating motion components while low spatial individuals do not. Thus, there is evidence that certain spatial skills are related to success in STEM subjects.

Sanchez (2012) showed that playing games can also have a benefit on learning in science areas through priming these visuospatial abilities. Participants either played 25 minutes of the first-person shooter game, Halo: Combat Evolved or the word anagram game Word Whomp before reading a lesson on plate tectonics. Participants did not significantly differ on prior knowledge in the subject area or spatial skills, as measured by the first section of both the card rotation task and the paper folding task. After playing the game participants then read a complex text about plate tectonics. They then completed an essay task in which they were asked to write a causal essay about "What caused Mt. St. Helens to erupt?" After the essay task they completed the second part of both the card rotations task and the paperfolding task. The results found that playing the action video game had a significant positive effect on essay quality and rotation task performance. Sanchez (2012) proposed that the first-person shooter game requires visuospatial skills that are important for learning in some science areas. The present study parallels Sanchez's methodology, but explores the domain of physics learning.

\section*{Current Study}

In the fall of 2011, the game company Valve introduced an educational program called Learn With Portals, which proposed using their games Portal and Portal 2 to help teach students critical-thinking skills and physics (http://www.learnwithportals.com/). The games, depicted in Figure 1, incorporate elements of physics, such as
momentum, into a problem solving game. Portal is intended to benefit physics learning because it applies realistic physics principles into the game experience, therefore allowing the player to build experience with physics concepts in a controlled environment.

It is unclear whether Portal has any effect on spatial cognition skills similar to previous research with firstperson shooters and Tetris. If Portal does facilitate cognitive ability development it could help students learn physics similar to Sanchez's (2012) work with plate tectonics. Playing Portal requires the participant to imagine what a room may look like from a different perspective. Placing the portals in order to solve the puzzles within the game may therefore require the use of the spatial skill known as spatial orientation or the ability to visualize what a different perspective may look like from another location (Hegarty \& Waller, 2004). Kozhevnikov, Hegarty, and Mayer (2002) found that performance on a spatial orientation test correlated with performance on a kinematics questionnaire, which included items from the physics test known as the Force Concept Inventory (FCI) (Hestenes, Wells, \& Swackhamer, 1992). In this study, Tetris is used as the control condition because although Tetris has been found to increase performance on mental rotation under certain training regimes (Okagaki \& Frensch,1994; Terlecki et al., 2008), Kozhevnikov et al. (2002) showed that mental rotation was not associated with kinematic problem solving.

Therefore, the objective of this experiment is to: (1) determine whether playing Portal can increase performance on a spatial cognition task; (2) determine whether an hour's worth of playing Portal versus Tetris can increase learning from a subsequent lesson on physics; (3) determine whether there is a relationship between spatial cognition skills and performance on physics problem solving.

Participants and Design Participants were 63 (39 male, 24 female) students from the University of California, Santa Barbara. Ages ranged from 17-23 years old with a mean age of \(19.03(S D=1.28)\). Participants received class credit for their participation. Thirty-four participants served in the Portal group and 29 served in the Tetris group.

Materials The pre-game paper-based materials consisted of a participant questionnaire and pretest. The participant questionnaire contained basic demographic items concerning the participant's gender, year in school, age, and also asked participants to rate their spatial cognition ability (i.e. being able to visualize objects or imagine rotating items) on a 5-point scale ranging from "Very Poor" to "Very Good". Participants were also asked how many hours they played video games, excluding card games and text based games, during a typical week ranging from "I do not play video games" to "More than 10 hours per week". Participants were also asked whether they had played Portal or Tetris before. To examine prior knowledge, participants were asked to indicate whether they had previously taken
physics courses during high school or college, or if they were in the process of taking a physics course.

The pretest asked participants to try to recall Newton's three laws of motion. Participants could receive a total of 6 points on this section, 2 points for each law if all of the elements were correct. For example, for the \(1^{\text {st }}\) Law, the Law of Inertia, participants had to state both that a body in motion will stay in motion while a body at rest will stay at rest and that the object's state will not change unless acted upon by an external force. Excluding either the "at rest" or "in motion" element would result in the student only receiving one point for the \(1^{\text {st }}\) law. The pretest also included 4 multiple-choice questions dealing with naïve physics. The first two were the cliff problem and the ball problem from McCloskey (1983). The cliff problem asks the learner to determine what path a person will take if they run at a constant rate of speed off the edge of a cliff. The correct answer to this problem is based on the \(1^{\text {st }}\) law of motion, while some of the incorrect options are consistent with impetus theory or the idea that objects contain force that runs out. The ball problem asks the learner to determine where a heavy ball will land if you dropped the ball while running forward at a constant speed. The last two questions came from White's (1993) testing materials and asked participants about two balls falling from different heights. This question was used to examine the participant's understanding of gravity. Students received one point for each correct answer in this section. Overall, the pretest scores could range from 0 to 10 .

The control game used for this study was the puzzle game Tetris. During Tetris the player must make lines of blocks using 6 different block shapes. Every time a line is completed the line disappears from the rectangular play area and the player receives points. The more lines that are completed at once, or the larger the combo, the higher the points the player receives. The player can press a button on the keyboard to rotate the blocks in increments of 90 degrees in order to best fit them into the available spots at the bottom. The block shapes fall from the top of the play area at a constant rate and as players gather more points the falling rate increases therefore increasing the level difficulty of the game. In the marathon mode version of the game,

Figure 1: Sample screen shot from Portal game play. Chamber 13.
play continues until the player fills the rectangular play area with incomplete lines.

The target game used in this study was Portal (2007), a first-person perspective puzzle game. The narrative of the game is that you are a test subject named Chell that has woken up in a facility in which you must navigate through testing chambers using portals. The player is given advice and feedback from a computer named GLaDOS who promises cake upon the completion of the testing regimen. During the game the player acquires the use of a portal gun, which shoots two portals, a blue and an orange one, which are linked to the left and right mouse buttons respectively. The two portals can be fired on specific surfaces during the game and can link those two locations so that when you enter one portal you will exit the other. The game sometimes requires the participant to make use of momentum so that the player can traverse large horizontal distances. To do this a player can place one portal at the bottom of a pit and another on a vertical wall so that falling into the portal at the bottom of the pit will increase their momentum using gravity and they will exit the opposite portal with enough speed to travel horizontally over pits and other obstacles (Chamber 10 of the game requires this solution). Solutions become progressively harder as the chambers continue requiring the use of more and more portals. There are a total of 19 levels/chambers in the game. In this experiment, participants started on the \(10^{\text {th }}\) chamber of the game since it is the first one that deals with momentum to solve the puzzle. The chamber also starts with GLaDOS explaining momentum, in which she states that portals do not affect forward momentum. She also informs the player that momentum is a function of mass and velocity. Participants were encouraged to get as far through the chambers as possible until the hour of game play was over.

The physics lesson consisted of an 18-slide presentation on Newton's three laws of motion and the law of conservation of momentum. The presentation also addressed the incorrect impetus theory and how it is a common misconception in physics. The lesson included the basic rules along with examples for each of the laws such as a canon recoiling after firing a cannonball for Newton's \(3^{\text {rd }}\) law or "for every action this is an equal and opposite reaction."

There were four paper-based posttests: a retention test, a shorten, adapted version of the Force Concept Inventory (FCI) (Hestenes, Wells, \& Swackhamer, 1992; Hestenes \& Halloun, 1995), a Portal based scenario test, and a spatial orientation test. The retention test asked the participant to recall the three laws of motion. This question was used to determine whether there were basic recall differences between the two groups. Once again, students could receive a total of 6 points for this section, 2 points for each law with all of the components correctly defined.
The adapted version of the FCI consisted of 24 multiplechoice items. Only items dealing with the first three laws were included since the short physics lesson only dealt with
these topics. This test was chosen because many of the items deal with the movement of objects and often includes items that could be answered incorrectly based on impetus theory instead of using Newtonian physics. The learner must apply what he or she knows about the three laws and momentum in order to select the correct answer. For example, one item asks participants to imagine that a bowling ball had been dropped out of the cargo bay of an airliner traveling horizontally and the participant must pick the correct path that the ball will fall from the plane to the ground below. There was only one correct answer for each item with a total of 24 possible points.

The scenario test contained two questions about scenarios taken straight from the Portal game and asked participants to determine whether the law of conversation of momentum had been violated. In one example, the direction of the individual changes (from traveling vertically to horizontally) while in the other the direction is kept constant (vertical to vertical). Participants are asked to justify their answers and must have the correct explanation to receive full marks on the two items with one point for correctly selecting whether the law had been violated or not and one point for justifying their reason, for example, explaining how momentum is a vector (speed and direction). The total score could range from 0 to 4.

To determine whether playing Portal affected the spatial skill known as spatial orientation, Hegarty and Waller's (2004) Perspective Taking/Spatial Orientation Test was used. During this task participants are given an array of 7objects including a house, a cat, a tree, etc. For each question, participants are asked to imagine that they are standing at one object facing the direction of another. They are then asked to "point" to the direction of a third object. To respond, below the picture array, participants are given a circle in which the first direction (i.e. cat facing the flower) is given and they must then draw a line indicating which direction the third object is relative to the other two. Participants are given 5 minutes to complete as many items as possible with a total of 12 possible items. Hegarty and Waller (2004) showed that the spatial ability known as spatial orientation is highly correlated with mental rotation but there is a disassociation between the two, suggesting two separate abilities.

Apparatus Both games were run on Dell computers with 17 inch color monitors, with ATI Radeon HD 2600 XT video cards. The lesson was also administered using the computers. All the testing materials, including the spatial orientation task, were given using paper and pencil.

Procedure Participants were randomly assigned to groups and tested in individual cubicles. Upon entering the lab participants were seated at separate computer cubicles. Participants were first asked to fill out the participant questionnaire sheet and the pretest, at their own pace. Participants were then informed that they were going to play their respective game for an hour followed by a lesson on
physics, a posttest, and the spatial orientation task. Each cubicle also had instructions for how to play the participant's particular game. Participants in the Tetris condition played on "marathon" mode in which the game becomes progressively harder as the player acquires points. For Tetris the experimenters recorded the scores and level reached for each of the completed games. At the end of the hour, the Portal group had their game progress saved, which was later accessed by the experimenter to determine how many chambers the participant had completed.

Next, the physics lesson was initiated on the participant's computer. Participants were told that they had a minimum of 8 minutes to review the physics lesson and could have more time if they wished. Upon completing the lesson the participants were given a packet including the retention test, FCI items, and the Portal scenario questions and told that they had as much time as they wanted to answer the questions. After turning in the packet, participants were then given the spatial orientation test. They had 5 minutes to complete as many items as possible.

\section*{Results}

For the analysis, only participants who were actively engaged during game play were included. The reasoning behind this decision is that only active participants who had Portal full exposure to all the elements within the game were of interest. Therefore participants were excluded from the analysis if they did not get past Chamber 11 while playing Portal or if they did not get beyond level 5 in Tetris. Using these criteria, 4 Portal participants and 2 Tetris participants were removed from the analysis, leaving 30 participants in the Portal group and 28 in the Tetris group.

The two groups did not differ significantly in the proportion of males and females, \(X^{2}(1, N=58)=.009, p\) \(=.92\), the proportion of individuals who were familiar with the game Portal, \(X^{2}(1, N=58)=1.62, p=.20\), and the proportion of individuals who were familiar with the game Tetris, \(X^{2}(1, N=58)=.283, p=.595\). The participants also did not differ on their self-ratings of spatial cognition ability, \(t(56)=-.431, p=.67\), and reported hours of video game playing, \(t(56)=.037, p=.97\). There was no significant difference on pretest performance, \(t(56)=-1.15\), \(p=.26\), or prior knowledge with physics, \(t(56)=.82, p=\) . 42 .

\section*{Does playing Portal improve students' spatial cognition?}

The perspective taking task was scored so that any item in which the participant was within 15 degrees of the correct angle was scored as correct and awarded 1 point while anything beyond 15 degrees and items that were not attempted were not awarded any points. Participants in the Portal condition significantly outperformed participants in the Tetris condition on the spatial orientation test, \(t(55)=-\) \(2.12, p=.04, d=0.57\). This is the major new positive finding in the study.

Table 1: Means and standard deviations for all posttest measures.
\begin{tabular}{lcccc}
\hline & \multicolumn{4}{c}{ Group } \\
\cline { 2 - 5 } & Portal & Tetris & & \\
Measure & \(M(S D)\) & \(M(S D)\) & \(p\) & \(d\) \\
\hline Retention & \(5.27(1.44)\) & \(5.39(1.06)\) & 0.71 & -0.09 \\
FCI & \(13.07(5.37)\) & \(12.75(4.45)\) & 0.81 & 0.06 \\
Portal Scenerio & \(1.77(1.50)\) & \(1.39(1.42)\) & 0.34 & 0.26 \\
Spatial Orientation & \(7.07(3.03)\) & \(5.52(2.41)\) & 0.04 & 0.57 \\
\hline
\end{tabular}

Importantly, there was a significant positive correlation between performance on the adpated FCI (which measures physics intuitive knowledge) and performance on the spatial orientation test, \(r(57)=.323, p=.014\). This finding suggests that spatial cognition skills such as spatial orientation may be related to success in physics learning.

\section*{Does playing Portal help students learn physics? Table 1} shows the means (and standard deviations) of the two groups on each of the four tests. There were no significant differences on recall of the three laws of motion in the retention test, \(t(56)=.378, p=.71\); applying what they had learned to answer the FCI items, \(t(56)=-.242, p=.81\); or answering questions involving conservation of momentum through portals on the scenario test, \(t(56)=-.972, p=.34\). Therefore, there was no evidence that playing Portal facilitated learning about the laws of motion.

\section*{Discussion}

On the negative side, playing Portal did not improve learning of physics content, paralleling the results of Masson et al.'s (2011) research with Enigmo. On the positive side, playing the first-person perspective puzzle game Portal for an hour resulted in higher performance on an important spatial cognition skill (i.e., spatial orientation) compared to playing the 2D puzzle game Tetris. In addition the results showed a significant correlation between performance on a measure of spatial cognition (i.e., the spatial orientation test) and a measure of physics knowledge (i.e., the adapted FCI), paralleling the results from Kozhevnikov et al. (2002) showing a connection between spatial skills and success in STEM learning.

This study provides evidence that spatial orientation is a learnable skill. Games such as Portal, which require participants to imagine taking different viewpoints, may facilitate the development of this skill. In contrast, a game like Tetris which can utilize mental rotation under certain circumstances, does not tax spatial orientation therefore causing no improvement. Overall, the results support the idea that training of spatial skills is domain specific, such that different kinds of computer games can promote
different kinds of spatial skills rather than improving spatial cognition in general.

These findings support the idea that if educators want students to improve in spatial orientation skill, they can benefit from playing a first-person perspective puzzle game like Portal. Improving in this skill appears to be related to STEM learning, so in order to help students that might be struggling in areas such as physics, perhaps developing their spatial orientation skills could facilitate learning. Educational physics games could incorporate both direct instruction and spatial components to increase learning.

\section*{Limitations and Future Directions}

One limitation for this study is the lack of a pretest measure for spatial orientation. None of the pretest or demographic measures showed any significant differences between the two testing groups; therefore random assignment should have balanced spatial ability between the two groups. The spatial orientation task only has one form with 12 items and dividing the task into 2 sections may have weakened the power of the measure. In the future, a second version of this test with an alternative array of objects could be used a pretest to determine spatial orientation ability before game play.

Although playing the off the shelf version of Portal for a brief period of time did not benefit students when learning physics, perhaps playing either for longer or playing chambers created to teach specific principles would result in higher learning gains. Our study found that there was a significant benefit on spatial orientation scores for playing Portal as well as a significant correlation between performance on the spatial orientation task and performance on the modified FCI. Perhaps with further game play participants could increase their spatial skills, therefore facilitating learning physics problems dealing with motion. Previous research with video games has shown that different cognitive skills can be improved by playing games (Green and Bavelier, 2003). While Tetris can improve mental rotation under some circumstances but not others (Terlecki, et al., 2008, Sims and Mayer, 2002) it is important to consider what skills are improved by a particular game and what skills are associated with success in a particular STEM
area. For example, Sanchez (2012) found improvements in mental rotation and learning about plate tectonics from playing a first-person shooter but no improvement in the paper-folding task. Spatial orientation has been found to correlate with performance on kinematic tasks, therefore a game which trains these skills could help participants with solving these problems.

In addition, the game company Valve has released a tool in which players can create their own testing chambers with the Portal 2 game software. Similar to White’s (1993) highly controlled simulations, if the Portal 2 software could be used to create lessons in which students build up prior knowledge through playing the game, then perhaps physics learning could be improved. One issue with Portal is that participants view the game from the first-person perspective so they are unable to see the falling trajectories of their game avatar caused by differences in momentum. Therefore, misconceptions about how objects fall can not be correctly addressed. By creating special testing chambers, other objects could be used to show how physics behaves in a controlled environment. Further research must be done to determine under what circumstances a lesson using the Portal game environment could facilitate learning and the development of spatial skills.

\section*{Acknowledgments}

This project was supported by a grant from the Office of Naval Research. We would also like to thank the game company Valve, specifically Dr. Mike Ambinder and Leslie Redd, for the electronic copies of Portal donated for research purposes.

\begin{abstract}
While social psychology has identified characteristics of intergroup dynamics, few studies have looked into the perceptions of robot group dynamics. In this experiment, we separate robots into majority and minority groups based solely on their behavior in a simple dance routine. We attempt to understand how people's perceptions of robots within those groups change based on group size and features of behavior. Participants viewed the robot dances and rated one robot from each group on a variety of characteristics. We find that being from the minority versus majority group has a significant impact on perceptions of a robot's creativity, interestingness, anti-sociality, dancing ability, and how much of a team player it is. At the same time, individual behaviors (leading the dance, following the dance, or performing an entirely unique dance) have no statistical effect on participants' ratings of robot characteristics. From these results, we conclude that group size has a larger effect than behavior on subjective evaluations of robots in majority and minority groups.
\end{abstract}

Keywords: Group dynamics; majority group; minority group; intergroup relations; robotics; human-robot interaction

\section*{Introduction}

The tendency to categorize people into established groups is an automatic social behavior, and influences much of how we perceive the world. Psychologists have studied the dynamics of intergroup relations, particularly when the group sizes are unequal, for many decades (Tajfel, 2010). Among many other findings, the literature reveals that minority groupsthose with fewer members-are susceptible to being influenced by a unanimous majority group (Asch, 1956), even when the majority's assertions are incorrect on a point of fact. Furthermore, people are biased toward perceiving their own group (an in-group) with more positive characteristics than a group of "others" (an out-group) (Tajfel, 1974).

In this paper, we pursue a systematic, empirical analysis of how simple manipulations of group dynamics can affect the perception of group members' personal qualities, some of which are not directly related to the behaviors being demonstrated. To accomplish this, we analyze peoples' judgments of a group of simple robotic agents in terms of characteristics such as interestingness, creativity, and sociality. We vary the agents' behaviors in systematic ways to tease apart which elements of their behavior affect these character judgments. In particular, we compare peoples' perceptions of a majority group robot-one member of a group of robots all exhibiting nearly identical behaviors-to their perceptions of a minority group robot-a single robot exhibiting a distinct set of behaviors different from the majority group.

In the last century, Michotte investigated the appearance of animacy by systematically varying the behavior of simple
moving shapes (Michotte, 1963). The current investigation is inspired by this and, in some sense, continues Michotte's work by investigating the characteristics of groups of agents by systematically varying the behavior of the group. Through this work, we hope to contribute a greater understanding of social attributions and the dynamics of groups.

Another benefit of this work is a greater understanding of the perception of robot groups. As technology improves, groups of humans are being joined by increasingly agentic technologies such as medicine-delivery robots in hospitals and package-retrieval robots in warehouses. Research in the field of human-robot interaction (HRI) has begun to examine intergroup relations in terms of including or excluding robots from human in-groups. Studies have shown that people respond more favorably to robots in their in-group than one in an out-group (Eyssel \& Kuchenbrandt, 2011; Kim, Kwak, \& Kim, 2010; Kuchenbrandt, Eyssel, Bobinger, \& Neufeld, 2011; Wang, Rau, Evers, Robinson, \& Hinds, 2009). However, much of this research investigates a single robot interacting with one or more humans. This paradigm is historically reasonable, because social robots have been typically designed for and deployed in single-robot environments. As robots become less expensive and more socially accepted, however, groups of robots may become more common. In these cases, understanding the dynamics of robot groups will be important for robot designers and users.

Few studies have explored intergroup dynamics for groups comprised exclusively of robots. Most importantly, little research exists that addresses the perception of groups of robots that are distinguished solely based on the behavior of the group members. We are interested in how the behavioral categorization of robots into majority and minority groups affects perceptions of group members' characteristics.

In this paper, we describe an experiment that attempts to identify the effect of majority group size on people's characterizations of majority group and minority group robots. We use a basic robot behavior-a simple dance-as the distinguishing feature between groups. In our experimental manipulation, we vary both majority group size (one, three, or seven robots in the majority group versus a single-robot minority group) and the type of dance performed by the minority group robot (same as or different from the majority group dance). We ask participants to rate the robots on a number of characteristics both related to and unrelated to dancing, in an attempt to understand how groups distinguished only by behavior are perceived. Our hypotheses are:

H1 The minority group robot will be rated more highly in in-
dividualistic characteristics (such as "creative" and "antisocial") than a majority group robot. Because its behavior will set it apart from the majority group, we expect the single minority robot to appear more independent than the group of similiarly-behaving majority group robots. We expect to see these characterizations with both positive and negative connotations.

H2 As the majority group size increases, the differences between minority and majority group members will increase. Research has demonstrated a positive correlation between group size and conformity (Tanford \& Penrod, 1984). Although participants in this study are not conforming themselves, they are making a character judgment about the conformity (and conversely, the individuality) of the minority group agent, so we expect this trend to hold.
H3 Dance type will affect how the minority robot is perceived relative to the majority. For instance, a dance in which the minority robot performs the motions one second before the majority group robots will lead to perceptions of the minority robot as the leader.

\section*{Related Work}

In this paper, we ask participants to make judgments of majority and minority group members from an outside perspective; the participant is not a member of either group. In contrast, in-group and out-group studies typically involve the participant being a member of one of the groups. Though we are analyzing majority versus minority groups in this paper, we are still influenced by research about in-group and out-group dynamics, and we briefly summarize the literature here.

Intergroup relations among human groups have been studied for over four decades, and there is a well-established body of literature describing the effects of in- and out-group membership on perception and behavior of people (e.g., (Tajfel, 1982; Turner, Hogg, Oakes, Reicher, \& Wetherell, 1987; Brewer \& Brown, 1998)). People exhibit positive responses to conformity with in-group norms, and they tend to be protective of the in-group stereotype (Castano, Paladino, Coull, \& Yzerbyt, 2002; Christensen, Rothgerber, Wood, \& Matz, 2004). People also tend to view an out-group as having less variety than their in-group (Boldry, Gaertner, \& Quinn, 2007). Similarly, members of a group of size one tend to be stereotyped by their distinguishing characteristic, such as gender (Wolman \& Frank, 1975).

Studies of group pressure between minority and majority groups have found that both groups can be swayed by the other, but that minority groups are particularly susceptible to being overridden by majority opinion (Asch, 1956). The amount of influence exerted by either a majority or a minority group is mostly affected by the size of the competing groups, and is less affected by the task or group characteristics (Tanford \& Penrod, 1984).

While human groups have been studied extensively, less research exists on peoples' perceptions of robot groups. Studies have shown that robots perceived as in-group members
appear more compelling, familiar, reliable, and anthropomorphic (Kim et al., 2010; Kuchenbrandt et al., 2011; Wang et al., 2009). Participants report more positive interactions with an in-group robot than an out-group robot, even when that grouping was established only implicitly by changing the robot's name and country of origin (Eyssel \& Kuchenbrandt, 2011). Participants exhibit greater perception of secondary emotions to in-group virtual agents (Besmann \& Rios, 2012). Responses to in-group membership may depend on culture: one study found that Chinese participants (i.e., from a more collectivist culture) were more comfortable with a robot than US participants (i.e., from a more individualistic culture) when that robot was presented as a strong in-group member (Evers, Maldonado, Brodecki, \& Hinds, 2008).

\section*{Experiment Design}

We used survey responses to videos of groups of dancing robots to investigate how in-group size and out-group behavior affected perceptions of group members. Surveys were completed using an interactive web page provided by SocialSci, an online social science research utility. Respondents were recruited from the SocialSci survey pool, a vetted collection of survey takers similar to Amazon's Mechanical Turk. Respondents were rewarded for their time with SocialSci credits which can be exchanged for gift cards and other rewards (SocialSci, 2012).

In all, 89 respondents were recruited. All survey respondents were over 18 years of age, with a mean age of 29 years (SD 10 years). About half ( \(54 \%\) ) of the respondents were male. Sixty-two percent of respondents identified themselves as white, \(6 \%\) were African-American, \(12 \%\) Hispanic, \(10 \%\) Asian, 2\% Pacific Islander, and 6\% identified as "Other."

\section*{Stimuli}

We employed a \(3 \times 4\) within-respondents design. The two factors in this design are group size (one majority versus one minority robot, three majority robots versus one minority robot, and seven majority robots versus one minority robot) and dance type (similar, unique, follower, and leader). The condition with a single majority robot was used as a control. Participants saw one video from each combination of group size and dance type for a total of twelve videos. We randomized presentation order of these twelve videos. To add to the perception of dancing, each video had an audio track containing one of five songs taken from a current top-40 pop music list. The robots' dance rates were altered with video processing to match the tempo of the current song. Song presentation order was also randomized.

Each video clip was 30 seconds long. Videos were created by stitching together multiple videos of the same robot (for majority-group members) or a different robot (the minoritygroup member) side-by-side (see Figure 1 for a still image from one video). The position of the minority-group robot was randomized across trials. In order to elicit a sense of realism, small delays were added to some majority-group members' videos at random; these delays were 10 frames
(about 160 milliseconds) at maximum, and simply served to strengthen the illusion that the video presented to participants showed several individual robots instead of one robot replicated several times.

To test how behavior affects characterizations of majority and minority group members, we created four distinct dance types. Figure 2 shows these four conditions. Dance types are described as a comparison of the minority robot's dance to the majority group's dance, and they can vary across two dimensions. First, the minority robot's dance can have the same available dance moves (repertoire) or a disjoint set of dance moves than the majority group's dance. Second, the minority robot's dance can have the same sequence of dance moves or a different sequence of dance moves than the majority group's dance. In the similar condition, the minority robot's dance has the same repertoire but a different sequence of moves. In the unique condition, the minority robot's dance has a completely disjoint repertoire. In the follower condition, the minority robot's dance has the same repertoire and the same sequence of moves, but the minority robot's sequence is one second behind that of the majority group members, eliciting the appearance that the minority robot is following the majority robots and struggling to catch up. Finally, in the leader condition, the minority robot's dance again has the same repertoire and sequence as the majority group's dance, but this time it is the minority robot that performs its sequence ahead of the majority robots by one second, in an attempt to simulate a single leader that is being followed by the other robots. These dances were designed to span the range of possible group dynamics, to identify how a robot's behavior with respect to other robots affects peoples' perceptions of it.

\section*{Survey}

The survey consisted of one page for each of the twelve videos and a final page to collect demographic information. Each video page contained a video that was 140 pixels tall and either 222 pixels wide (in the control, one-versus-one condition), 444 pixels wide (in the three-versus-one condition), or 888 pixels wide (in the seven-versus-one condition). Each robot was numbered with an overlay on the video which did not obstruct a view of the robot's motions (see Figure 1).

Following the video stimulus, respondents were asked to rate two of the robots (a random member of the majority group and the sole minority group member) on nine attributes using a seven-point scale:
- How well did robot \(x\) dance?
- How entertaining is robot x ?
- How likable is robot x ?
- How lifelike is robot \(x\) ?
- How interesting is robot \(x\) ?
- How much is robot x a team player?
- How mindless is robot x ?
- How creative is robot \(x\) ?
- How anti-social is robot \(x\) ?

Four survey questions were carefully selected for their positive and negative connotations of conformity or nonconformity. "Team player" and "mindless" represent positive and negative conformist words, respectively. Similarly, "creative" and "anti-social" have positive and negative connotations for non-conformity, respectively. Other survey questions address a range of attributes, including those having to do with the relevant behavior of dancing ("good dancer," "entertaining") and those not specifically related to dancing ("likable," "lifelike," "interesting").

\section*{Results}

In order to investigate our three hypotheses, we conducted within-subjects ANOVAs with group size (one-versus-one, three-versus-one, or seven-versus-one), dance type (similar, unique, follower, or leader), group affiliation (majority or minority), and their interactions as fixed factors, participant as a random factor and each of the nine ratings of the robot as dependent variables.

Dance type showed no statistically significant effect on ratings between minority and majority robots for any of the group size conditions, disproving hypothesis H3. Song type also showed no statistically significant effect, so in our subsequent analysis we combine all trials of a single group size together, regardless of dance type or song.

Hypothesis H1 predicts that the minority group robot will be rated more highly than the majority group robot in individualistic characteristics and less highly than the majority group robot in conformist characteristics. The survey attributes dealing with individualism and conformism are: creative, anti-social, mindless, and team player.

For perceptions of how creative the robot was, the majority group robot was rated lower than the minority group robot \((F(1,2128)=9.148, p<0.01)\). The interaction was also significant \((F(2,2128)=6.973, p<0.01)\). Individual group comparisons using Tukey HSD confirm significant differences between the minority and majority robots in the three-versus-one and seven-versus-one conditions (Figure 3a).

For perceptions of how anti-social the robot was, the majority group robot was rated lower than the minority group \(\operatorname{robot}(F(1,2128)=26.146, p<0.001)\). The interaction was significant as well \((F(2,2128)=8.706, p<0.01)\). Individual group comparisons using Tukey HSD confirm significant differences between minority and majority robots in the three-versus-one and seven-versus-one conditions (Figure 3b).

For perceptions of the robot as a team-player, the majority group robot was rated higher than the minority group robot \((F(1,2128)=158.06, p<0.001)\). The interaction was significant as well \((F(2,2128)=39.67, p<0.001)\). Individual group comparisons using Tukey HSD confirm significant differences between minority and majority robots in the three-versus-one and seven-versus-one conditions (Figure 3c).

No statistical differences were found for mindlessness. Analysis therefore shows significant differences for three of the four attributes dealing with individualism (creative, anti-

Figure 1: A still image from video of the seven-versus-one group size condition, showing the minority group robot (number 4) performing a different dance than the seven majority group robots.
\begin{tabular}{|c|c|c|c|}
\hline Condition Name & Available Repertoire majority minority & \begin{tabular}{l}
Sample Sequence \\
time
\end{tabular} & Explanation \\
\hline similar &  & \begin{tabular}{l}
maj: \\
min: \(-5-3-2\)
\end{tabular} & Same repertoire, different sequence \\
\hline unique &  & \begin{tabular}{l}
maj: \\
min: -
\end{tabular} & Different repertoire \\
\hline follower &  & maj:
\[
\min :
\] & Same repertoire, minority sequence is one second behind \\
\hline leader &  & \begin{tabular}{l}
maj: \\
min :
\end{tabular} & Same repertoire, minority sequence is one second ahead \\
\hline
\end{tabular}

Figure 2: A comparison of the four dance types used for the dance manipulation. Each row represents one dance type. The "available repertoire" column shows a graphical representation of the repertoire for majority and minority groups, where each shape is a distinct move (e.g., rocking back and forth). The "sample sequence" column shows example dances for each group.
social, and team player), partly confirming H 1.
Hypothesis H2 predicts that an increase in group size will increase the impact of being a minority. There were significant differences between the group size conditions on ratings of the team player attribute, positively correlated with group size \((F(1,2128)=14.64, p<0.001)\). Individual comparisons with Tukey HSD confirm significant differences in the minority robot's ratings between the three-versus-one and the seven-versus-one conditions. No other differences were observed across group sizes. Therefore, H2 is only upheld for the team player attribute.

Analysis of the additional attributes reveals statistical differences between majority and minority robot ratings for interestingness and dance ability as well. For perceptions of how interesting the robot was, the majority group robot was rated lower than the minority group robot \((F(1,2128)=\) \(4.128, p<0.05)\). The interaction was marginally significant as well \((F(2,2128)=3.611, p=0.058)\). Individual group comparisons using Tukey HSD confirm significant differences between minority and majority robots in the three-versus-one and seven-versus-one conditions (Figure 3 d ). For perceptions of how well the robot danced, the majority group robot was rated higher than the minority group robot \((F(1,2128)=30.35, p<0.01)\). The interaction was
significant as well \((F(2,2128)=6.22, p<0.05)\). Individual group comparisons using Tukey HSD confirm significant differences between minority and majority robots in the three-versus-one and seven-versus-one conditions (Figure 3e).

We also found a weak but highly significant correlation between positive and negative conformist words, "team player" and "mindless" (Pearson's \(r=0.165, p<0.001\) ), as well as between the positive and negative non-conformist words, "creative" and "anti-social" (Pearson's \(r=0.235, p<0.001\) ).

There were no significant differences in ratings of how mindless, lifelike, likeable, or entertaining the robots were. There was also no significant influence of demographic information such as age, gender, or ethnic background.

\section*{Discussion}

Hypothesis H1 was confirmed in the three-versus-one and seven-versus-one case for creative, anti-social, and teamplayer attributes. Furthermore, we found statistical differences between majority and minority robots for interestingness and how well the robot danced. In the control case-that is, in the one-versus-one condition-there was no statistical difference in ratings for either robot in these five traits, suggesting that the appearance of majority and minority groups elicited these differences in evaluation.

Figure 3: Graphs of participant ratings of minority and majority group robots for each of the group size conditions. The dotted line indicates an average rating on the seven-point scale. For brevity, we only show ratings that achieved statistically significant results (.: \(\mathrm{p}<0.1 ;{ }^{*}: \mathrm{p}<0.05 ;{ }^{* *}: \mathrm{p}<0.01 ;{ }^{* * *}: \mathrm{p}<0.001 ;\) NS: not significant).

We also predicted that majority group size would have an effect on the magnitude of differences between minority and majority robots (H2). For the team-player condition, as the group size increased, the differences between the majority and minority group robots also increased. Therefore, H2 was confirmed for one of the attributes. This result is interesting because it shows that group size can affect the intensity of "otherness" exhibited by the out-group member. Our finding is in line with other psychology research, which reports that group size affects the intensity of pressure to conform to group behavior (Tanford \& Penrod, 1984). This result also suggests that teams are identified not just by coordination of action but by size of population, because a larger majority group increased the difference in team-player ratings between the majority and minority robots. It would be interesting to identify whether there is an upper bound in majority group size for this effect. Future work might also analyze minority group sizes greater than one, to see if the effect of group size on the intensity of "otherness" is mitigated when the minority group grows proportionally to the majority group.

The dance types used in this experiment were carefully designed to account for many possible group interactions: one group leading another, one group following another, the groups having completely different behaviors, or the groups having the same behaviors but in a different pattern. Regardless, we found no significant differences due to dance type, disproving hypothesis H3. This suggests that it may not mat-
ter what the minority group robot is doing, as long as it is not doing exactly what the majority robot does. This supports Asch's majority effect (Asch, 1956), and is an interesting and novel finding in multi-robot interactions.

We chose the phrases "team player" and "mindless" as terms that have positive and negative connotations of conformity, respectively. Similarly, we chose "creative" and "antisocial" for their positive and negative connotations with nonconformity. Results indicate that the out-group robot was perceived as less conformist (team-player) and more nonconformist (creative, anti-social) overall. When comparing positive and negative connotations of those categories, we see weak but highly significant correlations between the two conformist words and between the two non-conformist words. Thus, if participants saw a robot as conformist, they were more likely to rate it highly for both positive and negative conformist words (and similarly with non-conformist words).

In this study, we measured participants' subjective evaluations, but they were not part of either group. The lack of situatedness of the robots, coupled with the fact that respondents did not participate in the task, make it unlikely that participants identified with either the majority or minority groups. Assigning participants to one of the groups might reveal further perceptions relating to group membership, and would allow comparisons to existing research on intergroup dynamics.

This paper investigates a social phenomenon-group dynamics-using controlled, precise stimuli and quantitative
metrics for evaluation. The general methods presented here, such as using recorded stimuli to manipulate a single social behavior within a group, can be useful for exploring many other social phenomena as well. The use of robots as stimuli further benefits researchers by allowing them to leverage the flexibility, precise control, and repeatability of movements, facial expressions, and other socially relevant behaviors, which may be impractical to achieve with human actors.

\section*{Conclusion}

Social psychologists have long known that group membership and size affect characterizations of group members, but there is a dearth of studies on this topic within the field of human-robot interaction. In this paper, we analyze the dynamics of robot groups: how are members of robot majority and minority groups perceived, and how does this perception change with differences in group size? We created majority and minority robot groups based on robot behaviors, by having robots perform simple dances which varied between the two groups in either timing (the minority group led or followed the majority group) or content (the minority group performed a different set of behaviors from the majority group). The minority group always contained one robot, while the majority group size varied from one robot (a control condition) to three robots to seven robots. We found a significant effect of group size on five characteristics: how creative, interesting, anti-social, much of a team player, and good a dancer the robot was. In contrast to this group size effect, there was no significant influence of behavior on any character attributions. This research suggests that group size has a strong effect on the evaluation of robot characteristics.

\begin{abstract}
Bar graphs and line graphs are commonly used ways of graphical communication. Due to the difference in their perceptual visuo-spatial properties, they facilitate comprehension of different events. Bar graphs are commonly used in the domain of precipitation although the data intrinsically carry information that is averaged over long time spans. In this study, we investigate how the presence of incongruence between consecutive graph pairs influences conceptualization of the represented information about precipitation. For this, we analyzed gestures and verbal descriptions produced by the participants as indicators of event conceptualizations. The results of the experimental investigation reveals that when incongruent graph pairs are presented, the participants show tendency to produce directional gestures that accompany the verbal descriptions of the specific regions represented by one/two bars, indicating that bar graphs presented in consecutive order facilitates comprehension of trend information as well as of discrete entities. Additionally, the presence of incongruence seems to enhance the production of comparative words accompanied with non-directional gestures.
\end{abstract}

Keywords: Gesture production; language production; bar graph comprehension; multimodal communication

\section*{Visualization - Bar and Line Graphs}

The primary goal of visualizing data is to (re-)present them in a format more suitable for using them in thinking, problem solving and communication (This view is taken implicitly or explicitly in most seminal publications on graphs, as well as on visualization during the last decades, see, e.g., Tufte 1983, Kosslyn 1989, 2006, Hegarty 2011). Line graphs and bar graphs are successful means to present data, both in the task of analyzing the data and in the task of communicating the results of data analysis. Communicating visualized data using bars or lines is used extensively in scientific publications, textbooks, magazines and newspapers; Zacks, Levy, Tversky, \& Schiano's (2002) study on the use of graphs in the print media shows that line graphs and bar graphs are the dominant, i.e. most frequently used, types of graphs in addressing non-experts in communication through graphs.

The primary gain in using graphs is not to make individual data points visible but to provide visual access to relations between data points ('xl-yl has a larger \(y\)-value than \(x 2-y 2\) ') or to second-order entities as 'trends'. This advantage can be ascribed to humans' pattern perception processes, in particular visual chunking (see, Shah, Mayer
\& Hegarty, 1999). Beyond these commonalities, there seem to be functional differences between bar graphs and line graphs. Zacks and Tversky (1999) investigate the bar-line message correspondence, which considers the systematic relations between the type of graph used and the type of message intended to be communicated. Zacks and Tversky point to a preferred "use of bar graphs to depict comparisons among discrete data points, and line graphs to depict trends" (p. 1073). On the other hand, participants in their experiments had a strong tendency for relational descriptions (e.g., "A is higher than B ") after comprehending bar graphs and for process-oriented secondorder descriptions as 'trends' (e.g., "X increases from A to B") in the of line graphs (p. 1078). Shah, Meyer and Hegarty (1999) report-with respect to these tendencies-a comparable view, but in presenting their perceptual organization hypothesis they lay an additional focus on Gestalt principles realizable in the graph types in question.

In addition to text-graphics documents, in many professional communication settings as well as in classroom settings, graphs, spoken language, and often gestures, accompany each other forming multimodal communication. In dynamic communication of this type, often recipients have to integrate messages communicated by a sequence of graphs. The present study investigates participants' verbal descriptions of pairs of succeeding bar graphs and the gestures produced during these descriptions. The first graph of each pair depicts averages (monthly precipitation over three decades) whereas the second graph depicts instances (monthly precipitation of a specific year). Due to the average-instance constellation, commonalities and differences, which we regard as 'incongruences', between the graphs play a major role in comprehending the graphs and in following production of verbal descriptions; in this setting the within-the-bar bias (Newman \& Scholl, 2012) did not occur.

\section*{Gesture and Language}

The studies on gesture-language interaction are mainly based on the assumption that concepts are sensorimotor, by emphasizing that they are grounded in physical world and based on perceptual experience (Barsalou, 1999; Garbarini \& Adenzato, 2004). There are several frameworks that investigate gestures from various perspectives, but all of them agree on that gestures rely on spatial representations. According to the GSA framework ('Gesture-as-simulated-
action', Hostetter \& Alibali, 2008), one of the frameworks that focus on how gestures are produced, gestures are byproduct of speech. In particular, linguistic planning involves simulation of visuo-spatial events; this activation during articulation is considered as a source of speech accompanying gestures. Another framework, that is closely aligned with the GSA framework and that focuses on how gesture and language production are integrated is the "Interface Hypothesis" (Kita \& Özyurek, 2003). The preparation for language production requires organization of rich and comprehensive information into small packages that contain appropriate amount of informational complexity within a processing unit. According to the "Interface Hypothesis", this processing unit may correspond to a clause for speech production, and the contents of a representational gesture are affected by the organization of these information-processing units, which are prepared for speech production. Therefore this close relationship between the gestures and language makes gestures an effective tool in the assessment of the reader's conceptualization of event, which is simultaneously described verbally (GoldinMeadow \& Beilock, 2010).

Although the interaction between language and gesture has been investigated for the past several decades in a variety of domains (Goldin-Meadow, 2003; Hostetter \& Alibali, 2008; Hostetter \& Sullivan, 2011; McNeill, 1992; 2005) specific investigations of graph comprehension in interaction with language and gesture, has been one of the scarce topics in the field of multimodal interaction. Gestures and graphical communications are visuo-spatial modalities, and they share similar perceptual visuo-spatial features to convey meaning such as quantity, direction and relations. (Tversky, 2011). Therefore during describing a visualization with an accompanying gesture, the places (or punctual events in the domain of our interest) become "fleeting positions" while marks and forms on the visualization become "fleeting actions" (Tversky et. al., 2009). Following this idea originated from the resemblance between two modalities, the vocabularies of gestures, speech and diagrams can be considered as parallel (Tversky, 2011).

For instance, within the context of communication through graphs, a fluctuating increase in a line graph may be verbally described by the term "increase" and it may be simultaneously accompanied by a gesture that represents the fluctuation in the increase. One of the studies focused on communication through line graphs (Acartürk \& Alaçam, 2012), showed that the perceptual features of the annotation that highlights the event presented in the sub-region of the graph (e.g., a graphical cue such as an arrow) have an effect on the conceptualization of the event, and this effect is observable in the gestures produced by graph readers. The results of this study indicated that in order to emphasize processes (e.g., increase, decrease) more vertical and diagonal gestures were produced by humans, whereas more pointing gestures were produced for emphasizing punctual states (e.g., a peak).

To sum-up, gestures can be used as a tool to assess how the graph reader interprets the graph and conceptualizes the event represented by the graph, because gestures provide additional information which is aligned with the visuospatial aspects of the graphical communication. Therefore gesture analysis helps to detect the hard-to-encode information and disambiguates, that are generally highlighted with the presence of accompanying gestures.

In the domain of bar graph comprehension and in communication through bar graphs, differences in gesture production are expected due to perceptual properties of bar graphs that contrast to those of line graphs. Bar graphs enhance comprehension of discrete events, since each bar on the graph perceptually corresponds to a single entity in the domain of discourse, while line graphs facilitate comprehension of trends. On the other hand, although the perceptual properties of graphs are crucial in the conceptualization, the comprehension is still highly dependent on their conceptual properties too (Zacks \& Tversky, 1999). Our goal in this study is to investigate the conceptualization of events that belong to average data (in the domain of precipitation, which is frequently represented with bar graphs), by analyzing the gestures produced during the description of the represented events.

We hypothesize that relations between events of the same domain that are represented with the same graph type (bar graphs) may be conceptualized differently when a perceptual change regarding small areas on the graph (in the case of incongruence) is introduced. In our experimental design, comparisons between regions of two consecutive graphs are required, rather than a comparison between two discrete entities in one graph. Therefore, in addition to discrete comparisons, trend evaluation may also play a major role during comprehension. Moreover, the differences in event conceptualization are examined by analyzing the speech accompanied gestures produced by the graph readers during the verbal description.

\section*{Experiment}

\section*{Participants, Materials and Design}

Twelve participants (university students at the Department of Human Computer Interaction, University of Hamburg, 4 female, Mean age \(=24.2, \mathrm{SD}=3.21\) ) participated in the study. The experiment was conducted in German, the native language of all participants.

Each participant was presented six precipitation graph pairs (two additional pairs of the graphs were employed for the familiarization part). The graphs represented average precipitation data of various cities. In the first graph of each graph pair, a bar graph that represented the monthly precipitation data average for the time period between 1970 and 2011 was shown for 10 seconds on a computer screen (the data were retrieved from Turkish State Meteorological Service). After the graph disappeared, the participant was asked to present a single-sentence verbal description of the first graph to a hypothetical audience. After then, the second
graph of the graph pair was presented. The second graph represented monthly precipitation data for the specific year (2011 for all stimuli) for the same city presented before, again for 10 seconds. The participant was asked to give a verbal description by taking into account both the first graph and the second graph. This procedure was applied for 6 graph pairs. The first graph in each graph pair was always the representation of the monthly precipitation data averaged over 1970-2011, whereas the second graph was always the representation of the monthly precipitation data for 2011 only (see Figure 1 and Figure 2). Participants' spontaneous gestures for 6 precipitation-graph pairs were video-recorded. The participants were informed only about producing verbal descriptions, therefore the gestures produced by the participants were spontaneous gestures.
The second within-subject condition in the experiment design was the congruency between the two graphs in each graph pair. In three graph pairs, the second graph was the same as the first graph, thus leading to a congruent graph pair (Figure 1). In the other three graph pairs, the second graph involved deviant bars (compared to the first graph), thus leading to an incongruent graph pair (Figure 2). The deviant bars were obtained by either increasing or decreasing the value of two/three bars drastically. The motivation for testing the congruency effect was to investigate how conceptualization differed when the congruency between the two related stimuli was systematically changed, even in the same domain and same graph type.

Figure 1: Sample graph for the average data (left) and the data for "instance" year with congruent graph (right)

Figure 2: Sample graph for the average precipitation data (left) and the data for "instance" year with anomaly in the distribution (right)

\section*{Coding}

The main experiment session consisted of six pairs of stimuli, all presented to each participant. Twelve
participants produced 144 sentences in verbal descriptions, 547 time period phrases in the sentences and 165 gestures that accompanied the verbal descriptions.

Gesture Annotation. The coding scheme was based on both McNeil's (2005) semantic gesture classification and syntactic features. The ANVIL software tool was employed for gesture annotation. In the first classification, the gestures were categorized according to their semantic classifications, such as beat gestures and representational gestures. Then each representational gesture was classified in terms of its directionality: non-directional, and directional (vertical/diagonal/horizontal). According to this classification, the hand movements conducted in small space without having any directed trajectory were categorized as non-directional gesture, whereas the hand movements with aimed trajectory on the air were classified as directional gestures.

Spoken Language Transcription. The sentences produced by the participants were transcribed and then the parts of the sentences were segmented into phrases. After this process, the phrases, which referred to temporal information on the graph, were classified into two categories in terms of the size of time interval. The time phrases that referred to multiple bars (such as in "summer" and "towards to winter") were classified into the "longterm" category. The second group covered the time phrases for specific time intervals (such as "in May" or "in July and August"). Finally, the phrases that referred to the previous graph in the comparative context were classified into the "comparatives" category.

\section*{Results}

The results revealed similar time spent for the description for the overall-data graph (i.e., the graph that represented monthly data averaged over 1970-2011, \(M=30.2\) seconds, \(S D=10.6\) ) and for the specific-year graph ( \(M=30.6\) seconds, \(S D=11.3 ; t=-0.38, p>.05\). As for the congruency, the participants spent similar time both for the congruent graphs ( \(M=28.4\) seconds, \(S D=10.9\) ) and for the incongruent graphs ( \(M=32.8, S D=11.7 ; t=-0.93, p>\) .05). Sample pairs of participants' verbal descriptions are presented in Table 1 and Table 2 below.

Table 1: Sample description for a congruent graph (translated from German)

\footnotetext{
Precipitation averaged over 30 years:
Looking at the past 30 years in Antalya there was almost no rain in the months of summer, but instead very very much in winter, it falls and then rises from the winter to the summer very strongly, in August I believe no rain at all, in the adjacent months only very very little.
}

\section*{The specific year:}

Also in Antalya 2011 reflects the past 30 years, because here we also have relatively little rain in the summer and in contrast very much in the winter and it is a quite steady decline and increase in the months in between.

Table 2: Sample description for an incongruent graph (translated from German)

\section*{Precipitation averaged over 30 years:}

In this graph, again in June, July and August, in the months of summer we have the least precipitation and it increases from August to September/December and January, where the highest point is reached and from January it decreases again slightly until it reaches the lowest point.

The specific year:
In this graph it is striking, that does not look like the average at all, because at the point where the lowest point should be we now have a little deflection upwards with much precipitation and also have less precipitation than expected in the months where a lot of rain falls.

In order to understand the underlying differences and similarities induced by the congruency, the speech parts accompanied by the gestures were focalized. The gestures were classified according to temporal information ("specific time" and "long term time" interval) referred in the accompanied speech parts as explained in the "Coding" section. Eight of 12 participants ( 2 female, Mean age \(=\) 24.3, \(S D=0.98\) ) produced gestures during verbal description of the graphs. Five of those eight participants produced representational gestures \((\mathrm{N}=146)\) classified according to scheme presented above. Two coders analyzed and classified the data. Interrater reliability between coders was calculated by Cohen's kappa. The results revealed an agreement value of .77. According to Landis and Koch (1977), a value above .61 indicates substantial interrater agreement. The results of Chi-square test revealed that during the congruent graph description, the gestures accompanied to "specific time" phrases ( \(\mathrm{N}=25\) ) were observed more than that for "long term" phrases ( \(\mathrm{N}=7\) ), \(\chi 2(1)=10.1, \mathrm{p}<.05\). On the other hand, in the description of the incongruent graphs, similar usage of gesture accompanied "specific" ( \(\mathrm{N}=30\) ) and "long-term" phrases \((\mathrm{N}=20)\) was observed \((\chi 2(1)=2.0, \mathrm{p}>.05)\). The production of non-directional and directional gestures were similar within congruency conditions, see Table 3.

Table 3: Number of gestures classified w.r.t. temporal information (NDir: Non-Directional, Dir.: Directional)
\begin{tabular}{ccccc}
\hline & \multicolumn{2}{c}{ Congruent } & \multicolumn{2}{c}{ Incongruent } \\
\cline { 2 - 5 } & NDir. & Dir. & NDir. & Dir. \\
\cline { 2 - 5 } Specific & 10 & 15 & 19 & 11 \\
Long-Term & 4 & 3 & 9 & 11 \\
\hline
\end{tabular}

The overall results that focuses on the difference between overall and instance graphs showed that the participants tend to produce the same amount of gesture for the first stimuli corresponding to overall precipitation amount for 30 years \((\mathrm{N}=64)\) and for the second stimuli corresponding to specific year \(2011(\mathrm{~N}=82)\), \(\chi 2(1)=2.22, \mathrm{p}>.05\). Additionally, the number of non-directional gestures ( \(\mathrm{N}=78\) ) and directional gestures ( \(\mathrm{N}=68\) ) produced during the course of verbal descriptions were similar. see Table \(4(\chi 2(1)=\) \(.65, \mathrm{p}>.05)\).

Table 4: Number of gestures produced during the verbal description for "Overall" and "Instance" Graphs (NDir: Non-Directional, Dir.: Directional)
\begin{tabular}{ccccc}
\hline & \multicolumn{2}{c}{ Congruent } & \multicolumn{2}{c}{ Incongruent } \\
\cline { 2 - 5 } & NDir. & Dir. & NDir. & Dir. \\
\cline { 2 - 5 } Overall & 18 & 18 & 18 & 10 \\
Instance & 14 & 18 & 28 & 22 \\
\hline
\end{tabular}

Since the congruency is always presented in the second stimulus ("Instance" graph), more detailed analysis was conducted on the scores of second stimulus (see Table 4). The results of a Chi-Square test, conducted to compare the overall number of gesture accompanied time phrases across different congruency groups, showed that more gestures were produced during incongruent graph description ( \(\mathrm{N}=\) 50) than that during congruent graph description ( \(\mathrm{N}=32\) ), \(\chi 2(1)=3.95, p<.05\). On the other hand, the results of the test, which compared the number of directional gestures ( N \(=40)\) and non-directional gestures \((\mathrm{N}=42)\) that accompanied the phrases, revealed no significant difference, \(\chi 2(1)=.05, \mathrm{p}>.05\). Similarly, there was also no difference within the incongruent graphs \((\chi 2(1)=.72, \mathrm{p}>.05)\) and congruent graphs \((\chi 2(1)=.50, \mathrm{p}>.05)\) in terms of the directionality of the gesture. However, in the description of the incongruent graphs, the participants produced more directional gestures compared to their previous description about overall data, indicating that incongruence on the data had a positive effect on the directional gesture production, \((\chi 2(1)=4.5, \mathrm{p}<.05\), while it had no effect on the production of non-directional gestures (see Figure 3). For the description of the congruent graphs, no such a significant difference in the production of non-directional and directional gestures was observed.

Figure 3: Gestures that accompany the description of the overall graph and the incongruent graph

More detailed analysis on the sub-regions with the incongruent data revealed the source of the increase in the directional gestures. The results of Chi-square test showed that for the description of the incongruent regions, more directional gestures \((N=12)\) were observed than nondirectional gestures \((N=3), \chi^{2}(1)=5.40, p<.05\). See Table 5 for the examples of produced sentences and Figure 2 for the corresponding graphs. These regions represented with one or two bars on the graph, their descriptions were accompanied with directional gestures.

Table 5: Directional Gestures that accompany the descriptions for the regions that present incongruence (translated from German)

\section*{Overall Rainfall over 30 years (see Figure 2 - Left for the corresponding graph):}

Ok, so here we have seen in the first months the rainfall was quite ... (non-directional), while in the months of summer relatively fast, quite low at about 20 and within the year the rainfall increased really significantly to about 30 I assume (directional).

\section*{The specific year (see Figure 2 - Right for the corresponding graph) :}

We have seen, that in this year the rainfall came off a little more steady (horizontal). They have decreased from month to month and overall in the first months came off smaller (diagonal) in general but in the months of summer the rainfall increased a little, but not so much, as now the rainfall in the former months have won (non-directional), especially not this time relatively steady decreasing from the average rainfall (diagonal) and in the end again there was a little increase.

Additionally, the verbal data that belongs to twelve participants (regardless of the accompaniment of the gesture) were also analyzed in order to examine the use of comparatives across the two congruency conditions. For each participant, the number of descriptions that referred to the overall graph at least once was counted for each congruency condition. The analysis showed that the participants tend to refer to the first graph in the graph pair, the overall precipitation graph, more in the description of the incongruent graph \((M=2.4, S D=1.0)\) than in the description of congruent graph \((M=1.9, S D=1.1), Z=\) 2.12, \(p<.05\), indicating that the incongruence between the overall graph and the specific-year graph enhanced the production of the comparative phrases. A similar pattern was observed for the comparatives accompanied by gestures: more comparative phrases in the incongruent graph description \((N=14)\) were accompanied by a gesture than in the congruent graph description \((\mathrm{N}=5), \chi^{2}(1)=\) 4.26, \(p<.05\). Additionally, the comparative speech parts are mainly accompanied with the non-directional gestures \((\mathrm{N}=14), \chi^{2}(1)=5.56, p<.05\).

\section*{Discussion}

The goal of the experimental investigation was to analyze the role of congruency between two graphs in a set of graph pairs in conceptualization of bar graphs. The first graph in the graph pair was always a monthly representation of 30 year average of precipitation data. The second graph was always a monthly representation of precipitation for a specific year. The results were analyzed in terms of the analysis of verbal descriptions of the participants, as well as the gestures produced by the participants. The results of the experimental investigation revealed that, in general, the participants spent similar amount of time to describe the congruent and incongruent situations with respect to overall graph (i.e., the graph which represented monthly precipitation data averaged over 30 years). On the other hand, a more frequent use of comparatives was observed in the incongruent condition during the course of the description of the second graph in the graph pair. This finding indicates that the participants noticed the difference between the overall graph and the specific-year graph and they found this anomaly worth mentioning in their verbal descriptions. Moreover, the comparatives were accompanied by non-directional gestures that aimed at referring to the previous graph in the graph pair.

As for the production of gestures, there was no difference in the type of the gestures that accompanied the speech parts. However, while gestures during congruent graph's description mainly were correlated with specific time phrases, during incongruent graph's description, gestures for "specific" and "long term" phrases were similar. This may indicate that unlike congruent graphs' description, description of two relational but incongruent events represented with bar graphs requires "as-a-whole" comprehension of the events as well as focusing on the specific regions of the graphs. Additionally, the number of gestures produced during incongruent graph description was higher than that during congruent graph description. Furthermore, when the incongruence was presented, differences in the event description between the incongruent graph and the overall graph were observed in the production of directional gestures: the participants produced more directional gestures for the specific-year graph compared to the overall graph, whereas there was no significant difference in the production of non-directional gestures. The increase in the number of directional gestures was considered as a likely indicator of a different conceptualization. Therefore, a more detailed analysis was conducted on the small region in the graph where the incongruence was presented. In the descriptions of those regions, the graph readers tended to use more directional gestures, indicating that those regions were interpreted as a trend, although those regions referred to a specific time period on the bar graph representation.

\section*{Conclusion and Future Work}

In this study, we investigated the conceptualization of events by focusing on the gesture production and verbal descriptions in the precipitation domain represented by bar graphs. Although the previous research on graph comprehension provides evidence that bar graphs are preferred to emphasize discrete entities, rather than trends, experts in specific domains, in our case meteorology, frequently use them. As the current study demonstrates as well, bar graphs are highly effective to communicate trends. The specific regions, where the incongruence is presented, are conceptualized as trends and the descriptions are accompanied by directional gestures. The perceptual properties of bar graphs that emphasize the entities may be helpful to catch the incongruence, but it also seems that the events are interpreted as "processes", similar to typical comprehension of the events represented by line graphs (Zacks \& Tversky, 1999). In order to understand the underlying mechanism in more detail, our future research will address the preference of the terms used to emphasize two different events, "process" such as increase or fluctuating and "state" such as peak, maximum, and their co-existence with the gestures in the case the congruency was systematically changed. Moreover, applying same experimental design with line graphs will also shed light into the effect of graph type on the conceptualization of the event that requires extrinsically comparison and also requires intrinsically trend evaluation.

Furthermore, the analysis of gestures seems as an effective tool to assess the graph reader`s comprehension and to obtain the important aspects considered as worth to mention in verbal descriptions. In addition to the rich data provided by verbal descriptions, the gestures point out the hard-to-encode information and conceptually salient points, as well as perceptually salient regions and entities of the graph.

Acknowledgments. We thank our student assistants Lena Andreeßen and Neele Stoeckler for their valuable effort. The study reported in this paper has been partially supported by DFG (German Science Foundation) in ITRG 1247 'Cross-modal Interaction in Natural and Artificial Cognitive Systems’ (CINACS).

\title{
Reactivity effects of concurrent verbalisation during a graph comprehension task
}

\begin{abstract}
We report an experiment investigating how concurrent verbalisation during a task can affect performance (a so-called "reactivity" effect). Participants studied three-variable line graphs while (a) concurrently thinking aloud or (b) silently studied the graphs and provided an interpretation once they felt they had understood it. Results showed that verbalisation hindered performance significantly compared to the silent condition. To support the claim that the act of verbalising was hindering performance, competing explanations were also tested, which confirmed thinking aloud as the most likely cause. This contradicts claims by Ericsson and Simon (1993) that thinking aloud reflects but does not affect performance and provides further evidence that verbalising thought processes can hinder performance.
\end{abstract}

\section*{Introduction}

Arguably one of the most important advances to have occurred during the cognitive revolution has been the attempt to develop theoretical justifications and rigorous methods for obtaining information about cognitive processes through the analysis of verbal reports produced during their execution.

Although the use of personal reports to infer mental processes has a long history, the approach has always remained controversial, with critics arguing that data obtained from them may be unreliable or that the methods themselves distort or react with the cognitive processes under investigation. The employment of verbal reports was given a cognitive basis and justification by Ericsson and Simon (1993) and their theory of protocol generation.

As a result of their analysis of the different types of verbalisation, the use of verbal protocol methods is now considered a legitimate approach for tracing thought processes and being a valid source of data about the steps involved in problem solving and decision making (Wilson, 1994). Since the original proposal, the think aloud method has been widely adopted, resulting in a large body of research into the processes underlying decision making, problem solving, text comprehension, diagrammatic reasoning, writing, and various other tasks (Crutcher, 1994).

The method considered by Ericsson and Simon (1993) as being the most valuable and rigorous is the concurrent think aloud method in which experiment participants are asked to simply verbalise their thoughts while carrying out a task. Ericsson and Simon (1993) claim that if appropriate instructions are given and followed carefully, the reports participants provide are an accurate reflection of the thought sequence that would have been followed if participants performed the task silently.

Questions remain however concerning the possible reactivity effects of thinking aloud while performing a task and a number of recent studies have revealed that verbalising while performing a task can hinder performance, challenging Ericsson and Simon's (1993) claim that verbal reports are nonreactive.

This area of research has primarily focused on tasks such as face recognition and insight problem solving where the processes involved in reaching a solution are not accessible to the individual to report (Chin \& Schooler, 2008). Schooler and Engstler-Schooler (1990) investigated whether describing a previously seen face would later hinder participants' ability to correctly recognise the face later. They found that compared to a control group who did not describe the face, those who did performed significantly worse in the recognition test. Schooler and Engstler-Schooler (1990) called this effect "verbal overshadowing", proposing that verbal overshadowing occurs when attention is directed to information that can easily be verbalised and so eclipses information that cannot easily be put into words.

Ericsson and Simon (1993) have challenged findings such as these arguing that the method employed did not adhere to guidelines of how protocols should be elicited. They distinguish between different techniques employed to elicit verbalisations-when participants are asked only to report their thoughts (Type 1 verbalisations) and when participants are asked to explain them (Type 3 verbalisations). Numerous studies (e.g., Wilson and Hodges (1992); Wilson, Hodges, and LaFleur (1995)) have reported reactivity effects but have required participants to provide a reason for their decision (e.g., "why do you prefer this painting over the other one?") which would elicit Type 3 verbalisations, a technique Ericsson and Simon accept is prone to reactivity effects. This is because when researchers ask "why?" questions, participants are required to process information which they would normally not need to, thus altering their thought processes and making the method susceptible to reactivity effects (Ericsson \& Simon, 1993). Therefore, there are only a handful of studies reporting reactivity effects when employing this method which adhere to the criteria outlined for eliciting valid protocols.

Despite this, there is a growing consensus that under certain circumstances, employing the verbal protocol method may result in reactivity effects (e.g., Schooler, Ohlsson, and Brooks (1993); Wilson (1994)). However, studies conducted to investigate this research question have focused on tasks
where verbal overshadowing of information is likely to occur (e.g., insight problems). Although this research is useful for identifying particular instances in which the think-aloud method may be susceptible to reactivity effects, the question remains whether these results generalise to tasks where information is more readily available for verbalisation. There is a need therefore for a greater range of tasks to be tested to determine whether reactivity effects are limited to tasks where information may be difficult to verbalise, especially considering the growth in areas this method has been applied to (Wilson, 1994).

In addition, it has been assumed that it is the act of thinking aloud itself which results in reactivity effects. There is the possibility of an alternative explanation however. When employing the think aloud method, the experimenter must be present with the participant, which may affect performancethe widely investigated "social facilitation/inhibition effect" (Zajonc, 1965; Rosenthal, 1976; Huguet, Galvaing, Monteil, \& Dumas, 1999).

One study which potentially indicates this could be the case was conducted by de Vet and de Dreu (2007), who studied the effects of concurrent verbalisation on creativity in a group setting. They found that thinking aloud impaired performance, particularly in individuals who were sensitive to other people's opinions of them. Although the authors concluded that the presence of others played a role in the performance impairments, it is difficult to generalise these results because the large groups used in the study are not typical of the scenarios used in the majority of verbal protocol studies.

\section*{Current experiment}

The aim of this study is twofold. Firstly, we seek to determine whether reactivity effects found in the literature are due to the demands of thinking aloud or whether potential competing explanations (e.g., experimenter presence) could account for this effect. Secondly, we also wish to investigate whether reactivity effects are limited to the types of tasks investigated in previous verbal overshadowing experiments by requiring people to think aloud while performing a task in which information is readily available for verbalisation.
To do this we employed a graph comprehension task for a number of reasons. First, in such tasks the information being processed is readily available at all times, thereby reducing the burden on working memory and freeing up resources for the interpretive task (Pinker, 1990). Second, previous research into graph comprehension employing verbal protocols (e.g., Ratwani, Trafton, \& Boehm-Davis, 2008) has demonstrated that such methods are able to provide a reliable trace of the problem solving processes undertaken by users.

Finally, the graphs we employed, although widely used in statistics to depict relationships between more than two variables, are relatively simple and constrain the interpretative processes available to users. Evidence for this assertion is provided by Halford, Baker, McCredden, and Bain (2005) who manipulated the number of graphically displayed statis-
tical interactions participants were required to process. They found performance for \(2 \times 2\) problems (the type employed in our task) was near perfect but a steep drop in performance emerged when the graphical representation depicted 3 or 4 way interactions; consistent with processing capacity constraints.

Based on these criteria, one might expect no effect of concurrent verbalisation to be found in this task. However, in a previous study in which we compared graph comprehension assessed by written and verbal reports, we found the written interpretation to be superior in terms of accuracy and detail (Ali \& Peebles, 2011). These findings did not reveal whether the differences were a result of a facilitation produced by the act of writing or a detriment from verbalising. The previous study laid open the possibility that this task may be susceptible to reactivity effects. Therefore this study will attempt to determine whether this is the case.

\section*{Assessing potential reactivity effects in a comprehension task}

To measure reactivity effects, the output from thinking aloud is compared to that of a "silent" condition using dependent measures such as number of correct responses and this is the method adopted in this study. In problem solving tasks the output of the silent condition may be simply a solution to the problem, e.g., \(29 \times 4=116\). In a graph comprehension task however, the output is a series of statements expressing the participants interpretation of the data depicted.

In the think-aloud condition this will result in participants verbalising their interpretation of the graphs until they complete the task. If reactivity effects are not an issue then performance will not differ between the think-aloud and silent condition, i.e., the demands of verbalisation will have no effect on the ability of participants to successfully apply the processes involved in graph comprehension. If however performance is superior in the silent condition to the think aloud condition then the act of verbalising is interfering in the processes involved in graph comprehension.

However, the silent and think-aloud condition is not comparable with these types of tasks because the silent condition involves two stages: an initial silent stage in which the participant constructs the interpretation and a second stage where this interpretation is reported to the experimenter. As this task is split into two stages it could be argued that improvement in performance could occur for a number of reasons other than remaining silent. For example, being explicitly required to communicate understanding to someone else could perhaps result in an improvement.
However, this effect can be balanced by including a further control condition where the second stage of the silent condition is incorporated into the think aloud condition. Therefore, in order to test whether communicating understanding affects performance, a third "summary" condition was included. If it is the act of communicating understanding (and not performing the task silently) which alters performance this condition
will be on par with the silent condition. If however the findings are similar to the think aloud condition then the silent and think aloud condition are comparable. This condition acted as a further control condition allowing for comparisons between the silent and think aloud condition.
Finally, the fourth condition tests any potential influence of experimenter presence on performance by including a "solitary" condition. These manipulations result in three conditions where participants are required to think aloud throughout the task and one condition where participants remain silent. If it is the demands posed by verbalisation resulting in reactivity effects performance should be superior in the silent condition than the other three conditions tested.

\section*{Method}

\section*{Participants}

Sixty undergraduate psychology students (41 female, 19 male) from the University of Huddersfield were paid \(£ 5\) (approximately \(\$ 8\) ) in grocery store vouchers to take part in the experiment. The age of participants ranged from 18.1 to 29.7 years with a mean of 22.2 years \((S D=2.1)\). The participants were in their first year of a three year psychology degree and were randomly allocated to the experiment conditions.

\section*{Design}

The experiment was an independent groups design with four between-subject variables: whether participants were in the think aloud, silent, solitary or summary condition. 15 participants were allocated to each of the graph conditions.

\section*{Materials}

The stimuli used were six three-variable line graphs depicting a wide range of (fictional) content. The graphs were generated using the PASW Statistics software package (produced by SPSS Inc.). Stimuli were printed in colour (with the levels of legend variable in blue and green) on white A4-sized paper. Examples of the stimuli used are depicted in Figure 1. The variables in the graphs were chosen so that no prior knowledge of the domain or relationships would influence interpretation.

\section*{Procedure}

In the first think-aloud control condition participants were informed that they were to be presented with a sequence of six three-variable line graphs and that their task was to try to understand each one as fully as possible while thinking aloud. The nature of the task was further clarified by telling participants that they were being asked to try to understand the relationships between the variables (rather than simply describing the variables in the graph), to try to comprehend as many relationships as possible, and to verbalise their thoughts and ideas as they did so. During the experiment, if participants went quiet, the experimenter encouraged them to keep talking. If participants stated that they could not understand the graph, it was suggested that they attempt to interpret the parts
of the graph they could understand. If they still could not do this, they were allowed to move on to the next trial.

In the second silent condition participants were informed there were two stages to the task. In the first "quiet" stage they could take as long as they wanted to understand the graph they were viewing as much as possible. In the second "talking" stage they were required to tell the experimenter what they had understood about the graph.

In the summary condition participants were instructed that the experiment consisted of two stages-in the first "think aloud" stage they were to think aloud whilst interpreting the graph. In the second "talking" stage they were to tell the experimenter what they had understood about the graph.

In the solitary condition instructions were identical to the think-aloud condition except participants were told they would be left alone throughout the experiment but it was important they remember to think aloud throughout the task.

The instructions were designed to be consistent with Type 1 verbalisations, where participants are required to think aloud throughout the task, but not explain or justify the statements they made. According to Ericsson and Simon (1993) eliciting protocols in this manner should result in no reactivity effects.

Stimuli were presented in random order and all participants were informed that there was no time limit to the task. Verbal protocols were recorded using a portable digital audio recorder.

\section*{Data analysis}

The verbal protocols participants produced while interpreting the graph were transcribed and their content analysed. Only statements in which a sufficient number of concepts could be identified were included for analysis. For example, the statement "low nitrogen levels have no effect on maize yield whether plant density is sparse or compact" was included whereas "low nitrogen affects. . . um. . . I'm not sure" was not. Data analysis was conducted according to the procedure and criteria employed in our original study (Peebles \& Ali, 2009; Ali \& Peebles, 2013). For each trial, the participant's statements were analysed against the state of affairs represented by the graph. If a participant made a series of incorrect statements that were not subsequently corrected, then the trial was classified as an incorrect interpretation. If the participant's statements were all true of the graph or if an incorrect interpretation was followed by a correct one, however, then the trial was classified as a correct interpretation. An example of a correct interpretation for the line graph in Figure 1a is "Whether nitrogen level is low or high when plant density is sparse, maize yield is two. When plant density is compact for low nitrogen level, maize yield is still at two but this increases to seven when nitrogen level is high".

In addition to this trial-level performance analysis, we also analysed the nature of the errors made in incorrectly interpreted trials. When participants made an erroneous interpretation that was not subsequently corrected, in addition to classifying the trial as an incorrect interpretation, we coded

Figure 1: Two of the six line graphs used in the experiment.
the type of error against the trial. As these graphs depict a relationship between three variables, if participants failed to incorporate all three variables into their interpretation the trial was coded as an error. The nature of the fault was categorised according to which of the variables had been ignored or misrepresented or whatever other error had occurred. Errors followed a similar pattern to the original experiment. An example of an incorrect interpretation for the line graph in Figure 1a is "When plant density is sparse, nitrogen levels remain low. When plant density is compact, nitrogen levels increase". In this instance the graph viewer is ignoring the dependent variable, maize yield. Verbal protocol evidence revealed participants were unable to provide an interpretation incorporating all three variables. One participant providing this interpretation stated "I don't understand how maize yield fits into it. I can understand the graph if I focus on plant density and nitrogen level" and then proceeded to ignore the dependent variable. The occurrences and explanations for why these errors occur are explained in greater depth in Ali and Peebles (2013).

In this way, each participant's trials were coded as being either correctly or incorrectly interpreted. The verbal protocol for each trial was initially scored as being either a correct or an incorrect interpretation by the first author and a sample (approximately 20\%) of trials were independently coded by the second author. The level of agreement between the two coders was approximately \(90 \%\). When disagreements were found, the raters came to a consensus as to the correct code.

\section*{Results}

Figure 2 displays the number of correct trials in each verbal protocol condition. The silent condition resulted in a higher
number of correct trials compared to the other three conditions. A comparison of the number of correct trials between the think aloud, solitary, silent and summary conditions revealed that the silent condition resulted in a significant increase (Kruskal-Wallis \(H=7.93, d f=3, p<.05\) ) in the number of correctly interpreted trials (mean rank \(=40.83\) ) compared to the think aloud (mean rank \(=24.60\) ), solitary ( mean rank \(=27.0\) ) and summary ( mean rank \(=29.57\) ) conditions.

Three post-hoc Mann Whitney U tests (with alpha levels Bonferroni adjusted to .017 ) revealed the significant difference to be between the silent condition and the think-aloud condition ( \(p=.005\) ), but not the solitary condition ( \(p=.713\) ) nor the summary condition ( \(p=.595\) ).

\section*{Discussion}

The results of this experiment reveal that participants who attempted to verbalise their interpretation of graphs were significantly less likely to provide a correct interpretation than subjects who interpreted the graphs silently before verbalising their interpretation. Additional control conditions revealed that it was not experimenter presence (the solitary condition) or the act of communicating understanding to someone else (the summary condition) which resulted in the performance differences between the think aloud and silent condition. These results definitively demonstrate that verbalisation results in reactivity effects; in this case a detriment in observed performance.

Although previous research has found that requiring participants to think aloud can result in reactivity effects, these findings have been challenged based on how the method was employed. For example, Cook (2006) required participants

Figure 2: Mean number of correct trials for the experiment conditions. Error bars indicate standard error.
to solve a series of algebra tasks with problems presented by computer in the silent condition but with cards in the verbalisation condition. This introduced a potential confound of verbalisation condition and stimulus format.

In a recent meta-review, Fox, Ericsson, and Best (2011) identified 95 studies employing verbal protocols. Studies were excluded from the meta-analysis if they did not include a comparison to a control condition, if findings were considered suspect because of potential confounding variables, or if effect sizes were not reported. Based on this analysis, the authors concluded that "Studies with confounds are common because few studies with verbal report and silent conditions are designed explicitly to test directly for reactivity" (p. 323).

The experiment reported here directly addresses these issues. We carefully followed Ericsson and Simon's guidelines for eliciting protocols and explicitly tested the think-aloud condition by comparing output to a silent condition as well as ruling out potential competing explanations for the difference observed between the think-aloud and silent condition.

These findings provide a strong demonstration that reactivity effects can emerge even when participants are asked only to report their thoughts (Type 1 verbalisations) and are not asked to explain them (Type 3 verbalisations). In addition, the task used in this experiment does not fall into a category where information is difficult to verbalise, demonstrating that reactivity effects are not limited to such tasks.

Although this task did not reveal any effect of experimenter presence, this issue deserves further investigation as tasks in the social psychology literature which can generate self-
presentation concerns may reveal findings which corroborate those of de Vet and de Dreu (2007). The increasing use of the verbal protocol method in the social psychology literature indicates further research is required to establish this method is appropriate for these types of research questions (Wilson, 1994).

Our knowledge of why reactivity effects emerge when employing the verbal protocol method is limited primarily because of the lack of studies explicitly testing for such effects. Based on previous findings, it appears that this effect is most likely due to a number of interacting factors and so such findings will not emerge consistently. Our findings demonstrate reactivity effects occur due to the demands of verbalisation and this effect is not restricted to tasks where information is difficult to verbalise.

One potential explanation which could account for the effect observed in our experiment is a competition for processing resources explanation. Russo, Johnson, and Stephens (1989) argued that the additional demands for processing resources (which occurs when individuals are required to verbalise whilst performing a task) can explain deterioration in performance. In order to deal with additional demands of verbalisation, participants can draw upon any unused resources which are not being employed. When the demands of the task exceed processing resources however, reactivity effects can occur, resulting in a detriment in performance due to the resources being divided between completing the task and verbalising throughout (Russo et al., 1989).

However, it is difficult to predict a priori whether or not
performance will be distorted by the generation of a concurrent protocol. Even when a task adheres to established guidelines for when the think aloud method is appropriate to use reactivity effects can emerge (Russo et al., 1989). Control conditions as standard practice when employing this method would help establish the conditions under which reactivity effects emerge; a necessary precursor for a theory of protocol generation which can account for reactivity effects. This practice would also allow more confidence in findings employing this method.

\title{
A Question of Timing: The Impact of Label Synchrony on Infants' Categorisation
}

\author{

\begin{abstract}
Recent research into the impact of labelling on infants' visual category formation has led to controversial results, with some findings indicating a beneficial role and others pointing to interference effects in the presence of labels. Here we present an eye tracking study with 12 -month-olds investigating the impact of the label's timing on categorisation. We find that synchronous presentation of words and objects leads to a decreased novelty preference, creating the impression of a dramatic detrimental impact on learning. Asynchronous presentation of the word one second after the image onset does not appear to interfere with processing. Detailed analyses of infants' gaze patterns with respect to object parts reveal that even synchronous labels do not hinder learning but slow down infants' shift from familiarity to novelty preference. Besides offering detailed insight into the effects of labelling on infants' attention our findings offer the potential to reconcile previous contradictory results.
\end{abstract}

\section*{Introduction}

The idea of linguistic influences on cognitive processes has been a heavily debated subject over the past century, with very extreme positions like Whorfian determinism (Whorf, 1956) gradually being replaced by less radical points of view (e.g. Boroditsky, 2001). From a developmental perspective, the question is fundamental: do infants use language, and words in particular, as cues to learn about the complex structure of the world? The almost universal presence of labels in an infant's environment, both in speech directed at the infant and in conversation between adults overheard by the infant, makes the hypothesis that labels may serve as meaningful cues very compelling. Shared labels indicate, after all, that dissimilar looking things may share attributes or function (e.g., a bonnet and a boater may both simply be called a "hat"). However, labels are not always readily identified by infants in their first year of life: language development is a gradual process involving learning about relevant dimensions in rhythm, prosody and phonetics before individual words are segmented from the speech stream and mapped onto referents (Tincoff \& Jusczyk, 1999; Bortfeld, Morgan, Golinkoff, \& Rathbun, 2005; Bergelson \& Swingley, 2012). In spite of this, several studies in the past 20 years have found facilitative effects of labelling on categorisation in pre-linguistic infants between six and twelve months (e.g., Waxman \& Markow,

1995; Balaban \& Waxman, 1997; Waxman \& Braun, 2005; Fulkerson \& Waxman, 2007), and more recently even in infants as young as three months (Ferry, Hespos, \& Waxman, 2010). This work suggests that even infants who are just at the beginning of language development can make use of labels when learning about objects and similarities between them. In fact, Plunkett, Hu, and Cohen (2008) and Althaus and Westermann (in prep.) have demonstrated that labels can serve to guide the formation of category boundaries when the structure of visual space is ambiguous, i.e. labels can cause infants to merge or split visual clusters depending on whether the visual exemplars are encountered with identical or differing labels. However, contradicting results which report "auditory overshadowing" effects in the presence of labels (as well as other auditory stimuli) have also been reported (Robinson \& Sloutsky, 2007), calling into question whether labelling has uniformly beneficial effects. It is as of yet unclear under what circumstances labels can facilitate learning, and what factors may contribute to labels attenuating learning.

From an information-processing point of view, labels provide additional information that may help learning - e.g., by increasing perceived similarity between objects that share labels (Sloutsky, Lo, \& Fisher, 2001), or by highlighting commonalities (Waxman \& Markow, 1995). However, processing this additional signal comes at a cost: attention and processing resources have to be allocated to two modalities rather than one - a feat which may be particularly problematic for young infants. This factor in particular makes it seem likely that the exact circumstances of how labels are encountered will play a role in whether they are going to interfere with, or aid, processing.

Here we explore the hypothesis that whether or not labels and objects can both be processed depends on the timing of the label: if both are presented in exact synchrony, i.e. image and label occur simultaneously, this may impose high cognitive load, and processing in one or both modalities may be attenuated. By contrast, if there is a delay between visual onset and auditory onset, this may allow infants to process both stimuli equally well - simply because some visual object recognition processes will already have been completed by the time the label occurs (Quinn, Westerlund, \& Nelson, 2006; Grossmann, Gliga, Johnson, \& Mareschal, 2009).

Whereas synchronous label onsets have been used in experimental scenarios (e.g., Robinson \& Sloutsky, 2007), delayed labelling scenarios appear to be much more likely to occur in a young child's experience (for example, a caregiver asking "Do you like the ball?" when the child is already attending to the toy). Even though some researchers have claimed that synchrony is beneficial for word-object association (Gogate, Bahrick, \& Watson, 2003), and cross-modal synchrony has been demonstrated to facilitate discrimination of amodal signals such as tempo or rhythm (Bahrick \& Lickliter, 2000), it is likely that synchronous picture-word pairings are unusual and surprising to infants at one year of age. These infants, after all, are at a stage in development where they may have learned some things about words (e.g., they often occur together with their referents, but not generally in synchrony like "causal" sounds, such as a hammer hitting a wall), but are far from being experts at processing speech sounds as phonetic units and mapping them to words.

In order to examine the impact of audiovisual synchrony on the interaction of labelling and categorisation, we familiarised three groups of 12 -month-olds with a novel category either in silence (Silent condition), with labels presented one second after the picture onset (Asynchronous Label condition), or with labels and pictures occurring simultaneously (Synchronous Label condition). In order to gain further insight into how infants process objects, the target category was constructed such that each exemplar consisted of two spatially separate object parts (a shell and a leaf, see Figure 1 for example objects). The shells were highly variable across exemplars, whereas the leaves were quite similar. This allowed us to track infants' encoding of features with different similarity structure. On test, infants were presented with an out-of-category item, as well as an object consistent with the familiarised category. In familiarisation/novelty preference paradigms, novelty preference for the out-of-category object has been established as an indicator of category formation. However, the two out-of-category items occurring in the first two test trials were constructed by replacing just one of the two parts (shell or leaf) with an item that differed from the familiarisation exemplars. We were therefore able to track on a very fine-grained, almost featural, level whether infants responded to novelty. Our hypothesis was that if infants were able to learn the category in silence, but labels (asynchronous or synchronous) interfered with learning, then infants should not exhibit novelty preference in the relevant conditions. A difference between Asynchronous and Synchronous conditions with regard to novelty preference would further indicate that the timing of the label plays an important role in infants' ability to process and integrate both stimuli.

\section*{Methods}

\section*{Participants}

A total of 87 infants participated in this study (mean age: 372 days, 43 girls). Eight additional infants were not included in the analysis due to failure to reach the looking time criterion.

Infants were recruited shortly after birth at the local maternity ward and English was the main language spoken in their home.

\section*{Stimuli}

A novel category was constructed by assembling 11 "objects" from images of a shell, a leaf and a pipe-cleaner in the Gnu Image Manipulation Program (see Figure 1 for example stimuli). Across the different objects, the leaves were very similar, the shells highly variable, and the invariable pipe cleaner served as a connecting limb between these two parts. In addition, three "out-of-category" objects were constructed (see Figure 2): Test object 1 contained a shell consistent with the category, but an inconsistent type of leaf ("novel leaf"), Test object 2 contained a leaf consistent with the category but an inconsistent shell ("novel shell"), and Test object 3 contained a sea urchin and a starfish instead of shell and leaf. All images were depicted against a medium grey background. Objects subtended approximately \(14 \times 10^{\circ}\) visual angle. On test displays, there was a gap of approximately \(5^{\circ}\) visual angle between out-of-category and within-category objects. A recording of the novel label "timbo", pronounced by a female British-English speaker in an infant-directed voice, served as the auditory stimulus in the Asynchronous and Synchronous Label conditions.

Figure 1: Example familiarisation stimuli.

Figure 2: Test objects 1, 2 and 3.

\section*{Procedure}

After a short warm-up phase during which written consent was obtained from the caregiver, infants were seated on the caregiver's lap at 75 cm distance from the eye tracker. A ninepoint calibration sequence was performed up to three times or until all points had been calibrated successfully.

Infants were presented with eight familiarisation images in pseudo-randomised order which were on the screen for 6000 ms each. Four of the familiarisation images appeared on the left half of the screen, and four on the right, in no
predictable order. Every image was preceded by an attention getter, a small animation at the centre of the screen (with a medium grey background) accompanied by an attractive chiming sound. Animation and sound lasted about \(1.5 \mathrm{sec}-\) onds, with the next trial beginning 2 seconds after the onset of the attention getter. In the Asynchronous Label condition, the sound file containing the label "timbo" was played 1000 ms after the picture onset. In the Synchronous Label condition, the label started at picture onset. Familiarisation was followed by three test trials, lasting 10000 ms each. On the test trials, the three test objects described above were paired with one of the three remaining objects from the familiar category. Test trials in all conditions were silent. Infants' looking was recorded using a Tobii eye tracker sampling at 120 Hz throughout the familiarisation and test phase.

\section*{Results}

We first focus on global measures of looking during familiarisation and test (i.e. with respect to whole objects), and then turn to a more detailed analysis of looking directed at individual object parts. In order to analyse gaze patterns with regard to object parts, areas-of-interest (AOIs) were defined to contain the area covered by the images of shell and leaf, respectively, plus a 30 -pixel margin around the image outline (corresponding roughly to the eye tracker's 0.5 degree visual angle accuracy). Recorded gaze data were analysed using custom Matlab code.

Figure 3: Looking time during familiarisation.

Looking time during familiarisation Looking time for each familiarisation trial was calculated as the sum of fixation time falling on the leaf and shell AOIs. Average looking times for Blocks 1 (Trials 1-4) and 2 (Trials 5-8) are shown in Figure 3. A mixed ANOVA with within-subjects factor Block (Block 1, Block 2) and between-subjects factor Condition (Silent, Asynchronous Label, Synchronous Label) revealed a near-significant main effect of Block \((F(1,84)=3.639, p=.06)\). Neither the Block x Condition interaction \((F(2,84)=2.231, p=.114)\) nor the main effect of condition were significant \((F(2,84)=1.76, p=.178)\). Planned comparisons (paired t-tests) showed that infants' looking decreased in the Silent condition \((t(28)=2.864, p=.008)\),
but not in either of the Label conditions (Asynchronous Label: \(t(28)=.46, p>.64\); Synchronous Label: \(t(28)=1.246\), \(p>.22\) ). This is consistent with previous research showing that auditory input causes infants to maintain their looking (e.g. Baldwin \& Markman, 1989; Robinson \& Sloutsky, 2007; Plunkett et al., 2008).

Part-based looking during familiarisation In order to investigate whether synchronous or asynchronous labels affected infants' processing of individual parts during familiarisation, we calculated a mean looking proportion for the "leaf" part by dividing the amount of looking at the leaves accumulated during familiarisation by the total looking time accumulated during familiarisation. These data were subjected to a one-way ANOVA with factor Condition, which revealed no significant effect \((F(2,84)=1.226, p=.299)\). Across all three conditions, infants spent less time looking at the leaves than at the shells, indicating that they were sensitive to the greater variability of the shells (Proportion of looking at leaf, collapsed across conditions: \(M=.33, S E=.01\); \(t(86)=13.1, p<.001)\).

Figure 4: Novelty preference scores in Test 1.

Preferential looking at test (object-based preferences) Object-based novelty preference scores were obtained for all test trials by dividing the amount of looking at the out-ofcategory object by the total looking time accumulated for the trial (within-category and out-of-category object).

Separate one-way ANOVAs on novelty preference scores with factor Condition were conducted for all three test types, which did not reveal any significant differences between conditions (all \(F \mathrm{~s}<1.4, p \mathrm{~s}>.2\) ). However, planned comparisons were conducted to test each group's performance against the chance level of 0.5 . If infants failed to form a category and

Table 1: Novelty preference scores for test trials 2 and 3 in all conditions. * indicates significance at the .05 -level, \({ }^{* *}\) indicates significance at the .005 level, \({ }^{* * *}\) indicates significance at the .0005 level.
\begin{tabular}{lll}
\hline & Test 2 & Test 3 \\
Condition & \(M(S E)\) & \(M(S E)\) \\
\hline Silent & \(.63(.05)^{*}\) & \(.66(.05)^{* *}\) \\
Async. & \(.64(.04)^{* *}\) & \(.65(.04)^{* *}\) \\
Sync. & \(.65(.04)^{* *}\) & \(.68(.04)^{* * *}\) \\
\hline
\end{tabular}
did not discriminate between the two objects, we would expect them to spend \(50 \%\) of their looking directed at each object. By contrast, if they successfully formed a category we would expect them to reliably prefer the out-of-category object.

The results for Test 1 are illustrated in Figure 4. Here, the out-of-category object contained a novel, inconsistent type of leaf and consistent shell. Infants in the Silent and Asynchronous Label conditions exhibited significant preference for the out-of-category object (Silent: \(t(28)=2.679, p=.01\); Asynchronous Label: \(t(28)=4.04, p<.001)\). Infants in the Synchronous Label condition, by contrast, failed to prefer the out-of-category object systematically \((t(28)=1.067, p=.29)\). Results for Test 2, where the out-of-category object contained a novel shell, and Test 3, where the out-of-category object contained two entirely novel parts, are provided in Table 1. In both Test 2 and 3, all infants exhibited systematic novelty preference, even those familiarised with synchronous labels.

In order to further understand the pattern of results in Test trial 1, we obtained the number of infants in each condition who spent more than \(50 \%\) of looking time on the novel object. This confirmed that infants in the Silent and Asynchronous Label condition were mostly successful at learning the category (Silent: \(N=20, p=.06\), two-tailed binomial test; Asynchronous label: \(N=22, p<.01\) ), whereas the number of successful infants was at chance level in the Synchronous Label condition ( \(N=16, p>.7\) ).

Infants' failure to recognise the out-of-category stimulus on Test 1 as novel in the Synchronous condition suggests a detrimental impact of the synchronous label on learning: it seems as though infants in this condition have not encoded the category equally well as infants in the other conditions. While this is in line with the hypothesis that synchronous labels impose greater processing load and therefore visual stimuli may be processed in less detail, it is possible to achieve a more fine-grained insight into infants performance at test. The out-of-category stimulus in Test 1 was designed to be novel owing to the presence of a different type of leaf its shell part, by comparison, is relatively consistent with the familiarisation category. Examining infants' looking patterns with regard to the two object parts and corresponding parts in the within-category object should therefore provide more information as to how infants process the object.

Figure 5: Looking proportions for individual object parts during Test 1: (a) Leaves belonging to out-of-category object (OOCO), here the "novel" part, and within-category object (WCO); (b) Shells belonging to OOCO and WCO. The inset shows an example test display with both objects. * indicates a statistically significant difference, \(\left({ }^{*}\right)\) indicates a trend.

Part-based looking at test Figure 5 (a) shows looking proportions directed at the leaves belonging to the two ob-
jects in Test 1, i.e. out-of-category leaf and within-category leaf, for every condition. All infants in fact had a clear preference for the novel leaf in comparison to the familiar leaf, even those in the Synchronous Label condition (paired t-test: \(t(28)=5.157, p<.001\), two-tailed). In contrast to what the standard analysis of global looking indicates, infants in the Synchronous Label condition as a group did not fail to encode the distributional properties of the "leaf", as they did not fail to perceive the novel leaf as unfamiliar. In fact, the only difference between the looking patterns across conditions is a trend for the "familiar shell" to be looked at more in comparison to the "novel shell" (illustrated in Figure 5 (b) ) in the Synchronous condition ( \(t(28)=1.76, p=.09\), paired t-test, 2-tailed) - which does not exist in the other conditions.

\section*{Discussion}

We familiarised infants with a novel object category, either in silence (Silent condition) or with novel labels. Labels were either presented one second after image onset (Asynchronous Label condition) or simultaneously with image onset (Synchronous Label condition). Global preferential looking results on three subsequent test trials indicated that infants in the Silent and Asynchronous Label conditions were highly successful at learning the target category, exhibiting novelty preference on all test trials. Infants in the Synchronous Label condition, however, did not exhibit novelty preference until the second test trial, pointing to a disruptive role of synchronous labels. Detailed looking patterns indicated, however, that infants in the Synchronous Label condition still preferred the novel leaf within the out-of-category object over the familiar leaf in the consistent test object.

While our present analysis of part-based looking during familiarisation did not reveal an effect of labeling, future analyses will focus on more fine-grained measures of looking (such as the time course of processing within a trial) in order to establish a link between individual infants' gaze patterns during familiarisation and their performance on test.

Preferential looking on the test trials shows that both infants in the Silent and the Asynchronous Label condition learned the category and showed novelty preference on Test 1 and 2 , where either the highly variable or the less variable object parts were replaced. This indicates that they successfully encoded the feature distribution of both parts. By contrast, infants in the Synchronous condition did not exhibit novelty preference until Test Trial 2. Using the established measure of object-based novelty preference as a marker of successful category formation this appears to indicate that learning was attenuated in comparison to silence by the presence of the label at the start of the trial. However, analysing infants' looking patterns at the level of individual object parts revealed that infants in the Synchronous condition did appear to be sensitive to the replacement of the leaf part, even though they spent more time inspecting the within-category object compared to
the other groups. In addition, on the subsequent test trial, in which the highly variable shell part was replaced by a novel type of shell, even infants in the Synchronous Label condition exhibited significant preference for the novel object. Taken together these data imply that rather than signifying a failure to learn, the looking patterns reflect a delay in the progression to novelty preference, or a lingering familiarity preference (Hunter \& Ames, 1988). This finding is consistent with the hypothesis that synchronous labelling increases cognitive load, but it is inconsistent with the hypothesis that visual processing as such is compromised as a result. Infants hearing synchronous labels during familiarisation have learned about the category in question - but they have a tendency to prefer looking at familiar elements.

This finding has implications for the interpretation of studies investigating the impact of labelling on categorisation. First of all, a decrease in novelty preference scores at the object level does not necessarily imply a decrease in visual learning, but can potentially be explained by changes in the speed in which the shift from familiarity to novelty preference is obtained. Null preferences therefore have to be interpreted with caution, specifically when comparing conditions that inherently differ in terms of cognitive load, such as a silent condition vs. one that includes auditory stimuli.

Secondly, this result highlights the role of timing in infants' early learning: even if it is not the categorisation success per se that has been compromised due to the synchrony of the label, a lingering familiarity preference still indicates greater difficulty processing the stimuli. This could potentially play a role in reconciling previous contradictory findings regarding the impact of labelling on categorisation. Most studies cited above (e.g. Fulkerson \& Waxman, 2007; Ferry et al., 2010; Plunkett et al., 2008; Althaus \& Westermann, in prep.) used a delayed label onset similar to our Asynchronous label condition, but Robinson and Sloutsky (2007), who found auditory overshadowing in the presence of labels, presented labels at picture onset. Further research will be necessary in order to determine whether the timing of the label can indeed explain the discrepancies between the findings.

Finally, the fact that infants can deal with asynchronous labels and may even benefit from them, whereas synchronous presentation seems to cause problems with cognitive load, is an important cue to how words and images are processed. Clearly stimuli are processed on-line, rather than stored in short term memory and processed separately and independently of their presentation time. While, in the context of cross-modal processing, synchrony is often claimed to be beneficial at least for young infants (Gogate et al., 2003), the increased load due to synchronous presentation here appears to slow down learning. The actual processing load of any coupling of visual and auditory stimuli is also dependent on the visual and auditory complexity or novelty. However, the fact remains that the likelihood of a label in real life occurring at the same time as an object comes into view is rather small. In terms of learning, this may be an ecological advantage rather
than a shortcoming. Perhaps having the opportunity to process visual and auditory information sequentially allows the learning of more complex visual structures. Specifically, the grouping of similar (but not identical) items into categories, for which more abstract visual processing may be needed than just for recognition of individual objects, could be facilitated in this way. Further research is needed in order to shed light on the relationship between exact time course of word-object integration and the ecological circumstances the auditory and visual signals occur in.

\begin{abstract}
When identifying basic-level categories (e.g., airplane, cow), typically developing (TD) children commonly use the overall shape of objects as basis for their judgments. This so-called shape bias is tied to the size of a child's vocabulary and as such might be a way of adaptively organizing an evergrowing vocabulary. The current study looks at whether the same is true for children with autism spectrum disorder (ASD). A group of participants with ASD and TD controls were asked to categorize objects that differed in the amount of item detail. Results show that vocabulary size was related to success in categorizing objects for TD participants, but not for ASD participants. We discuss the degree to which a link between shape bias and vocabulary size in ASD children may be an indication of differentiated patterns of adaptation.
\end{abstract}

Keywords: categorization; language development; autism
The overall shape of items is important when it comes to learning the words of basic-level categories. Whether we consider a dog, a car, an airplane, or a cake, the most salient difference among these items is their overall shape. Indeed, typically developing (TD) children show a pronounced bias toward the overall shape of objects (e.g., Diesendruck \& Bloom, 2003). For example, when children are asked to group novel objects, they overwhelmingly group objects based on their overall shape rather than other features (e.g., texture, color etc.; Samuelson \& Smith, 2005). The global feature of overall shape supersedes details.

While the "shape bias" has been documented repeatedly, it was found only recently that this bias is linked to the size
of a child's vocabulary (Pereira \& Smith, 2009). In Pereira \& Smith (2009), participants were TD toddlers with varying vocabulary sizes. They participated in multiple trials of a task in which they were asked to decide which of three toy objects (e.g., a car, a plane, a cake) matched the label offered by the experimenter (e.g., "show me the car"). Importantly, the degree of detail of the presented objects differed as a function of trial type. In some trials, objects were highly detailed, providing information about color and fine-grain shape. In others trials color was omitted, leaving details only about the fine-grain shape. And finally, in the third trial type, the objects were mere shape abstractions, missing both color and fine-grain shape. Results indicated that a child's productive count noun vocabulary (as compared to receptive vocabulary or general vocabulary) had a significant effect on performance. While children could categorize the detailed objects equally well, only children with larger count-noun vocabularies could identify the objects represented as shape abstractions.

In a similar vein, research has demonstrated that TD children with small vocabularies benefit from teaching props that focus their attention to the overall shape of items (Son, Smith \& Goldstone, 2008). Son and colleagues (2008) taught children the names of new objects that either had large amount of detail (e.g., texture, color, fine-grain shape) or were mere shape abstractions. In this latter case, shape abstractions approximated the overall shapes of the objects. Results show that training with shape abstractions yielded
better performance later identifying detailed objects from the same category than the training with detailed objects. Focusing children's attention on the overall shape of objects by removing irrelevant information promoted better learning. The ability to see gist, Gestalts, and global features appears integral to how TD children learn, categorize, and identify objects.

\section*{Detail Focus in ASD}

Compared to their TD peers, children with ASD have a tendency to focus on specific details. This may include fixation with the parts of objects (e.g., the wheels of a toy car) or having very limited and particular interests (e.g., former Secretaries of the Interior). Indeed, these types of detail orientation are included in the diagnostic criteria for ASD (American Psychiatric Association, 2000). Theorists have argued that the focus on detail may stem from what they describe as "weak central coherence" (WCC), or a decreased push toward Gestalts (e.g., Happé \& Frith, 2006; Happé \& Booth, 2008). This account of ASD does not postulate that children with ASD are incapable of processing global information, but rather that they tend to gravitate toward details. That is, when absolutely pressed, children with ASD are able to see Gestalts, but all things equal, will focus on detail.
The best example of this difference in focus was established with the classical Navon task, a task in which stimuli consist of many small letters configured in the arrangement of a large letter (cf., Navon, 1977). For TD participants, results show a distinct interference of large letters on the perception of small letters, both in children (Plaisted, Swettenham, \& Rees, 1999) and in adults (e.g., Navon, 1977). In particular, when participants are asked to focus on small letters, reaction time is longer for trials in which large and small letters differ than on trials in which large and small letters match. This global interference is indetectable in participants with ASD: They perform equally fast in both letter-mismatch trials and letter-match trials, in both cases with high accuracy (e.g., Plaisted et al., 1999).

Another example of weak central coherences in ASD comes from face perception tasks. The identity of a face is defined not only by its individual parts (e.g., nose, eyes, mouth), but also by the holistic configuration of these parts, something that appears to be disrupted when faces are presented upside down. For TD children, recognition accuracy decreases when faces are presented upside down, compared to trials in which faces are presented upright (Mondloch, Le Grand, \& Maurer, 2002). In contrast, children with ASD do not perform differently as a function of face orientation (e.g., Tantam, Monaghan, Nicholson, \& Stirling, 1989). Along the same lines, participants with ASD could classify faces better when local rather than global features were exaggerated (through the use of a high-pass vs. low-pass filter; Deruelle, Rondan, Salle-Collemiche,

Bastard-Rosset, \& Da Fonséca, 2008). The inverse pattern of results was obtained for TD children.

Applied to language learning, children with ASD do not show evidence of the same shape bias found in TD children (Tek, Jaffery, Fein, \& Naigles, 2008). While TD children demonstrated movement toward categorizing objects by global shape, ASD children did not. Compared to their TD peers, children with ASD also often have difficulty communicating, frequently displaying atypical language development (American Psychiatric Association, 2000). However, it is not clear whether the connection seen between vocabulary size and object categorization style exists in ASD as it does in TD. The current study aims to explore this explicitly, potentially providing evidence for differentiated patterns of adaptive mental functioning.

\section*{Rationale for the Current Study}

Very little research exists exploring how children with ASD categorize typical objects and what role shape might play. For TD children, the development of a bias toward categorizing objects based on shape may relate to the emergence of an overall tendency to focus on Gestalts, which may have an adaptive function. Compared to TD children, children with ASD tend to focus on details and do not show a natural shape bias. This may indicate an atypical pattern of adaptive functioning. To begin exploring this line of research, the current study aims to compare TD children and children with ASD who possess similar productive count-noun vocabularies on a task in which they are asked to identify objects that afford various degrees of detail.

\section*{Method}

\section*{Participants}

Seventy TD children (39 boys and 31 girls) were recruited from Cincinnati area schools and a local children's museum Ages ranged from 14-29 months ( \(M=20.78, S D=3.67\) ). Twenty-five children with ASD (22 boys and 3 girls) were recruited from Cincinnati area treatment centers and special needs schools. Their ages ranged from 2 years, 9 months -17 years, 5 months ( \(M=5\) years, 11 months; \(S D=3\) years, 7 months) Diagnoses of ASD were confirmed through contacting their pediatricians or therapists after written consent was obtained from their guardians.

\section*{Language Measure}

To assess each child's vocabulary, parents were asked to fill out the MacAurthur-Bates Communicative Development Inventories (MCDI; Bates, Dale \& Thal, 1995), a survey for parents that is widely used in the language development literature. Parental report of language abilities has been demonstrated to be a valid measure of both TD and ASD language abilities (Luyster, Lopez \& Lord, 2007; Tomasello, 1994). Parents completed the entire survey, but for the purposes of the current study, only the sum of items representing count nouns each child could understand and
say were used for comparison and analysis. It was a child's productive count noun vocabulary that Pereira and Smith (2009) tied to his or her ability to categorize objects based on global features.

\section*{Materials}

Stimuli were constructed to represent 12 noun categories commonly known by young children. These categories were: horse, cow, pig, fish, bird, butterfly, turtle, car, airplane, cake, shoe, and hamburger. Categories were represented by three objects, each from a different condition based on how much information they afforded the child.

The first object for each category, referred to as the detailed object, consisted of a toy or model purchased from toy stores. It contained detailed color, texture, and shape information (see Figure 1A). The second object, referred to as the rich-shape object, was constructed using a duplicate of the detailed object covered with black modeling clay. This clay served to remove the color and textural information while maintaining detailed shape (see Figure 1B). The object from the third condition, referred to as the shape abstraction, was made of Styrofoam. It was designed to represent the overall shape of the object category without providing any detailed information (see Figure 1C). Detailed objects served to confirm that children were able to identify the object categories. Shape abstractions, in contrast, provided information about whether children were able to identify global abstractions of objects. The intermediate, rich-shape condition served to help illuminate potential trends in identification abilities.

Figure 1: Examples of (A) a detailed turtle, (B) a rich-shape turtle, and (C) a shape abstraction turtle.

\section*{Procedure}

The procedure for the current study was adapted from Pereira and Smith (2009). To begin, there were four practice trials, carried out on a laptop computer, designed to acclimate the child to the researcher and, for lower functioning children, to ensure that they were able to follow directions. During each practice trial, the researcher showed the child two photographs of easily discriminable, common nouns (e.g., dog, bunny, train, and kitty). The experimenter
labeled the object on one of the photos and asked the child to point to it. Performance did not affect the child's eligibility to participate in the rest of the study.

For the main task, the experimenter told participants that they were going to play with some toys from a toy box. The experimenter then placed a red wooden tray ( 60 cm by 30 cm ) in front of the child so that it was out of reach. This served as a platform for stimuli and to help children focus their attention on the testing space. For each test trial, the experimenter placed three detailed objects, three rich-shape objects, or three shape abstractions on the board (see Figure 2 for an example). One object served as a target, the other two as distractors. The experimenter then asked for the target (e.g., "Give me horse."), and pushed the tray within reaching distance of the child. Clear pointing or picking up the target were considered correct responses. Regardless of whether or not the child was correct, neutral feedback was given. The experimenter recorded responses on a laptop computer. This procedure was repeated for 12 testing trials. Children never saw multiple versions of an object category. For example, if presented with a shape distraction airplane, children would not see the detailed airplane. Types of object were balanced across participants.

Figure 2: Example test trial showing a fish, car and pig in the shape abstraction condition.

\section*{Results}

For both TD children and children with ASD, productive count noun vocabularies ranged from 0-199 words (TD \(M=\) 78.17, \(S D=66.5\); ASD \(M=79.59, S D=66.91\) ). Similar to previous work by Smith (2003), participants from both the TD and ASD groups were divided into subgroups based on their productive count noun vocabulary sizes: Children whose productive count-noun vocabulary was between 0 and 100 words were classified as being in the LowVocabulary group (the largest vocabulary in this group was 92), and children with a vocabulary between 100 and 200 nouns were classified as being in the High-Vocabulary groups (the smallest vocabulary in this group was 102). The vocabulary groups, as well as associated descriptive statistics are shown in Table 1. Because analyses conducted utilizing divisions based on mean and median vocabularies yielded similar results, the above method was utilized to maintain continuity with previous work.

Table 1: Descriptives of TD and ASD Participants, Mean Age and Number of Count-Nouns in Productive Vocabulary Separated by 2 Vocabulary Groups.
\begin{tabular}{ccc}
\hline & \multicolumn{2}{c}{ Vocabulary Group } \\
& \(<100\) nouns & \(>100\) nouns \\

\section*{Categorization Performance: TD Sample}

The average performance on detailed objects, rich-shape objects, and shape abstraction for TD children in the Lowand High-Vocabulary groups are shown in Figure 3.

A 2 X 3 (Vocabulary Group X Object Condition) mixed measures analysis revealed a significant effect of Vocabulary Group, \(F(1,68)=33.31, p<.001\), with better performance for the High- than the Low-Vocabulary Group \(\left(M_{H}=88.46 \%, S D_{H}=34.12 \% ; M_{L}=60.93 \%, S D_{L}=\right.\) 27.25\%). There was also a significant effect of Object Condition, \(F(1,68)=48.50, p<.001\), with highest performance for detailed objects \((M=80.71 \%, S D=\) 22.99\%), followed by rich-shape objects ( \(M=68.57 \%, S D\) \(=27.15 \%\) ), and followed by shape abstractions ( \(M=\) \(58.21 \%, S D=27.16 \%\) ). While the interaction was not significant, \(p>.90\), TD children in the Low-Vocabulary group performed better on detailed object trials than richshape trials, \(t(48)=2.07, p<.05\), and better on rich-shape trials than shape abstraction trials, \(t(48)=2.08, p<.05\). In contrast, performance for TD children in the HighVocabulary group did not differ between rich-shape and shape abstraction trials, \(t(48)=1.31\) (though there was a difference between detailed object and rich-shape trials, \(t(48)=2.07, p<.05)\).

\section*{Categorization Performance: ASD Sample}

The average performance of children with ASD from the Low- and High-Vocabulary groups across the detailed, richshape, and shape abstraction trials is illustrated in Figure 4.

As was done with the TD sample, a \(2 \times 3\) (Vocabulary Group X Object Condition) mixed measures analysis was conducted. Surprisingly, there was only a marginal effect of Vocabulary Group, \(F(1,23)=3.18, p=.063\left(M_{H}=89.39 \%\right.\), \(\left.S D_{H}=25.79 \% ; M_{L}=72.02 \%, S D_{L}=31.33 \%\right)\). However, as was found with TD children, there was a significant effect of Object Condition, \(F(1,23)=7.07, p<.02\). Across vocabulary groups, performance was best for detailed objects ( \(M=88.00 \%, S D=22.96 \%\) ), second best for rich-
shape objects ( \(M=78.00 \%, S D=32.33 \%\) ), and lowest for shape abstractions ( \(M=73.00 \%, S D=32.21 \%\) ).
Importantly, the interaction was not significant, \(p>.50\). Looking at simple effects within vocabulary groups, performance did not differ between detailed object and richshape trials, \(p \mathrm{~s}>.30\). There was also no difference between rich-shape and shape abstraction trials, \(p \mathrm{~s}>.30\).

Figure 3: Mean proportion correct responses across object conditions for TD children as a function of vocabulary size.

\section*{Categorization Performance: Comparing Samples}

Categorization performance was compared between diagnostic groups for both the Low- and High-Vocabulary groups. For children in the Low-Vocabulary groups, performance did not differ between children with ASD and TD children on detailed object and rich-shape trials, \(p s\) > .37. However, children with ASD from the Low-Vocabulary group performed significantly better than TD children with similar vocabularies on shape abstraction trials, \(t(57)=2.43\), \(p<.02\). Children with ASD from the High-Vocabulary group outperformed TD children on detailed object trials, \(t(24)=2.14, p<.05\), but differences were not significant for rich-shape or shape abstraction trials, \(p s>.33\).

Figure 4: Mean proportion correct responses across object conditions for children with ASD as a function of vocabulary size.

\section*{Discussion}

Results provide evidence for a difference in the relation between count-noun vocabulary sizes and categorization abilities in TD children versus children with ASD. In particular, while there was a characteristic difference between TD children in the Low- versus High- Vocabulary group, this difference disappeared for ASD Children. Note that the TD finding is not as robust as previously found (e.g., Pereira \& Smith, 2009; Smith, 2003). Nevertheless, TD children in the High-Vocabulary group performed equally well in the rich-shape and shape abstraction conditions, whereas TD children in the Low-Vocabulary group performed differently across all three object conditions.

In contrast, children with ASD from both vocabulary groups demonstrated similar performance patterns across conditions. When performance patterns between diagnostic groups were compared directly, children with ASD from the Low-Vocabulary group performed better than their TD peers on shape abstraction trials, and equally well in other trials. Performance across the rich-shape and shape abstraction trial types were equivocal for TD children and children with ASD from the High-Vocabulary groups.

Before interpreting how the current results relate to global processing and contextual changes, the current study makes several assumptions. The first assumption is that vocabulary size is a contextual factor. The second assumption is that categorization of shape abstraction objects translates to the ability to process Gestalt information. The third assumption is that Gestalt processing is an adaptive function that arises when contexts make tasks difficult (in this case, as vocabulary size increases). Under these assumptions, the fact that children with ASD did not demonstrate stratified performance seen in TD children may suggest that they do not adapt to contextual changes in the same manner. The generally high performance for children with ASD across object conditions regardless of vocabulary size is in line with the argument that the focus on detail commonly seen in ASD does not equate to an inability to process global information, but rather a preference for local features.

Could alternate claims explain the findings? Most prominent is the issue of how vocabulary was measured. The MCDI only allows parents to indicate words that they believe their child does not understand, words that they understand, but cannot say, and words that they understand and say. Many children with ASD use alternate forms of communication, such as sign language or exchange cards. Thus, the MCDI may not have been an accurate measure of each child's true productive count-noun vocabulary. Furthermore, the MCDI only lists words that TD children tend to learn in the first few years of life. Children with ASD who learn language later in life may not learn the same first words. Thus, it is possible that a greater proportion of their produced words were not captured by this measure. Given the issues with the MCDI, it is possible that a more
detailed assessment of language, including receptive vocabulary, could influence results.

Other issues that could affect the interpretation of results include the current sample size of children with ASD and the methods used to confirm diagnoses. Only 25 children with ASD were included in the final sample. The current study also based diagnosis on physician confirmation, rather than using standardized measures, such as the Autism Diagnostic Observation Schedule (ADOS; Lord et al., 2000). Though best diagnostic practice suggests the use of standardized measures (Ozonoff, Goodlin-Jones, \& Solomon, 2005), the individual practices of clinicians may vary.

Nevertheless, even given the alternate explanations for the results of this study, there is evidence from previous research which supports the current claims. First, previous work that explored how children with ASD see Gestalts demonstrated that they have the ability to identify both global and local features (e.g., Ozonof et al., 1994; Plaisted et al., 1999). Second, there is an indication that the shape bias in children with ASD is different from the shape bias of TD children (Tek et al., 2008). Combined, these studies suggest that there is also a weakened connection between global processing and vocabulary. In the current study, children with ASD tended to perform well on shape abstraction objects regardless of their vocabulary size, indicating that they were, in general, able to categorize objects based on their overall shape.

Research involving children with language delays, socalled late talkers, may also provide evidence for current claims. In similar object categorization tasks, they demonstrate performance patterns are similar to both TD children and children with ASD. Like TD children, late talkers show a developmental trend in their ability to categorize objects by shape (Jones \& Smith, 2005). Specifically, Jones and Smith (2005) found that neither a late talker's receptive count-noun vocabulary nor age was significantly related to their ability to categorize objects based on overall shape. Productive count-noun vocabulary size, instead, was related. However, like children with ASD, they tend to not show an innate tendency to categorize objects by shape, and thus have an atypical shape bias (Jones, 2003). Though this provides evidence that in another clinical group, productive count-noun vocabulary size relates to categorization abilities, it does not address the issue of the accuracy of the MCDI for children with ASD.

The current study is a preliminary step towards better understanding the relationship between vocabulary size and object categorization style in children with ASD. It appears that though they may not have a bias toward global features, even those with poor verbal language skills have the capacity to categorize objects based on overall shape. This may have important clinical implications.

\title{
Gender and Sex: The Experiential Basis of Grammar
}

\author{
Elena Andonova (eandonova@nbu.bg) \\ Department of Cognitive Science and Psychology, 21 Montevideo Street \\ Sofia, 1618 Bulgaria
}

\begin{abstract}
There have been contradictory reports of sex differences in language processing. A novel approach is adopted here which explores the experiential basis of such differences. Two studies examine the auditory processing of grammatical gender in Bulgarian in a gender decision (gender monitoring) task and a cued shadowing (word repetition) task. Reaction times in both experiments reveal significant two-way interactions between the grammatical gender of words (masculine vs. feminine) and the sex of the voice (male vs. female). The sex of participants in the gender decision task also interacted with word gender in terms of decision accuracy. Women were relatively more accurate on their "own reference" word gender (feminine) and less accurate on masculine gender words. A two-way interaction between word gender and participant sex on response latencies in the cued shadowing task supports the view that these effects are not strategic but have a highly automatic nature instead. Findings are interpreted in terms of individual differences in the experience of grammatical gender in such gender-marking languages.
\end{abstract}

Keywords: grammatical gender, participant sex/gender, individual differences.

\section*{Introduction}

Over the past decades a number of studies have claimed to reveal sex differences in language performance, language ability and underlying brain cortical areas and hormonal levels. For example, Shaywitz, Shaywitz, Pugh, Constable, Skudlarski, Fulbright, et al. (1995) have suggested differences in language lateralization, Weiss, Kemmler, Deisenhammer, Fleischhacker, \& Delazer (2003) in verbal fluency tasks, Kramer, Kaplan, Delis, O’Donnell, \& Prifitera (1997) in verbal learning, etc., and theoretical accounts of such differences may attempt to explain them in terms of evolutionary origins and advantages and/or hormone level variation. Although sex differences may disappear in later childhood, large-scale studies have found robust evidence for the effects of gender on early language development, including vocabulary comprehension and production using the MacArthur Bates Communicative Development Inventories (Fenson, Dale, Reznick, Bates, Thal, \& Pethick, 1994). On the other hand, in a critical review of the research presented in numerous studies, Wallentin (2009) concludes that there is not much clear and uncontroversial evidence for sex differences in language
processing with the exception of the early language development advantage for girls and that although certain language-related deficits exhibit clear sex differences, such as stuttering, dyslexia, and autism whose occurrence is much higher in males, a causal link and a good theory of why and how such differences may arise are still lacking.
In this paper, an entirely different aspect of human experience with language is explored, which may lead to sex differences in language processing, more specifically grammar. Even if grammatical categories are learned and used by all typically developing speakers of a language, both men and women, the specific individual experiences with these categories may differ. The use of grammatical gender is a case in point here. Individuals vary on the dimension of sex and in at least some languages this individual characteristic is important in selecting the appropriate grammatical gender form used in reference to that individual. In the relatively poor morphology of the English language, this variation is observed in very few forms such as the personal pronouns in the \(3^{\text {rd }}\) person, Singular (he vs. she), in the richer morphology of the German language it is found in noun phrases referring to both animate and inanimate entities encoded in pronouns and articles (der, die, das), and in Slavic languages even further on word categories such as adjectives, verb forms, numerals, etc. Grammatical gender may furthermore be not as arbitrary as it is habitually seen. In a study of gender processing and lexical access in Bulgarian, Andonova, D'Amico, Devescovi, \& Bates (2004) discovered a significant contribution of semantic gender to processing in Bulgarian in contrast with previous findings for Italian. Particularly interesting, however, was another finding of this research, namely, an interaction between sex of the subject and noun gender, reflecting a bias toward one's own grammatical gender "counterpart" (especially for females) in Bulgarian. Triggered by this novel finding, a reanalysis of data from a prior study in Italian showed a similar interaction. How could such differences emerge? In contrast with biological and/or cultural explanations, we offer here an experiential account.

Both men and women produce gender-marked words (nouns, adjectives, verbs, etc.) in Bulgarian in large quantities on a daily basis, and so both sexes have a largely equivalent experience in terms of frequency of usage of the three genders. However, a woman's individual experience with gender-marked forms matching her own sex, i.e., Feminine gender words, would be different in some ways from the experience of a man with the same feminine gender forms, all else being equal. The difference is both in
the quantity and quality of the experience. Women speaking Slavic and Romance languages (for example) would produce a higher number of Feminine gender forms than men given that they use such forms in situations of selfreference, in which men would have to use Masculine gender forms, and vice versa. For example, a Bulgarian woman may express her feeling of fatigue by saying уморена съм (Eng., I am tired_Fem), an Italian woman would say sono stanca (Eng., I am tired_Fem) while in Italian, a man would have to admit sono stanco (Eng., I am tired_Masc). The individual experience women and men have with gender-marking forms is not only different in quantity (frequency of usage) but also in the degree to which there is personal relevance to the individual (in selfreference). Thus, a lifetime of using gender marked forms in a sex-specific way would lead to the accumulation to differences in the sensitivity to such forms in the two sexes.

\section*{Experiment 1}

This first experiment had the following objectives. First, it aimed at testing for an interaction between participant sex and word gender in the gender decision task and extending previous somewhat limited findings with Bulgarian and Italian speakers performing a gender monitoring (decision) task on nouns in their native language (Andonova et al., 2004).

Second, every noun typically has only one gender, i.e., Masculine, Feminine or Neuter, for example, стол (Eng., chair) is a Masculine noun, маса (Eng., table) is a Feminine noun, and куче (Eng., dog) is a Neuter noun, that is, grammatical gender is invariant. However, adjectives and some verb forms in Bulgarian have all three gender forms, for example, бавен, бавна, бавно are the translation equivalents of the English word slow but in three different forms, one for each of the three genders (slow_Masc, slow_Fem, slow_Neut). The second research objective was to test whether a participant sex by grammatical gender interaction would also emerge in the processing of adjectives and verb forms that can vary across gender categories. Note that in Bulgarian, there is typically a regular and transparent mapping between word form endings and the category of gender. This applies to nouns as well as the adjectives and verb forms included in the stimuli materials for this experiment.

The third objective was to examine the possibility of an interaction between grammatical gender and speaker sex in addition to participant sex. The motivation for this follows a somewhat similar rationale as that concerning the interaction of participant sex and grammatical gender and its possible explanation on the basis of the difference in the quantity and kind of experience the two sexes have with gender-marking word forms, as elaborated in the examples above. Speakers of gender-marking languages such as Slavic and Romance languages not only produce owngender matching word forms more frequently but they also
hear such forms more frequently in verbal interactions, viz., in situations where their interlocutor refers to them, for example, asks them whether they are tired, etc. (Note though later - that it is confounded without situational context - speaker talking about \(1^{\text {st }}\) or \(2^{\text {nd }}\) person etc.) Therefore, one might expect to find such an interaction between speaker sex (the voice for the auditory stimuli) and the grammatical gender of the words. This possibility was tested by presenting stimuli in the auditory modality instead of in writing and recording stimuli in two voices - male and female - to be used as an experimental variable.

\section*{Method}

The design of the experiment included Participant Sex (men vs. women), Grammatical Gender of the word (Masculine vs. Feminine) and Voice Gender (male vs. female voice) as independent variables and mean percent errors and response latencies as the dependent variables.

Participants 40 participants ( 20 men and 20 women) took part in the experiment. They were university students within the 19-30 age range who were paid a modest amount for their participation. All were native speakers of Bulgarian.

Stimuli and Procedure The experimental stimuli consisted of 3 different gender forms each of 62 verbs and adjectives in Bulgarian presented in a different randomized order for each participant in the auditory modality by two speakers of Bulgarian, i.e., in two voices (a male and a female voice). Words of all three grammatical genders in Bulgarian were included in the list of stimuli in order to make the task more natural and the research objectives less obvious so that participants would not be tempted to follow a simple binary choice strategy. The analyses, however, focused on the two critical grammatical genders (Masculine and Feminine) in line with the research hypotheses.

Participants were tested individually in a sound proof booth and were asked to listen to stimuli one at a time and press one of three available buttons to indicate the grammatical gender of the word they have just heard (Masculine, Feminine, or Neuter). Accuracy and speed in completing the task were both emphasized in the experimental instruction.

Presentation of stimuli and registration of participants' responses were controlled by Psyscope and a button box. Before the experiment began, participants did four to six practice trials to familiarize themselves with the task and procedure. In addition, since gender in Bulgarian is a threemember grammatical category, and in order to avoid bias, participants were assigned randomly to one of six spatial configurations of the three buttons in the gender-monitoring task, i.e., m-f-n, m-n-f, f-n-m, f-m-n, n-m-f, or n-f-m.

The 186 word forms were recorded by a female and a male speaker of Bulgarian in a neutral intonation with a falling tone. They were digitized using the Macintosh SoundEdit system, and were placed in a sound file within
the PsyScope experiment preparation package developed by Cohen, MacWhinney, Flatt, and Provost (1993) at Carnegie Mellon University. For each item, reaction times (RT) were measured from the offset of the stimulus word to the participant's response (the button press in the gender decision task).

\section*{Results}

All participants had a mean accuracy higher than \(90 \%\) and a mean RT below 900 msec . RTs for trials on which participants made a decision error were dropped from further analysis. The following outlier procedure was used. The means (M) and standard deviations (SDs) for each participant were computed, and all RTs less than three SDs below the mean of the participant or greater than three SDs above the mean were considered outliers. This resulted in the rejection of \(1.58 \%\) of all RT data. Here first the results of analyses run on participant means will be presented.

The data were analyzed in two 2 (Participant Sex: men vs. women) x 2 (Grammatical Gender of the word: masculine vs. feminine) x 2 (Voice: male vs. female) repeated measures ANOVAs on participant means of mean percent gender decision error and on mean response latencies measured from the end of presentation of the auditory stimuli with participant sex as a between-participants variable and word gender and voice as within-participant variables.

Accuracy In the analysis of the mean percent gender decision error, a main effect of words' grammatical gender was found, \(F(1,38)=6.77, p=.013, \eta_{p}{ }^{2}=.151\). Participants overall \((\mathrm{n}=40)\) had a lower error rate in their gender decision when responding to Feminine gender words (Mean \(=0.89 \%\), SD \(=9.38 \%\) ) than Masculine gender words (Mean \(=1.81 \%, \mathrm{SD}=13.34 \%\) ). There were no main effects of participant sex or voice. There was, however, a statistically significant two-way interaction between participant sex and word gender, \(F(2,38)=6.20, p=.017\), \(\eta_{p}{ }^{2}=.140\). Whereas men's error rate did not differ on the two grammatical genders ( \(M=1.29 \%\) and \(\mathrm{M}=1.25 \%\) for masculine and feminine words, respectively), women produced more inaccurate gender responses on words of masculine grammatical gender than of feminine grammatical gender ( \(\mathrm{M}=2.34 \%\) for masculine and \(\mathrm{M}=\) \(0.52 \%\) for feminine words). This interaction is illustrated in Figure 1. There were no further interactions.

Figure 1: Mean percent error of male and female participants in the gender decision task for words of Masculine and Feminine gender.

Response Times In the analysis of the mean reaction times, a main effect of words' grammatical gender was found again, \(F(1,38)=23.31, \mathrm{p}<.001, \eta_{p}{ }^{2}=.380\). Participants overall responded slower to words of masculine grammatical gender ( \(\mathrm{M}=576 \mathrm{~ms}, \mathrm{SD}=218 \mathrm{~ms}\) ) than to words of feminine grammatical gender ( \(M=525 \mathrm{~ms}\), \(\mathrm{SD}=\) 194 ms ). In addition, there was a main effect of participant sex, \(F(1,38)=6.26, p=.017, \eta_{p}^{2}=.141\). On average, women's decisions took longer ( \(\mathrm{M}=582 \mathrm{~ms}, \mathrm{SD}=201 \mathrm{~ms}\) ) than men's \((\mathrm{M}=512 \mathrm{~ms}, \mathrm{SD}=208 \mathrm{~ms})\). However, there was no participant sex by grammatical gender interaction on the mean reaction times.

Finally, in the analysis of reaction times, a main effect of voice emerged, \(\mathrm{F}(1,38)=125.33, \mathrm{p}<.001, \eta_{\mathrm{p}}{ }^{2}=.767\). Participants' decisions took longer for stimuli pronounced by the male voice ( \(\mathrm{M}=557 \mathrm{~ms}\), \(\mathrm{SD}=205 \mathrm{~ms}\) ) than by the female voice ( \(\mathrm{M}=536 \mathrm{~ms}\), \(\mathrm{SD}=209 \mathrm{~ms}\) ). This gender difference is likely due to acoustic characteristics of the voices such as baseline pitch, for example. More importantly, however, there was a significant two-way interaction between the independent variables of grammatical gender and voice, \(F(1,38)=36.22, \mathrm{p}<.001\), \(\eta_{\mathrm{p}}^{2}=.488\), such that responses to masculine gender words did not differ in latency with respect to the gender of the voice ( \(M=582 \mathrm{~ms}\) for male voice stimuli and \(M=570 \mathrm{~ms}\) for female voice stimuli) but, on the other hand, participants responded slower to the male voice pronouncing feminine gender words ( \(M=556 \mathrm{~ms}\) ) than to the female voice saying feminine gender words ( \(\mathrm{M}=493 \mathrm{~ms}\) ). This interaction is illustrated in Figure 2. There were no further interactions.

Figure 2: Mean response times in the gender decision task for words of Masculine and Feminine gender spoken by a male or a female voice. Note: RTs are measured from the offset of the auditory stimuli.

Analyses on Item Means A second set of analyses examined data patterns in item means. It yielded the same pattern of results as described above and will not be presented here in detail.

\section*{Discussion}

The data from Experiment 1 support the research hypothesis of an interaction between word gender and participant sex in the gender decision task. The results have shown that men and women respond in a different manner to the same stimuli in the Masculine and Feminine grammatical genders. The pattern of errors in this task is particularly revealing whereas men's gender decisions are equally accurate on both Masculine and Feminine gender words, women tend to make more errors on Masculine gender words than Feminine, a pattern that is in line with the expectation that after a lifetime of personal experience in a gender-marking language they have become sensitized to word forms that match their own gender in referential expressions. It remains to be studied further why the pattern is not mirrored clearly in the case of men and Masculine forms. One possibility is that their "own" referential gender overlaps with the unmarked, default member of the grammatical category while Feminine forms are also the marked member of the category and thus more salient generally but at this point it is hard to offer an explanation of sufficient specificity.

Secondly, a two-way interaction between word gender and voice/speaker sex on reaction times was also established. This is a novel and intriguing finding that deserves future investigation. Participants reached their gender decision faster when there was a match between the sex of the female voice and the grammatical gender of the words being heard. It appears that saliency of the feminine forms in combination with a matching 'speaker perspective' facilitated responses in this task.

\section*{Experiment 2}

The first experiment established the interaction of word gender decision times with speaker voice gender and the interaction of gender decision accuracy with the sex of participants. However, one might argue that these findings are task-specific. After all, participants were asked to reveal their linguistic competence by making a judgment on a clearly grammatical aspect of the stimuli. Although the participants in Experiment 1 performed the task with the kind of ease that shows them to be fully competent (low error rates) and highly efficient (low RTs) in making a gender decision, the question remains - would we find an interaction between word gender and each of the two extralinguistic variables of participant sex and speaker voice sex in a different task, especially one that is even more automatic and requires no conscious effort in everyday experience? One such highly automatic experimental task is cued shadowing in which participants listen to and repeat words as fast as they can. This was the task used in Experiment 2.

\section*{Method}

The design of the second experiment was exactly the same as the first experiment but this time the experimental task was cued shadowing. Participant sex (men vs. women) was a between-participant independent variable; voice (male vs. female) and word gender (Masculine vs. Feminine) were within-participant independent variables. No decision was required in this task and error rates were not of interest. The analyses were conducted on participant means and on item means of response times measured from voice onset registered by the Psyscope button box used as in Experiment 1.

Participants Another 40 participants (20 men and 20 women) took part in Experiment 2. They were university students within the 19-30 age range who were paid a modest amount for their participation. All were native speakers of Bulgarian.

Stimuli and Procedure The experimental stimuli consisted of two different gender forms each of 100 verbs and adjectives in Bulgarian presented in a different randomized order for each participant in the auditory modality by two speakers of Bulgarian, i.e., in two voices (a male and a female voice). As the cued shadowing task is a highly automatic and non-strategic one, there was no need to include neuter gender words to make the task more natural and the research objectives less obvious. Again, the analyses examined the two critical grammatical genders (Masculine and Feminine) in line with the research hypotheses.

Participants were tested individually in a sound proof booth and were asked to listen to stimuli one at a time and repeat each word. Accuracy and speed in completing the task were both emphasized in the experimental instruction.

Presentation of stimuli and registration of participants' responses were controlled by Psyscope and a button box. Before the experiment began, participants did four to six practice trials to familiarize themselves with the task and procedure.

The 200 word forms were recorded by a female and a male speaker of Bulgarian in a neutral intonation with a falling tone. They were digitized using the Macintosh SoundEdit system, and were placed in a sound file within the PsyScope experiment preparation package developed by Cohen, MacWhinney, Flatt, and Provost (1993) at Carnegie Mellon University. For each item, reaction times (RT) were measured from the offset of the stimulus word to the participant's response (voice onset as registered by the button box).

\section*{Results}

Hardly any errors were made by participants in this task except for fifty individual trials with false starts or where no response was registered by the button box. Data cleanup was accomplished in a two-step outlier procedure for the RTs of correct responses, following Balota, Yap, Cortese, Hutchison, Kessler, Loftis, et al. (2007). First, all negative response latencies, i.e., where voice onset preceded in time the end of the auditory stimulus, and all latencies longer than \(1,500 \mathrm{msec}\) were identified as outliers. Second, for the remaining RTs, the means and SDs were computed for each participant, and all RTs less than three SDs below the mean of the participant or greater than three SDs above the mean were considered outliers as well. This resulted in the rejection of \(1.87 \%\) of all reaction time data.

Here the results of the statistical analyses of participant means will be presented. The pattern of results from the analyses of the item means was the same and would be redundant to describe.

The data were analyzed in a 2 (Participant Sex: men vs. women) x 2 (Grammatical Gender of the word: masculine vs. feminine) x 2 (Voice: male vs. female) repeated measures ANOVAs on participant means of response latencies measured from the end of presentation of the auditory stimuli with participant sex as a betweenparticipants variable and word gender and voice as withinparticipant variables.

Response Times In the analysis of participants' mean reaction times, a main effect of words' grammatical gender was found again, \(\mathrm{F}(1,38)=93.68, \mathrm{p}<.001, \eta_{\mathrm{p}}{ }^{2}=.711\). Participants overall responded slower to words of masculine grammatical gender than to words of feminine grammatical gender. This result is consistent with the data pattern observed in the gender decision task. Since a decision was not involved in this task at all, however, the main effect of word gender in both experiments is likely due to the measurement of reaction times from the offset of the auditory stimuli.

There was no main effect of participant sex. In addition, a main effect of voice emerged, \(\mathrm{F}(1,38)=214.78, \mathrm{p}<.001\),
\(\eta_{\mathrm{p}}{ }^{2}=\).850. Participants' responses took longer for stimuli pronounced by the male voice than by the female voice. Again here, this gender difference is likely due to acoustic characteristics.

More importantly, however, there were two significant two-way interactions. One of them was an interaction between the independent variables of word gender and participant sex, revealing that women responded particularly fast to Feminine gender words, \(\mathrm{F}(2,38)=5.51, \mathrm{p}=.024\), \(\eta_{\mathrm{p}}{ }^{2}=.127\). This interaction is illustrated in Figure 3.

Figure 3: Mean response times by men and women in the cued shadowing task as a function of word gender. Note: RTs are measured from the offset of the auditory stimuli.

The second significant two-way interaction was between the independent variables of word gender and speaker voice, \(F(2,38)=59.33, \mathrm{p}<.001, \eta_{\mathrm{p}}^{2}=.610\). This interaction is illustrated in Figure 4. Participants responded to Feminine gender words particularly fast again when they were spoken by a female voice.

Figure 4: Mean response times in the cued shadowing task for words of Masculine and Feminine gender spoken by a male or a female voice. Note: RTs are measured from the offset of the auditory stimuli.

\section*{Discussion}

The results of experiment 2 mirror those of experiment 1 remarkably. Even though the two tasks were different in
their nature and task demands, participants' responses were strikingly similar in terms of speed of processing and the emergence of significant interactions between word gender as a grammatical feature and participant sex and speaker voice sex as extra-linguistic information sources.

\section*{Conclusion}

The studies reported here were guided by the research question whether the individual language experience of speakers may influence the way they process language online and offline, and how linguistic and extra-linguistic categories may interact as a result of this experience. In two studies with different language processing tasks and a total of 80 participants, the grammatical category of gender was found to interact with participant sex and with voice sex in the expected direction revealing the impact of individuals' usage of gender-marking forms throughout their lifetime on the speed and accuracy of gender decisions and on the efficiency of processing lexical items in a word repetition task.

It is worth pointing out here that these interaction effects were observed in the analyses of both participant means and item means and in both tasks, making them robust findings. The second task, word repetition, was particularly important in establishing the automatic, non-strategic nature of the effects, a finding that speaks in favor of extensive habitual use implicated in the emergence of these novel phenomena.

These findings have important implications of a methodological nature. Future studies of lexical processing in at least heavily gender-marking languages such as those from the Slavic and Romance language groups need to take into account the possibility of participant sex interactions with the grammatical category of gender, and implement the necessary control and counterbalancing mechanisms.

More importantly, however, the results from the two studies indicate the importance of studying individual differences in language processing and have further theoretical implications in line with the current growth of interest in embodiment and its experiential aspects and in alignment with our understanding of language and language usage being at least partially dependent on specific individual human experience instead of being an entirely arbitrary symbolic system without intrinsic or extrinsic motivation.

\begin{abstract}
Prominent theories of decision making, such as proportional difference model, priority heuristics, decision field theory and regret theory assume that people do not evaluate options independently of each other. Instead, these theories predict that people compare the options' outcomes with each other. Therefore the theories' predictions strongly depend on the association between outcomes. In the present work, we examine how the association between options can be best described. For options with two outcomes the standard correlation measure between option's outcomes does not provide a meaningful interpretation. Therefore, we propose the standardized covariance between options A and B , denoted as \(\sigma_{A B}^{*}\). We describe the properties and interpretation of this measurement and show its similarities and differences with the correlation measurement. Finally, we show how the predictions of different models of decision making vary depending on the value of the standardized covariance.
\end{abstract}

Keywords: decision making models; covariance; gambles; two-outcome; risky choice

\section*{Introduction}

Standard economic models of decision making like expected utility theory assume that people evaluate choice options independently of each other (Neumann \& Morgenstern, 1944). However, contrary to this basic independence assumption a vast amount of evidence has shown that people evaluate choice option depending on the set of alternative choice options (see Rieskamp, Busemeyer, \& Mellers, 2006 for more details).

For example, choice of between two health insurance offers is a choice between risky options with payouts depending on the occurence of an illness. An illness can occur with a certain probability that can be estimated based on teh patient's age and health history. When deciding between the two options, one would probably compare the insurance coverage in case of specific illnesses of both offers with each other, rather than first evaluate one offer and then another.

Many cognitive models of decision making assume that when people make choices between options they compare the options' outcomes with each other. For instance, the priority heuristics (Brandstätter, Giegerenzer, \& Hertwig, 2006) assumes that people first compare all options with respect to their minimum outcomes. If these outcomes do not allow to discriminate the options, the options are compared with respect to the probability of the minimum outcomes, and so forth. Regret theory (Loomes \& Sugden, 1982), proportional
difference model (González-Vallejo, 2002), and decision field theory (Busemeyer \& Townsend, 1993) are three other prominent models of decision making assuming that people compare options with respect to their outcomes. These comparisons are then accumulated to form an overall preference. Therefore the predictions of all these models depend on the associations between the outcomes of options.

How can these associations be best characterized? Using the covariance of the options' outcomes would be a sound solution, especially because many of the studies of decision making use monetary choices which are an analogy to investments. Indeed, in portfolio management covariance plays an important role for selection of assets (i.e. Pafka \& Kondor, 2003; Disatnik \& Benninga, 2007).

Also, many studies investigating decision making focus on comparing various models. In such case, the selection of the choice options, which are usually presented as gambles, is very important. As highlighted in the work on optimal experimental design, selecting gambles for discriminating between the models, is an essential issue that determines the effectiveness of the experiment (see Cavagnaro, Gonzalez, Myung, \& Pitt, 2013; Myung \& Pitt, 2009; Zhang \& Lee, 2010) The main problem with using covariance is that its value depends on the range of the outcomes' values which makes it hard to interpret.

As an alternative measurement one could use the correlation between the outcomes. However, a large part of the research is done with two-outcome choice problems (e.g. González-Vallejo, 2002; Birnbaum, 2008), for which correlation is either 1 or -1 (see Rodgers \& Nicewander, 1988), so that the correlation measurement does not provide a meaningful interpretation.

Therefore, we propose an alternative measurement, standardized covariance, as a measure of the strength of the association between the options' outcomes, which can be easily interpreted. In the following sections we will first explain how the standardized covariance is determined and how it should be understood. Next, we will present relations between the covariance, variances and expected value of twooutcome gambles, which will clarify the construction of the standardized covariance. Finally, we will show how decision making models make different predictions depending on the strength of the standardized covariance.

Table 1: Twelve examples of choice options with different standardized covariance. In each example, the top row indicates the probability of the occurrence of two outcomes. Two consecutive rows display the possible outcomes of Option A and Option B.
\begin{tabular}{|c|c|c|c|c|c|}
\hline \multicolumn{3}{|c|}{\(\sigma_{A B}^{*}=1\)} & \multicolumn{3}{|c|}{\(\sigma_{A B}^{*}=-1\)} \\

\hline A & 80 & 20 & A & 42 & 40 \\
\hline B & 50 & 40 & B & 80 & 6 \\
\hline
\end{tabular}

\section*{Standardized Covariance}

We denote standardized covariance of a pair of dependent choice options A and B, with each having two possible outcomes, as \(\sigma_{A B}^{*}\), where the non-standardized covariance is denoted as \(\sigma_{A B}\). Standardized covariance is equal to twice the covariance divided by the sum of the variances \(\sigma_{A}\) and \(\sigma_{B}\) of each of the options (see Equation 1).
\[
\begin{equation*}
\sigma_{A B}^{*}=\frac{2 \sigma_{A B}}{\sigma_{A}^{2}+\sigma_{B}^{2}} \tag{1}
\end{equation*}
\]

For stochastically non-dominant options, \(\sigma_{A B}^{*}\) is a continuous variable ranging from -1 (strong negative association) to 1 (strong positive association). When \(\sigma_{A B}^{*}=0\) either the options are completely unrelated (e.g. they are statistically independent, where two options do not depend on one external event) or the covariance between the options' outcomes is equal to 0 . The second case occurs, when one of the options is a sure thing. When \(\sigma_{A B}^{*}\) approaches 0 , the variances of both options are low, and so is the association between the options.

\section*{Properties of \(\sigma_{A B}^{*}\)}

When \(\sigma_{A B}^{*}\) reaches its maximum at 1 then the sum of the variances equals twice the covariance:
\[
\begin{equation*}
\sigma_{A B}^{*}=1 \Longleftrightarrow 2 \sigma_{A B}=\sigma_{A}^{2}+\sigma_{B}^{2} \tag{2}
\end{equation*}
\]

Analogically, for negatively related gambles the relation is:
\[
\begin{equation*}
\sigma_{A B}^{*}=-1 \Longleftrightarrow-2 \sigma_{A B}=\sigma_{A}^{2}+\sigma_{B}^{2} \tag{3}
\end{equation*}
\]

Situation from Equation 2 occurs when both options are the same (Example 1 in Table 1) and, analogically, by interchanging the outcomes of Option B we can obtain choice options for which \(\sigma_{A B}^{*}=-1\) (Example 2), which shows the symmetricity of options with positive and negative \(\sigma_{A B}^{*}\). Further, as shown in Examples 3 and 4, by altering one outcome from Option B so that the options are not the same any more, we obtain options with slightly lower \(\sigma_{A B}^{*}\). Interrestingly, the probabilities of the outcomes do not influence \(\sigma_{A B}^{*}\) (compare Examples 3 and 5). Also, the "perfect association" does not occur only when the options are identical, but also, when the difference between outcomes of option A and B is the same and this difference is the difference between expected values (Example 6 with the difference in expected values of 10 points). By making the outcomes corresponding to the same probabilities more dissimilar, one can decrease \(\sigma_{A B}^{*}\) (compare Examples 3 and 7). Finally, as shown in Example 8, when outcomes of one option are almost the same (almost a sure thing), while outcomes of the other option are dissimilar, \(\sigma_{A B}^{*}\) is almost 0 .

For stochastically non-dominant options, \(\sigma_{A B}^{*}\) is not higher than 1 or lower than -1 because it is not true that \(2 \sigma_{A B}>\) \(\left(\sigma_{A}^{2}+\sigma_{B}^{2}\right)\). Below, we provide the mathematical proof.

Proof. \(2 \sigma_{A B}>\left(\sigma_{A}^{2}+\sigma_{B}^{2}\right)\) is false
In stochastically non-dominant options the variances of options' outcomes are unequal, thus \(\sigma_{A}^{2}<\sigma_{B}^{2} \vee \sigma_{A}^{2}>\sigma_{B}^{2}\).
\(\sigma_{A}^{2}<\sigma_{B}^{2} \Longleftrightarrow \sigma_{B}^{2}=\sigma_{A}^{2}+s \wedge s \in \mathbb{R}^{+}\)
Then,
\(2 \sigma_{A B}>\sigma_{A}^{2}+\sigma_{B}^{2}\)
\(2 \sigma_{A B}>2 \sigma_{A}^{2}+s\)
\(0>\sigma_{A}^{2}+\frac{s}{2}-\sigma_{A B}\)
\(0>E\left[a^{2}\right]+\frac{E\left[b^{2}\right]-E\left[a^{2}\right]}{2}-E[a b]\)
\(E\left[a^{2}\right]<E\left[b^{2}\right] \Longleftrightarrow b=a+g \wedge g \in \mathbb{R}^{+} \wedge g=\) const.
By expanding the inequality we get
\(0>\frac{g^{2}}{2}\)
Since \(g^{2}>0\) the inequality is false.

\section*{Standardized Covariance vs. Correlation}

Examples presented in Table 1 indicate that there are similarities between correlation and standardized covariance and the "perfect" correlation overlaps with the "perfect" standardized covariance (e.g. Examples 1, 2 and 3 in Table 1). Correlation coefficient \(r\) equals to
\[
\begin{equation*}
r=\frac{\sigma_{A B}}{\sigma_{A} \sigma_{B}} . \tag{4}
\end{equation*}
\]

The relation between correlation coefficient and standardized covariance is as follows:
\[
\begin{equation*}
\sigma_{A B}^{*}=\frac{2 r \sigma_{A} \sigma_{B}}{\sigma_{A}^{2}+\sigma_{B}^{2}} \tag{5}
\end{equation*}
\]
and correlation is equal to standardized covariance when
\[
\begin{equation*}
2 \sigma_{A} \sigma_{B}=\sigma_{A}^{2}+\sigma_{B}^{2} . \tag{6}
\end{equation*}
\]

Because for stochastically non-dominant options with two outcomes correlation is always either -1 or \(1, \sigma_{A B}=\sigma_{A} \sigma_{B}\). Therefore, the relation between the sum of variances and the product of the standard deviation is the same as the relation between the sum of variances and the covariance. Thus, standardized covariance could also be written as
\[
\begin{equation*}
\sigma_{A B}^{*}=\frac{2 \sigma_{A} \sigma_{B}}{\sigma_{A}^{2}+\sigma_{B}^{2}} \tag{7}
\end{equation*}
\]
when the association between the options' outcomes is positive. When the association between the options' outcomes is negative, \(\sigma_{A B}=-2 \sigma_{A} \sigma_{B}\).

\section*{Variances and Covariance of Two-Outcome Options}

In stochastically non-dominant pairs of options which are not identical, one option has higher variance than the other (compare range of outcomes of options A and B in Table 1 in Examples 3, 4, 5, 7 and 8, to Example 6 which contains a stochastically dominant pair of options). Therefore the sum of variances is composed of a smaller and larger variance.

The relation between the smaller variance and covariance is close to linear and is symmetric with respect to the x -axis. In contrast, the relation of the larger variance to covariance takes the shape of a triangular area and is also symmetric with respect to the x -axis, as shown in Figure 1. This figure shows a very interesting pattern in which the graph on the right side fits into the graph on the left side like "key and lock". The data points in Figure 1 were obtained from 100000 randomly generated two-outcome choice options, with various differences between expected values. The outcomes' values ranged between 1 and 100, and probabilities of their occurrence ranged between 1 and \(99 \%\).

The relation between the sum of variances and covariance is symmetric with respect to the x -axis (Figure 2). The gray data points, which lay on the diagonal of the graph in Figure 2, are the only ones, for which standardized covariance is equal to correlation. This is the key property of standardized covariance, as the gray points correspond to the "perfect correlation" between the options, for which equation 6 holds. In contrast, all black points represent the pairs of options whose relation varies between -1 and 1 (not perfect correlation).

\section*{Options with Negative and Mixed Outcomes}

Until now, we have discussed the properties of standardized covariance, covariance and variances of options which generate only positive outcomes. However, some experiments might include choice options which generate only losses or might generate both, gains and losses. As a consequence, we randomly generated stochastically non-dominant options with only negative outcomes ( \(N=100000\) ), to which we will refer as negative options, and options that have one positive

Figure 1: Left: relation between the lower variance (more secure option) and covariance between two-outcome options, Right: relation between the higher variance (more risky option) and covariance between two-outcome options.

Figure 2: Relation of the sum of variances to twice the covariance. Gray points indicate the cases for which standardized covariance overlaps with correlation, such that \(\sigma_{A B}^{*}=r=1\) or \(\sigma_{A B}^{*}=r=-1\).
and one negative outcome ( \(N=100000\) ), which we call mixed options. The outcomes of negative options varied between -100 and -1 points, while the outcomes of mixed options were in range \([-100,1]\) and \([1,100]\) points. The probabilities of these outcomes ranged from \(1 \%\) to \(99 \%\). We repeated the analysis of the relation between variances and covariance, as well as the sum of variances and the product of standard deviations of the options for the two new types of options.

The obtained results for the negative and mixed options were the same as for the positive options. Thus, the properties of the choice options regarding their variances, covariance and the standardized covariance, depicted in Figures 1 and 2, apply to various kinds of choice options. The only difference is that the range of the values of variances and covariance of mixed options is much greater (range: \([-10000,10000]\) ). This is due to the fact that the range of the possible values is twice as big compared to the positive and negative options. In sum, standardized covariance is a stable measure of association between options.

Table 2: Ranges of values of standardized covariance, ratio of the smaller to the larger variance and the amount of pairs of options generated for each of the five differences between expected values between the options.
\begin{tabular}{lccc}
\hline\(\Delta E V\) & \(\sigma_{A B}^{*}\) & \(\frac{\min \left(\sigma_{A}^{2}, \sigma_{B}^{2}\right)}{\min \left(\sigma_{A}^{2}, \sigma_{B}^{2}\right)}\) & N \\
\hline 10 & \(.02-.99\) & \(.00-.72\) & 975021 \\
15 & \(.02-.94\) & \(.00-.49\) & 377750 \\
20 & \(.02-.94\) & \(.00-.49\) & 418251 \\
25 & \(.02-.94\) & \(.00-.49\) & 244734 \\
30 & \(.02-.89\) & \(.00-.36\) & 119241 \\
\hline
\end{tabular}

\section*{Standardized Covariance vs. Expected Value}

Standardized covariance is sensitive to the differences between expected values of two choice options. We generated all possible pairs of options with outcomes and probabilities as previously, for which the difference between the expected values was either \(10,15,20,25\) or 30 . As shown in Table 2, the greater the difference between expected values, the more narrow the range of possible values of \(\sigma_{A B}^{*}\). Thus, when manipulating the difference between the expected value of pairs of options, our analysis shows that this manipulation will most likely also change the covariance of the options outcomes. Thus, when not controlling for this aspect, then variations of the expected value differences will often be confounded with variations of covariance differences. Therefore, the experimenters should keep in mind that the strength of the association between the gambles that they present to the participants may depend on the differences between expected values ( \(\Delta E V\) ).

Interestingly, the greater the difference between the expected values, the fewer choice options could be obtained (see Table 2). Also, the greater the difference between expected values, the more narrow the ranges of possible values of standardized covariance and ratio between the lower and the higher variance within the pair of options (see Table 2). Therefore, in experiments that control for the expected value difference, it might be the standardized covariance between the options that influences people's choice, rather than the expected value.

Further, we selected a group of options for which \(\Delta E V=\) 15. For these options with fixed difference between expected values, we tested the relation between the variances of both options. As shown in Figure 3, the data points create a pattern that is symmetric with respect to the diagonal of the graph. In other words, when \(\Delta E V\) is fixed, the variances of both options are related to each other with respect to a certain ratio, whose ranges we listed in Table 2.

\section*{Options with More than Two Outcomes}

In order to analyze in more detail the relation between the correlation measure and the standardized covariance, one would have to extend the problem to choices with more than two

Figure 3: Relation between variances of two options with two outcomes.

Figure 4: Left: relation between the smaller variance and the covariance between four-outcome options. Right: relation between the larger variance and the covariance between four-outcome options.
possible outcomes. Therefore, we generated 10000 pairs of stochastically non-dominant options with four outcomes. The outcomes varied between 1 and 100 points, and probabilities varied betweeen \(1 \%\) and \(40 \%\).

Firstly, we investigated the relations between the variances and the covariance. As shown in Figure 4, the relations between both variances and covariance do not display the "keylock" pattern as in Figure 1, and the patterns are not symmetrical. Analogically, the relation between the sum of variances and twice the covariance is not symmetric with respect to the x -axis.

Secondly, we looked at the relation between correlation and standardized covariance. Figure 5 shows a strong relation between the correlation measure and standardized covariance. Pearson correlation between these two measures is very strong, \(r=.98, p<.001\). In the current sample of generated pairs of options, covariance and correlation are equal to each other for \(24 \%\) of the cases. Also, the slope of the regression line is high and the intercept very small (see caption of Figure 5). Thus, standardized covariance is a similar measure as correlation, but it has the advantage that it can be

Figure 5: Relation between the correlation coefficient and standardized covariance of options with four outcomes. Gray line indicates the regression line, with the slope of .87 and intercept 0027.
applied to both two-outcome choice options and options with several outcomes.

\section*{Model Predictions Depending on the Standardized Covariance}

In the previous sections, we have described features of stochastically non-dominant options with two outcomes and how one could measure the association between the options with the use of standardized covariance. In this section, we will show why the association between two options is important, based on two prominent theories of decision making, regret theory and decision field theory. Models of decision making generate different predictions for options with various differences between expected values. Thus, we focused on the choice options for which \(\Delta E V=15\).

For all of these options we generated predictions of the two models. Following Pathan, Bonsall, and Jong (2011), we defined the regret function of choosing option A over option B with outcomes \(x_{i}, i \in\{1,2\}\) as
\[
\begin{equation*}
R_{i A}=\ln \left(1+\exp \left(\beta\left(x_{i}-\max \left(x_{i A}, x_{i B}\right)\right)\right)\right) \tag{8}
\end{equation*}
\]

The total regret from choosing option A equals to
\[
\begin{equation*}
R_{A}=\Sigma_{i=1}^{2} R_{i A} \tag{9}
\end{equation*}
\]

Further, the probability of choosing option A over option B is estimated using softmax rule
\[
\begin{equation*}
\operatorname{Pr}(A \mid A, B)=\frac{1}{1+\exp \left(\theta\left(R_{B}-R_{A}\right)\right)} \tag{10}
\end{equation*}
\]
\(\beta\) and \(\theta\) are free parameters of the model. More details regarding regret theory is provided in Loomes and Sugden (1982). A parsimonious version of decision field theory was used, as described by Busemeyer and Townsend (1993).

The models' predictions are expressed as probabilities of choosing option A over B . We converted these results to the prediction that the option with the higher expected value

Figure 6: Average predictions of regret theory and decision field theory. To generate predictions the following parameters were used: regret theory \(\beta=.05, \theta=4.6\), decision field theory \(\theta=1.19\). The parameter of decision field theory was based on Rieskamp (2008) and the parameters of regret theory were adjusted so that the predictions of both models are at the same level. Error bars indicate standard deviations.
would be chosen, which resulted in all predictions ranging between 0.5 and 1 . Next, we grouped the options depending on their standardized covariance, such that group 1: \(\sigma_{A B}^{*}<0.2(21.2 \%)\), group 2: \(0.2<\sigma_{A B}^{*} \leq 0.5\) ( \(34.7 \%\) ), group 3: \(0.5<\sigma_{A B}^{*}(44.2 \%)\). For each of the three groups we calculated the mean prediction and its standard deviation.

As shown in Figure 6, the models' predictions differ among the three groups. This constitutes evidence that some theories of decision making not only assume on a theoretical level that the relation between the options' outcomes play an important role in decision making, but also provide quantitative evidence. Therefore, one should control for the association between the options. This is a crucial property of the standardized covariance, because in experiments in which the association between options was not examined, the results might depend on the selected set of choice options.

Furthermore, the models' predictions for choices with the same level of association could differ depending on the difference between expected values. From each group of options with difference between expected values of \(10,15,20\), 25 and 30 points, we picked all options for which \(\sigma_{A B}^{*}=.3\) and we generated models' predictions using the same set of parameters as previously. As shown in Figure 7, decision field theory makes very systematic predictions in which the higher the expected value difference, the higher the probability of choosing the option with the higher expected value. In contrast, regret theory indicates some differences but no trend can be observed.

In sum, predictions of models of decision making result from the interaction between the difference between expected values and the strength of the association between the choice options. This finding is very important, as in most studies

Figure 7: Average predictions of regret theory and decision field theory for choices with \(\sigma_{A B}^{*}=.3\) and various expected values. Error bars indicate standard deviations.
the researchers do not even consider the covariance of the options' outcomes, but only report the differences in expected values.

\section*{Discussion}

The association between two options' outcomes may play an important role in testing models of decision making. As we have shown, models can generate different predictions depending on the combination of the expected value difference and the association between the options. Experiments that control only for the expected value difference may obtain confounded results.

Therefore, a simple measure of the strength of this association is needed. For experiments that employ two-outcome choice options, we proposed the standardized covariance. Its values range between -1 and 1 , where 1 indicates "perfect positive association" and -1 indicates "perfect negative association". When standardized covariance equals to 0 , one of the options is a sure thing. When standardized covariance equals to \(-1,0\) and 1 it overlaps with correlation.

There is a strong association between correlation measure and standardized covariance. This constitutes solid evidence in favor of the reliability of the standardized covariance as a measure of the association between two choice options. Interestingly, there are very clear patterns of relations between variances and covariance of the two-outcome options. In contrast, these patterns are different when there are more outcomes. Therefore, future empirical research is needed to test the applicability of the standardized covariance and its perception by human decision makers. Also, as a future investigation, we suggest that one should test whether the predictions of the aforementioned models of decision making reflect the real human choice behavior.

In sum, this work was based on extensive simulations of random choice options and choice options with specific properties. We have shown that standardized covariance is a ro-
bust measure, with similar properties to the correlation. Finally, we showed that the covariance strongly influences the prediction of different cognitive models of decision making and should be given more attention in empirical work.

\title{
Probabilistic Language Modeling with Hidden Stochastic Automata
}

\begin{abstract}
In this paper, we introduce a novel dynamical Bayesian network model for probabilistic language modeling. We refer to this as the Hidden Stochastic Automaton. This model, while based on a generalization of the Hidden Markov model, has qualitatively greater generative power than either the Hidden Markov model itself or any of its existing variants and generalizations. This allows the Hidden Stochastic Automaton to be used as a probabilistic model of natural languages in a way that is not possible with existing dynamical Bayesian networks. Its relevance to Cognitive Science is primarily as a computational - in the Marr (1982) sense of the term model of cognition, but potentially also as a model of resource bounded cognitive processing, and as a model of the implementation of computation in physical dynamical systems.
\end{abstract}

A probabilistic language model is a hypothetical generative model of a language, where a language is defined most generally as a set of strings concatenated out of a finite set of symbols. By far the most widely used formalisms for specifying probabilistic language models are stochastic grammars, which are symbol rewriting rules with accompanying probabilities. The use of grammars is motivated by the fact that human languages are structurally complex, with properties that place them between the so-called context-free and contextsensitive formal languages (see, e.g., Chomsky, 1956, 1963; Shieber, 1985), and formal grammars are computationally universal in the sense that they can generate any recursively enumerable set (see, e.g., Hopcroft, Motwani, \& Ullman, 2001).

By contrast to the case of language modeling, in probabilistic modeling more generally, the most widely used formalism for specifying probabilistic models is the graphical model (see, e.g., Koller \& Friedman, 2009; Jordan, 2004). Graphical models are directed or undirected graphs whose vertices are identified with random variables and whose edges indicate conditional dependencies. The appeal of graphical models is their flexibility to represent complex relationships between large numbers of variables, and their graph-theoretic properties that afford general and computationally efficient algorithms for probabilistic inference, whether exactly or approximately by, for example, Monte Carlo methods. As a result, graphical models have effectively become a graph-based modeling language for developing and extending probabilistic models. They have had widespread application in fields such as bioinformatics (e.g., Fried-
man, 2004), computer vision (e.g., Oliver, Rosario, \& Pentland, 2000), machine learning (e.g., Bishop, 2006, 2013), expert systems (e.g., Lauritzen \& Spiegelhalter, 1988; Pearl, 1988), information retrieval (e.g., Salakhutdinov \& Hinton, 2009), and in cognitive science (see, e.g., Chater \& Oaksford, 2008; Griffiths, Chater, Kemp, Perfors, \& Tenenbaum, 2010, for overviews).

Despite their breadth of appeal, graphical models have had a rather limited role as language models, if by language models we specifically mean generative models of language. There are at least two important reasons for this. On the one hand, stochastic grammars can not, in general, be represented as graphical models. (In some cases, notably stochastic regular grammars, the terminal and nonterminal variables of the grammar can be identified with vertices of a directed Markovian graph. For the super-regular grammars, however, this is not the case and the variables of the grammar can not be identified with the vertices of any fixed graph). On the other hand, the most widely used graphical models for sequential probabilisitic modeling, including the Hidden Markov model and its extensions, are limited in their generative power to the regular languages (i.e. the Type3 languages in the Chomsky hierarchy). In other words, graphical models have had a relatively limited role as language models because the most widely used probabilistic models that have sufficient generative power to model human languages can not be represented as graphical models, and the most widely used graphical models for sequential structures do not have sufficient generative power to model natural languages.

There is, however, no inherent limitation to the generative power of graphical models. In this paper, we introduce a graphical model, specifically a dynamical Bayesian network, whose generative power is equivalent to that of an arbitrary stochastic grammar. This model, that we will refer to as the Hidden Stochastic Automaton, is based on a novel generalization of the widely used Hidden Markov model. As such, it retains many of the appealing characteristics of the Hidden Markov model while extending its generative power.

\section*{Hidden Stochastic Automata}

To introduce the Hidden Stochastic Automaton (HSA), it is necessary to first briefly describe the Hidden Markov model (HMM). Given a set of \(J\) independent discrete
valued sequences \(\mathbf{w}_{1}, \mathbf{w}_{2} \ldots \mathbf{w}_{j} \ldots \mathbf{w}_{J}\), where the \(j\) th sequence is \(\mathbf{w}_{j}=w_{j 1}, w_{j 2} \ldots w_{j i} \ldots w_{j n_{j}}\), the generative model assumed by the HMM treats each \(w_{j i}\) as drawn from one of \(K\) discrete probability distributions \(\phi_{1}, \phi_{2} \ldots \phi_{k} \ldots \phi_{K}\) over a finite vocabulary of length \(V\). Which distribution is chosen for \(w_{j i}\) is determined by the value of the unobserved variable \(x_{j i} \in\{1 \ldots K\}\) that corresponds to \(w_{j i}\). For all \(j\), each \(x_{j 1}, x_{j 2} \ldots x_{j i} \ldots x_{j n_{j}}\) is a first-order Markov chain, with initial distribution \(\pi\) and a \(K \times K\) transition matrix \(\theta\). More formally, the HMM assumes that for all \(j\),
\[
\begin{aligned}
w_{j i} \mid x_{j i}, \phi & \sim \text { Categorical }\left(w_{j i} \mid \phi_{x_{j i}}\right) & & 1 \leq i \leq n_{j}, \\
x_{j i} \mid \pi & \sim \operatorname{Categorical}\left(x_{j i} \mid \pi\right) & & i=1, \\
x_{j i} \mid x_{j i-1}, \theta & \sim \operatorname{Categorical}\left(x_{j i} \mid \theta_{x_{j i-1}}\right) & & 1<i \leq n_{j} .
\end{aligned}
\]

The graphical model for the HMM is shown below.

Figure 1: The graphical model or dynamical Bayesian network for the Hidden Markov model. The shaded nodes indicate the observed variables. For simplicity, we have omitted the priors on \(\phi, \pi\) and \(\theta\).

Precisely because graphical models naturally afford generalizations and extensions, the HMM has lead to many variants. Most notably, these include the mixed memory HMM (Saul \& Jordan, 1999), the coupled HMM (Brand, Oliver, \& Pentland, 1997), the factorial HMM (Ghahramani \& Jordan, 1997), and the hierarchical HMM (Fine, Singer, \& Tishby, 1998). These extensions are often based on introducing additional chains of latent variables with varying degrees of conditional independence between them. Despite the evident value of these models, they do not qualitatively alter the formal generative complexity of the underlying model. In all of these extensions, the sequences generated are equivalent to regular or Type-3 formal languages

\section*{From HMM's to Hidden Stochastic Automata}

It is possible, however, to generalize the HMM in such a way that its generative complexity is increased. This can
be done by replacing the single valued \(x_{j i}\) in the HMM by a variable sized array or vector. In other words, while in the HMM, each state variable is \(x_{j i} \in\{1 \ldots K\}\), this may be generalized to \(x_{j i} \in\{1 \ldots K\}^{*}\). Here * indicates Kleene star, or the union of all concatenations of the elements from \(\{1 \ldots K\}\) and \(\{\emptyset\}\). This change clearly increases the cardinality of the state space to a countably infinite set. Importantly, however, as we will elaborate, if the set of operations that can increase or decrease the state-vector are limited to a finite set, and if the the conditional dependencies on this state-vector are limited to a finite range of elements, then inference in this generalized model is almost identical in kind to inference in the standard HMM.

For reasons that will be made clear, we will collectively refer to generalizations of the HMM using a state-vector as Hidden Stochastic Automata (HSA). For the purposes of this paper, however, we will mostly concentrate on one specific form of the HSA. For simplicity, we will also refer to this particular case of the model as the HSA, with the understanding that it is but one of many variants based on the same principles.

Just as with the HMM, the HSA is a generative model of discrete valued sequences. It assumes that each variable \(w_{j i}\) in the sequence of observations \(\mathbf{w}_{j}=\) \(w_{j 1}, w_{j 2} \ldots w_{j i} \ldots w_{j n_{j}}\) is drawn from one of \((H+1) \times K\) discrete probability distributions \(\phi_{01}, \phi_{02} \ldots \phi_{h k} \ldots \phi_{H K}\) over a length \(V\) vocabulary. Which of these \((H+1) \times K\) distributions is chosen is determined by the values of two latent or unobserved state variables that correspond to \(w_{j i}\). On the one hand, there is a standard finite state variable \(x_{j i} \in\{1 \ldots K\}\). On the other hand, there is an additional state-vector variable \(z_{j i} \in\{1 \ldots H\}^{*}\), with \(w_{j i}\) being conditional on only the first element of \(z_{j i}\), if \(z_{j i} \neq \emptyset\). In other words, \(w_{j i}\) is sampled from \(\phi_{\left[z_{j i}^{1}, x_{j i}\right]}\), where \(z_{j i}^{1}\) indicates the value of the first element of the state-vector \(z_{j i}\), or else 0 when \(z_{j i}=\emptyset\).

For all \(j\), the sequence \(\left(x_{j 1}, z_{j i}\right),\left(x_{j 2}, z_{j i}\right) \ldots\) \(\left(x_{j i}, z_{j i}\right) \ldots\left(x_{j n_{j}}, z_{j i}\right)\) is a first-order Markov chain of coupled state variables. The distribution over \(x_{j 1}\) is given by the \(K\) valued distribution \(\pi\), and the value of \(z_{j 1}\) is deterministically set to \(z_{j 1}=\emptyset\). For \(1<i \leq n_{j}\), both \(x_{j i}\) and \(z_{j i}\) are conditional on \(x_{j i-1}\) and, if \(z_{j i} \neq \emptyset\), the first element of \(z_{j i}\). The value of \(x_{j i}\) is determined by sampling from the \(K\) dimensional probability distribution specified by \(\theta_{\left[z_{j i-1}^{1}, x_{j i-1}\right]}\), where \(\theta\) is a \((H+1) \times K \times K\) stochastic transition matrix, and \(z_{j i-1}^{1}\) is as above. The value of \(z_{j i}\) is determined by applying one of \(H+1\) different operations to \(z_{j i-1}\), specifically prepending \(z_{j i-1}\) by one symbol from \(\{1 \ldots H\}\) or removing the first element from \(z_{j i-1}\). For example, if \(\sigma_{1} \sigma_{2} \sigma_{3}\) (with each \(\sigma_{l} \in\{1 \ldots H\}\) ) is the value of the state-vector \(z_{j i-1}\), a possible sequence of
operations and their effect on the state-vector could be
\[
\begin{aligned}
& z_{j i-1}=\sigma_{1} \sigma_{2} \sigma_{3} \xrightarrow{\text { remove }} z_{j i}=\sigma_{2} \sigma_{3}, \\
& \quad z_{j i}=\sigma_{2} \sigma_{3} \xrightarrow{\text { prepend } 3} z_{j i+1}=3 \sigma_{2} \sigma_{3}, \\
& z_{j i+1}=3 \sigma_{2} \sigma_{3} \xrightarrow{\text { prepend } 2} z_{j i+2}=23 \sigma_{2} \sigma_{3} .
\end{aligned}
\]

Which of these \(H+1\) operations is applied is determined by sampling from the \(H+1\) dimensional probability distribution specified by \(\Omega\left[z_{j i-1}^{1}, x_{j i-1}\right]\), where \(\Omega\) is a \((H+1) \times K \times(H+1)\) stochastic transition matrix.

More formally, the probabilistic generative model defined by this HSA is, for \(i \leq i \leq n_{j}\),
\[
w_{j i} \mid x_{j i}, z_{j i}, \phi \sim \text { Categorical }\left(w_{j i} \mid \phi_{\left[z_{j i}^{1}, x_{j i}\right]}\right),
\]
and for \(i=1\),
\[
x_{j i} \mid \pi \sim \operatorname{Categorical}\left(x_{j i} \mid \pi\right), \quad z_{j i}=\emptyset,
\]
and for \(1<i \leq n_{j}\),
\[
\begin{aligned}
x_{j i} \mid x_{j i-1}, z_{j i-1}, \theta & \sim \operatorname{Categorical}\left(x_{j i} \mid \theta_{\left[z_{j i-1}^{1}, x_{j i-1}\right]}\right), \\
z_{j i} \mid u_{j i-1}, z_{j i-1} & =O_{\left[u_{j i-1}\right]}\left(z_{j i-1}\right), \\
u_{j i-1} \mid x_{j i-1}, z_{j i-1}, \Omega & \sim \operatorname{Categorical}\left(u_{j i-1} \mid \Omega_{\left[z_{j i-1}^{1}, x_{j i-1}\right]}\right) .
\end{aligned}
\]

Here, we use the auxilary variable \(u_{j i}\) to refer to the operation applied to \(z_{j i}\), and \(O\) is the set of \((H+1)\) functions that map \(z_{j i}\) to \(z_{j i+1}\) when these operations are applied. In other words, this makes clear that the value of \(z_{j i+1}\) is a deterministic function of \(z_{j i}\) when the value of \(u_{j i}\) is known, but this value is stochastically conditional on \(x_{j i}\) and \(z_{j i}\). In terms of the original variables, the graphical model for the HSA is as follows:

Figure 2: The graphical model or dynamical Bayesian network for the Hidden Stochastic Automaton. As with Figure 1, shaded nodes indicate observed variables and we have omitted the priors on \(\phi, \pi, \theta\) and \(\Omega\).

\section*{Generative Power of Hidden Stochastic Automata}

The generative power of the HSA model (as shown in Figure 2) relative to that of the standard HMM (as shown in Figure 1) arises from the fact that the statespace of the state-vector \(z_{j i}\), namely \(\{1 \ldots H\}^{*}\), is a countably infinite set yet the conditional relationships to and from \(z_{j i}\) are finitely specifiable. The consequences of this can be better appreciated by reference to discrete automata of the kind that form the foundations of theoretical computer science (see, e.g., Hopcroft et al., 2001).

As we have described it, the state-vector \(z_{j i}\) is identical to a pushdown stack with a symbol set \(\{1 \ldots H\}\). Prepending an element to the state-vector is equivalent to a push operation, while removing the first element is a pop operation. Assuming known values for \(\Omega\), which operation is applied to \(z_{j i}\) is dependent only on the value of the finite state variable \(x_{j i-1}\) and the first element or head of \(z_{j i-1}\). Likewise, assuming known values for \(\theta\), the value taken by \(x_{j i}\) is also dependent only on \(x_{j i-1}\) and the head of \(z_{j i-1}\). In other words, the HSA model described above is equivalent to a stochastic generative version of a pushdown stack automaton.
If we allow a greater variety of operations on the statevector than just prepending or removing symbols from the left, the computational power of the HSA can be beyond that of a generative pushdown stack automaton. For example, if
\[
\sigma_{1} \sigma_{2} \dot{\sigma}_{3} \sigma_{4} \sigma_{5} \sigma_{6}
\]
is the value of the state-vector, we may treat an arbitrary element - in this cases \(\sigma_{3}\) - as its head. If we allow for the appending of new elements to the left or the right of the head, or for the deleting of the element at the head, followed by the moving of the head pointer to the left or right, then this state-vector is equivalent to a two-way memory tape. As before, assuming known values for \(\Omega\), which of the operations is applied to the state-vector \(z_{j i}\) is again dependent only on the value of the finite state variable \(x_{j i-1}\) and the head of \(z_{j i-1}\). Likewise, as before, assuming known values for \(\theta\), the value taken by \(x_{j i}\) is also dependent only on \(x_{j i-1}\) and the head element of \(z_{j i-1}\). As such, with these changes the HSA is now equivalent to a stochastic generative version of the Turing machine.

\section*{Inference}

As is clear from Figure 2, only the variables \(\mathbf{w}=\left\{w_{j 1} \ldots\right.\) \(\left.w_{j i} \ldots w_{j n_{j}}\right\}_{j=1}^{J}\) are observed. In general, therefore, the problem of inference in the HSA is the problem of inferring the joint posterior
\[
\mathrm{P}(\theta, \phi, \Omega, \pi, \mathbf{x}, \mathbf{z} \mid \mathbf{w}, \alpha, \beta, \gamma, \nu),
\]
where \(\mathbf{x}\) and \(\mathbf{z}\) are the set of finite state and state-vectors variables, and \(\alpha, \beta, \gamma, \nu\) are the Dirichlet priors for \(\theta, \phi\), \(\Omega, \pi\), respectively.

The procedure for inference that we will follow is to use a collapsed Gibbs sampler to draw samples from the posterior
\[
\mathrm{P}(\mathbf{x}, \mathbf{z} \mid \mathbf{w}, \alpha, \beta, \gamma, \nu)
\]
that integrates over the values of \(\theta, \phi, \Omega, \pi\). This Gibbs sampler is identical in nature to the collapsed sampler used in Andrews and Vigliocco (2010) for the case of a hierarchical mixture of Hidden Markov models.

For all \(j \in\{1 \ldots J\}\) and \(i \in\left\{1 \ldots n_{j}\right\}\), the Gibbs sampler iteratively draws samples from the posterior over \(x_{j i}\) and over \(z_{j i}\), conditioned on sampled values for all remaining variables.

The posterior distribution over \(x_{j i}\), conditioned on known values for all the other variables is \({ }^{1}\)
\[
\begin{aligned}
& \mathrm{P}\left(x_{j i} \mid w_{j i}, z_{j i}, x_{\neg j i}, w_{\neg j i}, z_{\neg j i}, \alpha, \beta, \gamma\right) \propto \\
& \int \mathrm{P}\left(w_{j i} \mid x_{j i}, z_{j i}, \phi\right) \mathrm{P}\left(\phi \mid w_{\neg j i}, x_{\neg j i}, z_{\neg j i}, \beta\right) d \phi \times \\
& \int \mathrm{P}\left(z_{j i+1} \mid x_{j i}, z_{j i}, \Omega\right) \mathrm{P}\left(\Omega \mid x_{\neg j i}, z_{\neg j i}, \gamma\right) d \Omega \times \\
& \int \mathrm{P}\left(x_{j i+1} \mid x_{j i}, z_{j i}, \theta\right) \mathrm{P}\left(x_{j i} \mid x_{j i-1}, z_{j i-1}, \theta\right) \mathrm{P}\left(\theta \mid x_{\neg j i}, z_{\neg j i}, \alpha\right) d \theta .
\end{aligned}
\]

This leads to the following closed form:
\[
\begin{aligned}
& \mathrm{P}\left(x_{j i}=k \mid w_{j i}, z_{j i}, x_{\neg j i}, w_{\neg j i}, z_{\neg j i}, \alpha, \beta, \gamma\right) \\
& \quad \propto \frac{S_{h k v}^{\neg j i}+\beta_{v}}{S_{h k}^{\neg j i}+b} \times \frac{Q_{h k q}^{\neg j i}+\gamma_{q}}{Q_{h k}^{\neg j i}+c} \\
& \\
& \quad \times \frac{\left(R_{h k k_{+}}^{\neg j i}+\delta_{k_{-}, k, k_{+}}+\alpha_{k_{+}}\right)\left(R_{h_{-} k_{-k}}^{\neg j i}+\alpha_{k}\right)}{R_{h k \cdot}^{\neg j i}+\delta_{k_{-}, k}+a} .
\end{aligned}
\]

Here, we are assuming that the value of the observed variable at \(j i\) is \(v\), the value of head of the state-vector at \(j i\) is \(h\), its value at \(j i-1\) is \(h_{-}\), the value of the finite state variable at \(j i-1\) is \(k_{-}\)and its value at \(j i+1\) is \(k_{+}\). The \(S, Q\) and \(R\) are rank- 3 arrays of frequencies, with the superscript of \(\neg j i\) indicating that they are based on excluding variables at \(j i\). As such, \(S_{h k v}^{\neg j i}\) is the number of times the observed variable has a value of \(v\) when the finite state variables has the value \(k\) and the head (e.g., the first) element of state-vector takes the value of \(h \in\{0 \ldots H\}, Q_{h k q}^{\neg j i}\) is the number of times that statevector operation \(q\) occurs whenever the head element of the state-vector takes the value of \(k\) and the finite state variable takes the value of \(k\), and \(R_{h k k_{+}}^{\neg j i}\) gives the number of times the finite state variable takes the value \(k_{+}\)whenever its value at the previous index is \(k\) and the value of the head of the state-vector at the previous index is \(h\). The dot in place of the third index, e.g., \(S_{h k}^{\neg j i}\), indicates a sum over the index. The term \(\delta_{k_{-}, k, k_{+}}\)

\footnotetext{
\({ }^{1}\) We will provide the conditional distributions for values of \(x_{j i}\) and \(z_{j i}\) where \(1<i<n_{j}\). The distributions for the cases where \(i=1\) and \(i=n_{j}\) require minor modifications, which we will omit here in the interests in space.
}
takes the value of 1 is \(k_{-}=k=k_{+}\)and takes the value of zero otherwise. Likewise, \(\delta_{k_{-}, k}\) takes the value of 1 when \(k_{-}=k\), and takes the value of 0 otherwise. The terms \(a, b\) and \(c\) are the sums of \(\alpha, \beta, \gamma\), respectively.

For the case of the posterior distribution of the statevector, it is sufficient to infer the distribution over operations applied to it. As mentioned, the value of the state-vector \(z_{j i}\) is deterministic function of \(z_{j i-1}\) when the operation \(u_{j i-1}\) is known. The posterior distribution over \(u_{j i}\) is given by
\[
\begin{aligned}
& \mathrm{P}\left(u_{j i} \mid w_{j i}, z_{j i}, x_{\neg j i}, w_{\neg j i}, z_{\neg j i}, \alpha, \beta, \gamma\right) \propto \\
& \times\left[\int \mathrm{P}\left(w_{j i+1} \ldots w_{j n_{j}} \mid x_{j i+1} \ldots x_{j n_{j}}, z_{j i+1} \ldots z_{j n_{j}}, \phi\right)\right. \\
& \left.\quad \mathrm{P}\left(\phi \mid w_{\neg \overrightarrow{j i}}, x_{\neg \overrightarrow{j i}}, z_{\neg \overrightarrow{j i}}, \beta\right) d \phi\right] \\
& \times\left[\int \mathrm{P}\left(x_{j i+1} \ldots x_{j n_{j}} \mid x_{j i} \ldots x_{j n_{j}-1}, z_{j i} \ldots z_{j n_{j}-1}, \theta\right)\right. \\
& \left.\quad \mathrm{P}\left(\theta \mid x_{\neg \vec{i} i}, z_{\neg \overrightarrow{j i}}, \beta\right) d \theta\right] \\
& \times \mathrm{P}\left(z_{j i+1} \ldots z_{j n_{j}} \mid u_{j i}, z_{j i}\right) \\
& \times \int \mathrm{P}\left(u_{j i} \mid x_{j i}, z_{j i}, \Omega\right) \mathrm{P}\left(\Omega \mid x_{\neg \overrightarrow{j i}}, z_{\neg \overrightarrow{j i}}, \gamma\right) d \Omega
\end{aligned}
\]
where we see that because a change to the operation \(u_{j i}\) deterministically changes the values of \(z_{j i+1} \ldots z_{j n_{j}}\), the likelihood terms for the \(u_{j i}\) variable include the variables \(w_{j i+1} \ldots w_{j i+1}\) and \(x_{j i+1} \ldots x_{j i+1}{ }^{2}\). In the above, the notation \(\neg \overrightarrow{j i}\), e.g., in \(x_{\neg \overrightarrow{j i}}\), indicates the exclusion of variables \(j i \ldots j n_{j}\). This distribution leads to the closed form
\[
\begin{aligned}
& \mathrm{P}\left(u_{j i}=q \mid w_{j i}, z_{j i}, x_{\neg j i}, w_{\neg j i}, z_{\neg j i}, \alpha, \beta, \gamma\right) \propto \\
& \frac{\prod_{\left\{h k v: S_{h k v}^{q}>0\right\}} \prod_{s=0}^{S_{h k v}^{q}-1} S_{h k v}^{\neg \overrightarrow{j i}}+\beta_{v}+s}{\prod_{\left\{h k: S_{h k}^{q}>0\right\}} \prod_{s=0}^{S_{h k}^{q}-1} S_{h k}^{\neg \overrightarrow{j i}}+b+s} \times \\
& \frac{\prod_{\left\{h k q: Q_{h k q}^{q}>0\right\}} \prod_{s=0}^{Q_{h k q}^{q}-1} Q_{h k q}^{\neg \overrightarrow{j i}}+\gamma_{q}+s}{\prod_{\left\{h k: Q_{h k}^{q}>0\right\}} \prod_{s=0}^{Q_{h k .}^{q} .-1} Q_{h k .}^{\neg \overrightarrow{j i}}+c+s} \times \\
& \frac{\prod_{\left\{h k l: R_{h k l}^{q}>0\right\}} \prod_{s=0}^{R_{h k l}^{q}-1} R_{h k l}^{\neg \overrightarrow{j i}}+\alpha_{l}+s}{\prod_{\left\{h k: R_{h k}^{q}>0\right\}} \prod_{s=0}^{R_{h k}^{q}-1} R_{h k .}^{\neg \overrightarrow{j i}}+a+s} .
\end{aligned}
\]

Here, \(S_{h k v}^{\neg \overrightarrow{j i}}, Q_{h k q}^{\neg \overrightarrow{j i}}\) and \(R_{h k l}^{\neg \overrightarrow{j i}}\) have the same meaning as \(S_{h k v}^{\neg \overrightarrow{j i}}, Q_{h k q}^{\neg \overrightarrow{j i}}\) and \(R_{h k l}^{\neg \overrightarrow{j i}}\) with the difference being that the frequencies are calculated excluding variables at the indices \(i j \ldots j n_{j}\). By contrast, the arrays \(S_{h k v}^{q}, Q_{h k q}^{q}\) and \(R_{h k l}^{q}\) are the frequencies of the co-occurrences the values

\footnotetext{
\({ }^{2}\) In graphical model terms, the variables \(w_{j i+1} \ldots w_{j i+1}\), \(x_{j i+1} \ldots x_{j i+1}\) and \(z_{j i+1} \ldots z_{j n_{j}}\) are all children of \(u_{j i}\).
}

Figure 3: Strings generated by the probabilistic context-free grammar \(S \rightarrow 0 S 1(p=0.66), S \rightarrow 01(p=0.34)\) were used as observed data in a HSA. Shown above are samples of the binary strings generated by the HSA model on the basis of estimates of the parameters \(\phi, \theta, \Omega\) and \(\pi\) after \(3,5,10,20,50\) and 100 iterations of the Gibbs sampler. The dark shade codes the value of 1 . It is evident that by over 50 iterations, the HSA has inferred the correct generative model of the probabilistic language. By 100 iterations, it is only generating strings from the language \(L=\left\{0^{n} 1^{n}: n \geq 0\right\}\).
of the variables after operation \(q\) is applied to the statevector \(z_{j i+1}\) and the changes to the subsequent statevectors are deterministically applied.

\section*{Demonstration}

We demonstrate inference of a language from data by using the textbook example of a simple context-free language, namely \(L=\left\{0^{n} 1^{n}: n \geq 0\right\}\). We can generate strings from a probabilistic version of this language using the probabilistic context-free grammar
\[
\begin{array}{rlrl}
S & \rightarrow 0 S 1, & & p=0.66 \\
& \rightarrow 01, & p=0.34
\end{array}
\]

We sample \(J=25\) strings from this language and use them as the data \(\mathbf{w}=\mathbf{w}_{1}, \mathbf{w}_{2} \ldots \mathbf{w}_{j} \ldots \mathbf{w}_{J}\) for a HSA model of the kind described.

Using the collapsed Gibbs sampler, we can sample from the posterior over the finite state and state-vector trajectories conditional on w. From these, we may then draw sample estimates of \(\phi, \theta, \Omega\) and \(\pi\). Shown in Figure 3 are strings generated by the HSA model with parameters \(\phi, \theta, \Omega\) and \(\pi\) as estimated after, from left to right, \(3,5,10,20,50\) and 100 iterations of the Gibbs sampler.

\section*{Relevance for Cognitive Science}

Our initial motivation for the HSA model was put in terms of the computational advantages of graphical models as formalisms for probabilistic modeling. Graphical
models, we have argued, have effectively become a graphbased modeling language for developing and extending probabilistic models. They have had a remarkable influence on the progress of probabilistic modeling in a wide variety of fields, including cognitive science. It is notable, therefore, that graphical models have had a relatively limited role in the probabilistic modeling of natural language. The obvious reason for this is due to the structurally complex nature of natural languages. While this structure is modeled well by probabilistic grammars, grammars can not, in general, be represented by graphical models. By contrast, the graphical models most widely used for modeling sequential data do not have the structural complexity necessary for modeling natural language.

We have introduced the HSA as a dynamical Bayesian network model that is capable of modeling structurally complex sequences. Its principal relevance to cognitive science is therefore as a computational model of cognition, where by computational model we specifically mean the Marr (1982) sense of the term: a model of the abstract nature of problem being faced and of its rational solution. However, the HSA model is potentially as relevant as a model of the resource limited practice, or possibly even the physical implementation, of cognition. For example, the HSA is an incremental statespace model, where inference is naturally modeled by the kind of sequential Monte Carlo methods, particularly particle filters, that have been advocated by, for
example, Griffiths, Vul, and Sanborn (2012); Sanborn, Griffiths, and Navarro (2010); Levy, Reali, and Griffiths (2009) as models of memory and time constrained approximations to rational computational models. On the other hand, from the point of view of physical implementation, the state-vector of the HSA can be represented naturally by a real-valued variable. If the state-vector is \(\sigma_{1} \sigma_{2} \ldots \sigma_{i} \ldots \sigma_{n}\), this can be represented exactly by the real number \(\sum_{i=1}^{n} \sigma_{i}(H+1)^{-i}\) and the operations applied to the state vector correspond to real-valued functions. For example, if the state-vector is binary, prepending a \(\sigma \in\{0,1\}\) to \(\sigma_{1} \sigma_{2} \ldots \sigma_{i} \ldots \sigma_{n}\) is identical to multiplying \(\sum_{i=1}^{n} \sigma_{i} 2^{-i}\) by \(\frac{1}{2}\) and adding \(\frac{\sigma}{2}\). By treating the finite state variable as another real number, this allows us to represent the HSA exactly as a stochastic nonlinear dynamical system that is directly comparable to a recurrent neural network (see, e.g., Tabor, 2000, for related discussion).

\begin{abstract}
In this work, we propose an evolutionary account of reactions to a wrong as an integrated set. Unlike other theories, we are not interested in revenge, punishment or sanction per se, but in their co-existence. We posit that this variety of reactions is needed in order to achieve different goals, but it also implies an increase in cognitive costs that requires to be explained from an evolutionary perspective. Moving from the identification of the psychological traits that uniquely define each reaction, two concurrent hypotheses are suggested and discussed: either the richness of human social life requests a variety of reactions, or the benefits of single reactions at the psychological level allowed these reactions to be maintained in the social life.
\end{abstract}

Keywords: Evolution; punishment; revenge; sanction; cognitive influencing; norms; enforcing institutions social order.

\section*{Introduction}

Human actions are potentially unbounded and much more opportunities are available when other people are involved. When talking about social actions we have to distinguish between actions and reactions, i.e., actions triggered by someone's else previous action. Reactions are a constitutive part of living in societies, and the ability of displaying the appropriate reaction in the right content is extremely important for our "ultra-social" species (Richerson \& Boyd 1998, 2005; Hill et al. 2009). The nature and the intensity of reactions depend on both the actor and the triggering action, and it requires the capacity to forecast further reactions and to plan ahead, among other things. Humans are unique under this respect, and everyone has experienced how many reactions the same individual can display in response to the same action, even in the same context. Animals can modulate their reactions, in some cases they can also decide their behaviour on a cost-benefit analysis, but others' representations do not enter this picture (Clutton-Brock \& Parker 1995; Jensen et al. 2007). Humans react because of what they believe and want, and because of what they want others to believe and of how they want them to behave.

A particularly interesting class of social reactions is that triggered in response to a wrong. Retaliation, revenge,
punishment and sanctions have been a matter of interest since the rise of Western culture, as witnessed by the fact that the need to understand and explain motives for reacting to wrongs never ceased since pre-Homeric Greece to these days (for an analysis of the differences among these reactions see Giardini et al. 2010).

Philosophers, social scientists, political scientists, psychologists, anthropologists have been striving to answer the fundamental question: why do people react to a wrong? In many circumstances reacting is more costly than standing, it requires some kind of planning, and it also implies the possibility of suffering a counter-reaction. Even more striking, people react to wrongs suffered by strangers, intervene in others' disputes, and sanction others when failing to comply with norms that they are not supposed to enforce. Although several scholars have been interested in explaining the evolution of revenge, punishment and sanction (Lorenz, 1966; Hamilton, 1970; Boyd \& Richerson, 1992; Clutton-Brock \& Parker 1995; Gardner \& West, 2004; Jensen, 2010), these phenomena have been usually considered in isolation and not as a rich and complex repertoire. We propose that revenge, punishment and sanction are different reactions that should not be considered in isolation but as interdependent and complementary. If we look at them as an intertwined set, we need to explain the reason why they are different, but we also need to understand why we still have more than one reaction to an offense, and how the related extra cognitive costs are compensated. Our goal is to explain the decision to apply punishment in terms of the complementary decisions to use neither revenge nor sanction, thus understanding the motives behind each and every reaction.

We propose that this variety is necessary because, unlike animals, humans' reactions do not only target the offender's behavior, but also her mental states, as well as the victim's mental states. Comparing different reactions, we highlight an evolutionary trajectory that links revenge, punishment and sanction by explaining costs and benefits of each reaction. Having the opportunity to choose among several responses means higher cognitive costs to select between actions, and to choose the most appropriate one. Therefore, a set of questions arises: Why do we have such a repertoire? Can we identify evolved mechanisms that allowed us to
distinguish among reactions and to selectively apply them depending on the context?

Moving from the identification of the psychological traits that uniquely define each reaction, we propose a complex relationship between the richness of human social life, which requests a variety of reactions (society \(\rightarrow\) individual motivations), and the benefits of single reactions at the psychological level. These benefits favoured the maintenance of reactions in the social life (individual motivations \(\rightarrow\) society).

The rest of the paper is organized as follows: Section 1 outlines the evolutionary model, Section 2 defines the different phenomena and Section 3 introduces the main features of our taxonomy.

\section*{An evolutionary account of reactions}

Revenge, punishment and sanction are superficially similar but deeply different in terms of the evaluation of the wrong suffered (or its interpretation), the intended goal, the consequent cognitive influencing, the temporal dimension and the kind of target. Humans are usually effective in administering punishment, i.e., in selecting the best reaction, taking into account the differences and selecting, through a fast and efficient process, how to react according to the external circumstances and their internal states.
The computational demands associated with the choice are not negligible and the risks of a mismatch between the perceived wrong and the reaction are high. We propose that revenge, punishment and sanction require the evolution of specialized mental mechanisms regulating the activation of different responses to wrongs or rule violations. We suggest that humans have mechanisms designed to produce revenge, punishment and sanction that evolved because of their effectiveness in solving recurrent social problems that humans encountered during evolution (Petersen et al. 2012). Given the richness of human bonds and social life, the need for acquiring social bonds (Dunbar, 1996) and for maintaining them, also remembering who is related to whom, could have favoured the selection of different reactions that have different consequences in terms of relationships (McCullough, Kurzban, Tabak, 2012). Moreover, psychological benefits of reactions may motivate their maintenance at the individual level and thus foster their selection at the social one. On the one hand, restoring the status quo, achieving deterrence or promoting the norms are goals that cannot be achieved through a single reaction, and their related specific benefits at the psychological level may have prompted the maintenance of multiple responses. On the other hand, the costs of selecting among different reactions are not negligible, also because having more choices implies being more prone to errors, with negative consequences arising at both the individual level and the social level. In the latter case, this mismatch between the reaction chosen and the wrong suffered can be extremely dangerous, and it may challenge the social order. Avenging a wrong when there is a social norm and the related sanction, or punishing someone in a context in which
revenge was expected could result in a negative judgment about the reacting agent. Failing in interpreting correctly the situation and thus applying an inappropriate reaction may lead individuals to consider the avenger/punisher/sanctioner as socially inadequate and to avoid interactions with her. At the group level, frequent failures in using the appropriate reaction may undermine the cohesion of the group and make it more vulnerable to turmoil and fights.
In evolutionary terms, the risk associated with the application of the wrong kind of reaction were compensated by the evolution of specific psychological mechanisms for selecting among reactions.
Each and every reaction involves some unintended side effects, which may prevent the agent from achieving her goals and may also make the reaction inappropriate. In revenge, making the other suffer and regaining one's sense of control, together with restoring the status quo, require the agent to evaluate the wrong suffered and to estimate how much sufferance to inflict on the offender. Since there is not any objective criterion to estimate the sufferance experienced, this evaluation can only be subjective, thus exposing the avenger to the risks of damaging his reputation because the reaction was disproportionate (too harsh or too weak), or loosing social ties, or even triggering a feud with escalation of violence. Feuds are especially costly at the group level and they may even lead to the dissolution of the group. The punisher aims at deterring the wrongdoer from further hostility (by making it a costly option). There is not a pre-established and socially shared set of rules that govern how to punish. This lack of explicit and objective regulation can have several negative consequences. If the punishment inflicted is not appropriate in quantity or in kind, this can result in perception of the punishment received as unjustified, not legitimate and unfair. When punishment is perceived inappropriate it may also become ineffective in inducing deterrence, so the punisher is not able to achieve her main goal. In addition, the punisher can acquire a bad reputation for being too harsh, and she can see some social ties severed because of his action with the consequent risk of an escalation of violence, which has consequences for the whole group.
The risks of administering an inappropriate sanction are more limited and they are mainly related to the fact that the normative message is not clearly understood by those who receive the sanction. Therefore, when the normative character of the situation is not recognized, the sanction is ineffective, and the normative belief and the normative goal will not be formed in the mind of those who receive the sanction. An inappropriate sanction may also lead to counter-reactions, either in the form of a further sanction or as a retaliatory behavior.
In what follows we will detail our model of reactions, specifying the cognitive underpinnings and the dimensions of change characteristics of each and every phenomenon, and then supporting our model with a discussion of the relevant literature.

\section*{Distinguishing among reactions}

Although a number of accounts (for some representative work see Bowles \& Gintis 2004; Henrich \& Boyd, 2001; Henrich et al. 2006) have stressed the relevance of punishment in human societies, they suffer the flaw of considering punishment as a single behaviour. In our view, punishing actually consists in a complex behavioral repertoire in which it is useful to disentangle at least revenge, punishment, and sanction. In Giardini, Andrighetto, Conte (2010) it has been argued that this variety of punishing strategies can be differentiated on the basis of 1 . their mental antecedents, 2. the way in which they influence the future conduct of others, and 3. the effects they aim to achieve. Having more than one available strategy allows humans to tailor their reactions and to achieve their goals more easily but, at the same time, this implies higher cognitive and computational costs. In fact, agents must be able to categorize actions in the correct way, meaning that the context has to be interpreted adequately, the most appropriate reaction has to be chosen on the basis of the perceived wrong, of the situation, and of the offender and other agents' mental states. This calculation leads to a significant increase in the computational costs, which should be compensated, by some sort of benefits. Revenge, punishment and sanction result from psychological adaptations that allowed to solve recurrent conflicts that humans encountered during their evolutionary history, but we still do not know why we have more than one mechanism.
If animal societies are able to cope with aggressions by using just one form of reaction (Clutton-Brock \& Parker, 1995), usually termed "punishment", why do we need a collection of counter-reactions? What are the fitness benefits coming from revenge, punishment and sanction?

In our theoretical analysis of reactions to a wrong, we start by providing a preliminary list of the core elements that determine the kind of response that an individual will choose in response to an aggression (see Table 1):
- The wrong suffered, i.e., the cause of the response. The evaluation of the offense depends both on the intentions the aggressor (the offense was intentional vs the offense was not intentional), and on the nature and value of the goal(s) frustrated by the aggressor.
- The goal of the reaction. When deciding how to react to an aggression, individuals consider the goal(s) they want to achieve and then select the appropriate reaction.
- The kind of influencing the agent reacting wants to apply to achieve her goal(s). Our theory is based on the idea that different reactions are aimed to produce different changes in the mind-set of the victim. For example, the avenger is aimed at acting at the epistemic level, by changing the target's and audience's beliefs about herself. The punisher aims to act both at the epistemic and motivational levels, by generating in the victim's mind the goal -
usually under threat of punishment- of abstaining from doing the action that has triggered punishment again. Finally, the sanctioner wants to endow the offender with new normative knowledge and to generate in her mind the goal to comply with the norm in the future.
- The focus of the reaction refers to the agent herself (as it is in revenge), another agent (as it is in punishment), or a norm (as it is in sanction).

It is worth noticing that we do not consider reactions as clear-cut phenomena, but they are overlapping in several respects. In Table 1, we summarize the main features of each reaction, in an attempt to identify the key elements of each phenomenon.

Table 1: Dimensions of change

Figure 1 depicts the mental path that triggers to choose a specific reaction. In the following section, a cognitive anatomy of revenge, punishment and sanction will be provided. In section 3, an analysis of the intended and unintended effects of the three reactions is presented. The latter analysis will allow us to sketch an evolutionary explanation of why we have more than one reaction to an offense, and how the cognitive extra-costs resulting from this variety of reactions are compensated.

Figure1: The cognitive path of reactions to a wrong
A further consideration involves the role of emotions. The specific role that anger, but also social emotions, such as moral outrage, pride, shame, guilt, indignation, contempt, disgust, resentment, etc., (e.g. Fessler \& Haley 2003; Frank 1988) play in triggering the reactions under study deserves an attentive theoretical and experimental analysis. Although crucial, this analysis is beyond the scope of the present paper and will be developed in future work.

\section*{Taxonomy of reactions to a wrong: Revenge, Punishment and Sanction}

\section*{Revenge}

Revenge, according to the Merriam-Webster dictionary, is "punishment inflicted in retaliation for an injury or offence". In Elster's terms (1990) it is "the attempt at some cost or risk to oneself, to impose suffering upon those who made one suffer, because they have made one suffer" (p. 862). Broadly speaking, the term 'revenge' refers to two diverse but connected phenomena.
In the first of these phenomena, revenge is a social ritual that requires and prescribes specific behaviours to group members to repair an offence. Ethnographic studies highlighted the transition from tribal to modern societies, in which retributive concepts of law and the creation of institutions replaced vengeance and avoided blood feuds (Boehm 1986). Posner (1980) suggests that revenge and retribution may be partially determined by historical and economic circumstances, such the private enforcement of law and high probabilities of detecting and punishing offences. When these conditions are met, a pure vengeance system may appear, although it is unlikely to be optimal. These systems are not completely extinguished, as the culture of honour in the southern United States (Nisbett 1993; Nisbett and Cohen 1996) and the Kanun in Albania demonstrate. The Kanun, a customary set of laws used mostly in northern Albania and Kosovo, disciplined people's reactions to murder (blood revenge or gjakmarrje) and other offences (hakmarrje), according to the roles and degree of kinship of all the people involved. Shirking revenge or taking it without respecting what is stated in the Kanun leads to the same result: honour cannot be restored and the whole family or clan is to blame. Apparently, the Kanun has not disappeared completely, and in some areas it is still observed, showing how an institution that is preserved in the mind can out-compete another centrally enforced institution, because the latter one is not recognized as such.

The other way of looking at revenge is to consider it as an individual behaviour, which is present both in human societies (Zaibert 2006), and non-human primate groups (Jensen, Call and Tomasello 2007). Turning our attention to individual factors it becomes possible to provide a cognitive anatomy of this reaction. The avenger wants to repay the damage she suffered with an equal or greater offence, no matter how risky or dangerous this retaliation is. In a sense, we can say that the avenger is a backward-looker who revolves around the past and acts in the present to rebalance what happened, with no concern for the future. Unlike other authors (McCullough, Kurzban, Tabak, 2012), we do not see vengeance as a means to affect the likelihood that the wrongdoer will repeat the aggression in the future, inducing her to cooperate next time or deterring her from further aggressions. Long term, strategic planning does not seem to characterize the avenger's mind, although unintended deterrence effects can be obtained.
Revenge is motivated not only by the desire to make the target suffer, but also by the goal to change the target's and audience's beliefs about the avenger, in order to restore the image that has been damaged by the aggression suffered. In this case cognitive influence is aimed at changing the beliefs of the wrongdoer and of the audience: the avenger aims to repay the damage she suffered with an equal or greater offence in order to change the target's and audience's beliefs about himself. Revenge is a way to regain one's position after an offence and this applies also to the symbolic dimension: the avenger wants to restore her image, damaged by the aggression suffered. Revenge is aimed to modify what the others believe about the avenger, her role and status. Presumably, the greater the offence, the more efficacious the image restoration and the effort to restore the status-quo.

\section*{Punishment}

Enforcing institutions have evolved with society: starting out as simple systems of revenge and retribution imposed by the individual, family, or tribe, in modern societies they grew as institutions characterized by a higher concern for deterrence and rehabilitation. Institutions controlling modern societies moved from systems based on revenge to ones based on punishment. In primitive society enforcement was left to the individuals wronged, or their families, and was vindictive or retributive (Boehm 1986): in quantity and quality it would bear no special relation to the character or gravity of the offence. Gradually it arose the idea of proportionate punishment, of which the characteristic type is the lex talionis of early Roman law or in the Old Testament and Koran. Like revenge, also punishment refers to two distinct class of phenomena: punishment is both a social institution and an individual behavior.
As an institution, punishment serves to dissuade people from engaging in activities deemed wrong by law and by the society itself, thus reducing the frequency and likelihood of future offences. Deterrence theory suggests that punishment works by modifying the relative costs and benefits of
situation, so that wrongdoing becomes a less attractive option (Bentham 1962; Becker 1968). Punishment possibly has the effect of preventing blood feuds and giving more stability to the social order.
As an individual behaviour, punishment is a reaction intentionally aimed to minimize the chance that the aggressor will repeat the act again (Giardini, Andrighetto and Conte 2010). Unlike revenge, punishment is not inflicted in retribution for an offence or transgression. The punisher is driven by forward-looking considerations, and deterrence is intentionally pursued.
This enforcing mechanism, controlling modern societies, is not at all easy to distinguish from revenge (Zaibert 2006), at least from a mere behavioural point of view. Cognitive modelling allows us to disentangle them on the basis of their mental antecedents and the way in which they influence the future conduct of others. The punisher and the avenger are aimed at influencing and modifying the target and the audience's minds in different ways: unlike the avenger, the punisher has the explicit goal to deter the wrongdoer from repeating the aggression in the future. To achieve this goal, the punisher should act in such a way that the offender, and possibly the audience, generates in her mind the goal usually under threat of punishment (i.e., by generating the belief in the victim's mind that future aggressions will be punished)- of abstaining from doing the action that has triggered punishment again.

\section*{Sanction}

Social order can be explained as the mere result of the deterrence effect of punishment. However what makes human cooperation so spectacular with respect to all other species is the presence of social norms, efficiently orchestrating social life. When punishing institutions are able to work in tandem with social norms, they are much more viable and effective in achieving and maintaining compliance and are more robust across time (Andrighetto and Villatoro, 2011; Villatoro et al. 2011).
By analyzing a large number of spontaneously emerged institutions in different countries, the political scientist Elinor Ostrom has identified a set of characteristics that make them successful in promoting social order. She suggests that the most effective institutions are those that facilitate norms' elicitation, their spreading, and compliance (Ostrom 2005; see also Casari 2007). Punishment, when properly designed, should tell people which behaviours are acceptable, i.e., the (social) norms regulating society, and which actions will cause punishment.
We refer to punishing institutions enforcing social order through mechanisms intentionally aimed to focus people's attention on social norms and to condemn their violation as sanction institutions. We consider sanction institutions as the last step of the institutional evolutionary process.
As in previous work (Giardini et al. 2010; Andrighetto and Villatoro, 2011; Villatoro et al. 2011), we use sanction to indicate the enforcing individual behaviour that, in addition to imposing a cost for the wrongdoing, as punishment does,
is also intentionally aimed at signalling norms to the offender (and possibly to the audience) so that she will comply with them in the future.
The type of cognitive influencing sanction exerts on the offender is more complex than those in revenge and punishment. In order to deter future norms' violations, the sanctioner endows the offender with (new) normative knowledge. The sanctioner uses scolding to reign in wrongdoers, expresses indignation or blame, or simply mentions that the targeted behaviour violated a norm. Through these actions, the sanctioner aims to focus people's attention on different normative aspects, such as: (a) the existence and violation of a norm; (b) the causal link between violation and sanction: "you are being sanctioned because you violated that norm" (c) the probability that violations will be sanctioned; (d) the fact that the sanctioner is acting as a norm defender. As recent psychological and economic experimental evidence shows (Cialdini et al. 1990; Bicchieri 2006; Galbiati and Vertova 2008; Houser and Xiao 2010), the norm focusing effect of sanction plays an important role in eliciting norm compliance. Thus, despite punishment, we suggest that sanction has the further effect, possibly aimed at by the sanctioner, to encourage the target to ground future decisions on internal evaluative criteria, established by the norm. By facilitating the spreading, recognition and internalization of norms, sanction possibly has the effect of promoting social order in a more stable and less costly way with respect to punishment.

\section*{Concluding Remarks}

In this work, we proposed an evolutionary account of reactions to a wrong as an integrated set. Unlike other theories, we are not interested in revenge, punishment or sanction per se, but in their co-existence. We posited that this variety of reactions is needed in order to achieve different goals, but they also imply an increase in complexity, due to the costs associated with the interpretation of the situation and the selection among reactions. We proposed that the transition from one to the other has been allowed by specific cognitive patterns, and suggesting that these mental mechanisms selected among given social structures, at the same time reinforcing and being reinforced by them.
Modifying others' actions require a set of cognitive skills that allow to represent others' mental states, considering the way in which these are harbored in one's mind, giving rise to social beliefs, namely beliefs about others' mental states (e.g. beliefs, intentions, desires, emotions). In addition, this requires also cognitive influencing, as the willingness to modify others' goals. Having a set of available reactions means that individuals should also be endowed with cognitive mechanisms to recognize which reaction is more appropriate in a given situation. This theoretical analysis will be

\begin{abstract}
Research suggests that gestures influence cognitive processes, but the exact mechanism is not clear. Additionally, it has been shown that when a linguistic task (metaphor explanation) involves the right brain hemisphere, the left hand becomes more gesturally active. We hypothesized that gestures with a particular hand activate cognitive processes in the contralateral hemisphere. We examined whether gestures with the left hand enhance metaphoricity in verbal responses. Results showed participants produced more metaphoric explanations when instructed to produce gestures with their left hand as compared to the right hand or not gesture at all. In addition, we measured the mouth asymmetry during metaphorical speech to determine individual differences in righthemisphere involvement in metaphor processing. The leftside mouth dominance, indicating stronger right-hemisphere involvement, positively correlated with the left-hand-over-right-hand advantage in gestural facilitation of metaphorical speech. We concluded that left-hand gestures enhance metaphorical thinking in the right hemisphere.
\end{abstract}

Keywords: Metaphor; representational gestures; brain hemispheric lateralization; mouth asymmetry.

\section*{Introduction}

There are many studies providing evidence for the relationship between gestures and cognitive processes, and several theoretical accounts explaining how gestures may determine cognitive processing. However, there is a debate about the type of processes gesture influences (e.g., lexical retrieval, imagery maintenance, and conceptualization; for a review see Kita, 2000), and the mechanism through which gesture influences cognitive processes is not yet clear. In this study, we will focus on the self-oriented functions, that is, the effect that gestures - and in particular representational gestures - have for those who produce them, and we will explore a neural mechanism for gestures' self-oriented functions, which has not been investigated in the literature.

According to the Lexical Retrieval Hypothesis gestures help speakers retrieve the lexical form on a surface level. In particular, it is suggested that gesture related information enters the speech production system to help the grammatical and/or phonological encoding (for a review see Krauss \& Hadar, 2001). Evidence for this hypothesis comes mainly from speech fluency studies. For example, Rauscher, Krauss, and Chen (1996) showed that gesture prohibition
led to more dysfluencies and slower speech rate when talking about spatial concepts. Therefore, it is proposed that gestures promote and facilitate speech production.

Alternatively, according to the Image Maintenance Hypothesis (de Ruiter, 2000) gestures have been thought to help the working memory maintain mental imagery during speech production. In particular, Wesp, Hesse, Keutmann, and Wheaton (2001) have shown that when speakers described images from memory, they used more gestures compared to talking about images they had a physical experience with; thus, indicating that gestures facilitate speakers to represent spatial information and maintain spatial imagery in working memory.

Finally, according to the Information Packaging Hypothesis, gestures help speakers at the conceptualization level; that is to formulate the concept to be uttered. In particular, Alibali, Kita, and Young (2000) showed that speakers gestured differently in two lexically comparable yet conceptually different tasks. Similarly, a gesture prohibition study (Alibali \& Kita, 2010) showed that children who were allowed to gesture could focus more on present perceptual-motor information in their verbal descriptions compared to those who were prohibited from gesturing. Thus, it is suggested that gestures help speakers focus on relevant information, and plan concepts in the way suitable for verbalization.

The above theoretical accounts - which are not necessarily mutually exclusive, rather complementary have attempted to explain how gestures may influence various cognitive processes. However, the mechanism for such effects remains to be explored. The aim of the present study is to determine whether gestures activate cognitive processes in the contra-lateral hemisphere. This is plausible because the hand choice for gesturing is influenced by the brain hemisphere that is predominantly active in a given linguistic task. In particular, Kita, de Condappa, and Mohr (2007) have shown that in right-handers the right-hand over left-hand preference for gesturing is significantly weaker whilst interpreting metaphoric expressions compared to non-metaphoric ones. This finding has been explained in terms of differential hemispheric specialization for linguistic processes, and in particular the key role that the right hemisphere has in the processing of figurative language (following the Right Hemisphere Hypothesis for Metaphor; see for example, Brownell, et al., 2007; for alternative views, see Cardillo et al., 2012 and Rapp, et al., 2007); that
is when a metaphor task activates the right hemisphere, this activation increases the frequency of the left-hand gestures. The present study tested the reverse causality: Do left-hand gestures activate metaphorical processes?

To investigate this hypothesis, we manipulated which hand is used for gesturing and assessed the performance in a metaphor explanation task. More specifically, participants were asked to explain the metaphorical mapping in English idiomatic expressions with metaphorical meaning (e.g., "to spill the beans" meaning "to reveal secrets"). These expressions and task have been previously shown to engage metaphorical thinking, and furthermore to activate the right hemisphere. For example, when participants explain such metaphorical expressions they demonstrate reduced righthand choice for gesturing (Kita et al., 2007), and reduced right-sided mouth dominance (Argyriou \& Kita, in prep.) than when they explain non-metaphorical expressions. Gesture production was manipulated within-participants by asking subjects to gesture with their left hand only, right only, or do not gesture at all. If gestures activate cognitive processes in the contra-lateral hemisphere, then metaphor explanations should demonstrate higher level of metaphoricity when participants gestured with their left hand compared to the other two gesturing conditions.

In addition, in order to further support the hypothesis, mouth asymmetry measurements during metaphor explanation were collected from the same group of participants. Mouth asymmetry has been agreed to indicate relative hemispheric specialization for speech production, and in particular the right-sided mouth asymmetry observed during verbal tasks has been related to the left hemisphere cerebral specialization for language production (for a review see Graves \& Landis, 1990). Moreover, Argyriou and Kita (in prep.) showed that mouth openings are more left-side dominant in a metaphor explanation task than in a concrete phrase explanation task, indicating the right-hemispheric specialization for metaphor. Therefore, we expected that the observed left-side bias in mouth openings during metaphor explanation would be positively correlated with the lefthand gesture advantage on speech metaphoricity.

\section*{Method}

\section*{Participants}

31 right-handed, male, native English speakers and monolinguals before the age of 5 years (age: \(M=20.35, S D=\) 2.86) participated in the experiment for course credit or \(£ 4\). They were all right-handed according to a standardized 12item handedness questionnaire (Oldfield, 1971): a score of " 1 ", " 0.5 " and " 0 " was given for each right-hand, either and left-hand preference respectively. We calculated the mean of the sum of these scores, and defined as right-handed those participants who scored at least 8.5. None of the participants had any previous serious injury to the face or jaw. All of them were recruited at the University of Birmingham. We focused on male speakers because
bilateral representation of language processing in men is less compared to women (McGlone, 1980).

\section*{Stimuli}

For the main descriptive task we used eighteen English expressions with metaphorical meaning. We created three (plus one in case one expression was unknown) additional metaphorical and concrete expressions for the mouth asymmetry task (see Table 1).

Table 1: Complete list of stimuli for the two tasks.
\begin{tabular}{|c|c|}
\hline \multicolumn{2}{|l|}{Metaphorical expressions for main descriptive task} \\
\hline To burst someone's & To sit on the fence \\
\hline bubble & To skate on thin ice \\
\hline To cross that bridge later & To spill the beans \\
\hline To dodge the bullet & To stand your ground \\
\hline To fall back down to earth & To take the bull by the horns \\
\hline To get back in the saddle & To turn a corner \\
\hline To get hot under the collar & To turn the tables \\
\hline To hold all the cards & Water under the bridge \\
\hline \multicolumn{2}{|l|}{To leave a bad taste in the mouth} \\
\hline \multicolumn{2}{|l|}{To look on the bright side} \\
\hline \multicolumn{2}{|l|}{Metaphorical expressions for the mouth asymmetry task} \\
\hline To pour oil onto the fire & To spin a yarn \\
\hline To set your sights higher & (To hit the nail on the head) \\
\hline \multicolumn{2}{|l|}{Concrete expressions for the mouth asymmetry task} \\
\hline To pour oil into the pan To put a shelf higher & To spin a golf ball (To hit someone on the head) \\
\hline
\end{tabular}

\section*{Procedure}

Participants were tested individually. They were seated on a chair, which was located between two tables of the same height ( 71 cm tall). The experimenter was facing the participant, and the video camera (Sanyo HD camera) was placed next to the experimenter. Stimuli were presented one by one on a white sheet of paper (font size 72, Times New Roman), which was held by the experimenter until the participant started the description.

Participants were instructed to explain the meaning of stimuli as if they were explaining it to a non-native English speaker. To encourage metaphorical thinking, participants were instructed to include an explanation as to how the literal meaning can be mapped on to the metaphorical meaning of the expression (e.g., in the expression "to spill the beans", "beans" refer to secrets, and "spilling" refers to spreading them to everybody). During the description, participants were told to place one of their hands on the indicated marks (white sticky dots) on the surface of the table(s), and to keep it still for the whole procedure. For the total prohibition condition, participants were asked to place both their hands on the tables (see Figure 1). For the gesturing conditions, they were instructed to gesture with
their free hand during the description (gesture encouragement instruction followed the paradigm in Chu \& Kita, 2011). Participants were debriefed about the purpose of the hands immobilization after the experiment and the permission to use the data was allowed. Order of stimuli (forward - reverse), and order of hand(s) prohibition was counterbalanced across participants in a within-participants design.

Figure 1: Experimental conditions (from left to right) Right Hand Gesturing, Left Hand Gesturing, No Gesturing.

In the mouth asymmetry task participants were instructed to explain metaphorical expressions, just as in the main task, and concrete expressions whilst both hands were prohibited. The order of the tasks (concrete - metaphor) was counterbalanced across participants. Hand prohibition was a necessary experimental control in order to collect a pure measurement of participants' hemispheric specialization for metaphor without any influence from gesturing. Videorecording zoomed-in on the face area.

\section*{Measures}

The verbal responses from the main task were transcribed and coded for their level of metaphoricity. The level of metaphoricity was measured based on whether the explanations included an explicit link between the literal and metaphorical meanings, and whether participants explicitly referred to the mapping between the source and target domains of the conceptual metaphor underlying each idiomatic expression (adopted from McGlone, 1996). More specifically \({ }^{1}\), a ' 0 '' rating indicated that the explanation did not contain words or phrases referring to the source domain of the relevant conceptual metaphor, therefore there was no

\footnotetext{
\({ }^{1}\) To illustrate how the \(0-2\) metaphoricity coding has been used, consider the following explanations generated for the item "to spill the beans": (a) "To spill the beans is to tell someone a secret or gossip" was coded with 0 because the explanation includes the meaning of the expression only. (b) "To spill the beans means to let something out, to tell someone something perhaps that you shouldn't been telling them; I guess the beans like information make a mess once spilling them" was coded with 1 because there is an implicit reference to the beans representing the information. (c) "To spill the beans is to tell someone something that you were not meant to tell; something which was confidential, private, and the beans represent the information that was private and by spilling them you are telling the news." was coded with 2 because it includes an explicit mapping between the source and target domains, and participant mentions the representation of each concept.
}
metaphorical cross-domain mapping; a rating of " 1 " indicated that the explanation contained words or phrases that might be construed as references to the source domain, but the references were ambiguous, and the mapping between the two domains implicit; a rating of ' 2 '" indicated that the explanation contained words or phrases that clearly refer to the source and target domains, and the mapping was explicit.

One individual "blind" coder was trained and coded 33\% of the total verbal responses in terms of metaphoricity. All answers from 10 randomly selected participants were coded (in total 180 trials were double coded). Coding of metaphoricity matched between the two coders \(76 \%\) of the time (Cohen's weighted kappa \(\kappa_{\mathrm{w}}=.68, p<.001\), kappa maximum \(\kappa_{\max }=.91\) ).

Video recordings from the three gesturing conditions in the main task were analyzed using ELAN software (developed by the Max Planck Institute for Psycholinguists, Nijmegen, the Netherlands). They were coded on a trial-bytrial basis to locate the existence of at least one gesture type; that is representational gestures, palm-revealing gestures, conduit, and other (e.g., beats).

Video recordings from the mouth asymmetry task were analyzed on a frame-by-frame basis using ELAN software. The first ten mouth openings were coded per trial for each participant (sixty mouth openings in total). We measured the laterality at each maximum mouth opening. One maximum opening was defined as the widest point the mouth opens since the lips open to the lips resting or the lips meeting completely. The options for laterality classification were: right-side dominant, left-side dominant, or sides equally open (see Figure 2 for examples). Maximum openings during filled-pauses were included, but not the ones for nonspeaking purposes (e.g., smile), nor the ones whilst participants were repeating the phrase to be explained.

Figure 2: (From left to right) Examples of right, left, equal maximum mouth openings. "Right" and "left" refer to the speaker's right and left.

One individual "blind" coder was trained and coded \(22 \%\) of the data in terms of right, left or equal dominance of mouth openings. All mouth openings from 7 randomly selected participants were coded (in total 414 maximum mouth openings were double coded). Coding of dominance matched between the two coders 79\% of the time (Cohen's kарра \(\kappa=.66, p<.001\) ).

The degree of left-side mouth dominance was computed for each participant based on the laterality (right-R, left-L, equal-E) of their 30 maximum mouth openings for each task (concrete and metaphor), and using the following formula:
(L-R)/(L+R+E) (adopted and adjusted from Holowka \& Petitto, 2002). Thus, a positive and/or low negative mean score indicated more instances of left-side dominant mouth openings during metaphor explanation (right-hemispheric lateralization), and a high negative score indicated more instances of right-side dominant mouth openings (lefthemispheric lateralization).

In addition, we calculated a left-hand gesture advantage index whilst participants gestured and explain metaphors in the main descriptive task. That is, the average metaphoricity per participant when gesturing with the left hand minus the average metaphoricity when gesturing with the right hand. Thus, a high and positive mean score indicated that participants were more metaphoric when gesturing with their left hand compared to the right (= left-hand gesturing advantage on metaphoricity). A negative or low positive mean score indicated that participants were more metaphoric when gesturing with their right hand compared to the left.

\section*{Design \& Analysis}

Out of the 522 trials in total in the main task, \(4 \%\) was excluded as failed trials; that is when the participants did not proceed as instructed (e.g., no gesture production when right or left hand was free), and when they did not know the expressions. The independent variable was which hand was free to gesture: right-hand gesturing, left-hand gesturing, not gesturing. The dependent variable was the level of the metaphoricity of the explanations (see the section Measures).

\section*{Results and discussion}

Out of the 354 gesturing trials, \(99 \%\) included at least one representational gesture; 23\% included at least one palmrevealing gesture; 7\% included at least one conduit gesture; \(18 \%\) included at least one "other" gesture - comprising mainly of beat and metacognitive gestures. Thus, the instruction to produce gesture was effective and we may assume that whatever the gesturing effect is, it will be due to representational gestures during the gesturing trials.

One-way repeated measures ANOVA was conducted to compare the effect of gesturing hand on level of speech metaphoricity in the three gesturing conditions (left-hand gesturing, right-hand gesturing, not gesturing at all). There was a significant effect of the gesturing hand, \(F(2,60)=\) 13.92, \(p<.001, \eta^{2}=.32\). Post hoc comparisons with Bonferroni correction between conditions indicated that level of speech metaphoricity was significantly higher when participants gestured with the left hand than not gesturing ( \(t(30)=2.81, p<.001\) ); metaphoricity was significantly higher when gesturing with the right hand than not gesturing \((t(30)=1.38, p=.028)\); and metaphoricity was significantly higher when gesturing with the left hand compared to right hand \((t(30)=1.43, p=.038)\) (see Figure 3). Thus, the gesturing hand had an effect on the level of metaphoricity in
speech. Specifically, gestures, especially, those by the left hand, improved metaphorical thinking.

We focused on trials in which only representational gestures were produced, and we limited the analysis to individuals who had trials with representational gestures only (2 participants were excluded; \(N=29\) ). Pattern of the results remained the same: left-hand gesturing ( \(M=1.53\), \(S E=.08\) ), not gesturing ( \(M=1.15, S E=.06\) ), right-hand gesturing ( \(M=1.39, S E=.08\) ). Also, the one-way repeated measures ANOVA remained significant \((F(2,56)=14.87\), \(\left.p<.001, \eta^{2}=.35\right)\). Thus, there is evidence that effect of the gesturing hand is due to representational gestures.

Figure 3: Average metaphoricity in speech in the three gesturing conditions. Error bars represent standard errors.

Next we compared the left-side bias in mouth openings during concrete and metaphor explanations. A one-way repeated-measures ANOVA performed on the left-side mouth dominance index with linguistic task as the independent variable yielded significant effect of the task, \(F(1,30)=6.45, p=.016, \eta^{2}=.18\). The left-side bias was higher during metaphor explanations ( \(M=-.11, S E=.08\) ) compared to the concrete ones ( \(M=-.24, S E=.09\) ), thus suggesting a reduced right-sided mouth asymmetry during explanation of metaphorical expressions. More importantly, we assessed the relationship between the left-side bias in mouth openings and the left-hand gesturing advantage during metaphor explanation. The range on the mouth asymmetry measurement was -0.90 to 0.77 , where positive scores indicate a right-hemispheric lateralization (= that is participants open their left side of the mouth wider than the right whilst explaining metaphors). The range on the lefthand gesture advantage index was -0.30 to 0.83 , where higher positive scores indicate that participants were more metaphoric when they gestured with the left than with the right hand. There was a significant positive correlation between the two scores \((r(29)=.38, p=.036)\) (see Figure 4). Thus, the participants for whom the left-hand gesturing advantage was bigger tended to have a stronger righthemisphere involvement in metaphoric speech production. Note further that the mouth asymmetry during explanation
of concrete expressions did not significantly correlate with the left-hand gesture advantage \((r(29)=.32, p>.05)\).

Figure 4: The scatter plot for the correlation between the left-side mouth dominance and left-hand gesture advantage during metaphor explanations.

\section*{General Discussion}

The goal of the present study was to investigate a neural mechanism for gestures' self-oriented functions. We measured the level of metaphoricity in metaphor explanations as a function of the hand used for gesture: the right hand, the left hand, no hands. We found that speakers produced more metaphoric verbal responses when they gestured with either hand compared to not gesturing at all, and when they gestured with the left hand compared to the right. We propose that left-hand gestures led to better performance in metaphor explanation because they activated metaphorical processing in the right hemisphere.

The present findings are in line with the Information Packaging Hypothesis (e.g., Alibali, Kita, \& Young, 2000), indicating that gesture helps the conceptual planning of the speech, and in particular the conceptual mapping for metaphorical speech.

In addition, the present results are compatible with previous studies on gesture and metaphor. For example, the present study found that metaphoricity was higher when gesturing, regardless of the hand, than when not gesturing. This is compatible with the observations that gesture inhibition reduces the use of metaphorical spatial language (Bos \& Cienki, 2011). More importantly, the findings shed new light on the inter-relation between the hand used for gesturing and hemispheric specialization. Kita et al. (2007) showed that hand choice for gesturing can be determined by the relative hemispheric specialization during different linguistic tasks. Thus, right-hand preference is reduced during metaphor explanations compared to concrete or abstract ones. Our findings provide evidence for the reverse causal link. That is, the gesturing hand can determine the level of speech metaphoricity, and in particular left-hand gestures enhance metaphor explanations. So, there seems to be a bi-directional causal relationship between left-hand gestures and metaphorical processing.

Although there are several studies, which manipulate gesturing in order to assess gestures' effect on cognitive processes (e.g., Alibali \& Kita, 2010; Rauscher et al., 1996), as far as we know, this is the first study to explore the neural mechanism for gestures' self-oriented functions, and link it with the hemispheric lateralization of cognitive processes. Crucially, the left-hand gesture advantage for metaphoricity significantly correlated with the left-side dominance in mouth openings for metaphorical expressions, but not for concrete expressions. That is, the left-hand gesture advantage is stronger in speakers who have strong righthemispheric control for metaphor. Thus, it further supports the idea that gesturing activates cognitive processes in the contra-lateral hemisphere.

But, how exactly this neural mechanism works? We may speculate how based on our current findings, and also in light of metaphor theories. Metaphor is considered as a matter of conceptualizing one conceptual domain in terms of another (Lakoff \& Johnson, 1980), and specifically the metaphorical mapping requires speakers to map a concrete concept on to a more abstract one. In addition, this mapping requires the conceptualization of a distant semantic relationship between the source and target domains of the metaphor, and it is considered to be predominantly computed in the right hemisphere, which processes coarse grained semantic information (Jung-Beeman, 2005). For example, in the expression to "spill the beans" participants had to represent the abstract concept of IDEAS (target) in terms of the distant concrete concept of OBJECTS (source). Our findings revealed that left-hand gestures were particularly beneficial compared to the right-hand ones for the metaphorical mapping. Therefore, we suggest that lefthand gestures make the distant semantic relationship between target and source domains of the metaphor to become closer, and then speakers can represent the metaphorical mapping in speech, thus become more metaphoric. It seems that left-hand gestures give some kind of "feedback" to the contra-lateral right hemisphere ("Hemisphere-Specific Feedback Hypothesis") and promote metaphorical processing, which crucially involves the right hemisphere.

The present study did not account for what aspects of gestural hand movement influences metaphorical thinking. More specifically, our findings cannot address the question, "is it the gesture or the arm movement per se which activates the processes in the contra-lateral hemisphere?" Previous studies (Ravizza, 2003) have shown that meaningless arm movements, such as tapping, may facilitate lexical retrieval. However, this is only in tasks where lexical items have been selected by automatic spreading activations but not sufficiently so, and not in tasks where words have to be strategically searched. We may assume that metaphorical mapping requires strategic search of semantic fields, thus arm movement per se may not facilitate the process. Thus, it is the depictive nature of the gestural movement as described above that enhanced participants' performance rather than merely the arm movement. Moreover, even
when the analysis included trials with representational gestures only, the results remained significant and demonstrated the same pattern (= left-hand gesture advantage). Thus, it provided implicit support for the effect of the depictive nature of representational gestures. However, future research to compare the effect of meaningless versus meaningful arm movements on metaphorical thinking would directly assess this issue.

In conclusion, the current study has advanced our knowledge of and enhanced theoretical accounts on a neural mechanism for gestures' self-oriented functions, which have received little attention so far. We propose that gestures activate cognitive process in the contra-lateral hemisphere such that left-hand gestures enhance a right-hemispheric specialized process such as metaphor processing.

\begin{abstract}
When proponents of cognitive externalism (CE) have turned to empirical studies in cognitive science to put the framework to use, they have typically referred to perception, memory or motor coordination. Not much has been said about reasoning. One promising avenue to explore here is the theory of bounded rationality (BR). In this paper, we try to clarify the potential relationship between these two programs. We start by discussing Andy Clark's interpretation of BR, which we find unconvincing in several respects. Next, we take a closer look at CE in order defend a version of it that stands against mainstream internalism without committing itself to constitutional claims about the mind. We then turn to analyze BR from the CE perspective. Finally, we argue that internalism about cognition cannot explain important aspects of the BR program.
\end{abstract}

Keywords: extended cognition; bounded rationality; heuristics.

\section*{Introduction}

By Cognitive externalism (CE) we refer to the framework that accommodates the initially differentiated challenges to the internalist picture of cognition, developed under the flag of extended cognition and distributed cognition. CE departs from the original proposal introduced by Clark and Chalmers (1998) in which what determines the cognitive status of an extended process is its functional parity with an intracranial cognitive process. The core of this shift is the complementarity of internal and external elements (Menary 2007, Sutton 2010, Wilson and Clark 2009). The argument for extended cognition turns on the way different inner and outer components co-operate so as to yield an integrated system capable of supporting intelligent behavior.

One consequence of this revised CE is a broadening of the span of the putative cases considered, as it points our attention to the many ways in which "the computational power and expertise is spread across a heterogeneous assembly of brains, bodies, artifacts, and other external structures" (Clark 1998, p. 77). Once parity is not required, we can tackle any manipulation of structures or elements that is integrated -e.g. measurement instruments, information storage devices, representational systems, etc.

Typically, proponents of externalist accounts of cognition have sought for empirical support from research in lower cognition, mostly memory (Clark and Chalmers 1989, Sutton et. al. 2010), and perception (Wilson 2010). But seldom the literature has addresses the realm of higher cognition. Here we want to explore the benefits that CE could offer to empirical research on human reasoning, and whether such research can vindicate \(C E\).

\section*{Bounded Rationality}

A promising avenue to explore is the interplay between CE and the program of Bounded Rationality (BR) as it is developed by Gerd Gigerenzer and colleagues into the Fast and Frugal Heuristics theory. The core research question of BR is: "How do people make judgments and decisions in everyday life, when time and information is limited and the future uncertain?" (Gigerenzer 2008, p. 5).

From here, the program unfolds in three dimensions: (1) The core descriptive tenet is that people typically rely on fast and frugal heuristics. There are strategies, conscious or unconscious, that search for minimal information and exploit evolved capacities and environmental structures (Gigerenzer and Brighton, 2009). (2) The core normative tenet is that such reliance on heuristics is at least oftentimes desirable. Heuristics work remarkably well; as good as -or even better than- optimizing strategies. They are not merely second-best options for "wanna-be optimizers". (3) The core prescriptive tenet is that the BR picture of reasoning affords prescriptive guidance, opening a space in which to enhance reasoning by intervening on the environment rather than in the inner processing.

There is a strong prima facie affinity between BR and CE. In the BR literature one can find many claims that echo the externalist tenets. We find claims such as that "the heuristic lets the environment do much of the work" (Gigerenzer and Hutchinson 2005, p. 101), or that "in the ecological view, thinking does not happen simply in the mind, but in interaction between the mind and its environment" (Gigerenzer 2008, p. 17, emphasis added). Somewhat surprisingly, BR has attracted only one discussion within
the externalist camp, by Andy Clark. In the next section we turn to his discussion of BR.

\section*{Clark on Bounded Rationality}

Clark (2001, 2003) addresses the relation between CE and BR guided by his own defense of CE, but also by his favoring of a "naturalistic" or "mechanical" account of rationality, i.e. one that is merely descriptive. Clark claims that there are two ways to develop a "naturalistic" or "mechanical" account of rationality based on a noninternalist approach in cognitive science. First, a "biological cognitive incrementalism" (BCI), according to which "fullscale human rationality is reached, rather directly, by some series of tweaks to basic biological modes of adaptive response" (2001, p. 121). Defenders of BCI view reasoning or rationality as continuous to more "basic" processes, such as perceptual responses to one's environment, that do not require the manipulation of symbols. A second option assumes that rationality is at best indirectly based upon processes of BCI and, instead, strongly based upon "symbiotic relationships with knowledge-rich artifacts and technologies" (2001, p. 122). Not surprisingly, Clark favors the latter view, since it obviously comes down to his version of CE. His argument accordingly should have two sides, one being directed against BCI, the other in favor of CE.

In Clark's view (2001, p. 126), BCI can be characterized by three core assumptions: (1) the thesis of organismenvironment interaction, or anti-representationalism; (2) the modularity thesis (heuristics, short-cuts which are locally rather than globally active); (3) the thesis of distributed cognition. He illustrates these assumptions with research on the wing-flapping of houseflies and phonotaxis in robot crickets (ibid., pp. 126-129). All behave successfully in their environments using extremely simple means. This "breeds skepticism" that "symbols, internal representations and the like play little role even in advanced human problemsolving" (ibid., p. 129). However, as Clark rightly points out, the anti-representationalism entailed by this view must not be taken too far, since typical instances of reasoning, such as drawing an inference or making a choice, are all "representation-hungry" activities (ibid.). Clark does not claim that BR requires that assumption, but he does think that BR is committed to assumptions 2 and 3 . Simple heuristics, after all, are supposed to make us smart because of their joint exploitation of evolved capacities and the structure of (the information in) the environment. To that extent, BR seems to be a naturalistic account of rationality that also subscribes to BCI.

Let us assume for the moment that the program of BR is indeed to be understood as endorsing (2) and (3). What, then, is Clark's objection to these contentions? His claim is that BR, thus understood, still does not grasp what we understand as full-scale human rationality (Clark 2001, p. 131). As he also says, "In much of this recent work, traditional conceptions of thought, reason and action are not so much reworked as by-passed entirely." (ibid., p. 126). But what is missing? Elsewhere he declares: "Rational behavior is, in some sense, behavior that is guided by, or
sensitive to, reasons. Intuitively, this seems to involve some capacity to step back, and assess the options; to foresee the consequences, and to act accordingly." (Clark 2003, p. 314) But this is surely only a necessary condition, and it is surely not denied by Gigerenzer's program. Although he emphasizes that we should often rely on such heuristics, he does in no way think they are to be used blindly. Any reasoner must ask himself or herself, Am I in an environment where this heuristic works? If not, can I use another heuristic, and which one? That obviously involves the ability to step back, assess the options, and so on. We should also note in this context that Gigerenzer has explicitly distanced himself from characterizing heuristics in terms of the modularity thesis: While they are short-cuts that are tuned to specific domains, heuristics need not be viewed as implastic as, say, perceptual processes (see e.g. Gigerenzer 2007, p. 43f.).

Now, what about the argument in favor of Clark's own position, viz. that rationality can better be understood by his extended mind thesis? Clark (2001, pp. 132ff.) points to the frequent close coupling of reasoning processes with artificial aids and scaffolds. But he actually expresses his thesis in two different ways: (1) We do understand rationality only if we see it as a capacity "tuned and applied to the very special domain of external and/or artificial cognitive aids" (2001, p. 131). (2) "human thought and reason is sculpted, enhanced, and ultimately transformed" by technology (ibid.). Certainly it is one thing to view rationality as a capacity tuned to work with certain external technologies, and quite another thing that to say that this capacity is (partly) constituted by technology. If our faculty of reason is fitted towards such aids, it should exist beforehand. Conversely, if it is "sculpted and transformed" by those technologies, it probably does not exist beforehand. Claims (1) and (2) do not easily go together, at least not without much further ado.

Perhaps here there is a mixing of rationality as a faculty and rational processes. That reasoning processes are causally related to such technological aids, or even constituted by them, does not show that rationality as a faculty is constituted by these interactions. Indeed, it cannot: What constitutes any mental faculty is commonly understood to be expressed in terms of laws that guide the behavior of the capacity -in the case of rationality, the usual suspects include rules of logic, probability theory and heuristics. To explain the constitution of a faculty by the constitution of certain processes is simply a category mistake.

Against this, Clark might bring up his view that reasoning involves feedback loops between the potential for refinement through reflection on its own basis (Clark 2001, p. 134). Fair enough. When someone gives us a reason for a belief or a decision, it is common to ask back "Why?", requesting the thinker's grounds and principles. But these may always be questioned too, of course. Moreover, using technological aids or developing new notations (in mathematics or logic, say) has been an essential part of these feedback loops. This has led to the repeated
renovation of the laws of proper reasoning. Assuming that the faculty of reason is constituted by some fixed laws is therefore problematic. If rationality possesses no immutable nature, it may seem that the distinction between the faculty and processes of reasoning cannot be used to undermine Clark's position. By truly engaging in such processes, we are caught in those feedback loops, and create the faculty anew, with no end in sight.

The problem with this rejoinder is that it is inconsistent with Clark's focus on a purely descriptive, "mechanical" account of rationality. Insofar as we ask for better modes and principles of reasoning, we engage in genuinely normative issues. BR doesn't face this problem because, pace Clark's reading, it does not commit to such a purely descriptive account. In contrast, one of the most interesting features of BR is that it constitutes a new attempt for bridging Is and Ought, at least for certain domains of human reasoning (Gigerenzer and Sturm 2012). This bridging is, in part, possible because BR does not subscribe to BCI in the way Clark thinks it does.

To sum up: While Clark thinks there is some good in the BR approach, he also thinks it is too much committed to BCI. This is largely a misunderstanding of the program. Clark's alternative position is expressed by claims that tend to be inconsistent. Now, before getting back to its relation with BR, let's take a closer look at CE.

\section*{Cognition Embedded, Scaffolded or Extended?}

The cognitive externalist wants us to treat cases of complementary integration of internal and external resources as a whole, and not to frame cognition as the working of an organic system that is just causally embedded in external resources. One thing that critics object is that whatever the explanatory benefits of CE are, you can get the same from internalism, so it wins, if only for parsimony concerns. To address this charge, we need to spell out the precise statement of what CE proposes for the putative cases in which environmental resources are involved in cognitive processes. There are three basic options:
(a) Embedded cognition takes the domain of complementarity-motivated putative cases of external cognition as showing the ways in which cognition is causally embedded in features of the environment that surround and supplement real cognition, which remains still located within the organism. Ontologically speaking, it is a claim of mere causal dependence. On the methodological side, the claim is that cognitive sciences should be mostly concerned in studying processes that take place within the organism, and not outside (Sutton et. al. 2010).
(b) Scaffolded cognition is the idea is that (at least some of) our cognitive capacities both depend on and have been transformed by our manipulations of environmental resources. The claim here is not about mere causal dependence but about integrative coupling between internal and external elements. Accordingly, cognitive science should study these processes as they appear distributed across organism and environment, instead of isolating the internal (Sterelny 2010).
(c) Extended cognition claims that sometimes cognitive processes and systems are literally extended, having regions of the environment as proper parts located outside the organism. In other words, sometimes manipulated elements and structures of the environment, material or otherwise, constitute part of the cognitive system. This claim of constitution is held hand in hand with the urge for a revisionary attitude in the cognitive sciences towards the study of such extended processes without isolating its biological parts.

These views can be considered as stretches in a continuum, each best covering a different range of putative cases (Sterelny 2010, Sutton 2010). Adjudicating between the three options might be more a matter of degree and preponderance than a 'winner-takes-it-all' situation. This is so because the range of cognitive phenomena that motivates CE is heterogeneous. Among other dimensions of variation (Sterelny 2010, Wilson and Clark 2009) we can distinguish between (a) Individual artifacts, such as notebooks or sensory substitution devices, that given certain conditions might call for a genuine extended cognition reading à la Clark; (b) Collective resources, in which the external cognitive resources are embedded in a collective activity which involves several coordinated individual agents, as in Hutchins' (1995) case study of the distributed processes that enable ship navigation; and (c) public resources, like symbolic representational systems.

The relationship between agents and public resources is best seen as a process of cognitive niche construction in which humans sculpt their environment so that it affords novel cognitive possibilities (Sterelny 2010). The real issue, then, is not the current synchronic location of the elements that constitute the cognitive system, but the integration between internal and environmental resources. Thus, "resources can be extended in the relevant explanatory sense even when they are not literally external" (Sutton et. al. 2010, p. 535). It is the manipulation of such resources and the transformative effect they have on the individual cognitive profile that provides the explanatory cornerstone.

The common internalist strategy is to conflate embedded with scaffolded cognition and contrast them both with extended cognition. They stress the difference between claims of dependence and claims of constitution. By insisting that the putative examples of scaffolded cognition involve a claim of dependence, they see them as grist on the internalist's mill.

The way to resist this move is to highlight that, beyond ontological qualms, the idea of scaffolded cognition moves cognitive science in practice in the same line as that of extended cognition (Sutton et. al. 2010). Despite the skepticism that the ontological claims of extended cognition can bring about, when it comes to the explanatory tasks of empirical research, we take the most significant divide to be that between embedded cognition on one side and scaffolded and extended cognition on the other. That is the choice between cognitive internalism and cognitive externalism. In the next section we will address BR from the perspective here sketched.

\section*{Unpacking Bounded Rationality}

BR tells us that simple heuristics make us smart by exploiting the environment. But, what does that mean? In order to further assess BR, we need to unpack its vague appeals to the environment.

\section*{The Execution of Reasoning}

Let us focus first on the role that the physical environment has in reasoning. Some of the heuristics discussed by the proponents of BR require for their execution that agents are in current sensorimotor interaction with the relevant physical environment, although it is doubtful that they would qualify, within the broad realm of problem solving, as instances of genuine reasoning. A model example of this kind of heuristics is the gaze heuristic that people use to catch a flying ball: Fix your gaze on the ball, start running, and adjust your running speed so that the angle of gaze remains constant. "A player who relies on the gaze heuristic can ignore all causal variables necessary to compute the trajectory of the ball (...) the player will end up where the ball comes down without computing the exact spot" (Gigerenzer and Brighton 2009, p. 110).

The execution of these heuristics requires that agents are in current physical contact with the relevant environment. The agent relies on the manipulation of the environment to solve the problem. The baseball player alters the relative position of the ball in the egocentric space. This subset of heuristics, although not distinctively characterized in the BR literature, is best seen as epistemic actions. By acting on the environment itself, agents dispense with the need of otherwise required complex internal representations. As they alter the physical and informational structure of the environment, these processes take the agent closer to the solution; thus they are part of the agent's processing of the problem (Menary 2010).

However, just as much of human reasoning, many of the heuristics analyzed by the BR program do operate decoupled from the environment. What role does the environment play in those cases? Consider a much discussed cognitive task: estimating the relative size of two cities. Two suitable strategies provide a good illustration of the paradigmatic kind of heuristic that BR puts forth.

The first is the Recognition Heuristic: if one of the options is recognized and the others are not, infer that the recognized alternative has the higher value on the target criterion. That is, if we recognize one of the cities, we ought to infer that it is the larger. Research suggests this is indeed what people usually do (Todd and Gigerenzer 2007).

The second is Take the Best (TTB); "To infer which of two alternatives has the higher value (a) search through cues in order of validity, (b) stop search as soon as a cue discriminates, and (c) choose the alternative this cue favors" (Todd and Gigerenzer 2007, p. 168). That is, we consider the available cues (airports, tourism, industry, universities, etc.) sequentially, in order according to the degree to which they correlate with the population size, stop at the first cue that discriminates and infer that the city favored by that cue
is the largest. There is ample empirical evidence from behavioral studies that precise models of such heuristics better predict the subjects behavior in different task settings than optimizing models (Gigerenzer and Brighton 2009).

These heuristics typically operate upon internal representations. Construed as algorithmic process models, all that the algorithm requires is supplied by either the contents of our memory (i.e. cues) or by effects produced by their recall (i.e. perceived recognition). Thus, here the environment does not play any direct role in the execution of reasoning. So, apart from those peripheral cases of epistemic action, the bulk of BR's account of the execution of reasoning can be accommodated by internalism.

\section*{The Assessment of reasoning}

Defenders of BR do not merely claim that our reasoning often relies on heuristics; they also argue that this is frequently for the better. One of the major findings of BR is that often, for a given environment, fast and frugal heuristics outperform more costly strategies in terms of accuracy (Gigerenzer and Brighton 2009). Hence the claim that heuristics are rational; only that their rationality is ecological. Ecological rationality defines the rationality of heuristics by the match between internal processing and the environment. But what is meant by environment, here?

First, there are always some constraints on the strategy being applicable. In the case of the recognition heuristic, one of the items must be recognized while the others are not. If this obtains, there are further features of the environment that will determine the performance of the heuristic. Plainly, the recognition heuristic will perform well if and only if the target criterion correlates with the recognition of the item. This is called recognition validity, and it constitutes the relevant structure of the environment for the performance of the heuristic.

The necessary condition for the applicability of TTB is that we have different available cues and we can rank them in order of validity. Then, the main structural properties of the environment that determine its performance are that (i) the more correlated the available cues are, the less it pays to take them all into account (and accordingly, TTB performs as good as or better than optimizing strategies that demand taking all cues into account); (ii) the more the cue validities vary, the more it pays to use a strategy like TTB; and (iii) the smaller the learning sample, the better lexicographic strategies like TTB pay.

What is relevant and needs to be specified in order to evaluate reasoning strategies is the structure of the available information as defined by properties like cue redundancy, variability of cue validities, or size of learning samples. That is the environment that most heuristics exploit.

Reasoning performance is determined by the match between strategies and informational features of the environment that determine the strategy's relative success. Thus, the locus of ecological rationality is not only the internally processed algorithm, but the internal-algorithm-in-specific-environment complex. In this sense, the
environment does play a normative role in reasoning according to the BR program.

At this point, the internalist might object, "Fine, agents implement reasoning algorithms that operate upon stored information, and then it turns out that the performance of these algorithms is dependent upon how things are in the world. So what? This doesn't necessitate CE. There is no close internal-environmental resource integration here." However, this is not the whole story. Some of the features of the environment that play a normative role are not simply encountered out there. They are the product of the agent's ongoing coupling with the environment. Consider the role of uncertainty. As Gigerenzer has argued: "the degree of uncertainty reflects the environment (ontic uncertainty) as well as the mind's limited understanding (epistemic uncertainty); hence, the degree of uncertainty is located in the system mind-environment ... redundancy and variability of cues depend both on what is in the physical environment and on humans who select certain cues and not others, which can result in more or less redundant cues. Physicians, for instance, tend to look at redundant cues, but they could choose to analyze independent cues and thus in part create their environment" (Gigerenzer and Sturm 2012, p. 257).

A narrowly internalistic interpretation of BR takes heuristics as one-shot games. But in order to understand how rationality emerges from the use of such strategies, it is of much importance to consider the way in which the agents' behavior shapes the environment that shape the performance of their available reasoning strategies. Complementarily, the relative performance of a heuristic does affect its actual occurrence, albeit in an unexplained way. Part of the selection of a strategy operates upon internal representations, as memory constrains which heuristics can be applied. A second factor driving the selection of strategies is reinforcement by feedback. Still, beyond memory constrains and in absence of reinforcement, there is evidence that people rely on heuristics when they face those environments in which doing so pays off and not otherwise -i.e. relying on TTB when the validity of the available cues varies highly but not otherwise (Gigerenzer and Brighton 2009). This suggests that people are sensitive to the structure of the environment that determines the performance of heuristics.

The internalist can account for part of this story. It can explain how the heuristic strategy that the agent happens to apply is derived from a given structure of mental representations. It can also evaluate the performance of a strategy given a particular environment. It can even make inventories of heuristic-environment successful pairings. But, when it comes to deeper issues, such as why and how the agent chooses right and correctly applies a heuristic, or how and why certain environments have come to afford simple strategies, or how we have come to have such proficient heuristic tools, internalism seems to fall short. It faces the threat of falling into the "just happens" stance.

The emergence of normativity that results from the interaction between agent and environment is hardly the result of (only) internal computations. Whatever a much
needed further investigation into these frontiers of theorizing delivers, we contend that, at least for the large domain of uncertain reasoning, it is highly plausible that normativity is due to the ongoing process of back-and-forth manipulation (of the environment) and transformation (by the environment) that CE aims to unravel.

\section*{The Enhancement of Reasoning}

Next to the descriptive and the normative, BR also has a prescriptive dimension. Insofar as reasoning performance has to be assessed by the match between internal processing and environment (for some limits, see Sturm 2012), a dual perspective opens with regard to the enhancement of reasoning: we can either change what goes on within our heads, or change the environment. The development of both these prescriptive stances highlights a different point of connection between BR and CE .
A good example of the first line of prescription is fast and frugal decision trees for medical diagnoses. These are sequential trees designed for a very specific situation, like deciding whether a patient in the ER requires immediate attention facing a heart attack. They work as enacted protocols that the physicians must blindly follow. Interestingly, fast and frugal trees do not directly modify doctor's internal capacity of processing. From the doctor's point of view, they are an environmental resource, a cultural artifact they engage with in repeatable cognitive practices. It is part of the setting of the ER, upon which coordination between doctors is optimized. And indeed it has a transformative effect in doctor's cognitive behavior -i.e. leading their attention to certain cues while ignoring others.
The second path for reasoning enhancement that BR pursues is typically illustrated by drawing attention to the alarming lack of competence of physicians to assess risk probabilities (Gigerenzer 2008). Several studies show that when given information in percentages, physicians often perform poorly. They could be further instructed not to neglect base rates. But, as Gigerenzer puts it, "in the ecological view, thinking does not happen simply in the mind, but in interaction between the mind and its environment. This opens up a second and more efficient way to solve the problem: to change the environment" (2008, p. 17). The proposed prescription is to provide information in natural non-normalized frequencies (that is, in terms of " \(n\) out of every 1,000 people have disease \(x\). Of these \(n\) people, \(m\) will have a positive test, etc.").
Interestingly, "the relevant part of the environment is the representation of the information, because the representation does part of the Bayesian computation" (Gigerenzer 2008, p. 18). The object of manipulation of these change-theenvironment proposals is neither the material environment that plays a role in the execution of heuristics nor the information-structural properties of the environment that play a pervasive role in assessing the performance of heuristics. Instead, they point to symbolic and representational resources, which are thereby assumed to play a computational role. That is, cognitive practices carried upon the manipulation of symbolic structures. This
still squares perfectly with the work done by Menary (2010), Sterelny (2010) and Sutton (2010) on cognitive scaffolding, and the engagement with representational tools.

\section*{Conclusion}

Although Clark's characterization of BR is misguided, it is still true that BR's account of reasoning does not fit much with the old-school notion of extended cognition. Its processes and mechanisms do not involve agents in stable and durable couplings with technological resources they trust. But, pace Clark, this does not mean BR is a dead end for CE, since CE needs not be bounded to those cases in which the environmental resources constitute a proper part of cognition. BR's environmentalism does not consist in any ontological claim about the location and boundaries of the mind. It is a claim about explanatory variables and about normative criteria for understanding and improving human rationality. As such, it is best accommodated by the notion of scaffolded cognition.

From this moderate take on CE, we have shed light on the appeals to the environment made throughout the \(B R\) literature. We distinguished the role played by the physical environment in online heuristics qua epistemic actions, where we find instances of reasoning carried upon processes that functionally span through certain physical elements of the environment. But we also acknowledged that the execution of heuristics is typically decoupled from the real, mind-independent environment, and the account offered here by BR still fits with what a traditional internalist account would claim. Then we focused on the normative role played by the informational structure of the environment in determining heuristic performance, and on the role played by symbolic representations in the enhancement of reasoning performance. We believe that this conceptual clarification is quite a beneficial outcome of the whole debate for the development of the BR program.

Beyond that, we also pointed to some blind spots of internalism. The internalist can accommodate the actual processing of the heuristic, but it can hardly sustain the picture of rationality that emerges from the use of heuristics. Its narrow scope leaves important parts of the story on the dark, such as the emergence of the so-called "informational environment" and the co-enhancement process between agents and environments by which we can explain why we use the strategies we use and why is it that these happen to succeed beyond luck.

Those issues require further research that should be focused on the ongoing dynamic of interaction between agents and environments, and we contend that a moderate, scaffold externalism is the most fertile framework for this. In turn, we take these considerations to vindicate our take on CE, which acknowledges and incorporates the heterogeneity of cognitive engagements with the environment, and needs not be too much drawn by ontological claims, but rather to prove its explanatory value for cognitive science.

\begin{abstract}
Graphical password is an alternative method of authentication to alphanumerical passwords. From the perspective of research on human memory, it is yet another novel technology that introduces challenges on human memory components. In this study, we aim to investigate the previous findings in human visual memory in the domain of graphical passwords by analyzing the role of visual coherence in passwords. The results of an experimental study reveal that in terms of memorability, coherent images are better candidates as graphical password images than jumbled images.
\end{abstract}

Keywords: Graphical passwords; visual coherence, visual working memory, eye tracking.

\section*{Knowledge-Based Authentication Systems}

The extended use of human computer interfaces in the past few decades has introduced several challenges on users' working memory. One such challenge is the requirement to memorize numerous passwords for security authentication. From the viewpoint of information security, user access to a security system is granted in three phases: identification, authentication and authorization (Figure 1). After identification, the user supplies the proof of her/his identity in the authentication phase. The proof of identity is usually accomplished by employing methods such as using a smartcard (token-based authentication), using biometric information such as fingerprints (biometric-based authentication), or entering an alphanumeric or a graphical password (knowledge-based authentication).

Figure 1: A taxonomy of authentication methods in information security systems.

Recently, knowledge-based authentication methods-in particular, text-based, alphanumerical passwords-are largely used for information access in information security
systems (Herley et al., 2009). An alternative knowledgebased authentication method, namely graphical passwords, has been recently gaining an increased use.

\section*{Graphical Passwords as an Alternative Method to Alphanumerical Passwords}

Graphical passwords were developed to overcome some of the security issues involved in the use of alphanumeric passwords (Dunphy et al., 2008). Graphical passwords are of different types, such as recall-based, recognition-based, and click-based (Figure 2). In a click-based graphical password system, a pixel-based image acts as a cue for activating user's memory. When creating a password in a click-based system, the user selects a sequence of number of (e.g., four or five) points on the presented image. After then, to login the system, the user reselects the points on the image in the same order by clicking on (or near to) them (Blonder, 1996; Wiedenbeck et al., 2005; Chiasson et al., 2007; Chiasson, 2008).

Figure 2: Sample graphical passwords (Dhamija \& Perrig, 2000, Lashkari et al., 2009; Valentine, 1999).

From the end-user's point of view, the major motivation for the development of graphical passwords was to take the advantage of picture memorability over text while maintaining security (Wiedenbeck, et al., 2005), thus providing a solution to the security-usability dilemma. \({ }^{1}\) The motivation for the development of graphical passwords finds its roots in early studies in cognitive psychology research, which revealed that humans have a tendency to

\footnotetext{
\({ }^{1}\) The security- usability dilemma refers to the observation that "passwords are often either memorable-but-insecure or secure-but-difficult-to-remember" Chiasson, 2008, p. 3. Graphical passwords as a solution to the dilemma are beyond the scope of this study.
}
remember images longer and better than words (cf. the picture superiority effect, Nelson et al., 1976). Accordingly, images are usually expected to be "easier to remember and more secure than words" (e.g., Cranor, \& Garfinkel, 2005; Kirkpatrick, 2002; Suo, Zhu, \& Owen, 2005), thus leading to memorability advantages over alphanumerical passwords.

In addition to offering a more memorable solution for security system authorization, graphical passwords provide a naturalistic environment for research on visual memory in daily life tasks. Although the focus of research has been the security-usability dilemma from an information security point of view, there are many aspects that need further investigation from the perspective of cognitive science, such as the identification of the circumstances under which graphical passwords achieve better memorability. One such factor is visual coherence, as described below.

\section*{Visual Coherence in Graphical Passwords}

Two major aspects of binding of objects in visual working memory are the binding of objects to perceptual features, such as color, shape and orientation, and the binding of objects to locations (Hollingworth \& Rasmussen, 2010). In visual cognition, the concept of coherence has been studied by Biederman (1972) and Biederman, Glass and Stacy (1973), leading to research results which showed that the objects were recognized and identified more efficiently and quickly when the scene image was presented coherent rather than jumbled. \({ }^{2}\) Mandler and colleagues have shown that the presence of a coherent background scene improves memory for both the location and the perceptual features of the object in the scene (e.g., Mandler \& Parker, 1976; Mandler \& Ritchey, 1977; Hollingworth, 2009). The facilitating effect of context in memory retrieval has been observed in both short-term time scale and long-term time scale (see Brady et al., 2011 for a review) (Brockmole et al., 2006; Foulsham et al., 2011). Those findings in visual working memory research suggest that visual coherence in graphical password images would improve memory for graphical passwords. In other words, when used as a graphical password image, a coherent image may reveal advantages over jumbled images. To test this hypothesis, we conducted an experimental study, in which the participants were shown how to create a click-based graphical password and how to login with the password, as described in the following section.

\section*{Experiment}

In the practice session of the experiment, participants were guided by on-screen instructions about how to create a password. During the experiment, participants were presented a visual distraction task and then they were asked to login once. They were asked, however, to click on a black

\footnotetext{
\({ }^{2}\) The jumbled image was created by dividing the coherent image into multiple sections and manipulating the relative positions of the sections without rotating them.
}
screen to login, instead of the previously presented graphical password image. This was the end of the first session. In the second session, three days after the first session, they were asked to login by using their password, again on the black screen. In both sessions, participants' login success and time were recorded. Participants' eye movements were recorded by a 50 Hz . non-intrusive eye tracker, integrated into 17 '" TFT monitor. \({ }^{3}\) The experiment was conducted in an office environment, with a developed application which simulated the interfaces of operating system that the participants were already familiar with. Overall, the experimental setting provided a relatively naturalistic environmental setting.

\section*{Participants, Materials and Design}

Sixty-three participants (29 females, 34 males \(\mathrm{M}=32.1\); \(\mathrm{SD}=0.73\) ) participated in the experiment. All of the participants were employees at a governmental institution and the participation in the study was voluntary. The participants were divided into two groups, according to the type of the graphical password image they were presented in the password creation phase: (1) a coherent image or (2) a jumbled image. Each group was further divided into two groups according to the type of the image presented when participant failed to login on a black screen.: (1) the same image as the image presented in the password creating phase or (2) a shuffled version of the previous image. The base image for the graphical password was a high resolution (2362*2362) image taken in a professional setting. The image was converted into gray scale to reduce visual saliency effects due to color contrast. This image was used as the graphical password for the coherent-image group participants (henceforth, the coherent group). The jumbled image, which was used as the graphical password image for the jumbled-image group participants (henceforth, the jumbled group), was produced out of the coherent image by randomly jumbling the pieces of the coherent image, in the form of a \(3 x 3\) grid (Figure 3). There was at least one identifiable object in each cell of the grid.

Figure 3: The images \((600 * 600)\) for the graphical password in the coherent group (left) and the jumbled group (right).

\footnotetext{
\({ }^{3}\) The participants were seated at a distance of approximately 60 cm to the monitor. Spatial resolution and accuracy of the eye tracker was about \(0.25^{\circ}\) and \(0.50^{\circ}\) degrees respectively.
}

The participants were instructed to choose passwords which they could remember but that would be difficult for others to guess. They were guided by the instruction screens. The experiment consisted of two sessions. The first session was divided into five phases: practice, password generation, questionnaires, mental rotation task and login. In the practice session, the participant was shown how to create a graphical password and how to login with the selected graphical password. After the practice session, the participants picked their passwords by clicking four clickpoints on the provided image. After then, they filled out a demographic questionnaire and a usability questionnaire. A 30 second mental rotation task was then administered to disrupt visual memory. In the last phase of the first session, the participants were asked to use the selected password to login the system. The second session was a login session only; it was administered three days after the first session.

\section*{Results}

In the last phase of the first session, the participants were asked to login the system by clicking on a black grid screen, without the graphical password image on the screen. This screen consisted of nine black squares in the form of a grid. The motivation for using the black screen was to investigate participants' strategy for choosing the password items. If the participant chose password just by memorizing object properties, without memorizing the spatial locations, s/he would not be able to log in without seeing the graphical password image. This was a surprise task for the participants because they were not informed about the black screen beforehand. The results showed that, however, the participants achieved a very high success login ratio on the black screen: Fifty-seven of sixty-three participants were able to login on the black screen, before being presented the graphical image (i.e., in the first, the second and the third attempt). This finding suggests that the participants remembered very well the locations of the click points in the first session. The results also suggested that a comparative analysis between the coherent-group participants (who were presented a coherent image as the graphical password) and the jumbled-group participants (who were presented a jumbled image as the graphical password) would be possible, because the results were similar between the pairgroups and the further division according to the type of the image presented at the login phase (i.e., shuffled vs. same) was no more necessary. Accordingly, the analyses were performed in terms of the measures below
- The time to login, create and confirm the password
- Eye movement parameters (fixation count, duration, Levenshtein distance) and visual saliency
- Password creation strategies

All the analyses were performed on participants' performance on the black grid screen in the first session (i.e., the login test in the same day) and in the second session (i.e., the login test three days after the first session). Additional analyses were also reported below, on visual saliency and on answers to questionnaires. Overall, the
results suggested that coherent-group participants exhibited better memory performance compared to the jumbled-group participants, as presented below.

\section*{Login Success}

The participants were allowed to try to login three times on the black grid screen. We performed a comparative analysis for the login success of the 56 participants in the first login attempt only. A three-way loglinear analysis (Login Success x Session x Group Type) produced a final model that retained login success and group type effects. This indicated that the interaction between login success and group type was significant, independently from the session. \(\chi^{2}(1)=\) \(5.20, p=.02\) (Figure 4). Based on the odds ratio, the odds of success in the first attempt was 2.98 times higher for the coherent-group than the jumbled-group participants.

Figure 4: Login success of the participants in the first try (the numbers show the success and the failure ratios of the participants between 0 and 1)

The overall success ratio on the black screen, including the further attempts (up to three), revealed a similar finding, (i.e. the interaction between login success and group type was significant, independently from the session, \(\chi^{2}(1)=\) 4.96, \(p=.04\) ), showing that coherent-group participants were more successful to login than the jumbled-group participants in the overall login attempts on the black screen.

\section*{Login Duration}

The participants spent time to create the password and then to login on the first day of the experiment (i.e., the first session). In the first session, no difference was observed between the jumbled-group ( \(M=25.2\) seconds, \(S D=15.7\) ) and the coherent-group participants \((M=22.4 \mathrm{~s}, S D=11.6)\) in creating the password, \(t(61)=0.81, p=.42, r=.10\). Moreover, the time to login was not different between the jumbled-group ( \(M=9.75 \mathrm{~s}, S D=6.32\) ) and the coherentgroup participants ( \(M=7.85 \mathrm{~s}, S D=3.82\) ). Although the participants spent approximately the same time to login between the first session ( \(M=8.79 \mathrm{~s}, S D=5.25\) ) and the second session ( \(M=8.56 \mathrm{~s}, S D=5.69\) ), the time spent to login in the second session was different between the jumbled-group ( \(M=10.1 \mathrm{~s}, S D=7.19\) ) and the coherent-
group participants \((M=7.07 \mathrm{~s}, S D=3.19), t(57)=2.02, p=\) .048, with a small effect size of \(r=.26\). To sum up, the analysis of login durations showed that, in the second session of the experiment which was conducted three days after the first phase, the coherent-image group spent less time to login compared to the jumbled-group participants.

\section*{Fixation Counts}

In this study, the term fixation count is used for describing the number of fixations on the black grid screen. The fixation counts were analyzed for a comparison between the jumbled group and the coherent group. The results were similar to the results obtained for login duration: there was no significant difference between the jumbled group ( \(M=\) 18.3, \(S D=12.3\) ) and the coherent group ( \(M=14.4, S D=\) 8.83) in the first session. In the second session, however, the difference in fixation counts between the jumbled group ( \(M\) \(=18.6, S D=16.6\) ) and the coherent group ( \(M=11.1, S D=\) 6.57) was significant, \(t(56)=-2.00, p=.05\), with an effect size of \(r=.26\). There was also a significant main effect of the session in fixation counts, \(F(1,56)=10.16, p=.002\), showing that the participants produced more fixation counts in the first session than they did in the second session. As the final step of the fixation count analysis, we investigated whether each fixation location belonged to the password (i.e., a pass item) or it did not belong to the password (i.e., a non-pass item). The participants in both groups spent more fixations on their pass items than their non-pass items, both in the first session, \(F(1,61)=79.9, p=.00\), and in the second session, \(F(1,56)=111.3, p=.00\). Moreover, in the second session, the coherent group spent less fixations on the non-pass items ( \(M=0.47, S D=0.51\) ) compared to the jumbled group ( \(M=1.63, S D=2.07\) ), \(t(56)=3.17, p=.00\). To sum up, in the second session, the jumbled group produced more frequent fixations compared to the coherent group. Moreover, the coherent group focused more efficiently on their pass items compared to jumbled group, who were focusing on non-pass items as well as pass items.

\section*{Fixation Durations}

The term fixation duration is used in this study for the mean duration of single fixations on the black grid screen. There was no significant difference between the coherent group ( \(M=429.4 \mathrm{~ms}, S D=95.2\) ) and the jumbled group ( \(M=\) \(433.1 \mathrm{~ms}, S D=145.7\) ) in the first session. On the other hand, in the second session, the participants in the jumbledimage group had shorter mean fixation duration on the black \(\operatorname{grid}(M=453 \mathrm{~ms}, S D=171)\) than the participants in the coherent-image group ( \(M=496 \mathrm{~ms}, S D=125\) ). This difference was significant \(t(56)=-2.12, p<.04\) and it did represent small-sized effect \(r=.27\). As the final step of the mean fixation duration analysis, we investigated whether each fixation location belonged to a pass item or it belonged to a non-pass item. The participants in both groups made longer fixations on their pass items than their non-pass items, both in the first session, \(F(1,56)=30.5, p=.00\), and in the second session, \(F(1,56)=50.8, p=.00\). Moreover, in
the second session, mean fixation duration on pass items were similar for both the coherent group ( \(M=562 \mathrm{~ms}, S D=\) 259.8 ) and the jumbled group ( \(M=486 \mathrm{~ms}, S D=152\) ). On the other hand, the coherent group made shorter fixations on non-pass items ( \(M=228 \mathrm{~ms}, S D=173\) ) compared to the jumbled group ( \(M=373 \mathrm{~ms}, S D=250\) ), \(t(56)=3.33, p=.00\) in the second session. To sum up, the analysis of fixation durations revealed that in contrast to the similarities between the two groups in the first session, the jumbled group exhibited shorter fixations compared to the coherent group in the second session. Moreover, in the second session, the coherent group exhibited shorter fixations on the non-pass items.

\section*{Levenshtein Distance (LD)}

The Levenshtein Distance (LD) is a specific application of the string editing analysis, where the distribution of fixations on certain locations (in our case, the grid cells) is coded by letters. The letter strings of each participant are then compared with the password of the participant for similarity. The LD defines the number of modifications (i.e., insertions and deletions) on one string that is necessary to make it the same as the other.

In our study, LD was used a specification of the similarity between the two groups of participants. The results of the LD analysis revealed that, the participants in the first session ( \(M=8.22, S D=7.18\) ) exhibited longer LD compared to the participants in the second session ( \(M=\) \(6.97, S D=8.24), F(1,56)=9.69, p=.00\). In addition, in the first session, no significant difference was obtained in LD between the jumbled-group participants \((M=9.35, S D=\) 7.96) and the coherent-group participants ( \(M=7.08, S D=\) 6.25 ). In the second session, the difference between the jumbled-group participants ( \(M=9.64, S D=10.2\) ) and the coherent-group participants ( \(M=4.30, S D=4.29\) ) was significant, \(t(56)=2.57, p=.01\), with a medium-size effect of \(r=.32\), indicating more search effort in the jumbled-group participants compared to the coherent-group participants.

\section*{Visual Saliency Analysis}

The saliency maps of the coherent image and the jumbled image were computed by using the algorithm provided by Walther and Koch (2006). \({ }^{4}\) Based on this, the percentage distribution of the saliency of each cell in the \(3 \times 3\) grid was calculated. The resulting distribution provided the relative saliency distribution over the password image. The distribution of participants' pass-items was also calculated by analyzing the selected graphical passwords in the experiment. For the jumbled image, no relation was obtained between the saliency values and the ratio of being pass-item, \(\mathrm{r}=-0.11, p=.34\) (Figure 5).

\footnotetext{
\({ }^{4}\) SaliencyToolbox library, http://www.saliencytoolbox.net
}

Figure 5: The saliency distribution in the jumbled graphical password (left) and the percentage of being selected as a pass-item by the participants (right).

A similar analysis was conducted for the coherent image. Again, no significant relation was obtained between the saliency values and the ratio of being pass-item, \(r=0.30, p\) \(=.47\) (Figure 6).

Figure 6: The saliency distribution in the coherent graphical password (left) and the percentage of being selected as a pass-item by the participants (right).

In summary, visual saliency analyses revealed no useful results to account eye movement behavior characteristics in graphical passwords, in line with the findings in relevant domains of visual cognition (Tatler \& Vincent, 2009)

\section*{The Analysis of Password Creation Strategies}

After the participants created the password in the first session of the experiment, they filled in a questionnaire about their strategy for creating the password. Four choices were presented to the participants: (a) I created a pattern that looked like an L-shape or a V-shape (create pattern), (b) I memorized the names of the objects in the password (object recognition) (c) The objects I selected had common visual features (e.g., color, shape) or functional (e.g., cutting) features, (similar features) (d) I created a story (story). The participants were allowed to make multiple choices. The participants' answers were analyzed in terms of the relation between the group type, the session, the adopted strategy and the login success. A main effect was obtained for strategy, \(\chi^{2}(1)=91.7, p=.00\), indicating that there was a significant difference between the adopted strategies. Pattern creation was the most preferred strategy (33 out of 77). Furthermore, the interaction between strategy and group type was significant, \(\chi 2(3)=8.61, p=.03\), indicating that adopted strategy was significantly affected
by group type. On the other hand, no relationship was observed between the selected strategy and the login success, \(\chi 2(3)=4.46, p=.21\).

\section*{Discussion}

The results of the experimental investigation showed that a high majority of the participants (57 of 63 participants) in the first session was able to login the system by clicking on a black screen. This finding indicates that the participants memorized the locations of the pass-items in the graphical password. The rest of the analyses were conducted on those 57 participants. Overall, the coherent-group participants, who were presented a coherent image as the graphical password, achieved better memory performance compared to the jumbled-group participants, who were presented a jumbled image as the graphical password. This finding was obtained in terms of a set of measures, including login success, login time, eye movement parameters and visual saliency, as well as password creating strategies. The analysis of login success showed that the coherent group exhibited higher login success compared to the jumbled group, independent of the session. This difference was obtained both in the first attempt to login and in the analysis of all attempts to login (the participants were allowed to try three times to login). The performance difference between the groups was evident, for some of the measures, in the second session of the experiment, which was conducted three days after the first session. For example, the analysis of the login duration showed that in the first session, there was no difference between the groups. The difference, however, was significant in the second session in favor of the coherent group: the coherent-group participants were able to login in shorter time. These findings have implications for end-users, as well as password system designers. The facilitating role of image coherence suggests that users should be encouraged to select coherent images for graphical passwords rather than jumbled images.

The analysis of fixation counts revealed two major findings: not in the first session but in the second session, the jumbled group fixated more frequently on the black screen compared to the coherent group. Moreover, in the second session, the coherent group spent less fixations on non-pass items, thus exhibiting a higher memory efficiency for the pass items. The analysis of fixation durations revealed that in the second session, the mean fixations of the jumbled group were shorter than the mean fixations of the coherent group. Shorter fixation durations may be indicators for visual search (compared to normal scene viewing, Rayner, 1998). Jumbled-group participants’ higher effort to find the pass-items, as well as the longer Levenshtein distance exhibited by the jumbled group, provide support for our interpretation that they had more difficulty in remembering the pass items compared to the coherentimage group participants. Finally, we observed no relationship between likelihood of the selected pass items and their visual saliency. This may be due to participants' strategies in selecting the pass items. The analysis of the
strategies, however, returned no significant relationship between the selected strategy and the login success, though higher preference of certain strategies (in particular, pattern creation) by the participants over the others.

\section*{Conclusion and Future Work}

Coherence has been a research topic in relevant domains to human cognition. In linguistics, discourse coherence is described as constructing the continuity in context by constructing the meaning between the parts of the written text or spoken utterance (Wolf, 2005). A coherent discourse has comprehension advantages compared to an incoherent discourse. In visual cognition, the studies reveal an improved efficiency in object identification and memory in favor of coherent images. These findings reveal the importance of coherence for cognition in different modalities. The findings in the present study show that the coherence effect is also applicable to practical settings, in this case graphical passwords. The present study also shows that the advantages of visual coherence can be observed in various measures, including login success and duration, as well as eye movement parameters. Future studies will address extending the evaluation by additional eye tracking metrics, such as scan path ratio, the investigation of the role of specific memory components, and a more extensive analysis of users' strategies for creating graphical passwords.
Acknowledgments. Thanks the Capital Markets Board of Turkey for providing the setting for the experimental investigation. Thanks Deniz Zeyrek and our reviewers for their valuable comments and suggestions.

\title{
Conceptual change in proportional reasoning: Effects of collaboration, own / partner reasoning level and hypothesis testing
}

\begin{abstract}
Systematic research of instruction-based conceptual change in Mathematics and Science is characterized by examining the effectiveness of a particular instructional principle in isolation. It is suggested that the field could gain from studying how different instructional principles interact when they are combined. The goal of this research was to systematically study the combined effects of collaborative learning and hypothesis testing on cognitive growth. In a randomized experiment, 496 9th graders solved challenging tasks that required fully developed proportional reasoning. Half of them were given the opportunity to test their solutions. Based on individual pretests, each student was assigned to one of three competency levels (low, medium, high), and randomly assigned to either work alone or with a (low, medium, high) peer. The findings show that the effectiveness of hypothesis testing are conditioned by fine-grained differences in the contingencies between the target student's level of competence, the peer partner's level of competence and the feedback they receive from the objective testing device.
\end{abstract}

Most of the early research on cognitive growth through peer collaboration focused on the question of optimal dyad composition (e.g., Messer, Joiner, Loveridge, Light \& Littleton, 1993; Tudge \& Winterhoff, 1993). However, results have overall been inconclusive and research has largely been abandoned in favor of process-oriented investigations, such as peer dialogue (e.g., Asterhan \& Schwarz, 2007, 2009; Schwarz, Neuman \& Biezuner, 2000) or other instructional techniques to elicit cognitive conflict, such as collaborative hypothesis testing. (e.g., Howe, Tolmie, Duchak-Tanner \& Rattay, 2000; Howe, Tolmie \& Rodgers, 1992).Hypothesis testing tasks require learners to translate their conceptual knowledge into hypotheses and subject these to empirical evaluation. When disconfirmed, it may confront learners with compelling evidence that they should reconsider their prior understanding even when two learners agree on their predictions (e.g., Howe et al, 2000). Vice versa, when a prediction is confirmed, it validates the explanation that led to the prediction.

In this paper, we present findings from a new study that examines whether the effects of hypothesis testing techniques depend on dyad compositions. We predict that it is. First of all, hypothesis testing in collaborating dyads may create conflict in W-W dyads (two 'wrong' learners), and settle a social conflict between members W-R dyads (one 'right' and one 'wrong' learner), who each gave different predictions and explanation. The success of hypothesis testing in socio-cognitive conflict tasks, however, hinges on a careful design: only the correct explanation or strategy should lead to a confirmation. If not, the feedback may confirm an individual's naïve, incorrect conception.

If designed carefully, this can then lead to quite powerful learning opportunities: For instance, a 'wrong' (W) student that collaborates with a 'right' \((\mathrm{R})\) student will not only be exposed to a higher level of reasoning during the discussion phase, but will also receive empirical confirmation that this reasoning is correct. That is likely to be a quite powerful combination. Students in a \(\mathrm{W}_{\mathrm{x}}-\mathrm{W}_{\mathrm{x}}\) pair on the other hand, would be expected to reach quick agreement without much discussion, but shown wrong in the hypothesis testing phase, forcing them to generate a new, higher-level explanation for these findings all by themselves. Lastly, in \(\mathrm{W}_{\mathrm{x}}-\mathrm{W}_{\mathrm{y}}\) pairs the outcomes are likely to be contingent on the competency level of the particular student: A lower competency W student \(\left(\mathrm{W}_{1}\right)\) is likely to benefit more from interaction with a slightly more competent W student \(\left(\mathrm{W}_{2}\right)\) when there is no hypothesis testing than with it. The reason for this somewhat counterintuitive expectation is that if the \(\mathrm{W}_{1}\) student will be convinced by \(\mathrm{W}_{2}\) 's reasoning in the discussion phase, this solution will be proven wrong in the hypothesis testing phase. As a result, \(\mathrm{W}_{1}\) students may very well regress back to their prior level of reasoning and \(\mathrm{W}_{2}\) students may regress as well.

Very few studies have examined whether hypothesis testing techniques are more effective in collaborative or individual conditions. Two studies are particularly relevant to ours and are worth mentioning in further detail: The first is a study reported by Ellis, Klahr \& Siegler (1993) that sought to investigate the effects of feedback and collaboration on \(5^{\text {th }}\) graders' use of mathematical rules for decimal fractions. Each of the approximately 120 pupils in this study consistently used one of two incorrect mathematical rules that were equally wrong, but qualitatively different. They were assigned to either work alone or in \(\mathrm{W}_{\mathrm{x}}-\mathrm{W}_{\mathrm{y}}, \mathrm{W}_{\mathrm{x}}-\mathrm{W}_{\mathrm{x}}\) or \(\mathrm{W}_{\mathrm{y}}-\mathrm{W}_{\mathrm{y}}\) pairs. The results demonstrated that children who had the opportunity to collaborate with a partner were more likely to use a correct rule on a posttest than children who worked alone, but only if they were given feedback during the interaction as to whether their answers were correct or not. However, dyadic composition was not found to affect children's understanding on individual tests.

Tudge, Winterhoff and Hogan (1996) also investigated the effects of feedback (hypothesis testing) and dyad composition on early elementary school children's problem solving performance on a balance beams task ( \(N=83\) ). Children in this study either worked alone or with a partner who was equally, less, or more competent and either did or did not receive feedback on the correctness of their predictions. In direct conflict with the findings reported by Ellis et al, the presence of a partner was more effective than
working alone only when children did not receive feedback. When children received feedback, working alone was more effective than working with a partner. Similar to the Ellis et al findings, no differences were found between the different types of dyad compositions.

The findings from these two studies then lead to quite different predictions: Based on the Tudge et al findings, students may be expected to profit more from hypothesis testing when they work alone, whereas based on the Ellis et al study and findings reported by Howe et al students are expected to benefit particularly from the combination of hypothesis testing and collaboration and hypothesis testing.

The main aim of the present study is then to settle the disparate findings with regard to hypothesis testing and dyad composition in collaborative problem solving and address the following caveats in the literature. Moreover, none one of the above-mentioned studies systematically tested the effects of hypothesis testing for the full range of different dyad compositions that specifies the target student's and the partner's competence level. Finally, they did not control for nested effects of the individual within the dyad and reported findings may thus be overestimates.

The topic domain that was chosen for this study is proportional reasoning. Research suggests that students experience difficulty with proportional reasoning problems because they over-extend numerical equivalence concepts to proportional equivalence problems (e.g., Mix, Levine, \& Huttenlocher, 1999; Tourniaire \& Pulos, 1985). Sophisticated tests, such as the Blocks task, have been developed to serve both as instructional interventions as well as assessment tools (e.g., Schwarz \& Linchevski, 2007).

\section*{Method}

\section*{Participants}

Eight public junior high schools from the Jerusalem and Tel Aviv metropolitan areas in Israel agreed to participate in the study. The entire 9th grade population of each school (over 600 students) completed a screening (pretest) questionnaire, to assess each student's use of problem solving strategies. Students that did not complete the questionnaire, did not provide explanations for their answers or based their answers on superficial, visual features of the two target shapes only were excused from participation in the intervention phase (see Coding section for further details). The remaining 496 9th graders ( 301 boys, 195 girls) used either additive ( \(\mathrm{N}=196\) ), proto-proportional \((\mathrm{N}=194)\) or proportional \((\mathrm{N}=105)\) reasoning strategies and participated in the intervention stage of the study. Six students did not complete the post test ( 2 additive and 4 pre-proportional problem solvers, respectively).

\section*{Design}

Participating students within each classroom were randomly assigned to experimental condition within each group of initial level of proportional reasoning: additive (AddS), proto-proportional (ProtoS) and proportional (PropS) strategy. The basic experimental design was 2 (hypothesis testing / no hypothesis testing) * 2 (individual / dyadic work). The dyadic condition was furthermore subdivided into 5 different pairing options: AddS-AddS, AddS-ProtoS, AddS-PropS, ProtoS-PrepS and ProtoS-PropS. The entire study then included a total of 16 different experimental conditions (see Table 1 for a distribution of the participants according to conditions).

Table 1. The 16 experimental conditions of the study
\begin{tabular}{|c|c|c|c|}
\hline \multicolumn{2}{|l|}{Paring condition} & \multicolumn{2}{|l|}{Hypothesis testing condition} \\
\hline Dyad member 1 & Dyad member 2 & Without HT & With HT \\
\hline Adds & - & \(N=22\) & \(N=15\) \\
\hline Adds & AddS & \(N=40\) & \(N=40\) \\
\hline Adds & ProtoS & \(N=44\) & \(N=44\) \\
\hline Adds & PropS & \(N=36\) & \(N=34\) \\
\hline ProtoS & - & \(N=13\) & \(N=18\) \\
\hline ProtoS & ProtoS & \(N=42\) & \(N=40\) \\
\hline ProtoS & PropS & \(N=30\) & \(N=44\) \\
\hline PropS & - & \(N=15\) & \(N=19\) \\
\hline
\end{tabular}

\section*{Tools}

The task that was used for the screening, the posttest and the interaction phase is an adaptation of the Blocks task, originally developed by Harel, Behr, Lesh \& Post (1992). In any given trial in the current version of the Blocks test, students are shown 4 three-dimensional block constructions (blocks A, B, C and D), each made up of a number of bricks. The bricks in C and A are of identical color, and so are the bricks in shapes B and D. Students are told that the weight of each brick in shapes \(A\) and \(C\) is identical, and that the same is true for each brick in B and D . At each trial, students are given information about the relation between the two base block constructions A and B ( A is heavier than \(B, B\) is heavier than \(A\), or they are of equal weight). They are then asked to determine the relation between the two target blocks, C and D . They are given four different options to choose from ( C is heavier than \(\mathrm{D}, \mathrm{D}\) is heavier than C , they are of the same weight, or it is impossible to determine) and are asked to base their choice with appropriate explanations (see Figure 1 for an example).

5BlocksTaskTest. Individual student's proportional reasoning level at pre- and posttests was assessed with a pen-and-paper test compiled of five Block tasks of increasing difficulty, ranging from tasks that could be solved with any strategy correctly with any strategy (e.g.,

Figure 1. Example of a Blocks task item
Task 1) to tasks that could be only solved with S4 (task 4, 5).

Intervention tasks. The two items that were given during the intervention stage were not included in the 5BloksTaskTest and could only be solved correctly with proportional reasoning strategies (S4).

\section*{Coding procedures.}

Students' level of proportional reasoning was assessed with the help of a slightly adapted version of a coding scheme developed by Schwarz \& Linchevski (2007). Each written response to a test item (5 on pretest, 5 on posttest, and 2 during intervention task for each participant) was assigned to one of 3 different and mutually exclusive problem solving strategy categories, in ascending order of reasoning quality:

S2 (additive reasoning, grade: 2). The student takes into account the weight of a single brick in relation to the entire block, compares the target blocks to the base blocks. In this Strategy there is no multiplicative related also there is a hint to the right strategy. For example: If \(A\) and \(B\) have the same weigh then \(C\) and \(D\) have the same weight because we add to \(A\) and \(B 4\) bricks each to get \(C\) and \(D\).

S3 (proto-proportional reasoning, grade: 3). The explanation relates to all four blocks, but only refers to the nominal difference between the number of bricks of two blocks. Example: If blocks A and B have the same weight. But there is one more bricks in B, that mean one brick in \(A\) weights more than one brick in B. so 3 bricks that added from \(A\) to \(C\) are heavier than 3 bricks that added from \(B\) to \(D\). so \(C\) is heavier than \(D\).

S4 (full proportional reasoning, grade: 4). The explanation relates to all four blocks. This strategy is characterized by numerical calculation of the proportion between the four blocks. For example: The rate between \(C\) and \(A\) is \(24 / 10=2.4\) and the rate between \(D\) and \(B\) is 37/16 \(=2.3125\) so if they weight the same and \(A\) is multiplied in a bigger number to get \(C\) so \(C\) is heavier than \(D\).

Ten percent of the entire data set was coded by two independent raters, blind to condition. Inter-rater reliability was high, Cohen's \(\kappa=.925\). The highest strategy level a student used on the pretest version of the 5BlocksTaskTest formed the basis for assessing a student's initial level of proportional reasoning: S2 (S2 on each of the 5 pretest items), S3 (used S3 at least once, but not S4), S4 (used S4 at least once). Students that did not use at least S2 strategies on all five pretest items were excused from further
participation. Performance on pretests and posttests was calculated by the mean grade of the five tasks on each test.

\section*{Procedure}

All data collection and experimental interventions were completed locally in each of the 8 participating schools. Students participated in the following sequence of activities:

Stage 1: Assessment and selection. The 5BlocksTask test was administered in pen-and-paper format to all students in the participating 9th grade classes to assess their initial level of proportional reasoning and lasted between 25-40 min. Trained research assistants read aloud the instructions explaining the task. During each of the five Blocks tasks, the research assistants physically showed the 4 relevant constructions (A, B, C and D) for each task in the front of the classroom.

Stage 2: Intervention. Participating students were called to a separate room during regular school hours, in familiar rooms adjacent to participants' classrooms, either individually or in dyads, according to condition. Trained research assistants informed students that they were going to solve two additional tasks and repeated the Blocks task instructions. Students were shown the 4 physical block constructions during each task (A, B, C and D). Students in the dyadic condition were instructed to solve the tasks together. They were furthermore told that they did not have to reach consensus but that they should share ideas and explanation with each other before writing down a solution on one shared solution sheet. Students in the hypothesis condition additionally received the following instructions: "After writing down the solution you can test whether your solution is right or wrong by placing the two target constructions C and D on a scale. If you were wrong you may re-think [together] your solution and try to explain the outcome you received". The research assistant refrained from intervening, except to remind students of the instructions when this was needed.

Stage 3: Post-test assessment. The 5BlocksTaskTest was administered in pen-and-paper format in each classroom after all participating students had completed the intervention phase. All participating students completed the three stages in less than one month.

\section*{Results}

Analyses were conducted with a mixed model (SAS PROC MIXED) with random effects of dyad within condition and of individual within dyad and condition, on individual students' mean gains from pretest to posttest. Residuals were checked for each model separately and outliers ( \(z<-4\) or \(z>4\) ) were locally trimmed from a data set. In a few cases the kurtosis of a distribution was slightly greater than zero. When this was the case a separate analysis was conducted on the SQRT of the dependent variable (individual learning gains) and its outcomes compared to the model of its non-transformed counterpart. No differences were found in the overall pattern of results, and we therefore only report on the result from untransformed models only.

Table 3. Adjusted mean (and SE) learning gains for 'non-proportional' students by peer pairing and hypothesis testing condition, \(N=456\).

\section*{Overall effects of collaboration and hypothesis testing on learning}

Table 2 presents the adjusted mean learning gains of the entire data set, according to pairing condition (working alone or in a dyad) and hypothesis testing condition (with or without weighing apparatus). A significant main effect was found for hypothesis testing, \(F(1,422)=5.10, p=.024\), with students in the hypothesis testing conditions showing larger cognitive gains ( \(M=.25, S E=.04\) ), compare to those who did not ( \(M=.13, S E=.04\) ). No main effect of collaborative condition was found, \(F(2,422)<1, n s\), and the two factors were not found to interact, \(F(2,422)=1.48\), \(n s\).

Table 2.Adjusted mean (and SE) learning gains for collaborative condition (dyadic or individual) and hypothesis testing condition (with or without weighing apparatus), \(N=490\).
\begin{tabular}{llll}
\hline & Individual & Dyadic & Total \\
\hline With HT & \(.22(.06)\) & \(.28(.03)\) & \(.25(.04)\) \\
Without HT & \(.17(.06)\) & \(.10(.03)\) & \(.13(.04)\) \\
Total & \(.19(.04)\) & \(.19(.02)\) & \\
\hline
\end{tabular}

Effect of collaborating with a 'proportional' or 'non-proportional' problem solver.
We then tested whether the lack of effect for collaboration on individual learning gains could be explained by differences between students who were paired with a peer that had employed proportional strategies and students who were paired with a non-proportional peer that (i.e., either additive or proto-proportional). As in the previous model, a main effect was found for hypothesis condition, \(\mathrm{F}(1,326)=\) \(10.40, \mathrm{p}=.001\). In addition, a main effect was found for pairing condition, \(\mathrm{F}(2,315)=6.86, \mathrm{p}=.001\). Post-hoc analyses (with Tukey-Kramer adjustments) showed that students that collaborated with a proportional peer had larger learning gains \((\mathrm{M}=.31, \mathrm{SE}=.04)\) than both students that collaborated with a non-proportional peer ( \(\mathrm{M}=.12\), SE \(=.03), \mathrm{t}(233)=3.70, \mathrm{p}<.001\), as well as those that worked alone \((\mathrm{M}=.19, \mathrm{SE}=.04)\), \(\mathrm{t}(348)=2.00, \mathrm{p}=.046\). No interaction between hypothesis testing and pairing condition was found, \(\mathrm{F}(2,315)=1.97\), ns.

\section*{Effects of dyadic pairing and hypothesis testing for non-proportional students}

Next, we explored the effects of pairing and hypothesis testing amongst 'non-proportional' students only, that is: those students who had not solved any of the five pretest tasks with a full-fledged algebraic strategy. We distinguished between the following four pairing options: working without a partner (alone), being paired with a nonproportional partner of the same strategy level (same level W partner), with a partner of a different non-proportional strategy level (different level W partner) or with a partner of a full proportional strategy level (proportional R partner). Table 3 presents the adjusted mean gain scores for each of these eight conditions.

Similar to the previous models, a main effect was found for hypothesis testing, \(F(1,239)=4.13, p=.043\), such that regardless of whom they were paired with, non-proportional students gained more in the weighing condition ( \(M=.26\), \(S E=.03\) ) than in the non-weighing condition ( \(M=.16, S E=\) .03). A main effect for pairing condition was also found, \(F\) \((2,239)=10.98, p<.001\). Post-hoc analyses (with TukeyKramer adjustments) showed that being paired with a proportional student ( \(M=.31, S E=.04\) ) resulted in larger learning gains than being paired with a same-level, 'nonproportional' peer ( \(p<.001\) ), with a different level, 'nonproportional' peer ( \(p=.016\) ) or working individually ( \(p=\) .040).

In addition, the effect of pairing among nonproportional students was also found to be dependent on hypothesis testing condition, \(F(2,225)=3.22, p=.024\). Judging from Table 3 there are two conditions that stand out in particular: The condition with hypothesis testing and a proportional partner for its comparatively high mean gain score ( \(M=.58, S E=.06\) ), and the condition no hypothesis testing / same-level non-proportional partner for its comparatively low mean gain score ( \(M=-.02, S E=.06\) ). Tukey-Kramer tests for multiple comparisons confirmed these impressions: When students were given the opportunity to test their predictions with a testing device, being paired with a 'proportional' peer indeed led to better learning gains compared to working with a same-level, 'non-proportional' peer ( \(p<.001\) ), with a different level, 'non-proportional' peer ( \(p=.001\) ) or individually ( \(p=.007\) ). There were no differences between being paired with a same-level partner, a different-level wrong partner or working alone. device, \(t(240)=3.53, p=.012\). Comparisons between weighing and non-weighing condition in the other three pairing conditions did not yield any significant differences. Thus, it seems that

Figure 2 The effect of pairing with a non-proportional peer and hypothesis testing on learning gains, for additive (1a) and proto-proportional (1b) problem solvers
for 'non-proportional' learners as a group, neither hypothesis testing nor the pairing with a 'proportional' peer by itself resulted in learning gains, but only the combination of the two. This is further supported by the finding from post-hoc comparisons that 'non-proportional' learners in the hypothesis testing condition who were paired with a 'proportional' partner had significantly higher gains scores than students in each of the other 7 conditions.

However, when 'non-proportional' learners did not have access to a hypothesis testing device, being paired with a 'proportional' student did not have any advantage over any of the other pairing conditions (all comparisons were \(n s\) ). Moreover, 'non-proportional' learners who are paired with a 'proportional' student gain more when they are given the opportunity to test their predictions with a hypothesis testing

Interestingly, when learners did not have access to the hypothesis testing device, 'non-proportional' students gained least when they were paired with a partner from the same level, and significantly less so than when working alone ( \(p=.009\) ), with a 'proportional' partner \((p=.005)\) or with a different level 'non-proportional' partner ( \(p=.012\) ). No differences were found between the latter three conditions.

\section*{Effects of \(W_{x}-W_{y}\) pairing and hypothesis testing for different types of 'non-proportional' students}

The findings reported above seem to indicate that for non-proportional students being paired with a differentlevel, non-proportional partner student ( \(\mathrm{W}_{\mathrm{x}}-\mathrm{W}_{\mathrm{y}}\) pairing) is only preferable when students do not have access to a hypothesis-testing device, but that there is no advantage to this pairing when they have the opportunity to test their
predictions. However, these findings disregard differences in the target student's initial strategy level. The effect of \(\mathrm{W}_{\mathrm{x}}-\mathrm{W}_{\mathrm{y}}\) pairing and hypothesis testing was then separately tested for students that were initially diagnosed as 'additive' problem solvers in the Blocks task and for those that were diagnosed as 'proto-proportional' problem solvers (see Method section).

Figure 2 presents the adjusted mean learning gains for additive (Fig 2a) and for proto-proportional problem solvers (Fig 2b) that are paired with non-proportional peers. In contrast to the previous models, no main effects for hypothesis testing were found, neither for additive problem solvers ( \(F<1\) ), nor for proto-proportional learners ( \(F<1\) ). Among additive problem solvers, a main effect was found for pairing condition, \(F(1,56.7)=6.01, p<.017\), with students who were paired with a proto-proportional peer showing higher learning gains ( \(M=.24, S E=.03\) ) compared to those that were paired with a same-level peer ( \(M=.10\), \(S E=03\) ). Pairing condition was also found to interact with hypothesis testing, \(F(1,56.7)=5.56, p<.022\). Post-hoc analyses (with Tukey-Kramer adjustments) showed that when paired with another additive problem solver, they learning gains were higher with hypothesis testing ( \(M=.18\), \(S E=05)\), than without it ( \(M=.02, S E=05\) ), \(t(55)=2.39, p\) \(=.032\). When they were paired with a proto-proportional peer, on the other hand, additive problem solvers seemed to gain more without the hypothesis device ( \(M=.28, S E=06\) ) than with it ( \(M=.19, S E=06\) ). This apparent difference did not reach statistical significance however, \(t(73)=1.12\), \(n s\).

For the proto-proportional problem solvers, on the other hand, no effect were found for neither pairing condition ( \(F\) (81) \(=1.34, n s\) ), hypothesis testing ( \(F<1\) ), nor their interaction \((F<1)\).

\section*{Discussion}

Previous studies have examined the effects of hypothesis testing and collaborative learning on cognitive growth (e.g., Ellis et al, 1993; Howe et al, 2000; Schwarz et al, 2000; Tudge et al, 1996). Unfortunately, this literature has yielded a mixed pattern of results. In the present study we revisited the major research questions in this field with a controlled experimental design that systematically explored the full range of dyadic compositions and with statistical models that controlled for nested effects. Overall, the findings show that the answer to the question whether hypothesis testingbased interventions for learning are more effective in individual or collaborative settings, really depends on the level of analysis and the comparisons being made.

First of all, when all different types of dyadic compositions are included in the data set but not further specified, hypothesis testing was overall found to improve students' learning gains. This finding is consistent with earlier research on the effectiveness of providing students with feedback that consistently confirms correct predictions and disconfirms predictions based on incorrect understanding (e.g., Tudge \& Winterhoff, 1993; Tudge et al, 1996). Collaboration, on the other hand, was not found to have an overall advantage over individual work. It was neither found to improve learning through hypothesis testing as is often expected and as found in other studies (Ellis et al, 1993). It is often believed that peer collaboration allows learners to discuss different explanations and generate interpretations of the hypothesis testing outcomes (Howe et al 2000). However, such potential benefits of collaboration are not detectable when the full range of dyadic pairings are included but not further specified.

A further dissection of the general construct of 'collaboration' according to the target student's and the partner's competence levels uncovers that interaction with a more competent peer only improves learning under certain specific conditions: For non-proportional ("wrong") students, the combination of hypothesis testing and being paired with a proportional ("right") partner was particularly powerful. However, similar to Ellis et al (1993) we found that when students received no feedback from the equipment (no hypothesis testing), singletons, students paired with proportional peers and students paired with different level non-proportional peers showed only comparable (moderate-to-small) gains. In concordance with previous findings (Ames \& Murray, 1983; Schwarz et al, 2000), students who were paired with a same-level "wrong" peer without the opportunity to receive any feedback through hypothesis testing did not improve at all. The pattern that emerges from these findings seems to underline the importance of the combination of exposure to higherorder reasoning strategies and the confirmation of the correctness of these strategies by an objective test. This is not an additive effect, since neither the exposure to higherorder reasoning strategies, nor the conflict created by the disconfirmation of incorrect predictions alone led to substantive learning gains.

This subtle contingency of, on the hand, the kind of feedback that is obtained from objective testing and, on the
other, the persuasiveness of a higher-order reasoning strategy becomes even more evident when we considered the wrong-wrong pairings only: The benefits of interaction with a more competent peer and hypothesis testing were found to hold only when the test proved that the predictions of this more competent peer were correct. When less competent (using additive strategies) interacted with a more competent peers (using proto-proportional strategies), the former actually gained more without hypothesis testing. When there is no opportunity to test the correctness of predictions, the verbal explanation provided by the slightly more competent peer may convince the lower competence peer to the more sophisticated reasoning strategy, thus improving their performance on posttests. However, with access to hypothesis testing devices, the predictions of the more competent peer will be disconfirmed, and with it the (slightly) more sophisticated reasoning strategy.

\begin{abstract}
We investigated the use of iconic and deictic gestures during the communication of spatial information. Expert structural geologists were asked to explain one portion of a geologic map. Spatial gestures used in each expert's response were coded as deictic (indicating an object in the conversational space), iconic (depicting an aspect of an object or event), or both deictic and iconic (indicating an object in the conversational space by depicting an aspect of that object). Speech paired with each gesture was coded for whether or not it referred to complex spatial properties (e.g. shape and orientation of an object). Results indicated that when communicating spatial information, people occasionally use gestures that are both deictic and iconic, and that these gestures tend to occur when complex spatial information is not provided in speech. These results suggest that existing classifications of gesture are not exclusive, especially for spatial discourse.
\end{abstract}

Keywords: gesture; deictic; iconic; highlighting

\section*{Introduction}

People communicate and focus the listener's attention to different levels of spatial information in speech and gesture. Spatial information is expressed in gesture both for communicating with others and for individual problem solving (Alibali, 2005). Common spatial activities (e.g. giving directions) (Lavergne \& Kimura, 1987; Allen, 2003) and the communication of complex spatial ideas (e.g. geology) (Liben, Christensen, \& Kastens, 2010) often include gesture.

Communicating three-dimensional spatial relationships using only language is difficult. As most spatial words are qualitative and are not apt for asserting metric spatial information (Tversky \& Lee, 1998), gesture is critical in conveying relations that cannot be easily expressed in speech. Gesture allows one to communicate thoughts that do not easily fit into the categorical system language offers (Goldin-Meadow, 1999). The literature provides a classification for spontaneous gestures made during regular discourse (e.g. McNeill, 1992; Krauss, Chen, \& Chawla, 1996; Ekman \& Friesan, 1969). This study investigates
whether the existing classification is appropriate for gestures that occur during spatial discourse involving complex spatial reasoning.

Extant research indicates that gestures occur more frequently when communicating spatial information, than when communicating non-spatial information (e.g. Alibali, Heath, \& Myers, 2001; Rauscher Krauss, \& Chen, 1996; Lavergne \& Kimura, 1987). For example, Alibali, Heath, and Myers (2001) asked participants to narrate a Tweety and Sylvester cartoon to a naïve addressee, and found that the speakers were nearly twice as likely to produce gestures with units that contained spatial prepositions than with units that did not. Furthermore, gesture frequency varies depending on speech topic. Lavergne and Kimura (1987) asked participants to speak for six minutes each on neutral topics (e.g. describe your typical school day routine), verbal topics (e.g. describe your favorite books and authors), and spatial topics (e.g. describe the route you would take to walk from the university's main library to the main entrance of campus). Participants produced twice as many gestures when speaking about spatial topics than when speaking about verbal or neutral topics.

People convey information using gestures in many different ways. For the purpose of this paper, gestures are defined as movements of the hands and arms that are produced when engaging in effortful cognitive activity (e.g. speaking, problem solving) (Alibali, 2005). Much of the literature has focused on two broad categories of movements: beat and representational gestures. Beats are hand movements that match the rhythm of the associated speech. For example, when reciting his grocery list, the speaker moves his finger up and down for every item on the list, "apples, bananas, cheese, and bread." Within the category of representational gestures (gestures that convey semantic content by virtue of shape, placement, or motion trajectory of the hands - e.g. pointing to the right to mean "right") (Alibali, 2005), gestures can be categorized as iconic or deictic (McNeill, 1992). These two broad types of gesture are the focus of this paper.

Iconic gestures "bear a close formal relationship to the semantic content of speech" (McNeill, 1992, p.12). For
example, when describing a scene from a comic book in which a character bends a tree back to the ground, the speaker makes gripping and pulling gestures as he or she describes the same actions (McNeill, 1992). Deictic gestures indicate entities in the conversational space (the physical space visible to both participants of the conversation). Usually, deictic gestures are pointing gestures that indicate objects and events in the concrete world (McNeill, 1992). For example, when choosing a puppy at the pet store, the child points to the puppy that he wants to buy.

Starting at 9 to 12 months of age, humans use pointing gestures to indicate objects in the environment (Bates, 1976; Bates, Benigni, Bretherton, Camaioni, \& Volterra, 1979). Though pointing is an easy and efficient way of indexing an object in space, and although the distinction between iconic and deictic gestures may be helpful in classifying nonspatial discourse, we propose that in tasks involving the communication of complex spatial information, the current classification may be limiting. The current classification is implicitly mutually exclusive, perhaps for methodological reasons, such that gestures would be classified as either deictic or iconic, but not both. If this assumption is incorrect, researchers could be in danger of missing potentially informative gestures that are both deictic and iconic.

The existing classification does not capture gestures that simultaneously draw the listener's attention to a specific object and represent two or more dimensions of spatial information. Gestures that are not pointing (or tracing) can provide "deictic" information; for example, an "iconic" gesture that resembled an object could be used to refer to the object. Such gestures have been reported anecdotally, Roth (2000) details a middle school science student explaining to his class the mechanism behind a pulley system. In his explanation, the student says, "Pull here," and used a gesture that made salient both the location and direction of the pull (Roth, 2000). The gesture is both iconic and deictic. As in this example, one could use the hand to draw the listener's attention to the form and location of something in the environment. Since we know that listeners make use of the information in a speaker's gestures (e.g. Alibali, Flevares, \& Goldin-Meadow, 1997; Goldin-Meadow \& Sandhofer, 1999) and spatial concepts can be hard to convey in speech alone, we may learn more about the function of gestures by observing their use in discussion of complex spatial settings.

Thus, the current study examines the use of deictic gestures during a spatial task. The results presented here are part of a larger study investigating the communication of spatial information by structural geologists. Structural geology is a spatially complex and cognitively demanding field, where experts gesture extensively when they speak. A reason to begin research in this domain is that these experts' gestures are likely to focus on complex spatial information. In the future, we plan to investigate if the patterns of communication found here are also present in other, more common, spatial situations. In the study, expert structural
geologists were asked to complete a series of tasks, including explaining the geology of two regions using geologic maps. Here we investigate experts' use of pointing gestures versus iconic gestures to indicate one or more objects on a map.

One reason geologists gesture is they are often in a situation where it is not possible to see the entire object of interest. Since the information found on an outcrop is complex and only one face of a structure is usually visible (providing two-dimensional information), experts could use iconic gestures to highlight critical features since the whole three-dimensional structure is not observable (Frodeman, 1995). A geologic map shares some of the same characteristics. The information found on a geologic map is quite complex, and it is a two-dimensional representation of three-dimensional structures. Based on our observations of experts in the field, combined with the complexity and twodimensional quality of a geologic map, we hypothesize that structural geology experts will use iconic gestures, in addition to pointing gestures, to index specific geological entities. We predict that they will use iconic gestures for the following reasons: 1) pointing gestures may be ambiguous as the referent is located within a complex image with overlapping features; and 2) the object of interest is a threedimensional structure - something that is not shown, but needs to be inferred from the map as only a slice through the three dimensional form may be visible at the surface. To test our hypothesis and characterize the gestures experts use, we coded experts' gestures for type (deictic, iconic, or both), and kind of spatial information (point, line, plane, or form, process/event) for responses to one question about one geologic map.

\section*{Methods}

\section*{Participants}

Thirty-four attendees at a Structural Geology and Tectonics Conference participated in the study. To focus on experts' gestures, we restricted analysis to data from those participants with a PhD who were also professors at an academic institution. Thus, data from ten participants were excluded. Data from one additional expert was excluded because he or she was bilingual in English and American Sign Language. Therefore, data from 23 expert structural geologists ( 14 men, 9 women, \(M_{\text {age }}=45.8\) years, age range: 33-60 years) was used for this analysis.

\section*{Materials}

Explanations were recorded with a Canon HD Video Camcorder HV20 (3.1 Megapixels). The map used for this portion of the study was a Geologic Map of the Black Hills Area, South Dakota and Wyoming (DeWitt, Redden, Buscher, \& Wilson, 1989). It was presented on a flat 78 cm high table.

\section*{Design and Procedure}

The study took place in a quiet room where only the experimenter and the participant were present. After arriving, the participant completed the consent process. He or she was then asked to stand behind the empty table placed in the center of the room. Throughout the course of the study, the experimenter stood directly across from the participant, approximately five feet away.

The experimenter explained that this was a study investigating teaching and reasoning about geologic maps. A Geologic Map of the Black Hills Area, South Dakota and Wyoming (DeWitt, Redden, Buscher, \& Wilson, 1989) was then placed on top of the table so the participant could see it. Participants were first asked whether they were familiar with the map before beginning the task. They were then asked to pretend that the experimenter was a geology undergraduate student with some domain knowledge, specifically having completed an introductory course and one or two upper level geology classes. The task was to explain what structures were under the ground along a specific cross-section, and explain how he or she knew. This task would be a familiar one to a structural geologist, and the map was designed to provide this information. After providing the prompt, the experimenter indicated the crosssection region on the map for the participant. Gesturing was never mentioned. Responses were audio and videorecorded.

\section*{Coding}

Each of the experts' spontaneous gestures and accompanying speech was coded by the first-author. Interrater reliability was established by having a second trained coder who independently coded a subset (20\%) of the responses. Each gesture was coded for the following things:

Speech The speech accompanying each gesture was transcribed. Due to the complexity of the information communicated by the experts, participants' speech was used to clarify the information represented in the gesture. Furthermore, speech accompanying each gesture was coded for whether it included information about a structure (e.g. dome, mountain) or provided orientation information (e.g. layers are steeply dipping). Inter-rater agreement for speech was \(\kappa=0.80\) ( \(\mathrm{n}=182\) gestures).

Gesture Using the accompanying speech to clarify, each gesture was coded for whether or not it represented a spatial property (e.g. the spatial relations between two rocks). See Atit, Shipley, and Tikoff (2013) for more information about the spatial properties represented in gesture. Inter-rater agreement for spatial property represented was \(\kappa=0.79\) ( \(\mathrm{n}=182\) gestures). Gestures that represented spatial properties were further characterized as follows.
Spatial Information The categories for the spatial information in a gesture were created based on the dimensional information that the gesture conveyed. A
gesture that conveys 1 D information indicates a point, a gesture that conveys 2D information indicates a line, gestures that convey 3D information indicate planes and forms, and gestures conveying 4D information indicate changes or processes. For more information on this categorization of gestures, see Atit, Shipley, and Tikoff (2013).

Each gesture was coded for one of the following six spatial categories: 1) point: hand-shape used was typically an index finger indicating a location in space, 2) line: hand shape typically was an index finger indicating a line in space, 3) plane: hand shape typically was a flat palm indicating a plane in space (generally providing information about orientation), 4) form: hand formed a threedimensional shape in space (e.g., forming the hand in the shape of a dome or moving the hand to sculpt the shape of a dome), 5) process/event: hand conveyed a process or an event (e.g., hand showing the movement of magma representing an intrusion), and 6) other: all other gestures. Inter-rater agreement for spatial information in gesture was \(\kappa=0.81\) ( \(\mathrm{n}=182\) gestures).
Function Type Each gesture was also categorized into one of the following four types: 1) deictic: if it indicated an entity on the map (e.g. pointing to a specific fault line on the map, or tracing the fault line on the map), 2) iconic: if it "bears a close relationship to the semantic content of speech" (McNeill, 1992, p. 12), and depicted an aspect of an object within the conversational space (e.g. a curved hand used to represent a fold), 3) both: if it simultaneously drew the listener's attention to a specific object on the map while depicting an aspect of it (e.g. using a curved hand to show the shape and location of a fold on the map), or 4) unrelated: if it could not be classified into any of the three type categories. Inter-rater agreement for gesture type was \(\kappa=0.82\) ( \(\mathrm{n}=182\) gestures).

\section*{Results}

\section*{Spatial Gestures}

On average, each participant gestured 51.87 times over the course of the task ( \(S D=26.94\) ). We found no difference in the number of gestures produced by men ( \(M=51.00\), \(S D=29.14\) ) versus women ( \(M=53.22, S D=24.75\) ), n.s; and no difference in the number of gestures produced by participants who were familiar with the map ( \(M=58.60\), \(S D=30.93\) ) versus those that were not familiar with the map ( \(M=46.69, S D=23.37\) ), n.s.

When looking at the information conveyed within gestures, we found that participants gestured more about spatial information (gestures conveying a spatial property) ( \(M=0.73, S D=0.14\) ) than about non-spatial information ( \(M=0.27, S D=0.14\) ), \(t(22)=7.96, p<.001\). All means and standard deviations for the following analyses are provided in Table 1.

Table 1: Means and standard deviations of gestures
\begin{tabular}{c|ccc}
\cline { 2 - 4 } & Point & Line & Plane/Form/Process/Other \\
\hline Deictic & \(M=0.11\) & \(M=0.20\) & \(M=0.06\) \\
& \(S D=0.08\) & \(S D=0.15\) & \(S D=0.07\) \\
Non- & \(M=0.01\) & \(M=0.01\) & \(M=0.37\) \\
Deictic & \(S D=0.02\) & \(S D=0.02\) & \(S D=0.22\) \\
\hline
\end{tabular}

Note. Table presenting means and standard deviations across participants for the different kinds of gesture (point, line, plane/form/process/other) and for different types of gesture (deictic, non-deictic). The descriptives reported here are the means and standard deviations of the proportions of spatial gestures for each category. As there were no differences between the plane, form, process, and other categories, we collapsed across these categories. Gestures that were deictic indexed an object on the map, and could be composed of point, line, plane, form, process, and other gestures. Gestures that were non-deictic did not index an object on the map, but also could be composed of point, line, plane, process, and other gestures.

First, we looked at what proportion of spatial gestures was pointing gestures. On average, \(12 \%\) of each participant's spatial gestures involved pointing ( \(M=0.12, S D=0.09\) ). An overwhelming majority of those were identified as deictic ( \(M=0.11, S D=0.08\) ), with only \(1 \%\) of gestures being iconic and pointing \((M=0.01, S D=0.02), t(22)=5.98, p<.001\). Pointing gestures were mainly used to index an object in the conversational space.

Second, we considered the other cases of deictic gestures. The first notable observation is that while pointing maybe the prototypical deictic gesture, in this context the most frequent deictic gesture was tracing a line in the conversational space. On average, \(21 \%\) of each participant's spatial gestures were of this kind \((M=0.21, S D=0.15)\). More line gestures were classified as deictic \((M=0.20, S D=0.15)\), than non-deictic \((M=0.01, S D=0.02), t(22)=5.83, p<.001\), and the frequency of deictic line gestures \((M=0.20\), \(S D=0.15\) ) was significantly greater than pointing gestures ( \(M=0.11, S D=0.08\) ), \(t(22)=3.24, p<.01\).

Finally, when we consider the spatial gestures that were plane, form, or process/event gestures, we find that most of these were iconic \((M=0.37, S D=0.22)\). However, an intriguing portion was both iconic and deictic ( \(M=0.06\), \(S D=0.07\) ). The proportion of gestures classified as "both" iconic and deictic was significantly different from 0 , \(t(22)=4.25, p<.001\). Thus, most of the gestures made by experts could be classified as iconic or deictic, but there were a significant number of gestures that were both deictic and iconic. Experts in this task used complex iconic gestures to index objects in the conversational space.

\section*{Gestures Classified as Both, Iconic and Deictic}

To further explore the information represented in the gestures that were both deictic and iconic, we categorized them by the spatial information in the gestures. About half
of the \(6 \%\) represented planes \((M=0.03, S D=0.04)\) and half represented forms ( \(M=0.03, S D=0.05\) ). Less than \(1 \%\) of all gestures represented a process or event, or other kind of information. Experts may have used the planar and form gestures because the task was to explain the structures at a line of cross-section where orientation and shape information is not readily visible on the map. Without visible support for this spatial information in the diagram, experts may have employed gestures to ensure the threedimensional referent was clear.

Lastly, we investigated the information conveyed in speech when experts employed these iconic and deictic gestures compared to when they pointed or traced to indicate an object. To make this comparison, we computed the following for each participant: 1) the proportion of pointing deictic gestures paired with spatially complex speech (speech containing structure or orientation information) relative to the total number of pointing deictic gestures; 2) the proportion of line deictic gestures paired with spatially complex speech relative to the total number of line deictic gestures; and 3) the proportion of plane and form gestures classified as both iconic and deictic paired with spatially complex speech relative to the total number of plane and form gestures classified as both iconic and deictic.

We found that a greater proportion of pointing deictic gestures were paired with spatially complex speech ( \(M=0.34, S D=0.36\) ) than planar/form iconic and deictic gestures, \((M=0.04, S D=0.12), t(22)=3.57, p<.01\). Similarly, more line deictic gestures were paired with spatially complex speech ( \(M=0.27, S D=0.23\) ) than planar/form iconic and deictic gestures, \(t(22)=3.91, p<.01\). Thus, experts used gestures classified as both iconic and deictic especially in instances where the complex spatial information was not provided in speech.

\section*{Discussion}

This study investigated the relevance of an existing distinction made in the gesture literature, iconic versus deictic gestures, within the realm of communicating spatial information. Traditionally, deictic gestures are defined as hand movements that indicate entities in the conversational space and usually consist of pointing (McNeill, 1992). Iconic gestures are hand movements that "bear a close formal relationship to the semantic content of speech" (McNeill, 1992, p.12), and generally do depict some aspect of an object in the conversational space.

Data from this study indicates that when asked to explain the structures present in a section of a geologic map, expert structural geologists use gestures that can be classified as deictic or iconic, along with gestures that fall in both categories. When using gestures traditionally classified as deictic, experts tended to trace more than point to draw the listener's attention to an object on the map. When using gestures traditionally classified as iconic, we found that experts used some iconic gestures to indicate an object on the map. Furthermore, gestures that were both iconic and deictic and represented information about planes and forms,
tended to occur when there was no spatially complex information (e.g. structure or orientation information) conveyed in speech.

A number of studies have shown that gestures are useful in separating relevant from irrelevant information (e.g. Roth, 2000; Lozano \& Tversky, 2006; Heiser, Tversky, \& Silverman, 2004). Gestures help organize the conversational space into a salient foreground and an unrepresented, more diffuse background. Researchers in the past have likely focused on pointing because this hand shape is the most common one used to indicate the foreground. In contrast, here we replicate previous work (e.g. Lozano \& Tversky, 2006; Heiser, Tversky, \& Silverman, 2004) that has found that when the referent is complex and includes multiple kinds of information (e.g. maps), the speaker also uses tracing gestures to highlight objects for the listener. For example, Lozano and Tversky (2006) asked participants to explain to a listener how to assemble a piece of furniture, and found that participants used tracing gestures in addition to pointing gestures to draw the listener's attention to individual pieces (Lozano \& Tversky, 2006). Heiser et al. (2004) asked pairs of students to use a campus map to design and produce an optimal emergency rescue route. They found that students also used tracing gestures along with pointing gestures to focus their partner's attention to specific aspects of their sketch and to highlight certain routes (Heiser, Tversky, \& Silverman, 2004). We suspect that speakers used tracing gestures because pointing alone may be ambiguous when the referent has significant spatial extent and when it does not have clear boundaries.

The results from our study reveal an interesting type of gesture that is used to draw the listener's attention to an object. Experts in our study used complex gestures traditionally classified as iconic to highlight objects on the geologic map. A geologic map presents a horizontal crosssection through the three-dimensional topography of a region. Therefore, many objects of interest to a geoscientist will be three-dimensional structures that are not completely visible at the surface. Indeed what is visible at the surface may be a slice through a three-dimensional form. Since the two-dimensional information presented on the map does not directly resemble the actual three-dimensional form of these objects, the expert may use gesture to provide the listener with the missing information. For example, the elliptical outcrop pattern of rock layers presented on the map in this study does not resemble the three-dimensional form of the dome in the Black Hills region. Furthermore, it can be difficult to determine the orientation of the rock layers within a domal structure on a geological map because the inclination of the rock layers is typically represented using a symbol. Thus, the expert uses gestures to depict the shape of the dome and planar gestures to show the orientation of the layers in space. Whether it is the two-dimensional characteristic of the map, or the penetrative nature of geological structures that elicits this special type of gesture is a question for future research. For example, would an
architect use gestures that could be classified as both iconic and deictic when explaining a blueprint of a building?

Finally, gestures classified as both iconic and deictic were used in instances where the spatially complex information is not provided in speech. For example, an expert represents the orientation and location of a layer of rocks on the map while referring to their relative ages in speech. Since complex spatial information is difficult to convey using language (Tversky \& Lee, 1998) and gesture allows one to communicate thoughts that are not easily conveyed in speech (Goldin-Meadow, 1999), perhaps the speaker uses this type of gestures when providing multiple levels of information (e.g. location and orientation information) in language alone becomes difficult. Or, perhaps the expert could not produce the gesture and speech at the same time due to the cognitive load required by the task. A more global analysis of speech in the future can address this question.

One potential limitation of the current study may be that the experts were asked to pretend that the experimenter was a geology undergraduate to whom they were explaining the cross-section. It is possible the experts' language and gestures would have differed if they were providing explanations to real geology undergraduates. This seems unlikely as the experts were obviously engaged in their answers to the questions. Nevertheless, studies collecting and analyzing interactions between experts and novices in the field are in progress.
Supported by the findings of this study, we argue that the existing types of representational gestures (e.g. iconic and deictic) should not be treated as exclusive categories overlap between the two types exists. People do use iconic gestures (e.g. planar gestures) to indicate, or highlight, objects in the world when the important spatial information is three-dimensional. One open question is whether the number of gestures that fall into "both" categories is related to the spatial complexity of the information conveyed. Perhaps the communication of more spatially complex information elicits a greater use of this special type of gestures.

Understanding how different types of gestures are employed in simple communicative contexts to highlight and convey complex spatial information may serve as the foundation for developing pedagogical techniques for conveying spatial information. A richer understanding of the different types of gestures could inform geology professors, and science professors in general, about how to most effectively communicate information to their students.

\title{
The Role of Contextual Repetition During Fast Mapping on Word Learning
}

\begin{abstract}
Recent research suggests that children's ability to learn words via fast mapping is strongly related to the attentional demands of the task. Here we explore whether lowering the attentional demands during the initial fast mapping task facilitates word learning. Three-year-old children completed fast mapping and test trials using a touch screen computer. For half of the children, the non-targets (competitors) repeated across trials and for other children there was no repetition. All children received the same word learning test trials. Only children who had received repeating competitors (lower attentional demands) during the initial fast mapping task demonstrated word learning. Thus, these data suggest that children's ability to learn novel names is strongly influenced by the competition and attentional demands of the initial fast mapping context.
\end{abstract}

Keywords: fast mapping; word learning; competition; attentional demands.

\section*{Does Fast Mapping Enable Word Learning?}

Learning to comprehend the vast number of words that children are bombarded with daily is a daunting task. Arguably, it is equally daunting for researchers to explain the mechanisms responsible for children's developing ability to understand what a speaker is referring to when uttering a new word, but also children's ability to remember the link between the word and referent for later encounters.

Without direct instruction, children effectively determine the referent for a novel word on their own-particularly when the referent is presented in the context of known objects. Typically referred to as fast mapping (Carey, 1978), children appear to determine the referent via process-ofelimination (Halberda, 2003). That is, children use their prior knowledge (i.e., known vocabulary) to rule out the objects they have already linked to a name. Instead, they select a novel object as the likely referent of a novel name. Biases to novelty appear to be key in fast mapping. Recent research further indicates that even in the context of other nameless, novel objects, children will select the most novel object as a referent for a novel name (Horst, Samuelson, Kucker, \& McMurray, 2011; Mather \& Plunkett, 2012).

However, fast mapping is not word learning per se, but rather an initial step in the word learning process (Carey, 1978; Horst \& Samuelson, 2008). Fast mapping appears to be relatively easy for children, yet retention of the nameobject mappings is more difficult. For example, Horst and Samuelson (2008) presented 24 -month-old children with
referent selection (i.e., fast mapping) trials with one novel object and two known objects. Only 5 minutes later, they tested children's retention for the same novel name-object associations by presenting the targets among other novel targets that had been encountered during the initial referent selection trials and foils that had been seen during a preferential looking task. Children had little difficulty selecting the correct referents on the initial referent selection trials. However, children performed at chance levels on the retention trials, suggesting that the initial name-object mappings did not lead to robust representations in long-term memory. Other studies have found similar difficulties in long-term retention of name-object mappings despite demonstrations of minimal difficulty disambiguating novel from known objects (e.g., Bion, Borovsky \& Fernald, 2013; Gureen, Horne \& Erjavec, 2012).

Note, other studies do suggest minimal exposure to a novel word and object may lead to long-term retention of the association, but these have typically involved only naming a single novel object (e.g., Woodward et al., 1994). It remains unclear, therefore, whether children's selection of the target on the delayed test trials are really in response to the specific phonetic content of the new word or because that word was the only new word introduced during training, rendering it unique among the available alternatives (Dollaghan, 1985; Schafer \& Plunkett, 1998).

\section*{Task Demands}

Taken together, these studies suggest that children are adept at forming the initial associations between novel referents and their names, however, children's ability to retain these mappings may suffer when task demands are high. For example, in a recent study exploring the effect of the number of known competitors present during the initial fast mapping task on subsequent word learning, 2-year-old children were only able to retain novel name-object associations when task demands were relatively low (Horst, Scott \& Pollard, 2010). Specifically, children were only able to retain words when they had seen few known competitors across fast mapping trials (eight) but not when they had seen more competitors across trials (12 or 15)-although the number of targets was the same for all groups.

Clearly then, the non-target competitors play an important role in word learning via fast mapping. Horst and Samuelson (2008) found that children could only retain the novel name-object associations when ostensive naming was
provided after each fast mapping trial. That is, when the experimenter picked up a novel object, pointed to it and restated its name. Importantly, the experimenter physically moved the target away from the known competitors. For another group of children, naming was also provided after each trial, however, targets were not moved away from the competitors. These children did not learn the name-object associations. The authors argue that ostensive naming helps children focus on the target while simultaneously drawing their attention away from the competitors.

A follow-up study explicitly tested this explanation of ostensive naming by illuminating targets from below (a light flashed inside the tray the objects were on) and by covering competitors with semi-opaque boxes (Axelsson, Churchley \& Horst, 2012). Children who received this form of ostensive naming learned the name-object associations. The authors argue that ostensive naming helped children better encode the name-object association as their attention to the target object was sustained. Children who only received ostensive naming in the form of pointing (without moving the target away from the competitors) did not demonstrate significant word learning.

In both of these examples, the initial fast mapping task was made easier by decreasing the attentional demands. Specifically, the experimenter helped guide the child's attention away from the competitors, which facilitated processing of the targets.

Similarly, increasing attentional demands can also have a detrimental effect on subsequent word learning. Wilkinson, and colleagues (2003) presented one group of children with fast mapping trials with one novel object and three known competitors. Another group received fast mapping trials where each successive trial included not only a novel object and two known competitors, but also the novel object from the previous trial. Children who faced such increased attentional demands were less successful on subsequent fast mapping trials. Because children typically prefer novelty (Horst et al., 2011; Mather \& Plunkett, 2012), the presence of another novel object likely decreased attention to the target.

\section*{Contextual Repetition}

Similar effects of the reduction of attentional demands during word learning tasks have been demonstrated in other contexts (for a review, see Horst, 2013). In an investigation of word learning via shared storybook reading, Horst, Parsons and Bryan (2011) found that 3-year-old children who were read the same storybooks repeatedly (three times) successfully retained novel words from the books when tested one week later. In contrast, children who were read three different stories performed at chance levels when tested on the same novel words one week later. Importantly, children in both groups were exposed to the same number of novel words the same number of times. The critical difference was that the first group encountered the words in the same context repeatedly whereas the second group encountered them in different contexts. The authors
concluded that children who encountered words in repeated contexts were at an advantage because they had less information to process, facilitating long-term retention of the name-object associations. The question that remains unanswered, then, is whether the same mechanism is at play in other contexts.

\section*{The Current Study}

The aim of the current study is to examine the effect of contextual repetition during fast mapping on subsequent word learning. To examine the effects of the learning context, children either saw novel objects with the same or different known competitors across trials. Specifically, children either encountered the novel object in the same context (with the same competitors) across all three trials with that given target or encountered the novel object in different contexts (with different competitors) across trials. Thus, the attentional demands of the task were either relatively low (repeated contexts) or relatively high (different contexts). Therefore, the degree of attentional demand was expected to differ across the four groups during the fast mapping trials. As in the storybook studies (e.g., Horst et al., 2011), those presented with repeated contexts (competitors) during novel target referent selection trials were predicted to perform better at test. As attentional demands are presumably high during referent selection of novel objects, the repetition of competitors may aid in longterm learning of name-object mappings.

\section*{Method}

\section*{Participants}

Forty-eight typically developing, monolingual, Englishspeaking children aged 36 months ( \(M\) age 36 months, 13 days, \(S D=73.79\) days; range 33 months, 0 days -41 months, 30 days; 24 girls) participated. Children were from predominantly white, middle class homes recruited from southern England. Data from 1 additional child were excluded because she consistently touched the screen before waiting to hear the instructions. Parents were reimbursed for travel expenses and children received a small gift.

\section*{Stimuli}

Digital photographs of known (familiar) and novel objects served as the target stimuli. Specifically, six known objects (ball, cup, train, cow, frog, elephant) and three novel objects (the end of a foam arrow/zorch, a y -shaped rubber dog toy/gaz and a clacker/sprock) served as target stimuli on the referent selection trials. The known objects were chosen because they are highly familiar to 3 -year-old children. The novel objects were chosen because they are unfamiliar to most 3 -year-old children and they do not know names for these objects. Additional photographs of three aliens, a bed and a dresser were used during the experiment. A female, native British English speaker narrated the procedure for the child (henceforth the narrator).

\section*{Procedure and Design}

During the experiment, children were seated on their parents' laps at a table in front of a Dell computer with a touchscreen monitor. The keyboard and mouse were out of the children's reach. Stimuli were presented using ePrime 2.0. Children were asked if they would like to play a computer game. During the experiment, the experimenter stood behind the child to ensure the child remained on task, to answer questions and to minimize parental interference.

Introduction and Warm-up Trials The first screen depicted a red alien who the narrator introduced as Modo. The recorded script was carefully written so that no pronouns were used: thus each child could decide if Modo was male or female. The next screen depicted a bed, a dresser and small versions of each of the known and novel objects that would later be used on the referent selection trials. The narrator explained that Modo was very messy and asked if the child would "help tidy up Modo's room."
Three warm-up trials immediately followed. These trials served to introduce the child to the task and to help the child feel comfortable touching the computer screen. On each trial the child was presented with three additional known objects and asked to select an object by the narrator, e.g., "Can you find the spoon? Touch the spoon." If the child had not yet touched the screen after 1000 ms , the recording repeated and continued to loop with 1000 ms in between requests for up to 30 seconds, or until the child touched the screen. After the child touched a picture, a blank, white screen appeared to give the experimenter a moment to praise the child. The same objects were presented on each warm-up trial, but object positions (left, middle, right) were counterbalanced across trials so that each object appeared once in each position. Thus, the child was asked for a different object in a different position on each warm-up trial and could practice touching an object at each possible position.

Referent Selection Trials Referent selection trials immediately followed the warm-up trials and followed the same procedure except that children did not receive feedback after these trials. On each referent selection trial the child was presented with two known objects (e.g., elephant, cup) and one novel object (e.g., clacker) and asked to choose either a known or novel object, e.g., "Can you find the sprock? Touch the sprock." Children were presented with 18 referent selection trials including 9 known
name and 9 novel name referent selection trials, of which there were 3 trials for each novel name (e.g., 3 sprock trials). Which objects children saw on these trials varied across conditions depending on whether or not the same competitors were repeated across trials (see Table 1).

For half of the children the same competitors were repeated across all trials for a given novel name. For example, each time they were asked for the sprock (clacker), it was displayed with the elephant and the cup. For the other children, different competitors were displayed on each trial for a given novel name. For example, the first sprock trial may have included the elephant and cup, the second sprock trial the train and frog and the third sprock trial the cow and ball. Object animacy was also counterbalanced across trials.

Likewise, for half of the children, the same competitors were repeated across all trials with the same known name. For example, each time they were asked for the elephant, it was displayed with the cup and sprock (clacker). For the other children, different competitors were displayed on each known name referent selection trial. For example, the first elephant trial may have included the cup and sprock, the second elephant trial the ball and zorch, and the elephant was also a competitor along with the gaz on a train trial. Importantly, all children saw the same six known objects and three novel objects across referent selection trials an equal number of times. However, for this to evenly occur some targets (e.g., elephant) were also competitors in the non-repeat conditions.
This resulted in a \(2 \times 2\) design with four conditions: competitors repeat across all trials (i.e., both trial types), competitors repeat across novel trials (but not known trials), competitors repeat across known trials (but not novel trials) and competitors do not repeat on any trials. One can also consider the four conditions of the current study on a continuum of attentional demands from low (competitors repeat across all trials) to intermediate (competitors repeat across novel trials or competitors repeat across known trials) to high (competitors never repeat).

Children were asked for each of the novel targets once during trials 1-6, once during trials 7-12 and once during trials 13-18. Each novel target appeared once in each position (left, middle, right) when it was a target and once in each position when it was a competitor during the known name trials. The same objects were never presented on two consecutive trials and no more than two trials of either type (i.e., known or novel targets) were presented sequentially.

Table 1: Example targets and competitors (comp.) for the Repeat Across All Trials and the No Repeat Conditions.
\begin{tabular}{clllclll}
\hline \multicolumn{4}{c}{ Repeat Across All Trials } & \multicolumn{4}{c}{ No Repeat Across Trials } \\
Trial & Target & Comp. 1 & Comp. 2 & Trial & Target & Comp. 1 & Comp. 2 \\
\hline 1 & Sprock & Elephant & Cup & 1 & Sprock & Elephant & Cup \\
7 & Sprock & Elephant & Cup & 8 & Sprock & Train & Frog \\

Word Learning Trials After the final referent selection trial, the screen showed the bed, dresser and the small stimuli pictures from before but displayed in neat rows and the narrator told the child the room was now tidy. The next screen showed Modo with another alien who was blue. The narrator explained that Modo's friend ZeeBee had come over to play and asked if the child could help Modo share toys with ZeeBee. Then, the word learning test trials were presented again following the same procedure. Importantly, the word learning trials were the same for all conditions. On each trial all three novel objects were displayed and the child was asked to choose an object. Children were asked to choose each target once (for a total of 3 trials). Each novel object appeared once in each position (left, middle, right). At the end the narrator told the child "It's fun to share toys!"

\section*{Results}

\section*{Referent Selection Trials}

As can be seen clearly in Figure 1, children in all four conditions performed very well during the initial referent selection task. On the known name referent selection trials, children chose the target object significantly more than would be expected by chance (.33) in the repeat across all trials condition \((t(11)=19.34, p<.001, d=5.53)\), in the repeat across novel trials condition \((t(11)=14.45, p<.001\), \(d=4.12\) ), in the repeat across known trials condition \((t(11)\) \(=44.78, p<.001, d=12.78)\) and the no repeat condition \((t(11)=29.40, p<.001, d=8.40)\), all \(p\) s two-tailed. Children's proportions of target choices on the known name referent selection trials were submitted to an ANOVA with competitors repeat across novel trials (yes, no) and competitors repeat across known trials (yes, no) as betweensubjects factors. The ANOVA yielded no significant effects, indicating that contextual repetition during referent selection did not influence children's ability to select known objects.

Figure 1. Children's proportion correct during the referent selection trials. Dotted line indicates chance (.33), error bars indicate 1 standard error from the mean. \({ }^{* * *} p<.001\).

Similarly, on the novel name referent selection trials, children chose the target object significantly more than would be expected by chance (.33) in the repeat across all trials condition \((t(11)=6.30, p<.001, d=1.82)\), in the repeat across novel trials condition \((t(11)=6.96, p<.001, d\) \(=2.02\) ), in the repeat across known trials condition \((t(11)=\) 18.35, \(p<.001, d=5.23\) ) and the no repeat condition \((t(11)\) \(=11.08, p<.001, d=3.18\) ), all \(p\) s two-tailed. Children's proportions of target choices on the novel name referent selection trials were submitted to an ANOVA with competitors repeat across novel trials (yes, no) and competitors repeat across known trials (yes, no) as between-subjects factors. The ANOVA yielded no significant effects. Thus, contextual repetition during referent selection did not influence children's ability to select novel objects either.

\section*{Word Learning Trials}

In contrast, contextual repetition during referent selection did influence children's learning of previously fast-mapped novel names. As can be seen in Figure 2, children in the repeat across all trials and repeat across novel trials conditions identified referents of novel names at rates significantly greater than expected by chance (.33), both \(t(11)=3.87, p<.01, d=1.12\). However, in contrast, children in the repeat across known trials and the no repeat conditions performed at chance levels, \(t(11)=1.50, n s\), and \(t(11)=1.20, n s\), respectively. Thus, repeating the same competitors across multiple novel name referent selection trials did influence children's ability to learn novel words.

To best understand the individual contributions of repeating the competitors on both novel and known name referent selection trials, children's proportion of target choices on the word learning trials was submitted to an ANOVA with competitors repeat across novel trials (yes, no) and competitors repeat across known trials (yes, no) as between-subjects factors.

Figure 2. Children's proportion correct during the word learning test trials. Dotted line indicates chance (.33), error bars indicate 1 standard error from the mean. \({ }^{* *} p<.01\).

The ANOVA yielded a main effect of repeat across novel trials, \(F(1,44)=6.99 p=.01, \eta_{\mathrm{p}}^{2}=.14\). Children in the conditions where competitors repeated across novel trials learned more words ( \(M=.65, S D=.29\) ) than children in the conditions in which competitors did not repeat across novel name referent selection trials ( \(M=.44, S D=.27\) ). No other significant effects were found. These findings clearly demonstrate that repetition of competitors during novel name referent selection influences later word learning.

\section*{Reaction Times}

Finally, we wanted to assess how the attentional demands of the task influenced children's performance throughout the experiment. To this end, we examined children's reaction times (RTs) on all correct trials over the course of the experiment. RTs were submitted to an ANOVA with competitors repeat across novel trials (yes, no) and competitors repeat across known trials (yes, no) as betweensubjects factors and encounter (first, second, third, fourth) as a repeated-measure (the fourth encounters were the word learning trials). The ANOVA yielded a significant main effect of encounter, \(F(2.57,94.96)=10.39, p=<.001, \eta_{\mathrm{p}}{ }^{2}=\) .22. Overall, children became faster over the four encounters. There was also a significant encounter by competitors repeat across novel trials interaction, \(F(2.57,94.96)=3.63, p=.02, \eta_{\mathrm{p}}^{2}=.09\) (see Figure 3).

Figure 3. Children's reaction times across encounters to the novel targets including during the initial fast mapping trials (First, Second, Third encounters) and the word learning test (Fourth encounter).

Further analyses revealed a significant linear trend for this interaction, \(F(1,37)=6.88, p=.01, \eta_{\mathrm{p}}{ }^{2}=.16\). Specifically, in the conditions where the competitors did not repeat across novel trials RTs decreased from the first to the fourth encounter. In contrast, in the conditions where the competitors did repeat across novel trials RTs became faster during referent selection (first three encounters) but slowed down again on the word learning test (forth encounter).

RTs to the fourth encounter (i.e., word learning test trial) were then compared. In the conditions where the competitors did repeat across novel trials, children were marginally slower on the word learning test trials ( \(M=5408.09 \mathrm{~ms}, S D\) \(=3870.36 \mathrm{~ms}\) ) than children in the other conditions ( \(M=\) \(3909.67 \mathrm{~ms}, S D=1100.29 \mathrm{~ms}), t(25.91)=1.79, p=.084\), two-tailed, \(d=0.60\). This difference in RTs is interesting because it suggests that children in the different groups were processing the names and objects differently. Children in the conditions with high task demands (competitors did not repeat across novel name referent selection trials) may have been simply guessing on these trials-hence the quick RTs. In contrast, children in the conditions with low task demands (competitors repeated across novel name trials) may have been committed to the task and searching for the correct referent-hence the slower RTs. Overall, these data demonstrate that lowering the attentional demands through repeating contexts (competitors) facilitated word learning and influenced processing as measured by reaction times.

\section*{Discussion}

Word learning is typically a gradual process as children experience the statistical regularity of the co-occurance of a name and object across repeated encounters (Smith \& Yu, 2008). Repeated encounters also facilitate retention for novel name-object associations (e.g., Gurteen et al., 2012). In everyday life, children may be exposed to some names and objects multiple times in the same context (e.g., a rubber duck in the bathtub). When a new word and its referent are repeatedly encountered in the same context, the non-targets may become increasingly redundant and predictable, freeing up attentional resources for processing the target referent (for a review and discussion of how this relates to research using storybooks, see Horst, 2013).

The current study investigated the effect of contextual repetition in referent selection trials on word learning. The results demonstrate that children presented with contextual repetition (i.e., the same competitors across multiple novel name referent selection trials) were significantly better at learning the target words than children who did not receive contextual repetition. Repeating competitors across trials appears to facilitate the initial encoding of the novel targets, enabling robust learning of the name-object associations. Children may have also associated the targets with the context of the non-targets (e.g., sprocks occur with elephants and cups), as they likely do with real-life objects (e.g., rubber ducks occur with bathtubs). One could argue that this gave targets on the contextual repetition trials a "figure-ground advantage," however, this is an unlikely
explanation as the objects were all presented on a plain white background as in previous studies (e.g., Schafer, 2005), rather than as part of a real scene.

We also found a difference in reaction times between conditions in which the competitors repeated across novel trials and conditions in which the competitors did not repeat. Although all children responded faster across successive encounters with the novel target, the children who saw the same competitors across novel name trials slowed down on the word learning trials when the novel target was presented with the other novel objects. This group may have been meaningfully considering among the possible test alternatives while those who saw different competitors may have been responding randomly at test, resulting in speedier responses. Although all children received the same number of exposures to the target items, only those for whom the context repeated across exposures demonstrated significant word learning.

Other studies, however, indicate that variability across learning encounters may facilitate learning. (e.g., Thiessen, 2011). An important consideration, however, is what is varying and what is remaining constant (i.e., repeating). Previous studies have typically found an advantage for variability at the target-level across encounters. Here, we demonstrate an advantage for reducing variability at the non-target-level (i.e., the competitors). Future research is needed to investigate when and how variability and reduction of attentional demands work together to facilitate robust word learning over both short- and long-term timescales. Clearly, however, for word learning via fast mapping, reducing the attentional demands of the initial referent selection task facilitates subsequent word learning.

\section*{Acknowledgments}

This research was funded by ESRC grant number RES-000-22-4451 to J.H. We would like to thank Ruth Pearce for assistance in data collection and Emilly J. Scott for serving as our narrator and help with ePrime. We also thank the members of the WORD Lab for their help in recruiting and scheduling participants and the parents and children who participated.

\title{
On The Possibility of an Extended, Yet Reductionist Mind
}

\begin{abstract}
In the debate around the extended mind, the special alliance that the extended thesis often has with functionalism usually plays in favor of the former, with functionalism providing support for the extended thesis. Here I want to consider this alliance in the opposite direction: does the extended thesis provide support for functionalism by promoting the need of a level of explanation that is independent of implementational (in particular neural) details? In spite of a seemingly promising line of reasoning for an affirmative answer, I show here that a commitment to the extended thesis or any version of externalism neither paves the way for a functionalist (or any other anti-reductionist) position nor is incompatible with an explanatory reductionism about the mind. I arrive to that conclusion after analyzing an argument by van Eck et al. (2006) meant to conclude the opposite, and showing why it is unsound.
\end{abstract}

Keywords: externalism; reductionism; functionalism; Marr's computational level.

\section*{Extended, therefore abstracted away from implementational details?}

When the thesis that the mind extends beyond the limits of the head (in all its different versions: extended mind, extended cognition, environmentalism, wide computationalism, etc. Extended thesis for short) is developed together with some version of functionalism, often the latter provides support for the former, by guaranteeing the legitimacy of a coarse-grain level of analysis where the implementational particularities do not matter (e.g., Clark \& Chalmers, 1998; Clark, 2010). According to this extended functionalism, the details of implementation (be it inside of outside the head) are not what decide the mental status of a structure or process, but rather the causal role it plays in the total economy of the system. Thus, the functionalist stance paves the way for an extended mind. Sometimes, though, this union becomes a reason for criticism of the Extended thesis. One strong line of criticism against some versions of the Extended thesis that draw on this alliance, claims that there is no such substantive theory about the (extended) location of minds, but a mere consequence of functionalism (see Wheeler, 2010), which, in fact, does not care about where the implementational base is located. Thus, it seems that the

Extended thesis would be better off by elaborating an argument that does not rely on functionalist justifications. In line with this predicament, a second wave of the Extended thesis has been developed in the last years (Sutton, 2010; Wilson, 2010).

Instead of the beneficial or not so beneficial role that functionalism can play for extended theorizing, here I address the opposite possibility. My goal is to test the potential for externalist considerations in general to legitimize the autonomy of a level of explanation above implementational details, and therefore, to provide support to anti-reductionist views like functionalism. My motivation is the apparent appeal of a line of reasoning that takes externalist considerations to justify the autonomy of such a level, and so it justifies a functionalist position where what matters for mentality is not the physical particularities of a state but its functional profile, usually described in computational terms.

That apparently appealing reasoning goes as follows: "if environmental structures play a critical role in mental processes, then our explanations of them cannot be limited to neural descriptions, since we need to account for those external elements. Therefore in order to explain cognition we need to approach it from a higher level of explanation that abstracts away from implementational details. A perfect candidate for this is a computational level."

This argument says that the inclusion of external elements shows the necessity of a coarse-grain level of analysis. And so it can be used to argue for an anti-reductionist position. In Clark's version of the extended thesis (Clark \& Chalmers, 1998), this coarse-grain level responds to the need to account for what makes internal and external elements mental, which is their computational role in the total functional economy of the system. Here I want to show why this apparently appealing reasoning is wrong. My conclusion is that neither the Extended thesis nor in general any version of (vehicle or content) externalism provide support for the autonomy and legitimacy of an independent-of-implementational-details explanation of mental phenomena. I will focus on a particular case where the above argument has been applied, that is the work of van Eck, Looren de Jong \& Schouten (2006).

\section*{The environment in visual perception}
van Eck et al. (2006) provide us with an argument to dismiss explanatory reductionism on the basis of empirical research in visual perception suggesting the significance of the environment in vision, and in general in cognitive processes. Their conclusion is that the inclusion of the environment in cognitive process shows the irreducible nature of psychological explanations operating at the computational level, since only at that level we can account for the environmental elements.

Some relatively recent studies give support to the idea that vision is not exclusively an internal process (e.g., Ballard et al., 1997). The phenomena of change blindness (Rensink et al. 2000; Simons, 2000) and inattentional amnesia (Wolfe, 1999) show, contra what traditional representationalist theories claimed (Marr, 1982), that subjects do not build a complete and detailed representation of the outside world. Instead, they rely on the stability of the environment, exploiting its resources. These recent findings could be said to be sympathetic with Gibson's idea that the ecological context is a central component in visual perception (Gibson, 1972). Although representations are still on the arena and Marr's (1982) classical computational theory of vision is not challenged yet, these findings point towards a more direct relation of the perceiver with her environment: the subject is not representing the whole scene (only part of it), but constantly consulting it, as if the information needed to successfully perceive, was, as Gibson defended, (at least partly) already there in the environment.

Norman (2002) proposes a theory where, apparently, Marr's emphasis on representations and informationprocessing on the one hand, and Gibson's emphasis on action and environment, can be reconciled. Norman's Dual Process Approach exploits the anatomical distinction between two brain pathways serving two different functions. The dorsal pathway is for action, while the ventral pathway is for representation (this approach resembles the perception-action model developed by Milner \& Goodale (1995), where vision is said to have two different functions, carried out by two separate brain structures.)

We are interested in how van Eck et al. examine Norman's approach and conclude it is incorrect. The findings mentioned above, point towards outside the brain, while Norman's approach restricts the action-related aspect of vision to the functioning of the dorsal pathway within the brain. That is, while Norman's proposal recognises that visual perception also serves to guide motor behaviour (perception is here, as Gibson argued, related to action), it is still internalist, situating the ingredients of perception inside the head. Gibson's direct perception proposal, however, includes the organism's environment, and it is this environmental factor what van Eck et al. want to rescue from inside the head.
van Eck et al. draw on Norman's mistake, presenting it as a confusion between different levels of explanation. Norman seems to be missing the externalist implications of
recognizing the importance of the environment. In van Eck et al. proposed clarification I find, however, two mistakes. On the one hand, they confuse ontological and explanatory issues; on the other hand, they make a controversial identification between Marr's computational level and Gibson's emphasis on the environment.

\section*{Internalism vs. Externalism}

Norman is wrong in keeping everything inside the head. Ecological perception (Gibson's proposal) is not the creation of action-based representations. It is not (only) about internal mechanisms. In van Eck et al's opinion, "Norman ignores that environment constitutes an additional level above internal processes" (2006, p. 21). According to them, ecological Gibson-like theories cannot be equated with neurophysiological accounts of the dorsal system. Gibson's view "is much broader than the level of (action) representations, because ecological perception also encompasses the environment" (ibid, p. 21). van Eck et al. are here moving the debate towards internalism/externalism. Are mental processes exclusively determined by intraorganism facts, or also by external factors? Gibson's view and the findings mentioned above seem to support some version of an externalist position. Therefore any account of visual perception solely in terms of internal mechanisms is missing something (e.g. this account will be unable to explain why the phenomenon of, for example, change blindness, happens). The internalist mistake lies in ignoring that other level, the environment. van Eck et al.'s conclusion is that the environment constitutes a different level of explanation, distinct from the internalist one.

This reasoning paves the way for their anti-reductionist conclusion. To account for that extra level we need a discipline that is not confined to lower-level processes; a science that is concerned with mental processes and is not restricted to neural, and therefore, internal processes. That is psychology. Psychology explains mental processes at a higher-level (describing them first at a computational level), where not only neural, but also elements outside the organism can be accounted for. Thus, this goes against any reductionist attempt to explain mental processes with a lower-level science like neuroscience. Thus, findings supporting Gibson's view are said to support an antireductionist project where psychology is necessary. Let's summarize van Eck et al.'s argument in bullet points:
(i) Environment plays a critical role in (visual) perception; in order to understand this we need to consider organismenvironment interactions, and not only what is going on inside the organism.
(ii) To account for organism-environment interactions we need a description at a level wider than a merely internalist one, like Marr's computational level, where the function of (visual) perception is described.
(iii) Psychology provides this kind of description, since it draws on explanations at a level wider than that of neuroscience.
(iv) Psychology is therefore necessary to explain visual perception.

It is now time to consider this argument critically.

\section*{Two Confusions}

\section*{From externalism to anti-reductionism}

In my opinion, van Eck et al. 's argument fails as an antireductionist defence. First, they confuse two different discussions, that is, the internalism vs. externalism debate, with the reductionism vs. anti-reductionism debate. It is true, I believe, that they assume that many practices within neuroscience are internalist (e.g., Bickle, 1998; 2003). So in attacking internalism, their argument can count against internalist reductionists (like Bickle seems to be). But reductionism in general, as a not-necessarily-internalist program, is left untouched.

Once we admit that empirical findings suggest the critical role that environment plays in (visual) perception, we have to account for that environmental factor. This however does not in itself warrant the need for psychology. The need to break the limits of the skull in order to describe the explanandum does not warrant the necessity of a higher level of explanation. That is, premise (ii) is not as obvious as van Eck et al. seem to present it. We can hold an externalist position and at the same time opt for the lower level of explanation. To tell against reductionism van Eck et al. would need, besides empirical findings suggesting that environment is critical in visual perception (and in general in any mental process), a conceptual claim asserting that to account for the organism-environment critical interaction we need to do so in an independent-of-implementation level.

The key assumption in van Eck et al. 's argument, premise (ii) is, in my opinion, a non sequitur. We can recognise that the environment makes a critical contribution to cognitive processes, and we can even say that the environment is a constitutive part of the system (like some versions of the Extended thesis claim), and it would still be a different thing to claim that this contribution constitutes a different level that needs to be accounted for by an autonomous science that is independent of physical details.

Here it is relevant to bring up the distinction between ontological and explanatory questions. The former seeks the constitution of something, while the latter inquires into a proper explanation of something. The ontological question at issue here is what constitutes vision: processes exclusively inside the organism or also states and features outside the organism? The explanatory question asks for how best to explain vision, or what counts as a (good) explanation of it. The explanatory question that concerns us here asks how we should deal (assuming we accept there is such an ingredient) with the outside-the-organism dimension(s) of vision. A particular response to the ontological question does not (automatically) imply a
specific response to the explanatory question. These two questions have to be answered separately.

Thus, from a claim about the constitution of vision, it is a non sequitur to state that as a consequence vision has to be explained in a particular way. Moreover, the (explanatory) demand that an explanation of vision requires reference to the environment still does not entail that a description at Marr's computational level is necessary. In order to assert such an explanatory choice, an additional argument is required. The ontological proof (i.e. that environment is part of visual perception) is not sufficient, and neither is the explanatory demand (i.e. that environment has to be accounted for).

In conclusion, for van Eck et al.'s argument to work, in particular, for their premise (ii) to be true, they need to prove that the environmental factor needs to be accounted for in a different, higher level explanation, where the visual task is described in a functional way as an information-processing task, and without mention of the particular (physical) component parts. But they only provide evidence for premise (i), that is, for the fact that environment plays a significant role in vision. They rely on Marr's theory to claim that this critical role that environment plays has to be described at Marr's computational level, where the function of vision is described. It is debatable whether Marr's theory is internalist or externalist. In the former case, van Eck et al. 's argument fails, since, if visual processes are (taxonomically) located inside the organism, there is no need for this extra level of explanation, and then their next step towards psychology as the science that accounts for that level, does not follow. If we concede that Marr's theory is externalist, according to what I have said above about the two different types of questions (ontological vs. explanatory), they still have not provided any argument for their explanatory conclusion. It is one thing to maintain that environment is part of our visual processes (ontological assertion), and another, to state that to explain vision we need to do it at a higher level (explanatory claim). The former claim (within the internalist vs. externalist debate) does not imply the latter (which is part of the reductionism vs. antireductionism debate).

It is important to notice here that the distinction between ontological and explanatory questions does not map onto the two different debates (internalism/externalism, and reductionism /anti-reductionism). I am not assuming neither that the former debate is exclusively ontological, nor that the latter is solely an explanatory matter. On the one hand, externalist considerations might respond to an explanatory concern, i.e. what is the appropriate unity of analysis. On the other, the debate around reductionism might be presented as an ontological question, e.g. are psychological properties reducible to properties of their implementation basis? The argument I am examining here (i.e., van Eck's et al.'s), however, takes the ontological aspect of an externalist position to conclude against an explanatory reductionism. The reason why I find it misleading is not that this argument
drags externalism towards explanatory fields, but that it forces externalism to a particular explanatory position.

\section*{A wrong appropriation}
van Eck et al.'s argument also fails for another reason: they wrongly equate Gibson's emphasis on the environment with Marr's emphasis on an independent-of-the-physicaldetails description where the cognitive ability to be explained is described as an information-processing task. Let us pay some attention to premise (ii) again.

They claim that the environmental factor has to be explained at a level different from the strictly internal where mechanisms responsible for the task are accounted for. They could then simply rely on Marr's model reputation, as classical cognitive science has done, and claim that a description at Marr's computational level, where the function of the cognitive task is described, is necessary to understand that task. But they go further, and seem to pursue legitimating Marr's computational level. Empirical findings point towards the necessity of including the environment in our understanding of visual perception (what we said to be premise (i)), and this partly supports Gibson's proposal. Interestingly enough, in van Eck et al. 's argument these empirical findings are assumed to legitimate Marr's computational level, since it is at Marr's computational level where the interaction with the environment is approached (that is the level of organism-environment interaction, where the task at issue is described independently of the algorithmic and physical details).

Once they claim that we have an "ecological level" to be accounted for (that is, an environmental ingredient that, according to them, calls for a new, higher level of explanation above a purely neural one), Marr's upper level appears as the proper place for that explanation. After all, Gibson's theory is too simplistic, or so a fan of Marr's computational complexity would say, to account for the complexity of organism-environment interaction. And so, although it makes a good point about the importance of environment, Gibson's theory falls short to account for the information-processing complexity that is involved.

Thus, van Eck et al. go from empirical findings to the necessity of Marr's computational level, via the assimilation of Gibson's ecological level into Marr's three-level model. And this assimilation is what attracts my attention. Gibson's emphasis on the environment does not imply another level above the level of representations, but a completely different anti-representational account of perception. Gibson's ecological level, as van Eck et al. label it, is not meant to provide a competing, alternative account of the informationprocessing mechanisms of vision. Gibson's theory is a completely contrasting explanation of perception where there is no room for internal addition and manipulation of information.

It is this major difference between Gibson's and Marr's theories that invalidates van Eck et al's assimilation of Marr's computational level (where vision is decomposed as an information-processing task) with Gibson's ecological
level (where vision is considered as an interaction between organism and environment and senses are decomposed into their biological component parts). In my opinion, then, van Eck et al's are using Gibson's emphasis on the ecological level in an incorrect way. The ecological level has nothing to do with Marr's computational level, so it is not correct to use Gibson's ecological level (and the evidence supporting the importance of environment) to legitimate Marr's computational level and the necessity of psychology.

We see that premise (ii) hides an incorrect assumption. Proving the significant role that environment plays is not the same as legitimating Marr's computational level. Premise (ii) (i.e. to account for environmental contribution we need a description at Marr's computational level, where the function of -visual- perception is described) being incorrect, premise (iii) (i.e. psychology provides this kind of description) has no meaning, because it is unimportant whether psychology provides the kind of descriptions that are required at Marr's computational level. Premise (i), let's remember, is only concerned with the necessity of including the environment in our explanation, not with the necessity of providing a particular kind of explanation. Only premise (i) in van Eck et al.'s argument, where empirical findings are reported, reveals as arguably correct. And it is easy to see that empirical support for the importance of environment is not evidence for the necessity of psychology. Premise (i) by itself does not support their antireductionist conclusion.

\section*{Conclusion}

By analyzing van Eck et al.'s argument, I tried to show that externalist considerations, and the extended mind thesis in particular (understood as a proposal about the location of the object of study in our explanations of mental processes), neither guarantee nor promote an anti-reductionist methodology and the necessity of a higher level of explanation where mental processes are described at a computational level.

If my considerations above are on the right track, van Eck et al.'s anti-reductionist argument is a poor one. On the one hand, they are mixing explanatory and ontological questions, extracting an explanatory conclusion from an ontological claim. On the other hand, they wrongly equate Gibson's emphasis on the environment with Marr's emphasis on an independent-of-the-physical-details description where the cognitive ability to be explained is described as an information-processing task. The identification of the first mistake, so I have argued, reveals that they only provide evidence for the ontological claim, leaving the explanatory assertion without any defence. The second mistake draws on the former. The empirical findings suggesting that environment plays a decisive role in cognitive processes supports Gibson's emphasis on the environment, but does not necessarily legitimates Marr's computational level of explanation, where organism-
environment interaction is accounted for. By equating Gibson's emphasis on the environment with Marr's computational level, they are trying to provide the functionalist sympathy for a description at Marr's upper level with empirical support. If their strategy were right, empirical findings pointing towards the significance of the environment would give support to the (computational) functionalist claim that visual perception, and mental processes in general, need to be approached as a platformfree information-processing task.

The empirical findings they mention might or might not be said to be evidence for Gibson's theory. What I think is clear is that they do not give any support to the claim that cognitive abilities need to be described at Marr's computational level. Their anti-reductionist conclusion is not well supported by their argument. It would require more and different argumentation to go from ontological claims about the location of cognitive processes to an explanatory anti-reductionism (e.g. some claim linking the inclusion of environment in explanations of mental processes to the need of accounting for it in an independent-of-the-implementational-details way).

An extended mind, and in general an externalist mind where environmental factors are a key ingredient, does not necessarily call for a high-level of explanation á la Marr's computational level. In our quest for cognition, we can go out of the head and still expect to satisfy our explanatory demands at the implementational level.

\begin{abstract}
Categorical perception is a well studied phenomenon in, for example, colour perception, phonetics and music. In this article we implement a dynamical systems model of categorical rhythm perception based on the resonance theory of rhythm perception developed by Large (2010). This model is used to simulate the categorical choices of participants in two experiments of Desain and Honing (2003). The model is able to accurately replicate the experimental data. Our results supports that resonance theory is a viable model of rhythm perception and they show that by viewing rhythm perception as a dynamical system it is possible to model properties of categorical perception.
\end{abstract}

Keywords: Categorical perception; rhythm perception; dynamical systems; resonance theory

\section*{Introduction}

Categorical perception occurs when categorization is amplified by the perceptual systems so that distances within a category are perceived as being smaller and distances between categories are perceived as larger than they are according to the values of some physical measurement. It is a common phenomenon that is well studied in, for example, colour perception, phonetics and music (Harnad, 1990). A central question for understanding categorical perception is: What is the underlying mechanism? There have been attempts to model categorical perception in terms of neural networks (Damper \& Harnad, 2000). In this article, we will focus on modelling categorical rhythm perception and present a model that is based on oscillators.

In the field of music perception rhythm refers to a temporal pattern of sound onsets. A rhythm in this sense does not have to be periodic or recurrent. This is in contrast with how that word is used in other fields (cf. circadian rhythm or delta rhythm). A related concept that does involve periodicity is beat. When listening to a piece of music a common response is to move one's body with a perceived periodic pulse (Snyder \& Krumhansl, 2001), that pulse is the beat of the corresponding piece of music. It is not common that all beats in a piece of music are perceived as being equally accented and a periodically recurring pattern of strong and weak beats is called a meter. For example, a duple meter would imply that every second beat is perceived as having a stronger accent while every third beat is perceived as having a stronger accent in the case of a triple meter. Rhythm perception and the ability to entrain to a musical beat was long thought to be uniquely human and, while it has recently been shown that some vocal mimicking species are, to some degree, able to move in synchrony with a beat (Schachner, Brady, Pepperberg, \& Hauser,
2009), humans are still unique in their aptitude for rhythmic processing. Already infants have been shown to have a sense of rhythm (Honing, Ladinig, Háden, \& Winkler, 2009) and there exists only one documented case of "beat deafness" (Phillips-Silver et al., 2011), that is, the inability to reliably synchronize to a musical beat.

Desain and Honing (2003) showed in two experiments that listeners reliably experienced rhythms as belonging to rhythmic categories and that categorizations were strongly influenced when the listeners were primed with a metric beat before hearing a rhythm. Furthermore, participants agreed to a large degree on which rhythms belonged to what category and, similar to categorization of other kinds of stimuli (c.f. Jäger (2010) on colour categories), the categories were found to be roughly convex with respect to a temporal performance space (Gärdenfors, 2000). Honing (2013) concludes that: '"It is puzzling, however, that although meter was shown to exert a strong influence on the recognition of rhythm [...] existing computational models of meter can explain this phenomenon only to a small extent". In this article we show that an oscillation based, resonance theory model of rhythm perception (Large, 1996, 2010) can replicate many of the findings of Desain and Honing (2003). Our results support the notion that resonance theory is a viable model of rhythm perception and show that by viewing rhythm perception as a dynamical system it is indeed possible to model the properties of categorical rhythm perception.

\section*{Resonance Theory and Categorical Rhythm Perception}

Modelling of human timing and rhythm perception has a long history. One influential model is the one described by Wing and Kristofferson (1973), which is based on an information theoretic perspective. Like many such models (cf. Repp, 2005), it models a participant's behaviour when attempting to elicit isochronous timing responses. An alternative to this information theoretic perspective is to take a dynamical systems perspective and model time and rhythm perception as an emergent, dynamic phenomenon. A number of models of this kind have been proposed (e.g., Large, 1996; Noorden and Moelants, 1999). Here, the term resonance theory (cf. Large, 2010) will be used to refer to this type of models. Resonance theory does not dictate a specific model but rather incorporates a number of related models. All can be considered as dynamical system models and they consist of one or more resonating oscillatory units. Resonance theory provides a compelling framework since it is biologically plausible, has

Figure 1: (a) and (b) show examples of two possible rhythms and their placement in the triangular performance space (c) defined by Desain and Honing (2003). All one second long, four sound rhythms can be represented as a point in this space. (From Honing, 2013 with permission).
a solid base in dynamical systems theory and is able to model many aspects of meter and rhythm perception (Large, 2000). The general idea of resonance theory is that an external auditory rhythm can be represented by the rhythm of internal oscillatory units. These oscillatory units are coupled to the external rhythm and are by definition periodic while the external rhythm does not have to be periodic. Given a rhythm sequence as input the basic output of a resonance theory model, or resonance model for short, is the amplitude response of the oscillators over time. This high dimensional representation might be difficult to work with directly, however, and a more convenient representation is given by creating an \(a c\) tivation pattern, \(A\), by summing the amplitude responses of each oscillator over time, as in
\[
\begin{equation*}
A_{i}=\sum_{t=t_{s}}^{t_{e}} a_{i, t} \tag{1}
\end{equation*}
\]
where \(a_{i, t}\) is the amplitude for oscillator \(i\) at time \(t\) while \(t_{s}\) and \(t_{e}\) are the start and end time steps for the summation. Before the resonance model is given any input it is in a resting state and it takes a number of time steps before the system is activated by the stimuli. Therefore it is not necessarily desirable to sum over the whole extent of the duration of the rhythm sequence and an activation pattern created by summing over the latter time steps may represent the rhythm sequence better than an activation pattern created by summing over all time steps.

While not all resonance theory models claim biological plausibility, a number of neuroimaging studies have shown connections between neural resonance and rhythm perception
(e.g., Brochard, Abecasis, Potter, Ragot, and Drake, 2003). One persuasive study that clearly showed that rhythm perception involves neural oscillatory activity is that of Nozaradan, Peretz, Missal, and Mouraux (2011). They found that playing a rhythmic beat to a participant elicited a sustained periodic neural response, as measured by EEG, that matched the frequencies of the beat. Resonance theory models differ in their biological plausibility, the number of oscillatory units employed and the type of oscillators used. Eck (2002) constructed a model with a clear biological connection as it used the Fitzhugh-Nagumo model of neural action potential (Nagumo, Arimoto, \& Yoshizawa, 1962) as the oscillatory unit. Other models claim no biological plausibility, for example, the model by Scheirer (1998) that employs a comb filter as the oscillatory unit. Toiviainen and Snyder (2003) modelled participants behaviour when tapping along to excerpts of music composed by Bach using a single oscillatory unit while Large and Kelso (2002) used a bank of 96 oscillators to model participants' tapping to ragtime music.

To our knowledge, resonance theory models have not previously been used to model categorical rhythm perception. One reason for this might be that while the amplitude response of the oscillators in the resonance model reflects, perhaps even represents, the rhythm sequence given as input to the system it does not give rise to a categorization per se. That is, while the state the resonance model arrives at depends on the given rhythm sequence, there is no finite number of discrete states that can be said to constitute categories. Still, the state of the resonance model can be used as the basis of a categorical decision based on learnt prototype states or a discrete partitioning of the system state space. By considering the activation pattern of a resonance model as a point in an \(n\)-dimensional space, \(n\) being the number of oscillatory units, this space can be partitioned into regions corresponding to rhythm categories and used to produce categorical decisions (following the general model of concepts from Gärdenfors (2000)). The relation between the activation pattern of a resonance model and such a rhythm categorization is analogous to the relation between the hue, saturation and lightness of a colour percept and a colour categorization. That is, a colour percept can similarly be viewed as a point in a three dimensional space with dimensions hue, saturation and lightness and this space can be partitioned into regions, each representing a colour category, and used to produce categorical colour decisions.

If the state of the resonance model is viewed as the basis for a categorical decision then two predictions regarding categorical rhythm perception can be made:
(1) More distinct states will facilitate categorization. Here a distinct state refers to a subset of oscillators in a resonance model having a strong amplitude response while most oscillators show a weak amplitude response. This is in contrast to a non-distinct state where most oscillators have a similar amplitude response, that is, there are many competing signals and there is no clear single winning candidate among

Figure 2: Maps over categorization consistency. (a) shows the entropy of the categorical choices for the participant given the same rhythm sequences multiple times from Desain and Honing (2003, used with permission). (b) shows the signal-to-noise measure calculated from the activation patterns generated by the resonance model.
the categories. In an experimental categorical task it would then be predicted that a participant would categorize a rhythm sequence more consistently, and with more confidence, if the sequence resulted in a more distinct state in a resonance model than if the sequence resulted in a less distinct state.
(2) Rhythm sequences resulting in similar states are categorized similarly. That is, different rhythm sequences resulting in similar states when used as the input to a resonance model should be categorized similarly by participants in an experimental task.

In order to test these predictions, data from a rhythm categorization task is needed. A study by Desain and Honing (2003) provides suitable experimental data to do so.

\section*{The Rhythm Categorization Study of Desain and Honing (2003)}

Desain and Honing (2003) employed a novel paradigm where participants were asked to categorize 66 different rhythm sequences by transcribing them into common music notation. The sequences all lasted for one second and consisted of four tone onsets and were therefore uniquely determined by the three interonset intervals (IOI) between the tones. Two such
possible sequences are shown in figure 1 a and 1 b where a possible categorization of 1 b could be \(\lrcorner \curvearrowright . \mathrm{d}\) ( or 1-1-2 when written as an integer ratio). Any possible one second, four tone rhythm sequence can be thought of as a point in a three dimensional triangular performance space that determines the lengths of the three IOIs as shown in figure 1. The 66 rhythm sequences were constructed so that they evenly covered the area in the performance space with the constraint that no IOI would be shorter than 153 ms . The location of these sequences in the performance space can be seen in figure 2 b where each circle marks the position of one of the \(66 \mathrm{se}-\) quences.

In a first experiment, 29 highly trained musicians categorized the rhythm sequences and the result was that even though the rhythms were performed on a more or less continuous scale, the participants tended to stick to a limited number of categories with 1-1-1 being the single most common. Twelve categories, all categories considered, stood out as being the most common and the location in performance space of these categories are shown in figure 3a. One participant was presented with the 66 rhythm sequences multiple times and as a measure of consistency the entropy was calculated of her responses for each rhythm. These entropy values were mapped on to the performance space and the resulting entropy map is shown in figure 2 a .

In a second experiment two meter conditions were added. Duple meter versions of the rhythms were constructed by prepending the rhythms with a repeated, one second long, two sound beat, thus inducing a \(2 / 4\) meter feeling. Triple meter versions of the rhythms were similarly constructed by prepending a three sound beat instead. This resulted in three different meter conditions: The original no meter condition, a duple meter condition and a triple meter condition. Maps over what categories the participants ascribed to the different rhythms, similar to the map shown in figure 3a, were constructed (shown on p. 358 in Desain and Honing, 2003). A main finding was that the participants' categorization in the no meter condition was significantly more similar to the participants' categorization in the duple meter condition than in the triple meter condition.

For the purpose of the current study, data from Desain and Honing was downloaded from a web resource containing supplementary material \({ }^{1}\). The data downloaded was the information regarding which of the twelve most common categories was most often ascribed to each of the 66 rhythm sequences for the no meter condition in experiment one and the duple and triple meter conditions in experiment two. A data point for a rhythm sequence was excluded if none of the twelve most common categories was the most common for that specific rhythm. Information regarding the categorization entropy for the participant presented with the rhythms multiple times was unfortunately not available from the web resource. This information was retrieved manually from figure 2 a .

\section*{Resonance Theory and the Data of Desain and Honing}

It is possible to test the two predictions from resonance theory concerning how rhythms are categorized by implementing a resonance model that consists of an array of oscillators (as in Large, 2000). We used the rhythm stimuli from Desain and Honing (2003) as input to such a model and compared the results with the experimental data using the methods outlined below.

Prediction (1) implies that rhythm sequences resulting in distinct states in a resonance model should be the sequences that are categorized more consistently. In Desain and Honing's data, a measure of consistency is the categorization entropy for the participant presented with the rhythm sequences multiple times. The prediction is that this measure of consistency is correlated with a measure of distinctness of the state of a resonance model. Signal-to-noise ratio is a common measure of distinctness of a signal and a modified version of this measure can be used to quantify the distinctness of the state of a resonance model. For a resonance model that has been given a rhythm sequence as input, the activation pattern is first calculated according to equation (1). In this activation pattern, the signal \(A_{s}\) is defined as being the \(A_{i}\) with the highest amplitude. The signal-to-noise ratio is then defined
as:
\[
\begin{equation*}
S N R=\frac{A_{s}}{\sum_{i=1}^{n} A_{i}} \quad i \neq s \tag{2}
\end{equation*}
\]
where the sum in the denominator is over the rest of the \(A_{i}\) oscillator amplitudes. Notice that this measure of consistency should be negatively correlated with the entropy measure of Desain and Honing: As the signal gets weaker relative to the noise, the entropy of the participants choices of category should go up.

Prediction (2) implies that rhythm sequences resulting in similar states when given as input to a resonance model should be categorized similarly in an experimental task. A resonance model does not directly produce a categorization but this is not required for testing this prediction. It is possible to compare the resulting states of two rhythm sequences by calculating the respective activation patterns and comparing these. A suitable similarity measure is given by considering the activation patterns as points in an \(n\)-dimensional space, where \(n\) is the number of oscillators in the resonance model, and then taking the Euclidean distance between these two points, where a shorter distance corresponds to more similar states. Considering the twelve most common rhythm categories chosen by the participants in Desain and Honing's study as prototype categories, it is possible to use the rhythm sequences corresponding to these categories to generate prototype activation patterns. For example, to generate the prototype activation pattern for the category 1-2-1 (as shown in figure 4) the rhythm sequence with IOIs \(0.25 \mathrm{~s}, 0.5 \mathrm{~s}\) and 0.25 s would be used as input to the resonance model. A rhythm sequence's activation pattern can then be compared with these prototypes' activation patterns and the prototype category with the most similar activation pattern can be assigned to that rhythm sequence. In this way, all rhythm sequences can be assigned a category and these categories can be compared with the categories selected by the participants in Desain and Honing's study. Specific hypotheses are then that a resonance model categorization of the stimulus used by Desain and Honing should be similar to the categorization made by the participants in the no meter, duple meter and triple meter conditions. Furthermore, since the participants' categorizations of the rhythm sequences in the duple meter condition was more similar than the triple meter condition to the categorization in the no meter condition the same relation should be present in the categories generated by the resonance model.

\section*{The Setup of the Resonance Model}

The resonance model was implemented in MATLAB \({ }^{2}\) using the Nonlinear Time-Frequency Transformation Workbench (Large and Velasco, in preparation). The model consisted of 145 Hopf oscillators, a type of oscillator that entrains to periodic input and where the amplitude of an oscillator depends on that oscillator's intrinsic frequency and the periodicities

\footnotetext{
\({ }^{2}\) http://www.mathworks.se/products/matlab/
}

Figure 4: An example of an activation pattern generated by feeding the resonance model a rhythm with IOIs \(0.25 \mathrm{~s}, 0.5 \mathrm{~s}\) and 0.25 s .
of the input. The differential equation of the Hopf oscillator used is:
\[
\begin{gather*}
\frac{d z}{d t}=z\left(\alpha+i \omega+\frac{\beta \varepsilon|z|^{4}}{1-\varepsilon|z|^{2}}\right)+\frac{x}{1-\sqrt{\varepsilon} x} \cdot \frac{1}{1-\sqrt{\varepsilon} \bar{z}}  \tag{3}\\
\alpha=-0.1, \quad \beta=-0.1, \quad \varepsilon=0.5
\end{gather*}
\]
where \(\alpha\) is a damping term, \(\beta\) is an amplitude compression factor and \(\varepsilon\) is a scale factor. The last term in equation (3) is the resonant term, which is dependent on the stimulus \(x\). These parameter values and this specific formulation of the Hopf oscillator were not chosen on the basis of any specific theoretical considerations; many other configurations are possible and a more general form of the Hopf oscillator is derived in Large, Almonte, and Velasco (2010). The oscillators' intrisic frequencies were centred around 1 Hz with frequencies logarithmically distributed from 0.25 Hz to 4 Hz . The method used for creating activation patterns was that in equation (1) with \(t_{s}\) set to the time step corresponding to half the stimulus length and \(t_{e}\) set to the last time step \({ }^{3}\).

The 66 rhythm sequences from the no meter condition were encoded and given as input to the model yielding 66 activation patterns. This was repeated for the rhythm sequences from the duple and triple meter conditions. Additionally, the rhythm sequences of the prototype categories were encoded in the same way as the no meter condition sequences yielding twelve prototype activation patterns.

\section*{Results}

The signal-to-noise measure was calculated for all activation patterns in the no meter condition and, as predicted, a negative correlation between Desain and Honing's (2003) entropy measure of consistency and the signal-to-noise ratio (Pearson product-moment correlation, \(r=-0.33, p=0.006\) ) was found. The two measures of consistency are expected

\footnotetext{
\({ }^{3}\) The MATLAB code for the model and both input data and the resulting output are available on request from the first author. The code for the Nonlinear Time-Frequency Transformation Workbench (Large and Velasco, in preparation) has not yet been publicly released and has to be requested separately.
}
to have a reverse relationship, that is, low entropy in the experimental data should indicate high consistency, while a low signal-to-noise ratio in the simulated data should indicate low consistency. A comparison between these two measure of consistency is shown in figure 2 . To facilitate comparison, the colour scales have been matched so that red indicates low consistency while blue indicates high consistency. The measures of consistency are clearly comparable, showing the same broad patterns in both the simulated (figure 2b) and experimental data (figure 2a).

The activation patterns for all the three meter conditions were compared with the prototype activation patterns using Euclidean distance as the similarity measure and each rhythm sequence was assigned the category of the most similar prototype. A comparison with the categories assigned in the experimental task for the no meter condition is shown in figure 3. It is clear that the categorizations to a large extent agree. The \(1-1-1\) category is the most common in both the experimental and the simulated categorizations and both categorizations exhibit roughly convex category regions. A randomized permutation test \({ }^{4}\) also showed that the categorization generated by the resonance model and the categorization from Desain and Honing's data was more similar than would be expected by chance alone for all the three meter conditions. In the no meter condition (shown in figure 3) the agreement was \(71 \%\) ( \(p<0.001\) ) and in the duple and triple meter conditions \(67 \%\) ( \(p<0.001\) ) and \(61 \%(p<0.001)\) respectively.

In the experimental data, the categorization of the duple meter condition was more similar than the triple meter condition to the no meter condition and this was also the case for the simulated categorizations. The agreement between the no meter condition and the duple and triple meter conditions for the simulated categorizations was calculated as being \(77 \%\) and \(71 \%\) respectively with duple meter agreeing with the no meter categorization in 6 percentage points more of the cases ( \(p=0.045\), one-tailed randomized permutation test).

\section*{Conclusions}

Many models of categorical perception have been based on neural networks and there exist several models of rhythm perception based on neural networks (Mozer, 1993; Miller, Scarborough, \& Jones, 1992). We believe that using a dynamical

\footnotetext{
\({ }^{4}\) Randomized permutation tests (Ernst, 2004) were used to compare the categorization of the rhythm sequences from the behavioural data with the categorization from the resonance model. Given two different categorizations of the 66 rhythms a similarity score, is calculated as the number of rhythms that are given the same category by both categorizations. In the cases when the most common categorization of a specific rhythm sequence in the behavioural data is not one of the twelve prototype categories this rhythm sequence is excluded from further analysis. Next, all category labels are randomly assigned to different rhythm sequences and a new similarity score is calculated. This is repeated 10,000 times, yielding a randomized permutation distribution of similarity scores. A p-value is then calculated as the probability of achieving the actual similarity score, or a similarity score being more extreme, given the randomized distribution of similarity scores. The permutation tests were two-tailed (calculated according to the method in Ernst, 2004) in all cases except when noted.
}
system of resonating oscillators provides a more principled way of modelling such phenomena. By modelling rhythm perception in such a system, we have shown that it is possible to explain empirical findings of listeners' categorical perception of rhythm. Our oscillator model has been able to accurately replicate the experimental data from Desain and Honing (2003).

An advantage of oscillator models is that they can be generalized to other kinds of categorical perception. Examples from the domain of music are pitch perception and tonality perception (Large, 2010). Oscillatory models are not confined to temporal processes and can be used for other modalities. The main importance of our model is perhaps that the example of how oscillator models can be constructed for categorical rhythm perception can serve as inspiration for similar models of other cognitive phenomena.

\title{
Measuring Cultural Relativity of Emotional Valence and Arousal using Semantic Clustering and Twitter
}

\author{

}

\begin{abstract}
Researchers since at least Darwin have debated whether and to what extent emotions are universal or culture-dependent. However, previous studies have primarily focused on facial expressions and on a limited set of emotions. Given that emotions have a substantial impact on human lives, evidence for cultural emotional relativity might be derived by applying distributional semantics techniques to a text corpus of self-reported behaviour. Here, we explore this idea by measuring the valence and arousal of the twelve most popular emotion keywords expressed on the micro-blogging site Twitter. We do this in three geographical regions: Europe, Asia and North America. We demonstrate that in our sample, the valence and arousal levels of the same emotion keywords differ significantly with respect to these geographical regions - Europeans are, or at least present themselves as more positive and aroused, North Americans are more negative and Asians appear to be more positive but less aroused when compared to global valence and arousal levels of the same emotion keywords. Our work is the first in kind to programatically map large text corpora to a dimensional model of affect.
\end{abstract}

Keywords: Semantic Clustering, Emotion Analysis; Twitter; Core Affect Model.

\section*{Introduction}

The question as to whether the experience and expression of emotions is universal or relative to specific cultures has resulted in a wide variety of studies, with theories ranging from the universality hypothesis to culture-specific facial expressions. Here we present evidence that culture is a necessary framework for researchers studying variation in emotions. Independent of the question of biological differences in the experience of emotions, it would be unsurprising if culture shapes our conscious perception, expression and experience of emotions, as has been hypothesised for other cognitive phenomena (Hunt \& Agnoli, 1991; Fuhrman et al., 2011). Here, we use Latent Semantic Clustering on an emotional text corpus mined from Twitter to discern how the primary properties normally attributed to emotional keywords - valence and arousal - differ as the keywords are used in the same language (English) as exploited across different global regions.

\section*{The Conceptualisation of Emotion Qualia}

Emotion qualia refers to the raw feel of an emotion. The actual phenomenon of a particular emotion experienced may differ according to each person's perception or understanding of that emotion, with perception being the result of the individual's past and hypothesised responses, unique to each human being. Barrett (2006) describes the act of conceptualising core affect, or in other words, why people attach emotion labels to the experience of emotion qualia. Since emotion
keywords are constructed from conceptual knowledge about the world, emotions themselves may be concepts that humans begin learning in infancy and continuously extend and revise throughout life (Lindquist \& Barrett, 2008). This repeated experience of labelling a combination of core affect and the context in which it occurs as an emotion provides training in how to recognise and respond to that emotion. In this sense, Barrett describes emotions as simulations. This skill of conceptualising core affect as an emotion could be a core aspect of emotional intelligence, in much the same way as conceptual thinking is core to cognitive intelligence. Each person learns the label in association with their unique experience, thus each person's conceptualisation of their emotional spectrum is unique. Cultures, formed of communicating individuals, may therefore also be unique if individual experiences vary somehow systematically. We base our analysis on this hypothesis. The reader should bear in mind that we are not analysing emotion keywords in particular, rather, we are analysing emotion conceptualisations, or what cultures understand specific emotion keywords to mean, using Latent Semantic Clustering to infer these meanings.

\section*{Core Affect}

Core affect is an emerging paradigm in affective neuroscience, and postulates a continuous approach to defining emotions (Posner et al., 2005). Several core-affect, or circumplex models have been proposed (e.g. Watson \& Tellegen, 1985; Russell, 1980; Cacioppo \& Berntson, 1994), yet all have one thing in common: they represent emotions as a single point in a continuous space defined by two (or rarely three) dimensions. Different labels have been assigned to these two dominant dimensions by various theorists, such as pleasure and engagement, however most commonly, valence and arousal are chosen. Thus far, there has been no attempt to computationally pinpoint emotions or documents within a core affect model using 'online' and 'big' data; to date, research regarding the core affect model has either been theoretical (e.g. Watson \& Tellegen, 1985), or conducted via a limited survey (e.g. Russell, 1980).

Core affect is one of two main theories regarding the representation of emotions, the other being the Basic Emotion model, however, neither has thus far received unequivocal support. Basic emotions could turn out to map to multiple subtypes of coherent emotion networks, but this implies we need to split basic emotion categories into further subtypes to better reflect these emotion networks (Hamann, 2012; Bann,
2012). Here we extend this view and suggest that the core affect model enables us to quantify the properties of the basic emotions themselves.

\section*{Previous Work}

There is growing evidence that aspects of a person's psychology can be predicted from their language usage. In the 1990s, human semantics was shown to be recoverable from linguistic corpra independent of any further grounding (Lowe, 1997; Bryson, 2008). Recent applications to individual psychology include discovering individual differences in personality (Pennebaker \& King, 1999), discovering cultural change in moral beliefs (Bilovich \& Bryson, 2008), as well as for emotion categorization (Fitzpatrick \& Logan, 2011). French discovered that co-occurrence techniques such as LSA does not detect personality from short text samples (French \& Gill, 2007), but do reveal that texts expressing particular emotions have a greater semantic similarity to corresponding exemplar words (Gill et al., 2008).

A recent study by Jack et al. (2012) found significant evidence that facial expressions are indeed culture-dependent; that is, different cultures represent the same emotions differently. However, whether or not this is because they experience different emotion qualia is another question. Using language, rather than facial expressions, as an accessor to emotion will enable a much more detailed and less ambiguous analysis, increasing significance by "throwing more data at the problem" (Recchia \& Jones, 2009, p.3).

Currently, there have been few attempts to analyse cultural differences using language semantics. Language plays a key role in how emotions are conceptualised (and thus perceived); Lindquist states "language can be no more removed from emotion, than flour can be removed from an already baked cake" (Lindquist, 2009, p.1). Recently, Bann \& Bryson (2012) demonstrated how conceptualisations of emotions can be inferred by performing Latent Semantic Analysis on a corpus of self-reported emotional tweets. Their DELSAR algorithm analysed 21,000 tweets each labelled with an emotion, and clustered each document in the corpus to its most similar corresponding emotion label using Latent Semantic Clustering. Here we use the same algorithm as the basis for our analysis.

\section*{Corpus}

Typing emotion keywords into the Internet is increasingly becoming a significant technique for individual expression. There now exists a rich available source of information about emotions on the Internet, because so many people spend time expressing how they feel in blogs, forums, social networking websites and the like. We use data from the microblogging website Twitter to perform large-scale analysis of the language used in thousands of expressions of emotions within tweets. Acquiring a significantly larger corpus than Bann \& Bryson (2012), we use the Gardenhose level of Twitter's
streaming API \(^{1}\) to create a corpus of \(5,625,844\) tweets \(^{2}\) collected between 19th October 2012 and 18th January 2013. Each emotion keyword (see selection criteria below) is given a five-minute streaming window in turn for the duration of the period, ensuring an even temporal distribution of Tweets is collected. Table 1 describes our corpus, split by 'cultural' region. We use the tweet's timezone as an indication of the corresponding user's geographical location; seeing as it is very unlikely that a Twitter user would select a timezone other than that which they reside in, it is somewhat safe to assume that this reflects the cultural origin of each user.

Table 1: Distribution of tweets within our corpus.
\begin{tabular}{lrrrr}
\hline Emotion & Asia & Europe & NA & All \\
\hline Angry & 12194 & 27070 & 61293 & 200024 \\
Ashamed & 1008 & 5097 & 17107 & 46486 \\
Calm & 5975 & 10181 & 36681 & 102827 \\
Depressed & 3078 & 11615 & 43129 & 120473 \\
Excited & 30923 & 100792 & 292822 & 847679 \\
Happy & 149129 & 186709 & 730839 & 2201874 \\
Interested & 3527 & 9728 & 31891 & 86763 \\
Sad & 46351 & 83075 & 341912 & 966165 \\
Scared & 15435 & 42500 & 194130 & 517715 \\
Sleepy & 26031 & 10787 & 120473 & 290666 \\
Stressed & 2587 & 8774 & 41716 & 109295 \\
Surprised & 3032 & 12454 & 56332 & 135877 \\
\hline Total & \(\mathbf{2 9 9 2 7 0}\) & \(\mathbf{5 0 8 7 8 2}\) & \(\mathbf{1 9 6 8 3 2 5}\) & \(\mathbf{5 6 2 5 8 4 4}\) \\
\hline
\end{tabular}

Region definitions. We only include those timezones that have over 5000 tweets within our corpus. The Asia region consists of the timezones Kuala Lumpur, Beijing, Singapore, Jakarta, Bangkok, Hong Kong, Tokyo; the Europe region consists of the timezones London, Amsterdam, Athens, Edinburgh, Dublin, Berlin, Paris; the North American (NA) region consists of the timezones Eastern Time (US \& Canada), Central Time (US \& Canada), Mountain Time (US \& Canada), Pacific Time (US \& Canada).
Selection of emotions. As opposed to strictly using the basic emotions as identified by Bann \& Bryson (2012), we use the most popular emotions that are used on Twitter, that is, those emotions that have the highest stream rate. Twelve emotions were selected that had a high rate and that equally divided into positive/negative and engaged/disengaged theoretical categories (see Table 2).
Subcorpus creation. Each subcorpus is created using a limit of 1000 documents per emotion for all subcorpora to ensure consistency within our results; we chose 1000 as it is the lowest value in Table 1. To mitigate micro-temporal effects, if the number of documents for a particular emotion is significantly greater than 1000, we use a modulus function to extract 1000

\footnotetext{
\({ }^{1}\) https://dev.twitter.com/docs/streaming-apis.
\({ }^{2}\) Having first removed 34,725 duplicate tweets. Corpus and code is available to download at www.aeir.co.uk/code.
}
documents equally spaced across the subcorpus - for example, if a particular emotion in a particular subcorpus has 6000 documents, we take one document every six documents. We also create six control subcorpora so to compare our regionspecific results with a baseline. We use the same modulus function to extract 1000 equally spaced tweets, but without any timezone clause, selecting six random starting points.

\section*{Proposed Method}

We use DELSAR (Bann \& Bryson, 2012, see Algorithm 1) to generate the clustering matrix for each subcorpus - the three regions Asia, Europe and NA, and six random controls.
```

Algorithm 1 DELSAR
Require: Corpus $\mathbf{C}$ and Keyword Set $\mathbf{K}$, where each docu-
ment in $\mathbf{C}$ is mapped to one emotion keyword, emotion, in
$\mathbf{K}$ (through corpus generation)
Generate cosine document similarity matrix of $\operatorname{LSC}(\mathbf{C}, \mathbf{K})$
(document $\times$ document similarity matrix)
for each emotion $\in \mathbf{K}$ do
for each document that has emotion emotion do
delete emotion within the document
Find the closest document nearest where nearest $\neq$
document
Increment the count for the emotion that nearest is
labelled as in emotion_vector
end for each
return emotion_vector
end for each

```

For each subcorpus, DELSAR uses LSA (Landauer \& Dumais, 1997) to create a document-document matrix of cosine similarities (Similarity Matrix), in which similar documents are closer to one (i.e. the cosine of the angle between their vectors). It creates a clustering matrix that represents the corpus as an emotion-emotion matrix, describing how each emotion is similar to each other emotion.

All analysis was performed on a 64-bit Intel Core i5 CPU \(2 \times 2.67 \mathrm{GHz}\) with 4 GB RAM using the GENSIM framework for Python (Řehůřek \& Sojka, 2010) to create LSA spaces. For all tasks, we use a dimension of 36 and use Log-Entropy normalisation as our Association Function, found to generate optimal results (Nakov et al., 2001) and recommended for LSA (Landauer \& Dumais, 1997).

\section*{Valence and Arousal}

Here we take valance to mean the theoretical positive or negative attribution of an emotion keyword, and similarly arousal to mean the implied level of engagement. We should use the keywords theoretical valence and theoretical arousal as we are measuring emotion keywords relative to their generally accepted categorisation, although there does seem to be consistency in these categorisations between theorists. Table 2 shows the theoretical definitions of our keywords, accumulated using several circumplex models of affect (Watson \& Tellegen, 1985; Russell, 1980; Cacioppo \& Berntson, 1994).

Table 2: Valence and arousal categorisation of the twelve emotion keywords analysed.
\begin{tabular}{lll}
\hline Emotion & Valence & Arousal \\
\hline Angry & Negative & Engaged \\
Ashamed & Negative & Disengaged \\
Calm & Positive & Disengaged \\
Depressed & Negative & Disengaged \\
Excited & Positive & Engaged \\
Happy & Positive & Disengaged \\
Interested & Positive & Engaged \\
Sad & Negative & Disengaged \\
Scared & Negative & Engaged \\
Sleepy & Positive & Disengaged \\
Stressed & Negative & Engaged \\
Surprised & Positive & Engaged \\
\hline
\end{tabular}

We calculate the valence and arousal levels of each emotion for each subcorpus as follows. First, we run DELSAR on the subcorpus to generate clustering vectors for each emotion. Each emotion's valence is then calculated as the number of positive elements within its vector, as defined in Table 2 , divided by the total number of documents across all elements (which will always be 1000), or in other words, the percentage of positive elements within its vector. Similarly, each emotion's arousal is calculated as the percentage of engaged elements within its vector, again as defined in Table 2. We then normalise each valence and arousal value by taking away the average valence and arousal value, respectively, for all subcorpora analysed - Asia, Europe and NA regions and the six control subcorpora. This ensures relativity of the resulting circumplex model between these analysed groups; these groups can now be compared to one another to establish similarities and differences between them.

\section*{Results}

Figure 1 shows a plot of our circumplex of selected subcorpora. We can see that some emotions are more tightly packed than others, and interestingly, that low-valence-high-arousal and high-valence-low-arousal emotions are much more universally similar when compared to the other two quadrants of the circumplex. In order to visualise each separate region more clearly we illustrate the aggregate theoretical positivity and engagement for each subcorpus, shown in Figure 2. This clearly illustrates that our three regions do indeed have different conceptualisations of the same emotion keyword; we see that the region Europe is a much more positive and engaged culture; in other words, Europeans find the same emotion keywords to be more positive and engaging when compared to other cultures and indeed our control samples. Also, we discover that Asians find the same emotion keywords to be somewhat more positive, and North Americans somewhat more negative, with negligible arousal differences.

In order to analyse how tightly packed our emotion clus-

Figure 1: Circumplex of three regions and six controls.
ters are in Figure 1, we conducted K-Means cluster analysis to determine the centroids for each emotion, calculating the distances of each emotion to its centroid. We plot our centroids, shown in Figure 3, resulting in a circumplex that could be thought of as a universal emotion circumplex, illustrating what people think emotions to be, relative to each other emotion. We can see that the emotions scared, depressed and sad have a very similar valence, yet varying arousal levels; so too do the emotions sleepy and sad. We can also see, albeit less definitively, that the emotions stressed and surprised have a similar arousal level, but opposite valence; so too do the emotions sad and sleepy.

In order to identify which emotions have the most and least similar conceptualisations across cultures, we calculate the distance of each emotion to its respective centroid for each region, and calculate the sum of these distances for each emotion across all subcorpora, shown in Table 3. We discover that
the emotions sad and stressed have the most similar conceptualisations across all cultures; in other words, people understand these two emotions to mean the same thing independent of culture. Similarly, we find that the emotions surprised and depressed have the most widely varying conceptualisations across cultures; in other words, different cultures have very different valence and arousal attributions towards these two emotions. Note that we do not include the emotion ashamed in the top two due to a strange anomaly in control group 6 which skews an otherwise relatively tight cluster.

\section*{Discussion}

We would expect that the control groups would be tightly clustered around the centre of the circumplex in Figure 2, and for the most part, they are. The exceptions are control groups one and four, possibly due to the fact the the corpus is skewed in favour of tweets originating from NA (see Table 1);

Figure 2: Aggregate theoretical positivity and engagement for each subcorpus.

Table 3: Sum of subcorpus distances to respective centroids.
\begin{tabular}{lr|lr}
\hline Emotion & Distance & Emotion & Distance \\
\hline Sad & \(\mathbf{1 7 . 9 4}\) & Scared & 23.27 \\
Stressed & \(\mathbf{1 9 . 6 6}\) & Happy & 26.10 \\
Calm & 20.86 & Excited & 27.00 \\
Interested & 22.72 & Depressed & \(\mathbf{2 9 . 5 6}\) \\
Angry & 23.18 & Surprised & \(\mathbf{3 2 . 8 9}\) \\
Sleepy & 23.19 & Ashamed & 40.70 \\
\hline
\end{tabular}
this is somewhat verified by their closeness to the NA subcorpus. Other than these anomalous subcorpora, the circumplex does illustrate how different cultures significantly conceptualise emotions differently, in keywords of valence and arousal. Interestingly, there are certain emotions in certain regions that stick out of our analysis. One example is the emotion depression; Asians find this emotion much more negative than all other cultures and control groups. This could be due to cultural differences such as coping strategies (Aldwin \& Greenberger, 1987). Another example concerns the emotions happy and calm; Europeans and Asians find these emotions much more positive than North Americans and all control groups. Another suggests that Asians find interest a very positive and aroused emotion, compared to North Americans who conceptualise the same emotions, relatively, as negative and disengaged.

\section*{Limitations}

We document several limitations of our approach. Firstly, our database may still contain duplicate tweets, as some users duplicate tweets by appending, for example, a number at the end, making them unique from one another. Second, our

Figure 3: Centroid emotion circumplex.
modulus function does not take an even sample for our control groups at the country level, so they may be skewed in favour of countries with a higher frequency of documents within the database (our corpus on the whole is in fact skewed in favour of NA). Thirdly, we assume that the emotion keywords we have selected are in fact emotion qualia as opposed to adjectives. Fourth, our corpus is essentially a snapshot in time and may reflect, for example, the political or economic climate at the time, or skew due to global events such as the US election. Finally, our corpus consists entirely of English tweets, which skews our results in favour of Western cultures; our Asia, and to some extent, Europe subcorpora may not be entirely representative of their respective cultures as we disregard all native languages other than English. In addition, the subpopulations of those regions who choose to use Twitter, and do so in English, may be a biased sample.

\section*{Conclusions}

Emotions are being increasingly expressed online, and being able to understand these emotions is rapidly becoming a concern of AI and Cognitive Science. By mapping culturespecific emotion circumplexes, we hope to be better able to understand culture-specific perceptions or even experience of emotions. From the work presented here we can conclude the following:
Emotional semantics depends on culture. The same emotion keyword in one culture may describe different valence and arousal properties in another. This seems to be more true of some keywords than others, and could be critical where, for example, a significantly differing conceptualisation of the emotion depression would require a different understanding and response.
Emotions vary by geographic region. Europeans are more likely to express positiveness and engagement. Asians are
also more positive than North Americans, both relative to each other and to the control subcorpora. Note that this may reflect cultural differences in the public expression of emotion rather than its actual qualia - our method cannot disambiguate these.
Some emotions do seem to be conceptualised universally. The emotion keywords sad and stressed have the same conceptualisation across cultures, whereas cultures have the most disagreement regarding the conceptualisation of surprised.

We hope that our research paves the way for a better understanding of how language can be used to identify specific properties of emotions, and we encourage the reader to verify our results by downloading our code and corpus at http://www.aeir.co.uk/code.

\title{
Modeling the Emergence of an Exemplar Verb in Construction Learning
}

\author{
Libby Barak, Afsaneh Fazly, and Suzanne Stevenson \\ Department of Computer Science \\ University of Toronto \\ \{libbyb,afsaneh,suzanne\} @cs.toronto.edu
}

\begin{abstract}
Using a computational model of verb argument structure learning, we study a key assumption of the usage-based theory: that the acquisition of a construction relies heavily on the existence of a high-frequency exemplar verb that accounts for a large proportion of usages of that construction in the input. Importantly, unlike the psycholinguistic experiments that focus on the learning of an artificial novel construction using novel verbs, here we examine the acquisition of the English sentential complement construction from naturalistic input. Our results provide new insights into exemplar-based learning in the context of naturalistic input with multiple semantic classes, and a diverse set of constructions for the verbs.
\end{abstract}

\section*{Introduction}

Verb argument structure acquisition is a challenging task that children face early in their life. In order to correctly use a verb, children must learn the syntactic structures that the verb appears in, as well as the semantic relations among the arguments of the verb. Nonetheless, children learn the correct usages of many verbs at a young age. Usage-based theories of language acquisition suggest that children learn the argument structure regularities mainly from the input they receive. These theories are supported by observing that children initially learn verb argument structures on an item-by-item basis, and only later generalize their verb-specific knowledge into abstract constructions that map a particular syntactic form to certain semantic properties (Tomasello, 2000).

The distributional properties of verb usages in childdirected input highly affect the developmental path of the acquisition of argument structure constructions. For example, several studies have shown that children tend to learn highfrequency verbs earlier (Naigles \& Hoff-Ginsberg, 1998; Matthews, Lieven, Theakston, \& Tomasello, 2005), and that they are more likely to detect grammatical anomalies in sentences containing such verbs (Theakston, 2004; Ambridge et al., 2008). Moreover, the relative frequency of a verb with a particular syntactic construction has been shown to positively correlate with the ability of young children to recall sentences containing that verb (Kidd, Lieven, \& Tomasello, 2006, 2010). Most importantly, there is evidence that the acquisition of a construction is connected to a high-frequency exemplar verb; e.g., give is the exemplar for the ditransitive construction (Goldberg, 1999; Kidd et al., 2006, 2010). In fact, several studies have shown that it is not just the amount of overall exposure to a construction that affects its acquisition, but instead learning seems to be facilitated by a high number of usages of a particular exemplar verb (Casenhiser \& Goldberg, 2005; Wonnacott et al., 2008).

The above psycholinguistic studies perform experiments on children, and hence are often limited in the number of
items they can investigate, and in how much they can tease apart the various interacting factors that might play a role on the results. For example, the sentence recall tasks performed by Kidd et al. (2010) examine only eight complement-taking verbs (CTVs). Moreover, due to their choice of verbs, they cannot separate the effects of overall frequency and relative construction frequency on their results. Using a computational model of argument structure learning, we extend these investigations into a larger set of CTVs, and also manipulate input in such a way that we can tease apart the effects of the various frequency factors. Our results are consistent with the findings of Kidd et al. \((2006,2010)\), that the relative frequency of a verb with a sentential complement is positively correlated with the ability of young children to recall sentences containing the verb in that construction. However, through computational modeling, we are further able to provide evidence on the interaction of verb frequency and relative construction frequency in accounting for their findings.

Studies examining the effect of a high-frequency exemplar verb in the acquisition of novel constructions often do so in the context of an artificial language learning task, where children are introduced to a novel verb mapped to a novel (or familiar) event semantics (Casenhiser \& Goldberg, 2005; Wonnacott et al., 2008). We use our computational model to investigate the existence and role of an exemplar verb in the acquisition of the English finite sentential complement (SC) syntax - a complex structure that has received less attention in the experimental studies (though see Kidd et al., 2006, 2010). Importantly, the use of a model enables us to vary distributional properties of the input in a way not easily achieved in a human experimental setting. Inspired by the work of Casenhiser and Goldberg (2005), we study the role of a highfrequency exemplar verb (think) for the acquisition of SC, but we do so in the context of a diverse set of verbs and constructions, as is the case in the naturalistic input that children receive. Our results suggest that the acquisition of a construction is facilitated by the relative frequency with which a class of semantically-related verbs appear with the syntactic form associated with the construction.

\section*{The Computational Model}

We use an extended version of the verb argument structure acquisition model of Alishahi and Stevenson (2008), which we have used in studying the acquisition of mental state verbs (Barak, Fazly, \& Stevenson, 2012). This model has appropriate characteristics for our study: (i) it focuses on argument structure learning, and the interplay between syntax and semantics; (ii) it is probabilistic and hence can naturally reflect

Input Utterance: He thinks Mom made pancakes.
Extracted Frame:
\begin{tabular}{|l|l|}
\hline main predicate & think \\
\hline other predicate & make \\
\hline event primitives & \{state, consider, cogitate, action \(\}\) \\
\hline event participants & \begin{tabular}{l}

\{agent, animate \(\}\) \\
\{ theme, changed \(\}\)
\end{tabular} \\
\hline syntactic pattern & arg1 verb arg2 verb arg3 \\
\hline argument count & 3 \\
\hline complement type & finite \\
\hline
\end{tabular}

Table 1: An example of an input frame based on the utterance He thinks Mom made pancakes, and the semantic information assumed to be available from the scene (not shown).
the role of the statistical properties of the input in the formation of constructions; and (iii) it is incremental, which allows us to investigate changes in behaviour over time.

The input to our model is a sequence of frames, where each frame is a collection of features that resemble what children can extract from the utterances they hear and the typical learning scenes they preceive from their environments. We use features that include both semantic properties (i.e., event primitives and event participants), and syntactic properties (i.e., syntactic pattern, argument count, and complement type). Table 1 presents an example of an input frame given a child-directed utterance in a typical learning scene.

The model incrementally clusters the input frames into constructions that reflect probabilistic associations of semantic and syntactic features across similar verb usages. Note that a cluster is not simply a set of similar frames, but instead an abstraction over these frames represented as probability distributions over the possible values of each feature.

\section*{Algorithm for Learning Constructions}

The model clusters input frames into constructions on the basis of their overall similarity in the values of their features. Importantly, the model learns these constructions incrementally, considering the creation of a new construction for a given frame if the frame is not sufficiently similar to any of the existing constructions. Formally, the model finds the best construction (including a new one) for a given frame \(F\) as in:
\[
\begin{equation*}
\text { BestConstruction }(F)=\underset{k \in \text { Constructions }}{\operatorname{argmax}} P(k \mid F) \tag{1}
\end{equation*}
\]
where \(k\) ranges over all existing constructions and a new one. Using Bayes rule:
\[
\begin{equation*}
P(k \mid F)=\frac{P(k) P(F \mid k)}{P(F)} \propto P(k) P(F \mid k) \tag{2}
\end{equation*}
\]

The prior probability of a construction \(P(k)\) is estimated as the proportion of observed frames in \(k\), assigning a higher prior to constructions that are more entrenched (i.e., observed more frequently). The likelihood \(P(F \mid k)\) is estimated based on the values of features in \(F\) and the frames in \(k\) :
\[
\begin{equation*}
P(F \mid k)=\prod_{i \in \text { frameFeatures }} P_{i}(j \mid k) \tag{3}
\end{equation*}
\]
\begin{tabular}{|l|l|l|l|}

\hline
\end{tabular}

Table 2: The Overall frequency of the 13 CTVs in our data, along with their relative frequency with finite-SC. Verbs are grouped by semantic class, and only the 13 verbs that appear with this construction are listed.
where \(i\) refers to the \(i^{t h}\) feature of \(F\) and \(j\) refers to its value. The conditional probability of a feature to have value \(j\) in construction \(k\), is calculated using a smoothed version of:
\[
\begin{equation*}
P_{i}(j \mid k)=\frac{\operatorname{count}_{i}(j, k)}{n_{k}} \tag{4}
\end{equation*}
\]
where \(\operatorname{count}_{i}(j, k)\) is the number of times feature \(i\) has the value \(j\) in construction \(k\), and \(n_{k}\) is the number of frames in \(k\).

\section*{Generation of the Input Corpora}

We generate artificial corpora for our simulations, since we do not have access to sufficient data of actual utterances paired with scene representations. To create naturalistic data that resembles what children are exposed to, we build an inputgeneration lexicon that is based on the distributional properties of actual child-directed speech (CDS). We extracted our verbs and their distributional properties from the CDS to 8 children from CHILDES (MacWhinney, 2000). \({ }^{1}\) We selected 31 verbs from different semantic classes and different frequency ranges, including 11 Physical Action (come, go, fall, eat, play, get, give, take, make, put, sit), 5 Perception (hear, listen, look, see, watch), 5 Communication (ask, say, speak, talk, tell), 5 Belief (think, know, guess, bet, believe), and 5 Desire (want, wish, like, mind, need). For each verb, we manually analyzed a random sample of 100 CDS usages (or all usages if fewer than 100) to extract distributional information about argument structures. Many of these verbs can take a (finite or infinitival) SC. Our focus in this work is on the finiteSC construction, and so we use the term Complement-Taking Verb (CTV) to refer to verbs that appear with the finite SC, following Kidd et al., 2010. Table 2 lists the 13 CTVs in our data, along with their semantic class, their overall frequency, and their relative frequency with the finite SC ).

\footnotetext{
\({ }^{1}\) Corpora of (Brown, 1973; Suppes, 1974; Kuczaj, 1977; Bloom, Hood, \& Lightbowny, 1974; Sachs, 1983; Lieven, Salomo, \& Tomasello, 2009).
}

We construct the input-generation lexicon by listing each of the 31 verbs (i.e. the main predicate), along with its overall frequency, as well as the frequency with which it appears with each argument structure. Each entry contains values for the syntactic and semantic features (see Table 1 for examples). By including these features, we assume that a learner is capable of (i) understanding basic syntactic properties of an utterance, such as syntactic categories (e.g., noun and verb) and word order, and (ii) perceiving and conceptualizing the general semantic properties of events - including mental, perceptual, communicative, and physical actions - as well as those of the event participants. Values for the semantic features (the event primitives and event participants) are taken from several resources, including Alishahi and Stevenson (2008), VerbNet (Kipper et al., 2008), and Dowty (1991). For each simulation in our experiments (explained below), we use the input-generation lexicon to automatically generate an input corpus of frames that reflects the observed frequency distribution in CDS. We perform 100 simulations, each on 20,000 frames, and examine the behaviour of our model over the course of learning.

\section*{Experiment 1: The Imitation Task}

Our goal here is to examine the role of verbs' overall frequency and their frequency with finite-SC, and the interaction of these frequencies, in the acquisition of argument structure constructions. Our simulations are inspired by the imitation task in which participants are asked to repeat a recently-heard utterance. Kidd et al. \((2006,2010)\) use this approach to examine the effect of verb frequency with finite-SC on how well children repeat utterances, in particular focusing on the relation between frequency of a verb with finite-SC and its likelihood of being correctly repeated, or substituted by another verb.

\section*{Experimental Setup}

Following Kidd et al. \((2006,2010)\), we focus on whether our model correctly repeats the verb of a sentence in an imitation task involving CTVs with sentential complements. We present the model with a full frame representing a complete utterance plus its corresponding scene, analogous to the presentation of a sentence with an accompanying picture, as in the psycholinguistic experiments. We then ask the model to predict the best verb in response to that frame, essentially asking it to repeat the just-presented verb.

To consider the responses of the model over a developmental trajectory, we train it on the full corpus, and at periodic fixed points during training, we present it with a test frame for each of the 13 CTVs in our lexicon, to see how it responds to each CTV. All the test frames have the same syntactic features (i.e., syntactic pattern, argument count, and complement type) corresponding to a finite SC that contains a transitive action verb, paired with the appropriate semantic features for the given CTV (see Table 1). For consistency, we use the same physical action verb for the embedded verb
(other predicate) in all 13 test frames, but randomly vary this verb across each of 100 simulations.

As in Kidd et al. \((2006,2010)\), we focus on the patterns of verb repetition and verb substitution among the model's responses. We record for each of the 13 test frames (at each point of testing) which verb the model predicts as its best response to that frame. To do this, we calculate the likelihood of each of our 31 verbs \(v\) given a test frame \(F_{\text {test }}\), as in:
\[
\begin{equation*}
P\left(v \mid F_{\text {test }}\right)=\sum_{k \in \text { Clusters }} P_{\text {main }}(v \mid k) P\left(k \mid F_{\text {test }}\right) \tag{5}
\end{equation*}
\]
where \(P_{\text {main }}(v \mid k)\) is the probability of the main predicate feature having the value \(v\) in cluster \(k\), calculated as in Eqn. (4), and \(P\left(k \mid F_{\text {test }}\right)\) is calculated as in Eqn. (2) (see Section for details). The model's response is taken to be the verb with the highest likelihood; this resembles the single choice of a verb made by the participants in the psycholinguistic experiments.

\section*{Results: Verb Repetition}

Kidd et al. \((2006,2010)\) observe a positive correlation between the frequency of a verb with finite-SC and the proportion of its correct repetitions. We focus on how frequency with finite-SC impacts our model's correct repetition of a verb. Figure 1 presents the proportion of times that each of the 13 CTVs are correctly repeated, which we refer to as the repetition accuracy. According to these results, a high frequency with finite-SC is neither a necessary nor a sufficient condition for a verb to be correctly repeated by our model. For example, although the two verbs with the highest repetition accuracy (i.e., think and say) have high frequencies with finite-SC, other verbs with high frequency with finiteSC (i.e., bet, guess, know, wish, and hope) are not easy for our model to repeat. In addition, see is among the top four verbs to be correctly repeated, although it has relatively low frequency with finite-SC (see Table 2). These results suggest that other factors beyond the frequency with finite-SC examined by Kidd et al. \((2006,2010)\) may play a role here.

Our model enables us to explore some of the possible factors, and to make predictions that could be verified through experiments with children. For example, the overall frequency of the verb affects the model's responses: Out of the four highest-frequency verbs (think, see, say, know), three also have a higher repetition accuracy compared with the other CTVs. However, like frequency with finite-SC, overall frequency alone does not predict the responses: The repetition rate is not in frequency order, and know is high frequency but has a low repetition rate. In fact, we note that, except for the verb think, the model rarely repeats Belief verbs correctly, regardless of their frequencies. These results point to another factor that might affect the performance of our model in repeating a verb: the frequency with which semanticallyrelated verbs appear with the same syntactic pattern as the verb to be repeated. To illustrate, when given a test frame that represents the semantic properties of a Belief verb with SC syntax, the model predicts the Belief verb with the highest frequency since it will have more occurrences in the clusters

Figure 1: Verb repetition accuracy for each of the 13 CTVs.
that the model bases its predictions on (see Eqn. 5). E.g., the verb know will have usages in clusters with many more occurrences of think, and hence the model will mainly produce think in response to test frames containing the semantics of know with the SC syntax. To further understand the interaction of overall frequency and frequency with finite-SC, and distribution over semantic classes, we next look at the patterns of verb substitution by our model.

\section*{Results: Verb Substitution}

Interestingly, Kidd et al. \((2006,2010)\) found that in a large number of cases, children specifically substituted the verb think in place of the verb they heard. They thus suggest that think is an 'exemplar' for the finite-SC construction. Figure 2 presents the proportion of times each of the 13 CTVs is produced by our model in place of the other 12 verbs, which we refer to as the substitution rate. That is, for each verb \(v\), its substitution rate reflects the proportion of times that our model incorrectly produces \(v\) in response to the test frames for the other 12 CTVs (out of 100 simulations). In line with the findings of Kidd et al. \((2006,2010)\), the model substitutes the verb think for the other verbs with a very high likelihood from an early stage (See Figure 2)

Kidd et al. \((2006,2010)\) attribute their finding to the high frequency of the verb think with finite-SC. However, we have observed that think also has the highest overall frequency among the 13 CTVs (see Table 2). In addition, think is a Belief verb, and it is known that people form a strong association between Belief verbs and the finite-SC syntax (Gleitman et al., 2005). It is thus not clear whether the status of think as an exemplar for the finite-SC construction is solely due to its high frequency with finite-SC, or if it is also affected by these other factors: (a) the high overall frequency of think, and/or (b) the overall strong connection of Belief verbs to the construction. We explore these factors in the next set of experiments.

\section*{Interaction of the Different Frequency}

One of the advantages of using a computational model is that we can manipulate the input to study the effects and interactions of the different frequency factors. Here, we manipulate

Figure 2: Verb substitution rate for each of the 13 CTVs.
the input such that we can examine the effects on the substitution patterns in our model of: overall frequency, frequency with finite-SC, as well as the frequency with finite-SC of a verb class as a whole. We perform three new experiments, in each of which we switch the overall frequency of think with one of the following three verbs: guess, believe, and tell. The goal is to change the input such that it is not the case that the verb with the highest overall frequency is also the verb with a frequency of \(100 \%\) with finite-SC (as is the case with think)-that is, we want to tease apart the effect of these two frequencies.

The first interesting finding is comparing the results of making guess vs. believe (other Belief verbs) the highestfrequency verb (in place of think). This explores the impact of a relatively high (but not \(100 \%\) ) frequency with finite-SC (for guess, of \(76 \%\) ) and a low frequency with finite-SC (for believe, of \(21 \%\) ), in the context of a very high overall frequency. We find that, as in the original results with think, guess is substituted for other verbs a very high proportion of the time ( \(75 \%\) ). However this does not hold for believe; when it is the highest-frequency verb, the Belief verb with next highest overall frequency and relatively high frequency with finite-SC (know) becomes the verb most often substituted for others, with a substitution rate of \(43 \%\). This behaviour predicts that both a high overall frequency and a relatively high frequency with finite-SC are required for a verb to be treated as an 'exemplar' of the finite-SC construction.

We also examined the result of making tell, which is not a Belief verb, the highest frequency verb with fintie-SC (again, in place of think). Interestingly, although tell is a verb with a relatively high frequency with finite-SC (like guess above), tell does not become the verb the model most frequently substitutes for other verbs (in contrast to guess). In this case, know - a Belief verb - is the verb most frequently substituted for others. This suggests that the semantics of the verb also plays an important role in determining the substitution behaviour. The strong association of particular (Belief-verb) semantics with the finite-SC syntactic pattern are necessary to the verb substitution behaviour.

In summary, our findings suggest a somewhat different view from that of Kidd et al. (2010), who suggested that think
was an exemplar verb in their experiments mainly because of its \(100 \%\) frequency with finite-SC. The results of the input manipulation with guess and believe predict that for a verb to be the exemplar for a construction (here the finite-SC), it has to have a sufficiently high overall frequency and also appear with the construction with a relatively high frequency. In addition, although a semantically diverse group of verbs appears with finite-SC, the input manipulation involving tell suggests that the exemplar verb will come from the Belief class, since Belief verbs as a whole have an overall high frequency of appearance with the SC syntax.

\section*{Experiment 2: Generalization}

Experiment 2 further examines the role of verb, construction, and semantic verb class frequencies in the acquisition of the finite SC. Given the noted strong association between the finite-SC syntax and Belief semantics, we focus here on the emergence of a 'Belief-SC' construction.

\section*{Experimental Setup}

Following Casenhiser and Goldberg (2005), we focus here on the effect of the distributional pattern of verb usages with a particular construction on the acquisition of that construction. Casenhiser and Goldberg (2005) introduce five novel verbs appearing in a novel construction (a novel syntactic pattern paired with a novel meaning), to 5-to 7 -year-old children in two input conditions: The skewed condition where one verb accounts for half of the occurrences of the construction, and the balanced condition with roughly equal number of usages of each verb. The study used a preferential-looking paradigm to show that participants in the skewed condition were significantly better at generalizing the newly-learned construction to a new novel verb (by looking at the scene with the appropriate semantics), compared to the balanced condition.

Our results in Experiment 1 imply that, in addition to the frequency with finite-SC of the individual verbs, their semantic class also influences the learning and use of verbs in a construction. This interaction of semantic classes is not addressed by the artificial language experiment of Casenhiser and Goldberg (2005), since it includes only a single class. Using a computational model enables us to explore the impact of a skewed vs. balanced distribution in a naturalistic setting, in which verbs from different semantic classes occur in the same syntactic frame under investigation (here, the finite SC), and verbs occur with multiple constructions (not just the one under investigation). Specifically, we examine how strongly our model learns the Belief-SC construction given the skewed input of our CDS-based data, compared to a balanced input, both with the same total exposure to CTVs. We form the balanced input by re-distributing the overall number of occurrences of CTVs so that each CTV would have an equal number of occurrences with finite-SC. Note that, all CTVs have an equal number of occurrences with finite-SC in the balanced input. However, because there is a different number of CTVs in each semantic class, the total number of finite-SC usages still slightly differs across classes.

Figure 3: The 3 highest likelihood values of semantic properties of the event (a) given the CDS-based distribution, (b) given artificially balanced frequencies with finite-SC.

We need to evaluate the ability of the model to generalize its knowledge of the Belief-SC construction in response to a novel verb when training on these two types of input. However, the model is incapable of engaging in preferential looking, as in Casenhiser and Goldberg (2005). Instead, we simulate preferential looking in our model as a choice between possible sets of event primitives, given a test frame. Following the psycholinguistic settings, we construct the test frame with a novel verb in place of the main predicate, where event participants are associated with a belief event, but the semantics of the predicate is missing. In other words, the test frame represents the belief construction used to test the children, and each set of event primitives represents one of the test scenes in a preferential looking task. At each point of testing, over 100 simulations, we record the set of event primitives that the model predicts as its best response to the partial test frame. This prediction corresponds to the selection of the scene with the appropriate action, given the arguments and syntax of the construction (as in Casenhiser and Goldberg).

\section*{Results}

Figure 3(a) and (b) report the proportion of times each of the three most likely sets of event primitives is chosen by our model as the most appropriate one, which we refer to as the event prediction rate. \({ }^{2}\) Figure 3(a) shows that the semantics of Belief events is highly associated with the arguments and syntax of novel Belief verbs from an early stage, given

\footnotetext{
\({ }^{2}\) Other sets of event primitives have lower likelihoods than the likelihoods presented here.
}
the skewed condition. That is, the Belief-SC construction is strongly entrenched given the naturalistically-skewed input.

However, in the balanced condition, as shown in Figure 3(b), only much later in training is the Belief event semantics predicted with the highest rate for the test frames. As in the results of Experiment 1, there is an effect of overall frequency in addition to frequency with finite-SC, of both verbs and classes. In the balanced input, each CTV has the same number of occurrences with finite-SC; hence there is only a small difference in the total number of occurrences of the different classes with this pattern. Recall that, to balance the input in terms of the CTV usages, we had to change the overall frequencies of the verbs and classes. In particular, we note that the overall frequency of the Belief class in the balanced input is much lower than that of the Perception class. The model is thus exposed to many more usages of Perception verbs with the finite-SC compared to the usages of Belief verbs with the same syntax, causing the observed delay in the formation of a strong Belief-SC construction.

\section*{Summary}

We have used a computational model to examine the effect of various distributional properties of the input on the acquisition of argument structure constructions. Specifically, we have examined the interaction of several factors in the emergence of an exemplar verb for the finite SC construction. Our results suggest that exemplar-based learning of a construction (such as the finite SC ) is sensitive to several properties of the input, including overall verb frequency, frequency of each verb with the construction, and the frequency of each semantic verb class with the construction. These results are in line with the psycholinguistic findings (e.g., Naigles \& HoffGinsberg, 1998; Casenhiser \& Goldberg, 2005; Wonnacott et al., 2008; Kidd et al., 2006, 2010). Moreover, they further our understanding of the exemplar-based learning mechanism by providing a broader investigation of the role of each of the above factors in the context of naturalistic input that contains multiple classes of verbs each appearing with multiple constructions. Our findings signify the importance of considering the interaction of the various distributional factors in the design of psycholinguistic experiments.

\begin{abstract}
We explore the interaction between information sampling and the structure of the social environment in the case of two prominent social learning strategies: imitate-the-best and imitate-the-majority. In a series of simulations a group of agents made repeated choices between options. We varied the building blocks of the strategies used by agents, the structure of the social network and characteristics of the task environment. A key factor influencing strategies' success is the speed with which they are able to respond to environmental change. In general, imitate-the-best provides a faster response compared to imitate-the-majority and larger samples help the former but hurt the latter. Less efficient networks decrease the performance of both, but are more detrimental for imitate-the-majority. Our findings highlight the role of sampling and social structure in the study of social learning, an area not sufficiently explored before.

\section*{Introduction}

Humans and other animals obtain information via social learning. This is an efficient way to save the time and effort involved in individual trial-and-error learning and is known to underlie our capacity for culture. Despite the diverse list of empirical evidence for its use in the wild (Laland, 2004; McElreath, et al. 2008), theoretical models exploring the adaptive nature of social learning strategies lack sufficient detail to explain when we should expect to observe them. Most models study unstructured groups and focus only on the decision phase of implementing a strategy (e.g. imitate-the-majority), leaving open an important dimension affecting strategy performance: the interaction between information sampling and the structure of the social environment. The present study is an attempt towards filling this gap in the literature.

Social learning is often based on limited samples of the social environment. Most communities consist of sizable groups where an individual cannot survey all other group members within reasonable time before making a decision. Consider migrating animals deciding between multiple directions, individuals in an organization trying to jointly
solve a problem or stock traders trying to predict the best investment option (Couzin, Krause, Franks \& Levin, 2005; March, 1991). In such situations the way information about options is sampled from the social environment is likely to be an important aspect of any strategy. The structure of the social network in which social learning takes place can then in turn affect the options available for sampling. Previous work has shown that different network structures and their efficiency can affect the diversity of options in the population and the time it takes groups to converge on a solution (Lazer \& Friedman, 2007; Mason \& Watts, 2012). How does the performance of different strategies depend on the way they sample information and on the social environment in which they are embedded?

To address this question we study two representative social learning strategies: imitate-the-best and imitate-themajority (Boyd \& Richerson, 1985; Laland, 2004) and model them as decision heuristics that consist of different building blocks: search, stop and decision rules (Gigerenzer, Todd \& the ABC Research Group, 1999). By explicitly modeling these three phases we are able to test their relative contribution to strategy success in different social environmental structures.

Overall, a general characteristic shared by many social learning strategies, including those we study here, is that they alter the structure of the social environment by increasing the frequency of the correct option (i.e. the one with the highest payoff) and simultaneously decreasing the diversity of options in the group. This is a result of their bias towards specific sources (best member, majority) and their selectiveness (e.g. copy only if payoff better) \({ }^{1}\). This property has been extensively studied in the context of biased cultural transmission (Boyd \& Richerson, 1985) and suggests a key factor influencing strategy success in a changing environment: the speed with which they increase the frequency of the correct option in the group and, therefore, their ability to respond to environmental change. Our goal here is to show how this speed can be influenced by the strategy's building blocks (their sampling and decision rule) and by the structure and efficiency of the social network.

In what follows we derive specific expectations, based on previous literature and preliminary analytic calculations,

\footnotetext{
\({ }^{1}\) One can relax this assumption if other selective forces (e.g. natural selection) are at work.
}
about the effects of different building blocks and network structures on imitate-the-best and imitate-the-majority.

We consider a hypothetical situation where a group of agents make repeated choices between two options (one correct, the other incorrect). Whenever the environment changes, the previously correct option becomes incorrect and vice versa.

Effects of decision rules. In general, as long as the correct option is used by the majority of agents in a group and the environment is stable, both imitate-the-best and imitate-themajority will converge to the correct option. However, under the assumption that the best member can be reliably identified within the sample, the imitate-the-best will always converge faster because it requires only a single agent with the correct solution to reach a decision, whereas imitate-themajority requires at least two out of three. As soon as the environment changes, the correct option will be in minority. In this case, imitate-the-best will still be able to find it, however, as predicted by the Condorcet Jury Theorem (CJT), imitate-the-majority will never find the correct option because it requires that the proportion of agents with the correct option be higher than 0.5 (e.g. Grofman, Owen \& Feld, 1983).

Effects of information sampling and sample size. The CJT prediction may no longer hold when sampling is involved. Even if the correct option is in minority, imitate-the-majority may still be able to find it. Sampling as opposed to group-level aggregation can create situations where the correct option is more frequent in one's sample than overall in the group. When agents with such samples choose the correct option, this further increases the correct option's frequency in the group as a result of the environment altering feature of social learning discussed earlier (Boyd \& Richerson, 1985). Smaller samples are more likely to produce such situations, both because they are more likely to be biased and because they require fewer agents with the correct option in order to reach a decision. This suggests two situations where smaller as opposed to larger samples should benefit imitate-the-majority. First, whenever the group is converging towards the incorrect option, smaller samples will delay this process and keep the payoffs of the group higher for the longer time. Second, when the correct option is in minority, smaller samples will make it more likely to accidentally have a majority of agents with the correct option. In contrast, for imitate-the-best larger samples are always more advantageous, because they increase the chance of finding at least one agent with the correct solution.

Effects of network structure. Previous studies have demonstrated that higher network efficiency increases the speed with which information spreads and consequently decreases the diversity of information in the group. More efficient networks should, therefore, favor all strategies. Network efficiency depends on a variety of factors (Mason \& Watts, 2012); here we focus on clustering and average path length. As networks become more clustered and average path lengths increase, their efficiency decreases, and they maintain diversity for a longer time (Lazer \&

Friedman, 2007). We hypothesize that in such networks, the speed with which different strategies can find the correct option will become more important. As a result, the difference in speed between imitate-the-best and imitate-the-majority should become even larger. More clustered networks could have an additional effect by enabling the occurrence of relatively homogeneous clusters using the same option. If this option is incorrect, imitate-the-majority using a sample within that cluster will not be able to find the correct option. In contrast, imitate-the-best should be less affected by diversity of information as it only requires a single agent with the correct option.

\section*{Method}

\section*{Overview}

We simulated a situation where multiple agents \((N=100)\) had to make repeated choices between different number of options by acquiring information from their contacts. The choices they made directly affected their payoffs.
We created three social networks differing in their efficiency (as measured by clustering and average path length). Each agent had the same number of contacts in the network ( \(d=10\) ) and was assigned one of four decision strategies. Each strategy sampled randomly among one's contacts but differed in its stopping and decision rule. The agents' task was to make repeated choices between different number of options (2 or 10) at each time-step using their decision strategy. The environment could change on each time-step \(\left(t_{i}\right)\) with some probability \(\left(p_{c}\right)\) affecting the payoff of options at the next time-step \(\left(t_{i+1}\right)\). The simulation was run for \(t=1000\) time-steps and each condition was replicated 30 times \(^{2}\). To evaluate the performance of different strategies we tested them both in isolation and in an evolutionary competition where better performing strategies could replace worse performing ones. More specifically the simulation consisted of the following steps:
1) at \(t=0\) agents were placed in the networks and randomly assigned a decision strategy and an initial option
2) from \(t=1\) onwards, agents sampled the options and corresponding payoffs at \(t_{i-1}\) of their contacts
3) made a choice between sampled options based on their decision rules
4) only in the evolutionary competition: switched strategies with a small probability (introduced from \(t=50\) )
5) the environment changed with a certain probability, leading to a different option with the highest payoff
6) payoffs for the choice from step 3) were determined

Note that there is a lag between the information acquired from contacts and the realization of the agent's payoff in the sense that information is collected before environmental change occurs, thus allowing for the possibility of acquiring

\footnotetext{
\({ }^{2}\) Sensitivity analyses revealed that running the simulation for 2000 time-steps and 60 replications produced identical results.
}
outdated information when the environment changes to a new state.

\section*{Decision strategies}

We studied four decision strategies that differed in their building blocks (see Table 1). For each strategy we assumed that agents sample among their contacts randomly, and stop after collecting either a small \((n=4)\) or a large sample \((n=10)^{3}\). They then decide to try an option that is either endorsed by the majority of the sample contacts or by the agent that had the best payoff in the last time-step. In all cases agents only switch to a new option if that option's payoff was higher at the previous time-step than the option they are currently using. In situations where these two payoffs are equal or when the majority rule results in ties, agents chose randomly.

Table 1: Decision strategies
\begin{tabular}{cll}
\hline Sampling rule & Stopping rule & Decision rule \\
\hline random & \(n=4\) & imitate-the-majority \\
sample of & \(n=10\) & imitate-the-majority \\
contacts & \(n=4\) & imitate-the-best \\
& \(n=10\) & imitate-the-best \\
\hline
\end{tabular}

In order to keep track of a changing environment any social learning strategy requires that there is some form of individual learning generating novel options, therefore, we allowed new information to enter the population through copying error, a parameter we fixed at \(p_{e}=0.01\). That is, on each step there was a 0.01 chance that the agent does not consider the option used by its contacts, but a randomly selected option, however, agents only switched to this option if it had a higher payoff at the previous time-step. This lies in contrast with other studies which allowed new information to enter the group by assuming that whenever other agents' payoffs are lower or equal, the agent does not stick with its own option but explores other options randomly (Lazer \& Friedman, 2007; Mason \& Watts, 2012). These studies, therefore, allowed for a higher amount of innovation than our model. In this way we explore the performance of social learning strategies when aided with only a minimum amount of individual learning.

\section*{Decision environment}

Two factors affecting the decision environment were varied in different simulations: a) the number of options available and \(b\) ) the rate of environmental change. To manipulate the first factor we assumed that agents choose either between 2 or 10 options with payoffs ranging from 1 to 2 and from 1 to

10 respectively. At any given time, only one option had the highest payoff. On the first time-step agents were assigned options randomly. In conditions with 2 options, we varied the initial proportion of the correct option in the group ( \(p_{\text {init }}=0.2,0.5\) or 0.7 ). For 10 options each option had the same initial proportion. For the second factor we assumed that the payoffs of options can change on each time-step with probability \(p_{c}=0.001,0.01,0.1\) or 0.4 reflecting a discreet scale between slow and fast rates of change. We ran all possible combinations of environmental change on all 3 network structures described below.

\section*{Network structure}

Three different networks were created, ranging from most efficient to least efficient as measured by two standard indicators in the network science literature (Mason \& Watts, 2012): clustering coefficient and average path length. The clustering coefficient measures the extent to which the network is dominated by isolated cliques, which from a communication perspective decreases the efficiency of a network by making it harder for information to spread the higher the clustering. Consider an example where small groups of tightly connected agents exchange information but because groups are isolated from other groups information spreads much slower between these small units.
Another measure of efficiency is average path length, the average number of steps it takes to get from any agent to any other agent in the network. The shorter the path length the more easily information can spread. The efficiency of a network is known to affect how quickly information spreads from one part to another, however, it can also enable maladaptive information to spread more rapidly as in the case of panics following flu pandemics or stock bubbles. Many real-world networks are known to have both high clustering and low average path lengths thus representing an intermediate level of efficiency. These small-world networks (Watts \& Strogatz, 1998) can be mimicked by performing random re-wirings on edges of a lattice. In line with previous studies (e.g. Schwenk \& Reimer, 2007), we started by first generating a random directed lattice and then rewired it with a 0.1 probability to obtain a small-world network \({ }^{4}\). In addition we created a fully-connected network absent of any structural properties to be able to compare to previous studies that focused on unstructured groups (see Table 2). All three networks had a fixed degree of 10 and a total of 100 nodes \((d=10, n=100)\).

\footnotetext{
\({ }^{3}\) Sensitivity analyses with sample sizes \(n=3\) and \(n=9\) produced similar results and we do not report them here.
\({ }^{4}\) Other networks with lower values of rewiring produce similar results, therefore, we omit them.
}

Table 2: Types of networks used in the simulation ( \(\mathrm{n}=100, \mathrm{~d}=10\) )

\end{tabular}

\section*{Evolutionary competition}

In order to properly evaluate each strategy we look at their performance both in isolation (in homogeneous groups using the same strategy) and by directly testing different strategies against each other (heterogeneous groups) in an evolutionary competition. In the former we are interested in isolating the factors contributing to the success of different strategies, whereas in the latter we wish to evaluate them in a competitive setting where the performance of a strategy can depend on the strategies used by other agents in the group. Evolutionary competitions are a popular method in the study of social learning (e.g. Rendell, et al. 2010) where the strategy accumulating the highest payoff has the best chance of reproducing and spreading in the population, while the worst performing strategies die out. The prevalence of a strategy is, therefore, a clear-cut measure of its success in a given environment.

There are many ways to implement an evolutionary dynamic. Here we chose the 'imitation process' (Nowak, 2006) in order to reflect a plausible real-life scenario. We assumed that on each time-step, randomly selected agents change their strategies to one of their contacts' strategy with a probability proportional to the cumulative payoff of that contact. If none of the contacts has a higher payoff, the agent keeps its strategy, and in situations of equal payoff random choice is implemented. We fixed the parameter specifying the probability of strategy change to \(p_{s}=0.02\) thus expecting 2 agents switching strategies on each time-step. Evolutionary dynamics were introduced from the \(t=50\) timestep to allow for a burn-in period.

\section*{Simulation results}

Figure 1A shows the overall performance of the four different decision strategies observed in isolation, measured by their rate of environmental tracking (percentage of agents using the correct option on each time-step). We show the results for 2 options, probability of environmental change \(p_{c}=0.001\), and initial probability of correct option \(p_{\text {init }}=0.5\), averaged across networks \({ }^{5}\). To make the main results easier to view, we focus on the time-steps before and after environmental change occurring at \(t=100\). Figure 1B shows the frequency of different strategies in the evolutionary
competition averaged across networks for the same environmental condition. Overall, imitate-the-best consistently outperforms imitate-the-majority both in homogeneous and heterogeneous groups. This result holds in all network structures and in environmental conditions.

Figure 1. Panel A. Performance of strategies observed in isolation. Panel B. Frequency of strategies in the evolutionary competition. Results are shown for environmental conditions \(p_{c}=0.001\) and \(p_{\text {init }}=0.5\), averaged across networks.

\section*{Effects of information sampling}

From Figure 1A we can see the number of time-steps it takes groups using each of the strategies to converge on the correct solution after the environment has changed. As expected, imitate-the-best benefits somewhat from larger samples, however, even its small sample version outperforms both versions of imitate-the-majority. The opposite is the case for imitate-the-majority, which is hurt by larger samples and actually performs better when it samples fewer people. This result highlights that speed with which different strategies can recover after environmental

\footnotetext{
\({ }^{5}\) Results for 10 options and other rates of environmental change and initial probability of correct option do not change the main conclusions and we do not present them here.
}
change is crucial to their success and demonstrates that different sampling regimes should be adopted depending on the decision rule used.

As mentioned before, without sampling, imitate-themajority will converge on an incorrect option whenever the proportion of agents using the correct option is smaller than 0.5 . As expected, these results do not hold when decisions are based on sampled information as opposed to overall group aggregation. As visible in Figure 1A, imitate-themajority is able to find the correct option even when the proportion of agents using it falls under 0.5 . As a sensitivity check, we reran our simulations with \(p_{\text {init }}=0.2\) and copying error of \(\mathrm{p}_{\mathrm{e}}=0\), allowing no new information to enter the population. Even then, imitate-the-majority can still converge on the correct option, in particular when it uses small samples.

Figure 2. Performance of different strategies in the three network structures. Results are shown for environmental conditions \(p_{c}=0.001\) and \(p_{\text {init }}=0.5\)

\section*{Effects of network structure}

Overall, we find that regardless of strategy, more efficient networks are faster at spreading information and that this helps groups in all conditions. However, we observe an effect for network structure on the relative difference between strategies. Figure 2 shows that the difference between strategies is least pronounced in the fully connected network absent of any structural properties, however, as networks become more structured (thereby decreasing the efficiency and speed with which information flows), the difference between imitate-the-best and imitate-the-majority becomes more pronounced.

The effect of network structure is especially visible immediately after environmental change. In networks with high clustering and long path lengths such as lattice, relatively isolated agents may form homogeneous groups possessing the same information. In these situations, imitate-the-majority has problems finding the correct option. The larger the sample, the more prone is this strategy to get stuck. As expected, the performance of imitate-the-best is less affected by network structure.

\section*{Discussion}

Our goal was to study how information sampling and the structure of the social environment affect the performance of two representative social learning strategies: imitate-thebest and imitate-the-majority. We modeled social learning strategies as heuristics consisting of different building blocks and embedded them in three social networks in a task involving repeated choices between multiple options.

Overall, we find that imitate-the-best consistently outperforms imitate-the-majority and our results suggest that the reason underlying this finding is the speed with which different strategies are able to respond to environmental change. This speed is affected both by different building blocks and the structure of the social environment. Imitate-the-best is always faster at finding the good option because its decision rule requires fewer correct instances in the sample and larger samples are always beneficial. In contrast, sample size has a counterintuitive effect on imitate-the-majority with smaller samples increasing the likelihood and thereby the speed of finding the correct option. The relative difference between imitate-the-best and imitate-the-majority, however, is moderated by network structure. More efficient networks (those with lower clustering and shorter path lengths) benefit all strategies and decrease the difference between them while less efficient networks (with more clusters and longer path lengths) increase the difference by having a worse impact on imitate-the-majority.

Information sampling as opposed to group-level aggregation has an additional effect on imitate-the-majority: it can still converge on the correct option, even if less than \(50 \%\) of the group is using it. This result lies in contrast to the predictions of the Condorcet and related Theorems on full group-level aggregation of information in a single trial (Grofman, Owen \& Feld, 1983).

Both imitate-the-best and imitate-the-majority have been extensively studied both theoretically and empirically (e.g. Conradt \& Roper, 2003; Garcia-Retamero, Takezawa \& Gigerenzer, 2006; Hastie \& Kameda, 2005; Katsikopoulos \& King, 2010; McElreath, Wallin \& Fasolo, 2012). Much of this work has studied small and unstructured groups and focused exclusively on the decision-phase of implementing these strategies (but see Pachur, Rieskamp \& Hertwig, 2005; Schwenk \& Reimer, 2007 for exceptions in other contexts). We believe that this leaves many important details affecting strategy success unaddressed and can be one reason why some studies reach different conclusions. The present study is a first step towards developing a more general framework for capturing the interactions between the building blocks of social heuristics and the structure of the social and task environments that they exploit. We propose that their study can bring novel insight into our understanding of social phenomena including the evolution of different social learning rules, the diffusion of innovations in cultures or the strategy selection process in social domains.

\begin{abstract}
Related languages, like English and Spanish, often have similar orthographies but use the same letters to represent different sounds. Learning a second language frequently involves learning additional letter-sound mappings that mismatch those in the native language. In the current study, we investigated whether L2 spoken words activate L2 orthography despite conflict with L1 orthography-to-phonology mappings. Participants first learned an artificial language with letter-sound mappings that mismatched English (e.g., the letter 'G' represented the sound \(/ \mathrm{h} /\), and the word /gufo/ was spelled 'hane'). Next, fixations of L1 crosslinguistic orthographic competitors (e.g., 'cane') in response to auditory L2 input (e.g., /gufo/) were assessed using the visual world paradigm. Results showed that participants fixated L1 competitors that overlapped with L2 targets orthographically (but not phonologically) more than unrelated fillers. We conclude that second language learners can rapidly acquire novel letter-sound mappings, and words based on these mappings are integrated into the existing lexicon where they can activate orthographic competitors in the native language.
\end{abstract}

Keywords: Language processing; Language learning; Crosslinguistic competition

\section*{Introduction}

Spoken language processing involves decoding an incoming auditory signal to access words in the mental lexicon. It's not obvious that this process should be affected by orthographic knowledge, because written language is a relatively recent invention, and is learned years after spoken language. Yet, there is evidence that orthography, once acquired, influences performance on phonological tasks (Jakimik, Cole, \& Rudnicky, 1985; Johnston, McKague, \& Pratt, 2004; Salverda \& Tanenhaus, 2010), suggesting tight interconnectivity between orthography and phonology. This interconnectivity may be a source of difficulty during second language acquisition, because the same letters can represent different sounds across languages. For example, the letter 'W' maps onto the phoneme /w/ in English, but /v/ in German (one is a labiovelar approximant, while the other is a voiced labio-dental fricative, which differs on both voicing, place, and manner of articulation). Second language learners thus need to learn and use these novel letter-sound correspondences in the appropriate language context, despite years of experience with a different set of mappings in their native language.

Orthographic knowledge can help or hinder phonological processing, depending on the context. Literate adults perform better than illiterate adults on metaphonological tasks
such as adding or deleting sounds at the beginning of nonwords (Morais, Cary, Alegria, \& Bertelson, 1979), because literate adults can use their orthographic representations as a mental aid. On the other hand, orthography can also distort phonological perception. French speakers are more likely to misperceive the phoneme \(/ \mathrm{p} /\) as a \(/ \mathrm{b} /\) in spoken words when the sound is represented by the letter ' \(B\) ', as in the French word 'absurd,' pronounced /apsyrd/ (Hallé, Chéreau, \& Segui, 2000). Furthermore, orthography can affect online processing of speech. Orthographically-related primes improve auditory lexical decision times (Jakimik et al., 1985), but written words can act as competitors during auditory visual world search tasks (Salverda \& Tanenhaus, 2010). Based on timecourse analyses from research on event-related potentials (ERPs), these orthographic effects occur early in the speech signal and are time-locked to the source of orthographic effects in the word, suggesting that orthography is activated online during speech processing, and not strictly as a postlexical decision process (Perre \& Ziegler, 2008).

The link between orthography and phonology extends to novel words as well. In a recent study (Johnston et al., 2004), monolingual English speakers were taught a series of novel words but only learned the words' phonological forms, and were never presented with orthography. During a subsequent masked priming task, orthographic versions of the trained words showed a significant priming effect, compared to the absence of any effect for completely novel written nonwords. This finding suggests that learners automatically generate orthographic forms for novel auditory words, based on the phonotactics of their native language. When these generated forms are accurate, they can accelerate vocabulary learning and improve reading of previously learned auditory words (McKague, Pratt, \& Johnston, 2001). During second language learning, though, they are more likely to be inaccurate and impair learning. For example, an English-speaking learner of German may hear the auditory German word /vek/ (spelled 'weg') and create an incorrect orthographic representation 'veck' based on their knowledge of English. This incorrect representation may then impair learning to read and write in German, as the learner's internal representations must be inhibited and relearned. Previous work indicates that English speakers are able to learn words and letter-sound mappings in artificial languages with training, even when they include
non-English phonemes (Kaushanskaya \& Marian, 2009a), graphemes (Bitan \& Karni, 2003), or a combination of the two (Kaushanskaya \& Marian, 2008). In the current study, we isolated acquisition of novel letter-sound mappings by recombining familiar English letters and sounds. Even when there are no new letters or sounds to be learned, acquiring novel mappings can be difficult - for example, two of the most challenging letters for English learners of Russian to learn are B (pronounced \(/ \mathrm{v} /\) ), and Y (pronounced \(/ \mathrm{u} /\) ), which are often mispronounced as /b/ and /i/ respectively, representing interference from existing English mappings (Comer \& Murphy-Lee, 2004). Full language acquisition requires learners to form new mappings between orthography and phonology that are appropriate for the target language, and to be able to inhibit their native language mappings during L2 processing.

In sum, there is a tight interconnectivity between orthography and phonology, but letter-sound mappings often conflict across languages, which may lead to second language learning difficulties. The current study was designed to investigate how learners manage these difficulties. The first goal of the study was to assess how well learners are able to acquire vocabulary in a novel language with letter-sound correspondences that mismatch English. The second goal was to determine whether auditory words in the L2 will activate L2 orthography, based on spreading activation from the L2 to words that resemble the L2 orthographic form. These questions are addressed by teaching participants a L2 vocabulary with letter-sound correspondences completely distinct from English. If participants are able to learn the novel orthophono mappings, then presentation of the auditory form of the word will lead to activation of the corresponding orthographic form. In a connectionist model of language processing, activation should then spread to similarly spelled words in the lexicon.

Because the novel language and English have different letter-sound mappings, auditory targets in the new language do not overlap phonologically with their English orthographic competitors (e.g., the novel word /gufo/, spelled 'hane', overlaps orthographically but not phonologically with the English word 'cane'). If participants look at crosslinguistic orthographic competitors upon hearing L2 words, they must have activated the target's L2 orthographic form, which then spread activation to orthographically related items, including the crosslinguistic competitor. The current study thus allows us to simultaneously assess the effects of novel orthophono mappings and cross-linguistic interference on speech processing in a newly learned language.

\section*{Methods}

\section*{Participants}

Twenty monolingual English speakers ( 16 females, 4 males) participated. Eyetracking data was unavailable for one participant due to equipment error. All participants reported current English use at \(99 \%\) of the time or more, and a proficiency
of three or less on a scale of 1 (no knowledge) to 10 (perfect) in a second language (LEAP-Q, Marian, Blumenfeld, \& Kaushanskaya, 2007).

\section*{Materials}

A miniature artificial language named Colbertian \({ }^{1}\) was created using a novel alphabetic system. Thirteen English graphemes (four vowels and nine consonants) were paired with thirteen English phonemes so that the English and Colbertian sounds for each letter differed maximally in voice, place, and manner for consonants, or height, backness, and rounding for vowels (Table 1). Reusing English phonemes ensured that participants needed only to learn the novel lettersound correspondences, but not any new phonetic categories.

Table 1: Colbertian Alphabet
\begin{tabular}{|c|c|c|}
\hline Grapheme & English Phoneme & Colbertian Phoneme \\
\hline a & /eı/ /æ/ & /u/ \\
\hline e & /i/ /e/ & \(1 / 1\) \\
\hline i & /ai/ /I/ & /æ/ \\
\hline o & /ov/ /o/ & /i/ \\
\hline b & /b/ & /s/ \\
\hline d & /d/ & /t \(\mathrm{f} /\) \\
\hline h & /h/ & /g/ \\
\hline k & /k/ & /w/ \\
\hline n & /n/ & /f/ \\
\hline p & /p/ & /z/ \\
\hline r & /.I/ & /h/ \\
\hline t & /t/ & /d3/ \\
\hline v & /v/ & /t/ \\
\hline
\end{tabular}

Twenty-four words were then created using the Colbertian alphabet (Table 2). Each word was recorded by a female speaker of Standard American English, and was associated with an easily-nameable black and white line drawing (naming consistency higher than \(80 \%\) from the International Picture Naming Project database, Bates et al., 2003, or norming with Amazon's Mechanical Turk). Each of the novel words was designed to overlap orthographically, but not phonologically, with an English competitor word in order to isolate the effect of English orthographic knowledge on Colbertian auditory word processing. Target words, competitor words, and filler words were matched on the following variables: phonological neighborhood size (IPhOD; Vaden, Halpin, \& Hickok, 2009), orthographic neighborhood size (N-Watch; Davis, 2005), English lexical frequency (SUBTLEX-US; Brysbaert \& New, 2009), concreteness, imageability, or familiarity (MRC Psycholinguistic Database; Coltheart, 1981), all \(p\) 's \(>0.05\).

\footnotetext{
\({ }^{1}\) The language was named after comedy show wordsmith and Northwestern University alumnus Stephen Colbert to engage participants in the learning task.
}

\end{tabular}

\section*{Procedure}

Participants learned Colbertian in a single experimental ses－ sion in four steps．In the first step，participants were exposed to each of the Colbertian words＇spellings and pronunciations． A single written word appeared in the center of a computer screen，and the auditory form of the word was pronounced over headphones．The participant repeated the word aloud and clicked the mouse to advance to the next word．Each word was presented once，for a total of 24 exposures．In the second step，participants practiced associating the words and their pronunciations until they reached a \(90 \%\) learning cri－ terion．In a single trial，four Colbertian words were shown on the screen，and the auditory form of the target word was played over headphones．After selecting one of the four words，participants received feedback：the target word turned green，the three foils disappeared，and the word was replayed over headphones．This ensured that participants had an op－ portunity to relearn the words they answered incorrectly．Af－ ter 24 trials，with each word as a target once，the participant was shown their accuracy for the block．Each participant re－ peated blocks of 24 trials until they reached \(90 \%\) accuracy on two consecutive blocks．

In the third step，participants were familarized with the meanings of the words they had just learned．Four pictures appeared on the screen，and after 1500 ms ，a Colbertian word
appeared on the center of the screen and was played over headphones，and the picture it represented was outlined with a red box（nontarget pictures remained visible）\({ }^{2}\) ．In the fourth step，participants practiced associating Colbertian words with their pictures until achieving the \(90 \%\) learning criterion．In each trial，four pictures were displayed on the screen，and the target word was simultaneously presented in written and auditory forms．After selecting a picture，feedback was pro－ vided：the target picture was outlined in a red box（nontarget pictures remained visible）and the target word was replayed over headphones．Each trial，including response time and feedback，lasted exactly six seconds to equate picture view－ ing times across trials．After 24 trials，with each word as a target once，the participant was shown their accuracy for the block．Participants continued doing training blocks until they reached \(90 \%\) accuracy on two consecutive blocks，at which point they were finished learning Colbertian．

After learning Colbertian，participants immediately began a visual world eyetracking task to assess the effect of English orthographic knowledge on Colbertian spoken word process－ ing．Each trial began with a 1000 ms fixation cross to ori－ ent participants＇gaze．Next，the cross disappeared and four pictures appeared in the corners of the screen．After a 500 ms delay，a Colbertian word indicating the target picture was played over headphones（the orthographic form of the target was never shown）．The participant＇s task was to click on the target picture as quickly and accurately as possible．No feed－ back was provided．Trial presentation was controlled by the experimental software（MATLAB with Psychophysics tool－ box），and monocular eye gaze was recorded with an SR Eye－ link 1000 eyetracker at 1000 Hz in order to assess changes in activation of pictured referents over time．In 24 Experimen－ tal trials，the English name of one of the three filler pictures overlapped orthographically（but not phonologically）with the orthographic form of the Colbertian target word in three out of four letters（Targets and Competitors are shown in Table 2）．Twenty－four Filler trials，in which none of the pictures overlapped orthographically or phonologically with the Col－ bertian target，were included to mask the experimental ma－ nipulation．

Finally，participants＇knowledge of Colbertian＇s letter－ sound correspondences was assessed with a novel word gen－ eralization task．In each of 48 trials，four novel Colbertian words，one target and three foils，were presented in the four corners of the screen，and the novel auditory form of the target was played over headphones．The participant selected a word and the next trial began after an inter－trial interval of 1500 ms ．Accuracy and response time were recorded，but no feed－ back was provided．Twenty－four of the trials constituted the Simple Discrimination condition，in which none of the foils used any of the target word＇s letters in the same position（e．g．， Target／suzo／spelled＇bape＇and Foils＇kovi＇，＇vedo＇，＇rina＇）．

\footnotetext{
\({ }^{2}\) To control for picture familiarity，targets，competitors，and fillers from the visual world task were viewed equally during train－ ing．Competitors never appeared with the overlapping Colbertian targets．
}

As such, knowing only one of the letters in Colbertian was sufficient to identify the target. The other 24 trials constituted the Hard Discrimination condition, where one foil overlapped the target in the first consonant, another overlapped in the second consonant, and the third overlapped in both vowels (e.g., Target / wotfæ/ spelled 'kedi', with C1 Foil 'kova', C2 Foil 'nado', Vowel Foil 'beri'). Thus, a correct response required additional knowledge of the target beyond a single letter-sound mapping. Simple and Hard Discrimination trials were presented in an intermixed fashion.

\section*{Results}

\section*{Learning}

Participants reached the \(90 \%\) criterion for whole word learning after \(\mathrm{M}=10.10\) blocks ( \(\mathrm{SD}=7.40\), Range [2, 31]). For learning the semantic meaning of the words, participants reached the \(90 \%\) criterion after only \(\mathrm{M}=3.05\) blocks ( \(\mathrm{SD}=\) 0.69 , Range [2, 4]).

Participants demonstrated high competence with Colbertian orthography on the generalization task. Accuracy was \(92 \% ~(\mathrm{SD}=8)\) in the Simple Discrimination condition, and \(75 \% ~(S D=19)\) in the Hard Discrimination condition (significantly lower, \(t(19)=4.55, p<0.001\) ). Consistent with accuracy, RTs were significantly faster in Simple Discrimination, \(\mathrm{M}=3.56\) seconds \((\mathrm{SD}=0.86)\), compared to Hard Discrimination, \(\mathrm{M}=4.20\) seconds \((\mathrm{SD}=1.39), t(19)=3.04, p<0.01\).

Though the training paradigm equated participants on Colbertian proficiency, learning rate was associated with Colbertian generalization skill. Faster learning rate in wholeword training blocks was associated with increased accuracy in Simple Discrimination, \(R^{2}=-0.23, p<0.05\), and highly associated with increased accuracy in Hard Discrimination, \(R^{2}=-0.49, p<0.001\). Faster learning rate was also associated with longer RTs in Hard Discrimination, \(R^{2}=-0.27, p<\) 0.05 , but not in Simple Discrimination, \(R^{2}=-0.03\), ns.

Figure 1: Proportion of looks to orthographic competitors compared to fillers. Asterisk denotes significance at the . 05 level, error bars indicate standard error.

\section*{Cross-Linguistic Orthographic Interference}

Proportion of Looks Visual fixations lasting at least 200 ms were analyzed (shorter fixations are mostly parts of a preplanned path for rapidly analyzing a newly-presented scene, since eye-movements in visual world tasks take about 200 ms to plan and execute, Viviani, 1990) from auditory target onset to 1600 ms post-target onset, at which point visual fixations reached an asymptote. The proportion of looks to English orthographic competitors was compared to the average of both fillers present on the same display in a one-way repeated measures ANOVA. Participants looked more often at the orthographic competitor pictures than filler pictures, \(F_{1}(1,17)=\) 17.09, \(p<0.001, F_{2}(1,23)=3.98, p=0.05\) (Figure 1).

Fixation Timecourse Proportion of looks to Competitors versus Fillers were analyzed with point-to-point t-tests in 100 ms time bins from -500 ms pre-word-onset to 2000 ms postword onset (Figure 2). Participants looked more often at orthographic Competitors than Fillers from \(0-100 \mathrm{~ms}\) and from \(100-200 \mathrm{~ms}\) post-word onset ( \(p\) 's \(<0.05\) corrected).

Figure 2: Proportion of looks to targets, orthographic competitors, and fillers in 100 ms time windows. Participants fixated orthographic competitors more than fillers from 0-200 ms post-target onset. Asterisks denote significance at the .05 level.

\section*{Discussion}

In this experiment, we examined the role of orthography on novel language learning and auditory processing. We found that participants were successfully able to learn a novel language containing letter-sound mappings that contrasted with English. Learners successfully generalized their knowledge to novel, untrained words, suggesting that they acquired Colbertian's phonetic rules and did not rely on whole-word learning alone. In fact, faster learners were also better at identifying novel words; it may be that these participants were able to
extract and make use of Colbertian's letter-sound mappings early in their training, which accelerated their learning. In contrast, those who struggled to learn the novel words appeared to have learned less about specific ortho-phono mappings, and performed more poorly identifying novel words.

Auditory presentation of learned words activated their corresponding orthographic forms, as evidenced by more frequent visual fixations to cross-linguistic English orthographic competitors from \(0-200 \mathrm{~ms}\) post target word onset. The early timecourse of the effect suggests that orthography affected speech processing online rather than at a post-lexical decision level, a finding that converges with evidence from ERPs (Perre \& Ziegler, 2008). Note that because of the contrasting letter-sound mappings between English and Colbertian, competitor items did not overlap with the target phonologically. By design, this rules out phonological competition, providing strong evidence for automatic activation of crosslinguistic orthographic competitors during spoken word processing. Overall, our findings indicate that not only were participants able to activate orthographic forms of novel words despite conflict with existing letter-sound mappings in their native language, but these words were also able to spread activation to similarly spelled words in the native language, suggesting some integration with the existing lexicon.

These findings suggest that when people hear words in one language, not only do they experience activation of the letters in that language, but that they also experience activation of words in other languages they know or are learning that are spelled similarly. In other words, when an English learner of German hears a German word that is pronounced /za:gə/ and is spelled 'sage', (conjugation of the verb 'sagen,' meaning 'to say'), the English word 'sage' (pronounced /seid3/) becomes activated due to its overlapping orthography, despite having minimal phonological overlap with the actual auditory input. This spreading co-activation of phonology and orthography across languages testifies to the highly interactive and dynamic nature of the human language system.

In the present study, since all the phonemes of the novel language also exist in English, we would expect English orthographic mappings to be more easily accessible based on their greater frequency of use. However, participants were able to activate the novel language's orthographic forms, which suggests that the language system may contain a mechanism to increase activation of newly-learned letter-sound mappings, enabling them to match or exceed mappings in the native language. Although we did find that participants activated orthographic forms of spoken words using L2 lettersound mappings (e.g., 'hane' for the spoken word /gufo/), it's unclear whether an orthographic form based on L1 lettersound mappings, such as 'goofaw' was also activated. The current study was unable to probe for this kind of L1 activation, given that an orthographic competitor, like the word 'goofy,' would also overlap with the target phonologically, obscuring orthographic effects. Overall, it's unlikely that the native language was completely suppressed during the task,
given that we saw fixations to competitors in the visual display based on L1 lexical knowledge, which suggests that both the novel language and the native language remained active to some degree.

The present results indicate that orthographic information plays an important role during second language learning and auditory word processing. Future work should investigate how different types of language experience affect learning and processing of a novel orthography. The English monolinguals in the current study had moderate experience with contrasting letter-sound mappings (e.g., the phoneme /s/ can be represented by either ' \(S\) ' or ' \(C\) '), compared to speakers of a transparent language (low experience) or bilinguals (high experience). Transparent languages with nearly one-to-one mappings between orthography and phonology, like Italian and Finnish, may not prepare speakers well for acquisition of contrasting mappings in a novel language, resulting in more cross-linguistic interference. On the other hand, bilinguals should acquire novel mappings faster and exhibit less interference compared to English monolinguals, since bilinguals already have experience with two sets of letter-sound correspondences. Indeed, bilinguals learn novel languages better than monolinguals (Cenoz, 2003; Cenoz \& Valencia, 1994; Kaushanskaya \& Marian, 2009a, 2009b; Sanz, 2000; Thomas, 1992; Van Hell \& Mahn, 1997) and can control phonological competition more efficiently (Bartolotti \& Marian, 2012), and it's likely that these advantages will extend to acquisition of a novel orthography. In sum, language perception and learning can be shaped by existing language knowledge across modalities, which emphasizes the highly interactive nature of the language system.

In conclusion, our results show that orthography can be activated online during auditory word processing, and furthermore, that the individual links between letters and sounds can be updated as part of learning a second language. Acquiring the orthographic and phonological systems of a new language is an important step in achieving proficiency. Identifying both how previous experience with language may affect acquisition of novel letter-sound correspondences, and the rate at which novel words become integrated in the lexicon, will help uncover the essential components to successful language learning.

\title{
Syntactic category disambiguation within an architecture of human language processing
}

}

\begin{abstract}
Syntactic category ambiguities are very frequent in natural languages, and all architectures of language processing need a mechanism for disambiguating syntactic category ambiguities. Corley and Crocker (2000) suggested that syntactic category disambiguation can be assigned its own module within a modular architecture. We will show that the model defined by Corley and Crocker can account for a considerable amount of variance in reading times of naturally occurring texts. In addition, we provide evidence that syntactic category disambiguation may be independent of syntactic top-down expectations, emphasizing the important role of bottom-up processes within an architecture of human language processing.
\end{abstract}

Keywords: sentence processing; reading; eye-tracking; ambiguity; lexical access.

\section*{Introduction}

Successful language processing requires the integration of bottom-up information extracted from the current input and top-down expectations generated from what has been processed so far. When and how bottom-up and top-down processes interact has been a distinguishing feature of different processing architectures. On the one hand, there are constraint-based models (e.g. MacDonald, Pearlmutter, \& Seidenberg, 1994; Trueswell \& Tanenhaus, 1994; Tabor, Juliano, \& Tanenhaus, 1997), which assume one single processing unit, in which all available information is considered simultaneously. Modular architectures, on the other hand, consist of several distinct processing modules (e.g. Frazier, 1987; Frazier \& Clifton, 1996; Corley \& Crocker, 2000). These modules are restricted to each having its own internal representation, and they are independently predictive and informationally encapsulated (Crocker \& Corley, 2002). Assuming this definition of modules in terms of information flow, bottom-up processes are more likely to be modular than top-down processes (Appelbaum, 1998; Fodor, 1983).

One particular process, for which constraint-based and modular models make contradicting predictions, is syntactic category assignment or disambiguation: constraint-based models assume that rich contextual information is utilized to determine the syntactic category (i.e part of speech) of a word, while modular architectures only allow context-independent information. Although previous research may seem to have provided evidence for both positions, Corley and Crocker (2000) (see also Gibson, 2006) have shown that most of the evidence
for constraint-based models can also be accounted for under a modular architecture with a module for bottom-up syntactic category assignment. In this paper, we follow Corley and Crocker's proposal and provide further evidence for the existence of a syntactic category module by showing that Corley and Crocker's model of syntactic category disambiguation is a significant predictor of reading times in naturally occurring texts. In addition, we provide evidence that syntactic category disambiguation may be independent of syntactic top-down expectations, emphasizing the critical role of bottom-up processes within a modular architecture of human language processing.

\section*{Syntactic Category Ambiguity}

Many words in English (and presumably all other languages) are ambiguous, they can have different senses and/or belong to different syntactic categories or part-of-speech (i.e. noun, verb, adjective, etc.). The following example (from Boland, 1997) illustrates these ambiguities:
(1) I saw her duck ...
a. ... under the porch to eat some potato chips.
b. .... under the porch eat some potato chips

In (1), the word duck is ambiguous between its verb and noun readings, and only the following context can disambiguate between the two syntactic categories and senses. Syntactic category ambiguity and lexical ambiguity (in terms of different senses) need not come together like in (1). Lexical ambiguity often occurs within the same syntactic category as in the word cabinet, which as a noun can denote either a group of advisors or a closet. Syntactic category ambiguity, on the other hand, does not require lexical ambiguity, as evidenced by the English verbal system, where for all regular verbs there is only one form for the past-tense and the past-participle. This ambiguity is crucial to many garden-path sentences.

The horse raced past the barn fell.
The horse ridden past the barn fell.
While example (2) is a classical garden-path sentence, which upon first encounter may be nearly impossible to understand, example (3) is unambiguous and relatively easy to process. The fact that example (2) is derived
from (3) only by replacing the ambiguous word raced with the unambiguous ridden demonstrates the important role of syntactic category disambiguation in language processing (cf. Chomsky \& Lasnik, 1977).

\section*{Previous Research}

One particular type of syntactic category ambiguity, which has received considerable attention in research is the noun-verb ambiguity. Based on three experiments, Frazier (1987) suggested that the processor delays resolving the ambiguity until disambiguating information is encountered, as readers spent less time on ambiguous words and more time on disambiguating context than on unambiguous words and their respective contexts. These results were put into question by MacDonald (1993) (see also MacDonald, 1993), who in turn argued that different statistical measures and biases such as semantic biases, syntactic context and word co-occurrences could influence syntactic category disambiguation. Similarly, Tabor et al. (1997) showed that readers are sensitive to syntactic context when resolving syntactic category ambiguities between the determiner and complementizer readings of that: a reading time delay occurred when that following a verb was disambiguated as a determiner or sentence-initial that was disambiguated as a complementizer.

While the results cited so far suggest that syntactic category disambiguation is - at least to some degree - dependent on syntactic or discourse context, Boland (1997) and Boland and Blodgett (2001) demonstrated in a series of experiments that when reading a syntactic category ambiguous word like duck, readers are sensitive to its lexical bias, i.e. the relative frequencies of the lexical entries for this word, independent of the syntactic or discourse context it appears in. In a similar vein, Stolterfoht, Gese, and Maienborn (2010) showed that for German adjectival passives (e.g. closed), whose forms are ambiguous between passive participle and adjective, there is an increase in reading times when preceded by an adjective-copula auxiliary as compared to the passive auxiliary, and as compared to unambiguous adjectives. This suggests that syntactic category disambiguation has a strong bottom-up component, which cannot be overridden by any top-down information. It is thus rather uncontroversial that lexical bias plays an important role in syntactic category disambiguation (cf. e.g. Gibson, 2006).

However, it remains open to what extent additional contextual information is used in this process: Gibson (2006) proposed that in addition to the contextindependent lexical bias syntactic category disambiguation is also affected by context-dependent syntactic expectations, which he broadly formalizes as the probability of a syntactic category in a given 'syntactic environment'. A more restrictive notion of sufficient contextual information in syntactic category disambiguation, which
was proposed by Corley and Crocker (2000), will be introduced in the next section and forms the basis of this paper.

\section*{The Statistical Lexical Category Module}

One curious fact about syntactic category disambiguation is that computers seem to be nearly as good at it as humans are: unlike many other tasks in natural language processing, part-of-speech tagging has been an area in which rather simple models can achieve near-ceiling accuracy (Charniak, 1993). Inspired by this observation, Corley and Crocker (2000) assumed that syntactic category disambiguation is distinct from syntactic parsing. Reasons for this assumption are that syntactic category disambiguation happens extremely locally, that the relevant statistics are different from syntactic parsing, and that syntactic category disambiguation does not involve structure building. This means that syntactic category disambiguation can have its own internal representation, be informationally encapsulated and independently predictive, thus constituting the requirements for a separate module, the Statistical Lexical Category Module \({ }^{1}\) (Corley \& Crocker, 2000).

Corley and Crocker's model for the Statistical Lexical Category Module (SLCM) is based on a simple bigram statistical part-of-speech tagger defined by Equation 1, which expresses the assumption that the joint probability \(P\left(t_{0}, \ldots, t_{n}, w_{0} \ldots w_{n}\right)\) of all part-of-speech tags \(t_{0}, \ldots, t_{n}\) and all words \(w_{0} \ldots w_{n}\) read so far can be reasonably approximated by the product of the lexical bias (i.e. the probability of word \(w_{i}\) given tag \(t_{i}\) ) and the category bigram transitional probability.
\[
\begin{equation*}
P\left(t_{1}, \ldots, t_{n}, w_{0} \ldots w_{n}\right) \approx \prod_{i=1}^{n} P\left(w_{i} \mid t_{i}\right) P\left(t_{i} \mid t_{i-1}\right) \tag{1}
\end{equation*}
\]

Since lexical bias \(P\left(w_{i} \mid t_{i}\right)\) is a property of the word, the category bigram transitional probability \(P\left(t_{i} \mid t_{i-1}\right)\) is the only means to capture context-dependence in this model of syntactic category disambiguation, implying that syntactic context-dependence is in fact only a dependence on the syntactic category of the preceding word.

One may object that limiting context-dependence to the category of only the preceding word is a too restrictive assumption, but Corley and Crocker (2000) (see also Crocker \& Corley, 2002) showed that it is enough to model the results reported by MacDonald (1993) and Tabor et al. (1997).

However, the aim of this paper is not to try to explain all psycholinguistic evidence involving syntactic category disambiguities. Instead, we will evaluate Corley and Crocker's SLCM model on a larger scale as a predictor of reading times in naturally occurring text. While Corley

\footnotetext{
\({ }^{1}\) Corley and Crocker (2000) refer to syntactic category ambiguity as 'lexical category ambiguity'.
}
and Crocker assume a direct link between the probabilities derived from Equation 1 and human processing difficulties, we follow common practice (e.g. Demberg \& Keller, 2008; Pynte, New, \& Kennedy, 2008) and take the logarithm as the linking function between probabilities and reading times.

We thus obtain the following measure \(\log P_{S L C M}\) for a word \(w_{i}\) given its tag \(t_{i}\) and the tag \(t_{i-1}\) of the previous word:
\[
\begin{equation*}
\log P_{S L C M}=\log P\left(w_{i} \mid t_{i}\right)+\log P\left(t_{i} \mid t_{i-1}\right) \tag{2}
\end{equation*}
\]

This measure is evaluated in Experiment 1, where we show that it is a significant predictor of reading times in naturally occurring texts. In Experiment 2, we evaluate both terms in Equation 2 separately and show that lexical bias and category bigram transitional probabilities make independent contributions to the model fit observed in Experiment 1. In the final experiment, we provide evidence that syntactic category disambiguation may be independent of syntactic top-down expectations as measured by surprisal (Hale, 2001) based on a probabilistic context-free grammar.

\section*{Experiments}

In recent years, it has become standard to evaluate computational models of language processing on 'eyetracking corpora', i.e. on eye-tracking data of people reading naturally occurring texts (Pynte et al., 2008; Demberg \& Keller, 2008). The basic idea is to fit two regression models to a measure of readings times. One regression model (baseline model) includes as predictors control variables, which are known to have an influence on reading times. The second regression model includes all those predictors as well, but in addition it also includes our computational model of language processing as a predictor. To test whether our computational model of language processing is a significant predictor we compare the fit of the two regression models to the data by means of a log-likelihood test.

\section*{Methods}

In this section we describe the methodological detail common across all three experiments.

Data and Dependent Variable All three experiments use the Dundee Corpus (Kennedy \& Pynte, 2004), a collection of eye-movement data from 10 participants reading 51,501 words each of the British newspaper The Independent. We approximated lexical categories by part-of-speech (PoS) tags, which were obtained by tagging the Dundee Corpus with the CLAWS tagger (Garside, 1987). Since syntactic category disambiguation is assumed to happen 'early' in processing, we chose first-pass reading times as our dependent variable. Firstpass reading times are calculated for a given word and participant as the sum of all eye fixations on that word
in the first pass, i.e. before leaving the word either to the right or to the left. Data points were removed if a word was not fixated, appeared as the first or last word in a line, or contained any non-letter symbol.

Control Variables All regression models included the following control variables, which are known to have an influence on reading times (c.f. Demberg \& Keller, 2008): number of characters per word, position of word in a sentence, an indicator variable whether the previous word was not fixated, and indicator variable whether the following word was not fixated, the frequency of the word, the frequency of the previous word, the forward transitional probability, i.e. bigram probability \(P\left(w_{i} \mid w_{i-1}\right)\), and the backward transitional probability \(P\left(w_{i} \mid w_{i+1}\right)\). All frequencies and transitional probabilities were obtained by fitting a unigram or bigram model with modified Kneser-Ney smoothing (Chen \& Goodman, 1998) to the British National Corpus (100 million words) using the SRILM toolkit (Stolcke, 2002). All continuous variables were centered and scaled to two standard deviations to minimize collinearity. In addition, all frequencies and transitional probabilities were logtransformed before scaling.
Estimating Probabilities in the SLCM Model The probabilities in Equation 2 were estimated from a corpus obtained by concatenating the CLAWS-tagged versions of the British National Corpus and the Dundee Corpus. The lexical bias \(P\left(w_{i} \mid t_{i}\right)\) was estimated as is, i.e. without any smoothing. For estimating the the category bigram transitional probability \(P\left(t_{i} \mid t_{i-1}\right)\) we again used a bigram model with modified Kneser-Ney smoothing.

Regression Models For the regression models we used linear 'mixed-effects' models (Pinheiro \& Bates, 2000; Gelman \& Hill, 2007) of first-pass reading times with participant, word and text number as random effects, as a generalization of the common by-subject and by-item analyses, thus taking into account that the different words and texts read by the participants are random samples in the same sense as the participants are (cf. Clark, 1973). All models were fit in R (R Development Core Team, 2011) using the lme4 package (Bates, 2005).

\section*{Baseline Model Results}

The coefficients and standard errors of the baseline model are shown in Table 1. The coefficients are as expected based on prior research: e.g. reading times decreases with increasing position in the sentence and increasing word frequency, and increase with an increasing number of characters in a word.

Table 1: Baseline model coefficients
\begin{tabular}{lrrr}
\hline Predictor & Coeff. & Std.Error & \(t\) \\
\hline (Intercept) & 206.34 & 7.31 & 28.22 \\
Position in Sentence & -6.02 & 0.51 & -11.76 \\
Number of Characters & 51.68 & 1.16 & 44.45 \\
Frequency of Word & -23.89 & 1.58 & -15.15 \\
Freq. of Prev. Word & -12.84 & 0.61 & -20.90 \\
Forward Trans. Prob & -10.24 & 0.94 & -10.94 \\
Backward Trans. Prob. & -1.95 & 0.70 & -2.77 \\
No Fixation Next & 10.14 & 0.49 & 20.61 \\
No Fixation Previous & 27.84 & 0.52 & 53.70 \\
\hline
\end{tabular}

\section*{Experiment 1}

The objective of Experiment 1 is to evaluate Corley and Crocker's model of the SLCM as a predictor of reading times. The predictor to be evaluated is the full model as stated in Equation 2.

Figure 1: Partial effect of full SLCM model with all other predictors held constant

Results The coefficient and standard error of the full tagger-based model of syntactic category disambiguation (Equation 2) are shown in Table \(2^{2}\). A log-likelihood test between the regression model with the predictor \(\log P_{S L C M}\) and the baseline model confirmed that Equation 2 is a significant predictor of reading times \(\left(\chi^{2}=\right.\) \(29.955, p<.0001)\). The relation between \(\log P_{S L C M}\) and reading times is plotted in Figure 1, which shows the

\footnotetext{
\({ }^{2}\) Coefficients for the control variables are not listed as they are qualitatively similar to the ones reported for the baseline model.
}

Table 2: Model coefficient of full SLCM model
\begin{tabular}{lrrr}
\hline Predictor & Coeff. & Std.Error & \(t\) \\
\hline \(\log P_{S L C M}\) & -6.85 & 1.05 & -6.54 \\
\hline
\end{tabular}
partial effect of \(\log P_{S L C M}\) with all other predictors held constant at their respective means. It can be seen that reading times increase as \(\log P_{S L C M}\) or \(P_{S L C M}\) decrease.

Discussion The above result shows that the simple model of syntactic category disambiguation in Equation 2 cannot only account for many empirical results in psycholinguistic experiments, but is also a significant predictor of reading times in naturally occurring text. The direction of the effect is in line with experimental evidence modeled by Corley and Crocker (2000) in the sense that a lower probability in Equation 2 leads to higher reading times.

\section*{Experiment 2}

In Experiment 2 we investigate whether lexical bias and category bigram transitional probability are also independently significant as predictors of reading times. To test this hypothesis, we fitted three models, one with only lexical bias (log-transformed \(P\left(w_{i} \mid t_{i}\right)\) ), one with only category bigram transitional probability (logtransformed \(P\left(t_{i} \mid t_{i-1}\right)\) ), and a third one with both terms as additional predictors to the baseline model.

Results The coefficients and standard errors for lexical bias and category bigram transitional probability are shown in Table 3. The negative coefficients indicate that increasing the lexical bias (i.e. making the 'correct' category more likely) and increasing the category bigram transitional probability both lead to shorter reading times. A log-likelihood test confirmed that a model with either lexical bias \(\left(\chi^{2}=7.37, p<.001\right)\) or category bigram transitional probability \(\left(\chi^{2}=22.97, p<.0001\right)\) yields a significantly better fit to the data than the baseline model, and that a model with both predictors significantly improves over a model with only one.

Discussion Our results show that both lexical bias and category bigram transitional probability are significant predictors of reading times. For lexical bias this is in line with the results of Boland (1997) and Boland

Table 3: Model coefficient for lexical bias and category bigram probabilities
\begin{tabular}{lrrr}
\hline Predictor & Coeff. & Std.Error & \(t\) \\
\hline Lexical Bias & -4.86 & 1.57 & -3.09 \\
Category Bigram & -4.28 & 0.69 & -6.18 \\
\hline
\end{tabular}
and Blodgett (2001), who also found a significant effect of lexical bias on reading times. The effect of category bigram transitional probabilities shows that the immediately preceding category contains information beyond what is contained in the corresponding preceding word, as including category bigram transitional probabilities improves over a baseline model, which already contained word bigram transitional probabilities.

\section*{Experiment 3}

In Experiment 3 we test whether the effects of syntactic category disambiguation accounted for by the SLCM model can be ascribed to syntactic top-down expectations. If this were the case, it would provide strong evidence against any modular approach to syntactic category disambiguation. Syntactic top-down expectations are often measured by surprisal (Hale, 2001), which can be calculated from a probabilistic context-free grammar.

We calculated unlexicalized surprisal values for all words in the Dundee Corpus using the top-down parser described in (Roark, 2001) and (Roark, Bachrach, Cardenas, \& Pallier, 2009) and included it as an additional predictor in our baseline model. We than compared this enriched baseline model to a regression model, which contained both surprisal and the log-probabilities of the tagger-based model of syntactic category disambiguation (Equation 2).

Results The coefficients and standard errors for surprisal and the tagger-based model of syntactic category disambiguation are shown in Table 4. As in Experiment 1 , the coefficient of the tagger-based model is negative coefficients indicating that increasing the probability in Equation 1 leads to shorter reading times. The coefficient of surprisal is positive. This is expected as higher surprisal is associated with longer reading times (Hale, 2001; Demberg \& Keller, 2008). A log-likelihood test confirmed that a model with the tagger-based model and surprisal improves significantly over a baseline model with only surprisal \(\left(\chi^{2}=13.18, p<.001\right)\).
Discussion The above results show that SLCM model is a significant predictor of reading times even if surprisal is included in the baseline regression model. Although this does not rule out the hypothesis that the effects of syntactic category disambiguation accounted for by the SLCM model may be reduced to syntactic top-down expectations, it provides strong evidence against such a hy-

Table 4: Model coefficient for surprisal and the full SLCM model
\begin{tabular}{lrrr}
\hline Predictor & Coeff. & Std.Error & \(t\) \\
\hline Surprisal & 2.17 & 0.69 & 3.13 \\
\(\log P_{S L C M}\) & -5.67 & 1.11 & -5.10 \\
\hline
\end{tabular}
pothesis, and suggests instead that syntactic top-down expectations and bottom-up syntactic category disambiguation may be independent processes, as suggested by Gibson (2006) and Corley and Crocker (2000).

\section*{General Discussion}

In our experiments, we have shown that the model of a Statistical Lexical Category Module as formulated by Corley and Crocker (2000) is a significant predictor of reading times in naturally occurring texts. While our results do not necessarily imply that syntactic category disambiguation is a separate module, they provide further evidence for modular models relying on simple context-independent statistics for lexical category disambiguation. The observation that SLCM model is a significant predictor of reading times in addition to syntactic expectations as measured by surprisal indicates that Corley and Crocker's model may indeed account for bottom-up processes in reading, while surprisal accounts for top-down processes.

Since any architecture of language processing needs to integrate bottom-up and top-down processes, one may conclude that the combination of a restricted (or modular) model of bottom-up syntactic category disambiguation with a model of syntactic top-down expectations may ultimately lead to better models of the architecture of human language processing and, more specifically, to a better understanding of syntactic category disambiguation as a phenomenon at interface of lexical access and syntactic processing, as recent experiments have shown that syntactic category ambiguity also plays a crucial rule in lexical-semantic access and disambiguation (Jones, Folk, \& Brusnighan, 2012).

Finally, our results may also contribute to the ongoing debate on lexicalized vs. unlexicalized measures of syntactic expectations and their reflections in reading times (for a review, see Roark et al., 2009): since bigram probabilities are the simplest form of syntactic expectations, our observation that category bigram probabilities are a significant predictor of reading times, even if controlled for word bigram probabilities, suggests that lexicalized and unlexicalized measures of syntactic expectations may have independent contributions to reading times.

\section*{Acknowledgments}

The author would like to thank the four anonymous reviewers for their suggestions and Masaya Yoshida and Daniel Müller-Feldmeth for many fruitful discussions.

\begin{abstract}
As tools in science, diagrams not only serve as vehicles for communication but also facilitate and constrain scientific reasoning. We identify roles that diagrams play when computational models and synthesized organisms are used to recompose mechanisms proposed to explain biological phenomena. Diagrams not only serve as locality aids for constructing computational models but also help in identifying ways to manipulate these models and interpret the results. Moreover, they serve as blueprints for constructing synthetic organisms and then guide the interpretation of discrepancies between these organisms and computational models.
\end{abstract}

Keywords: diagrams; computational models; mechanistic explanation; circadian rhythms

\section*{Introduction}

Cognitive scientists have contributed analyses and experiments on the roles diagrams play in reasoning and problem solving (e.g., Hegarty, 2004, 2011; Tversky, 2011) and have even designed new diagram formats that facilitate learning in math and science (Cheng, 2002, 2011). However, there have been only a few studies of the roles diagrams play in the natural sciences (Nersessian, 2008; Gooding, 2010). The most obvious role, evidenced by the ubiquity of diagrams in talks and publications, is communication of methods, results, and proposed mechanistic explanations (Perini, 2005). Less visibly, but crucially, diagramming is a tool that scientists use to reason about phenomena (Bechtel \& Abrahamsen, 2012) and the mechanisms that might explain them (Sheredos, Burnston, Abrahamsen, \& Bechtel, in press).

In many fields of biology, such as cell and molecular biology, the primary goal of research in the \(19^{\text {th }}\) and \(20^{\text {th }}\) centuries was to identify and decompose mechanisms to determine their parts (e.g., proteins) and operations (e.g., catalyzing particular chemical reactions). As recognized in the new mechanistic philosophy of science, the organization of these parts and operations must also be determined to arrive at a basic mechanistic explanation of a phenomenon of interest (Bechtel \& Richardson, 1993/2010; Bechtel \& Abrahamsen, 2005; Machamer, Darden, \& Craver, 2000; Thagard, 2003). That is, to understand how the parts and operations contribute to producing the phenomenon, researchers must recompose the responsible mechanism either conceptually or physically. Through most of the \(20^{\text {th }}\) century this involved proposing a simple sequence in which the operations might occur, perhaps using mental simulation to verify its plausi-
bility (Bechtel, 2006). By the last decades of the century, however, the operations of numerous biological mechanisms were understood to display nonlinear, continuous dynamics and complex interactions. As sequential organization broke down, so too did biologists’ ability to mentally track the functioning of the proposed mechanisms. Hence, they turned first to computational models and later to synthetic organisms as tools for recomposing mechanisms, with an emphasis on investigating the complex dynamics and interactions of operations by which a mechanism generates a phenomenon. In this paper we identify some of the roles diagrams play in the design of computational and synthetic models of mechanisms in actual scientific practice.

Computational modeling in biology, in contrast to that in much of cognitive science, has been grounded in considerable knowledge of the physical parts and operations of the mechanisms being targeted (Bechtel \& Abrahamsen, 2010). Diagrams showing how different parts are thought to operate on each other serve as locality aids that "group together information that is used together" in the mechanism itself and hence often in computational models of its dynamics (Jones \& Wolkenhauer, 2012, p. 705). But such diagrams also figure centrally in conceiving how manipulations made to the computational model correspond to possible perturbations of the mechanism, thereby relating experiments on models to experiments on actual mechanisms or to pathologies known to result from damage to actual mechanisms. Moreover, as the efforts to recompose mechanisms increasingly take a step beyond computational modeling to synthesizing organisms, a diagram can serve both as a blueprint for synthesizing an organism and as a medium for adjudicating mismatches in behavior between organism and model.

We focus on one domain of biology, circadian rhythms: the daily oscillations in a variety of physiological and behavioral processes in species ranging from bacteria and fungi to plants and animals. The phenomena of greatest interest involve three characteristics of these rhythms: they are endogenously generated, entrained to the day-night cycle on our planet, and sustained over time (not dampened). Their complex dynamics have made circadian rhythm research a model case for developing computational models and synthesized organisms to determine how a proposed mechanism might account for relevant phenomena. By examining specific exemplars of this research, we show how diagrams can play an important role in the reasoning that goes into computational modeling and synthetic biology.

\section*{Diagrams for Modeling "How-Possibly" Mechanisms}

Computational modeling of circadian rhythms began shortly after behavioral researchers determined that the daily oscillations in organisms are endogenously generated, with a period varying slightly from 24 hours (Bünning, 1960). Since engineers had shown that negative feedback systems generate oscillations, biologists were attracted to the idea that feedback loops are involved in circadian oscillations. But most feedback systems dampen, settling into a steady state. The challenge was to determine how a biological mechanism might generate sustained oscillations, which entailed computational modeling of its dynamics.

Goodwin (1963) accepted this challenge, and took as his starting point one of the first molecular feedback mechanisms identified in biology: the lac operon. Jacob and Monod (1961) had specified how synthesis of the enzymes needed to metabolize lactose could be restricted via negative feedback to occur only when glucose levels are low. Although the molecular parts and operations involved in the circadian mechanism had not yet been identified, Goodwin borrowed the architecture of the better-understood lac operon to construct a diagram depicting a possible circadian mechanism (Figure 1). In it he included not only generic labels for the putative parts and operations but also associated variables and parameters relevant to their dynamics. The mechanism has five types of molecular parts, three of which undergo changes in their concentration. These concentrations are represented by the variables \(X, Y\), and \(Z\). Arrows depict six operations that affect the concentrations: three (labeled) involve aspects of gene expression and three indicate decay of a particular type of molecule, at rates associated with the parameters \(k_{1}, \ldots k_{6}\). Thus, \(X\) is the concentration of mRNA transcribed from the gene, \(Y\) the concentration of the enzyme resulting from translating the mRNA, \(Z\) the concentration of the repressor molecule whose synthesis is catalyzed by the enzyme, \(k_{4}\) to \(k_{6}\) the rates of decay, and \(k_{1}\), to \(k_{3}\) associated with rates of gene expression operations.

There are three equations in the computational model. Each specifies the change in concentration of one molecular component by subtracting a term for its decay from a term

Figure 1. Diagram of the generic mechanism for feedback control of gene expression that Goodwin used as a locality aid in constructing his computational model of circadian rhythms (adapted from Goodwin 1963).
for the impact of one of the operations in the feedback loop. Consulting the diagram, it is easy to see which variables and parameters should be in the same equation. Each variable has one arrow from it (its decay) and one arrow to it from another variable; its equation includes that variable and the parameters on those arrows. By providing these groupings, the diagram does service as a locality aid.
\[
\begin{aligned}
& \frac{d X}{d t}=\frac{k_{1}}{Z^{n}+1}-k_{4} X \\
& \frac{d Y}{d t}=k_{2} X-k_{5} Y \\
& \frac{d Z}{d t}=k_{3} Y-k_{6} Z
\end{aligned}
\]

Five of the terms simply multiply a concentration by a rate parameter. The first term is more complex: since the repressor reduces synthesis of mRNA, its concentration \((Z)\) is in the denominator and raised to the power \(n\); known as the Hill coefficient, \(n\) represents the number of molecules that must interact. As the only nonlinear term, this first term is crucial for generating sustained oscillations.

It is difficult to determine exactly how a mechanism will behave when even one component exhibits nonlinearity and also when appropriate parameter values are not yet known. For both of these reasons, it is important to run simulations by solving the equations with different initial values and parameter settings. Doing so on an analog computer, Goodwin concluded that such a mechanism could generate sustained oscillations when \(n\) equaled 2 or 3 . These are biologically plausible values, but when Griffith (1968) ran simulations on a digital computer he determined that sustained oscillations resulted only when \(n>9\), generally recognized as biologically unrealistic. Accordingly, he concluded that negative feedback with a single gene product operating on a gene could never "give rise in practice to undamped oscillations in the concentrations of cellular constituents" (p. 207). This reasoning highlights an advantage of grounding a computational model in a representation of the associated mechanism. A biologist, having noticed that the term in question relates to molecules interacting to inhibit a biochemical reaction, can draw on knowledge of such reactions to judge the plausibility of different parameter values. Lacking such grounding, the modeler has no independent check on the values obtained from parameter fitting.

\section*{Diagrams for Modeling Known Parts and Operations}

Diagrams continued to serve as locality aids after researchers discovered some of the actual parts and operations of the circadian mechanism, and modelers turned to modeling their specific dynamics. As we will see, the diagrams also supported additional reasoning about the mechanism.

The first component part of a circadian clock was discovered by Konopka and Benzer (1971) through a process of generating mutant fruit flies with short, long, or absent circadian rhythms. They named the gene in which mutations
produced altered rhythms period (per). When cloning techniques became available, Hardin, Hall, and Rosbash (1990) were able to measure the mRNA into which per was transcribed and the protein into which it was translated. They determined that these concentrations oscillated over 24 hours, with the peak concentration of the protein lagging several hours behind that of the mRNA transcript. They thus hypothesized a feedback mechanism whereby the protein PER fed back to inhibit the transcription of the gene per.

This research physically identified some of the parts and operations of the proposed mechanism, but the "feedback hypothesis" left open the question of whether and under what specific conditions it could generate sustained oscillations. Goldbeter (1995) took up this question by developing a computational model, drawing upon Hardin et al.'s empirical discoveries and inspired in part by Goodwin's abstract model. Like Goodwin, he portrayed the mechanism in a diagram (Figure 2) in which each part and operation was accompanied by its corresponding variable or parameter. Shown within the dashed box is the operation occurring in the nucleus in which the PER protein inhibits per transcription. The rest of the diagram shows the operations of transcription and translation and an additional post-translational operation through which the protein PER is phosphorylated

Figure 2. Goldbeter's (1995) diagram that guided his computational model based on the mechanism proposed by Hardin, Hall, and Rosbash (1990).
(a step that had been determined to be necessary before PER could be transported back into the nucleus).

Like Goodwin, Goldbeter then constructed differential equations, each characterizing the change in concentration of one of the molecular components. Again, the grouping of arrows around each variable served as a locality aid in determining the equations. As a result of including additional nonlinearities in the terms representing decay, Goldbeter's model exhibited sustained oscillations using parameter values deemed biologically realistic.

In the same window of time during which Goldbeter was constructing his model, molecular researchers were searching for additional parts to fill known gaps in the mechanism. They recognized, for example, that PER could not directly inhibit its own transcription since it lacked the needed binding region. Mammalian researchers identified a gene, Clock, in which a mutation could eliminate circadian function and whose protein contained a DNA-binding region (Vitaterna, King, Chang, Kornhauser, Lowrey, McDonald, Dove, Pinto, Turek, \& Takahashi, 1994). In short order, it was found that CLOCK forms a dimer with BMAL1 that binds to the promoter region of \(\operatorname{Per}\) (as well as a second gene, Cry) and that by interacting with this dimer, PER and CRY inhibit their own transcription. Realizing that concentrations of BMAL1 oscillate, researchers hypothesized a second negative feedback loop in which it inhibited the transcription of its gene. The introduction of this additional feedback loop raised the question of whether the results of Goldbeter's (1995) simulation were still applicable: would the two loops generate sustained oscillations? To address this question, Leloup and Goldbeter (2003) constructed a diagram (Figure 3) that included a variable for the concentration of each molecular part and a rate parameter for each operation. Again, the grouping of arrows around each variable served as a locality aid. With 16 variables being tracked this time, the computational model consisted of 16 differential equations.

Figure 3. Leloup and Goldbeter's (2004) diagram of the mammalian circadian oscillator in which proteins are represented as ovals (labeled within) and operations as arrows (some identified in adjacent boxes, and all with rate parameters shown).

Leloup and Goldbeter employed their computational model not only to establish that the mechanism could generate sustained oscillations, but to determine as well whether it could account for other circadian phenomena. Of prime importance is the ability of circadian clocks to be entrained by light. Light had been shown experimentally to affect PER expression, and hence Leloup and Goldbeter incorporated light in their diagrams as a black box with an arrow feeding into the box for Per transcription. This in turn guided their strategy for simulating light exposure in the computational model: instead of a setting a single value for the parameter \(v_{s P}\), which set the maximum rate of Per expression, they used a square wave function to alternate between a high value (simulating light) and a low value (simulating darkness). Leloup and Goldbeter were then able to use their model to show that the mechanism's responses to light exposure varied with time of day in ways similar to the responses of mammals.

Leloup and Goldbeter were also interested in whether the proposed mechanism could be perturbed in ways that correspond to known circadian pathologies. Advanced sleep phase syndrome is a condition in which people naturally go to sleep around 7 PM and rise around 3 AM . Genetic studies of families with this pathology had revealed a mutation affecting the interaction of PER with a kinase that phosphorylates it. The diagram includes the parameter \(v_{I P}\) at this location, and Leloup and Goldbeter showed that they could replicate the characteristics of the pathology by altering it.

In a subsequent paper Leloup and Goldbeter (2004) explored the sensitivity of the model to variations in all of the parameters. Here the diagram facilitated identifying which operations in the actual mechanism correspond to those perturbed by varying parameters in the computational model.

A question researchers often ask when they encounter a mechanistic account is whether all of the parts are required for the phenomenon to occur. Leloup and Goldbeter questioned which of the two feedback loops in their diagram were essential for circadian rhythmicity, and explored this by setting the parameter governing PER synthesis to 0 . The model ceased to exhibit oscillation. They then explored whether oscillation could be rescued by increasing parameters regulating the synthesis of BMAL1. This restored oscillation, but with a shorter period of approximately 19 hours.

This question of what different components contribute to the generation of circadian rhythms remains one of great interest to modelers. Some have pursued the question using highly reduced models, but adopting Goldbeter's approach instead, Relógio, Westermark, Wallach, Schellenberg, Kramer, \& Herzel (2011) included in their model all of the currently identified operations in the mammalian circadian mechanism. They developed the diagram in Figure 4 as a locality aid. Like the other diagrams, it includes variables and parameters adjacent to the relevant parts and operations. An innovation is use of a dashed line to differentiate two sub-mechanisms. By running the model with targeted variables set to constant values-first those for concentrations of parts above the line and then those below-they concluded
that it was the feedback loops involving BMAL1 that were crucial to the generation of circadian rhythms.

Figure S 1
PC loop
Figure 4. Relógio et al's (2011) diagram of the mammalian circadian oscillator. They use a dotted line to differentiate two sub-mechanisms investigated in their model.

The diagrams discussed in this section all serve as locality aids in constructing computational models, but then serve additional roles in determining which variables to manipulate in various simulations and in relating simulations back to the hypothesized mechanism.

\section*{Diagrams of Mechanisms to be Synthesized}

Traditionally, biologists have been limited to analyzing extant mechanisms to determine what parts, operations, and organization are responsible for a phenomenon of interest. But the development of techniques for inserting genes into host organisms (typically, E. coli) has generated a new field of synthetic biology, in which researchers use computational models to help design regulatory networks, insert them into organisms, and assess the effects on behavior. As Cookson, Tsimring, and Hasty (2009) make explicit, diagrams play a central role in this research. In the first step "genetic wiring diagrams are translated into equations that can be analyzed." After such analysis, "modern recombinant DNA techniques are used to construct gene-regulatory networks in living cells according to the design specification." In this endeavor, diagrams are not only locality aids for developing mathematical models, but also blueprints for constructing an organism. Once the behavior of the synthesized organism can
be assessed, diagrams play a further role in analyzing that behavior and revising the network design in light of the effects discovered in the synthesized organism.

This practice is illustrated in the efforts of Stricker, Cookson, Bennett, Mather, Tsimring, \& Hasty (2008). They explicitly drew upon the mechanism understood to be operative in the fruit fly circadian clock to construct a synthetic clock in E. coli. Specifically, they added a lacZYA promoter to the naturally occurring \(\operatorname{araBAD}\) promoter and then situated the hybrid promoter on the araC, lacI, and yemGFP genes (the last generates a green fluorescent protein used as a reporter of oscillations). Before inserting this mechanism into the bacterium, Stricker et al. constructed a diagram (Figure 5) from which they developed a computational model. Satisfied that the proposed mechanism would generate sustained oscillations under a limited set of parameter values (especially, of IPTG levels), they then employed the diagram as a blueprint for synthesizing the mechanism and as a guide to what components would have to be fine-tuned to generate sustained oscillations.

Figure 5. Stricker et al.'s (2008) diagram, which they used both to develop a computational model and to synthesize a bacterium that could generate oscillations.

The organism Stricker et al. synthesized did not behave as the model had led them to expect. Most surprising, it generated sustained oscillations under almost all parameter values tested. This led Stricker et al. to return to the mechanism as represented in the diagram and question whether processes that they had not represented in the diagram or in the equations of the model, such as protein folding, multimerization, and DNA-binding, were important to the process. They constructed a new diagram (Figure 6) and computational model that incorporated additional operations. The behavior of this model now corresponded closely to that of the synthesized bacterium. Stricker et al. concluded that the delays introduced into the feedback by these additonal steps were responsible for the oscillations.

In this example from synthetic biology, the diagram serves not only as blueprint for building the mechanism but also as a guide to determining why the mechanism did not behave as expected and then for proposing an alternative account of the mechanism.

Figure 6. Stricker et al. (2008) revised diagram motivated by the discrepencies between the behavior of the synthesized organism and their computational model.

\section*{Conclusion}

We have focused on one of the contexts in which diagrams provide the basis for reasoning in the development of mechanistic explanations-recomposing mechanisms through computational models and synthesized organisms. Through examples we have identified a widespread practice of constructing a diagram of the hypothesized mechanism that includes variables and parameters and using it as a locality aid in constructing equations to model the dynamics of the mechanism. But this is only the start. One of the interests in constructing a computational model is to experiment on it to determine whether the mechanism could explain various identified phenomena. A diagram can help with this, by guiding the selection of parameters to be reset or of variables to be given fixed values. When researchers set out to synthesize organisms, diagrams function both as locality aids in developing the computational models and as blueprints guiding the determination of components to include. When a synthesized organism fails to behave as the computational model suggested, researchers returned to the diagram to explore alternatives.

Our examination of published diagrams is only a first step in understanding researchers' cognitive engagement with diagrams as they seek to recompose mechanisms. Although unlikely, we cannot rule out the possibility that the diagrams we have discussed are epiphenomenal-constructed after developing the computational model as a means of communicating it to others. Given the utility of the diagram for grounding the modeling and the experiments on the model, it seems most likely the scientists would have so used it. Having identified ways diagrams appear to function in recomposing mechanisms, our hope is that other cognitive scientists will contribute to further understanding this aspect of scientific reasoning. One strategy would be ethnographic studies of modelers in which one can observe interactions with the diagrams in the process of developing and experimenting with computational models. Another strategy would involve experiments in which some modelers were allowed to create or consult diagrams while constructing a computational model and others were restricted from doing so. Such studies may help elucidate the cognitive operations that go into the construction of computational models. Further, such studies can also go beyond what we have been
able to do and address the specific features of diagrams that serve the aims of developing computational models and whether different representations, including different diagram formats, might serve these ends better. What we hope to have done is demonstrate a widespread practice of using diagrams in constructing and experimenting with computational models of biological mechanisms.

\begin{abstract}
The development of social robots that convey emotion with their bodies-instead of or in conjunction with their facesis an increasingly active research topic in the field of humanrobot interaction (HRI). Rather than focusing either on postural or on dynamics aspects of bodily expression in isolation, we present a model and an empirical study where we combine both elements and produce expressive behaviors by adding dynamic elements (in the form of Perlin noise) to a subset of static postures prototypical of basic emotions, with the aim of creating expressions easily understandable by children and at the same time lively and flexible enough to be believable and engaging. Results show that the noise increases the recognition rate of the emotions portrayed by the robot.
\end{abstract}

Keywords: Bodily emotional expression; human-robot interaction; affective robotics; Perlin noise.

\section*{Introduction}

Echoing the importance of emotional expression in social interaction and communication among humans, the development of expressive robots that can interact with us in a human-oriented way is nowadays a very active research topic in the field of human-robot interaction (HRI). Interest in using robot's bodies for emotional expression is rapidly increasing. This is partly due to two main factors. On the one hand, an increasing corpus of research in psychology and neuroscience (e.g., (Wallbott, 1998; De Gelder, 2006; Avizer, Trope, \& Todorov, 2012)) is emphasizing the role of the body in conveying emotion-specific information rather than merely nonspecific information related to intensity as it was previously thought. On the other hand, the fact that a number of robotic platforms currently available have complex bodies with a high number of degrees of freedom and/or good motion capabilities, but do not necessarily have articulated faces-that is the case in \(\mathrm{Nao}^{1}\), the robot that we have used in this study.

While researchers typically focus either on the use of expressive postural elements or on expressive aspects of movement (Coulson, 2008)—see (Kleinsmith \& BianchiBerthouze, 2012) for a survey-the combination of both aspects has not received as much attention in robotics. In the study resented here, we combine both elements and produce expressive behaviors by adding dynamic elements to a subset of static postures prototypical of basic emotions. Our underlying motivation from the point of view of \(\mathrm{HRI}^{2}\), as part of the European project ALIZ-E (www.aliz-e.org), was to create a set of expressions easily understandable by children and at

\footnotetext{
\({ }^{1}\) www.aldebaran-robotics.com.
\({ }^{2}\) See (Cañamero, 2002, 2008) for discussions of design issues regarding expressive robots for HRI.
}
the same time lively and flexible enough to be believable and engaging.

\section*{Affect Space}

This study is part of our research investigating the elaboration of an Affect Space for the generation of emotional body language to be displayed by robots. It builds on an Affect Space that was generated using key poses (Beck, Cañamero, \& Bard, 2010; Beck, Hiolle, Mazel, \& Cañamero, 2010). In the context of this paper, a key pose is a posture modeled after an actor performance so that it clearly describes the emotion displayed.

\section*{Static features}

In animation, one of the standard methods for creating convincing and believable displays relies on expressive key poses rather than body language in motion (Thomas \& Johnston, 1995; Vala, Paiva, \& Rui Gomes, 2008). Taking inspiration from this method, in previous work (Beck, Cañamero, \& Bard, 2010; Beck, Hiolle, et al., 2010) we used static key poses as a basis to produce expressive animated behaviors in a humanoid robot. This method presents the advantage of permitting to investigate and model independently postural and motion-related expressive elements. This approach is also consistent with research on affective body expression suggesting that form and movement information are processed by separate pathways in the brain (Kleinsmith \& BianchiBerthouze, 2012). The key poses that we used are consistent with the static features \({ }^{3}\) in (Kleinsmith, Bianchi-Berthouze, \& Steed, 2011).
Our initial experiments (Beck, Cañamero, \& Bard, 2010) showed that it is possible to successfully convey emotions using static key poses displayed by a Nao humanoid robot. Based on these results, we started to develop a continuous Affect Space for our robot by "blending" key poses to generate new expressions (Beck, Hiolle, et al., 2010). The resulting system maps static key poses into a continuous dimensional model of emotion. Empirical results regarding the interpretation of the static key poses generated by this Affect Space can be found in (Beck, Hiolle, et al., 2010). While some of the expressions were clearly recognized, our results also show that some of the generated key poses are ambiguous and do not convey a clear emotion. In addition, feedback from people interacting with the robot indicated that they found it too static, which might have a negative impact on the perception on the

\footnotetext{
\({ }^{3}\) In particular, the collar joint angle was also found to be salient to the expression of emotion through body posture.
}
robot and hence on the interaction. This led us to hypothesize that the addition of dynamic aspects to the key poses could greatly improve the understanding and believability of the expressions

\section*{Animating Emotional Key Poses Using Perlin Noise}

To endow the key poses with a dynamic dimension, we added Perlin noise \({ }^{4}\) (Perlin, 1990) to them. In animation, Perlin noise-a coherent noise that is highly controllable-is a wellknown tool used to procedurally generate movements and increase the lifelikeness of animations. It presents the advantages of being simple and computationally cheap, which are important factors for implementation on a robotic platform. Moreover, the parameters used to generate it can be modulated, resulting in different types of animations. Perlin noise can be used to modify movement but also to create different types of non-repetitive and "idle" behaviors, as well as to generate textures. In robotics, Perlin noise and similar methods have also been used, applied to joint angles, to increase the lifelikeness of robot movements and to generate idle behaviors (Snibbe, Scheeff, \& Rahardja, 1999; Ishiguro, 2005).

Going beyond standard practice, in the work reported in this paper we have used Perlin noise to generate all the movements of the robot, rather to simply modify existing trajectories. The addition of Perlin noise values to the current joint angles produces a Perlin noise-based animation for the current pose of the robot. Although this step has not been validated with formal perceptual studies, the movements generated have been successfully used as idle behavior in empirical interaction studies with children carried as part of the ALIZ-E project (Nalin et al., 2012).

\section*{Using Perlin Noise to Express Emotions}

Following a "deep" approach to emotion modeling (Cañamero, 2008), affective expression in our robot is driven by the dynamics of the internal "affective state" of the robot in its interaction with the world. Consequently, movements produced by Perlin noise can be modulated by the internal state of the robot and used as a tool to express emotions. This novel use of Perlin noise can potentially be a powerful tool to create more subtle expressions in robots, since it permits to procedurally create non-repetitive body movements that convey different emotions or nuances of the same emotion. Another advantage of our approach is that such expression would not be limited to a single platform and could be reused across different robots-both humanoid and non-humanoid.

One of the main challenges posed by the use of Perlin noise to express emotions is to find a mapping between the parameters used to generate the noise and the emotion to be conveyed. In our model, we used the following mappings:
- Velocity was mapped to the time taken by the robot to move, i.e., the shorter the time the higher the velocity.

\footnotetext{
\({ }^{4}\) See http://freespace.virgin.net/hugo.elias/models/ m_perlin.htm for a description of the method used.
}

This mapping was chosen, rather than directly using the speed of the motors, due to constraints imposed by our robot. However, it should be noted that the actual velocity of the movement also depends on the amplitude of the noise, since the time is kept constant but the amplitude varies. Based on the existing literature, we expected that this parameter would have a significant effect on the perception of the emotion as it is related to Quantity of Motion (Camurri, Mazzarino, \& Volpe, 2003), Speed (Roether, Omlor, Christensen, \& Giese, 2009; Bernhardt, 2010) and Activation (Wallbott, 1998; Hartmann, Mancini, Buisine, \& Pelachaud, 2005).
- Jerkiness was introduced by applying random variations to the duration parameter, slightly modifying the interval of update of the joint angle. The literature suggests that jerkiness has a strong effect on the expression of emotion (Hartmann et al., 2005; Lee, Park, \& Nam, 2007; Bernhardt, 2010)

\section*{The Experiment}

To assess the potential of using Perlin noise to express emotions in robots, we designed a study to investigate the relation between characteristics of the movements generated using Perlin noise and the perceived emotion.

Independent Variables: Three independent variables were manipulated: Emotional Key Pose, Velocity and Jerkiness.
- Key Pose had five different values that corresponded to the different emotions tested.
- Velocity had three levels and described how fast the robot moved.
- Jerkiness had two levels. In the Jerky condition, the velocity of each movement (generated using Perlin noise) was multiplied by a random value between 0.5 and 1.5 ensuring that the mean of the velocity remained the same but introducing variation of speed during the animation. In the Regular (non-Jerky) condition, the speed (given by the Velocity condition) remained constant throughout the whole animation.

This resulted in 35(5 KeyPoses \(* 3\) Velocity \(* 2\) Jerk +5 static \()\) animations tested.

Dependent Variables: Perception of emotion was defined in terms of Emotional Label, Valence and Arousal.

\section*{Participants}

20 Participants were recruited, mostly members of staff of the University of Hertfordshire ( 9 females and 11 males) ranging in age from 18 to \(55(\mathrm{M}=29.31, \mathrm{SD}=11.93)\).

\section*{Apparatus}

Five key poses were selected from previous studies (Figure 1): two positive, two negative and one neutral that had been

Figure 1: The five key poses (from left to right: sadness, anger, neutral, pride, happiness)

recognized well above chance level in previous studies (Beck, Cañamero, \& Bard, 2010; Beck, Hiolle, et al., 2010). To ensure stability, the robot was sitting and only the joint angles of the upper body were modified while changing key pose. The animations were generated by adding Perlin noise to the joints of the upper body (as described above).

\section*{Procedure}

The same experimenter tested all participants individually. Once each participant had given consent at the beginning of their session, they were given standardised explanation regarding the questionnaire that they were expected to answer and were instructed to imagine that the robot was reacting to something. In this context, Valence was defined as the extent to which this "something" was positive or negative, and Arousal was defined as the level of energy (low to high energy).

After confirming that they understood all the questions, participants watched and assessed the 35 animations. Each animation was displayed only once in a randomized order different for each participant. A distance was introduced to avoid having the same pose coming twice in a row. Each time, the robot took a pose and displayed an animation during 15 seconds and returned to a non-expressive key pose (a second neutral pose) until the participant answered. For each animation, participants were asked to describe the animation using their own terms and eventually choose an emotion label from a list of six emotions. The list was comprised of Anger, Sadness, Fear, Neutral, Pride, Happiness and Excitement. Participants completed ratings of Valence and Arousal on a 10 -point Lickert scale. After all the poses had been assessed, participants were fully debriefed. Each session lasted approximately 30 minutes.

\section*{Results}

Since this experiment uses a modified set of key poses (unlike in the test of the static key poses, here the robot is sitting), it was necessary to validate the material created for this study.

\section*{Validation of the Sitting Key Poses}

Recognition rates showed that it was possible for participants to correctly identify the different static key poses far above chance level (Chance level would be \(17 \%\) ). Thus, it was possible for participants to identify the static key poses displayed (Table 1).

Table 1: Recognition rate of the Key Poses with and without added movements
added movements
\begin{tabular}{|l|l|l|l|}
\hline Emodion & Recognition Rate Static & Recog. Rate with Movement & Best Condition \\
\hline Sadness & \(84 \%\) & Slow Regular \\
\hline Anger & \(42 \%\) & \(68 \%\) & Fast Regular \\
\hline Pride & \(63 \%\) & \(68 \%\) & Medium Regular \\
\hline Happiness & \(99 \%\) & \(74 \%\) & Fast Jerky \\
\hline Neutral & \(84 \%\) & \(95 \%\) & Medium Regular \\
\hline
\end{tabular}

Figure 2: Effect of Changing the Key Pose on Valence

As part of the validation of the material, a two-ways (static vs. highest recognition rate) Repeated Measures ANOVA was conducted on the total Number of Correct Interpretations comparing the static display and the highest recognition rate with movement for each emotion. This was done to check that it was possible to increase the recognition rate by adding movements generated with Perlin noise in at least one condition for the different key poses. The results show that this was the case \(\left(F(1,18)=9.08, p<0.01, \eta^{2}=0.33\right)\). Table IV also highlights the recognition rates as well as the conditions in which the highest recognition rates were obtained.

In the following sections, the data was analysed using 5(Key Pose)*3(Velocity)*2(Jerkiness) Repeated Measures Anovas on the dependent variables. It should be noted that since they do not have a Jerkiness condition, the static poses were not included in these tests.

\section*{Effect of Changing the Key Pose Displayed}

Effect on the Number of Correct Interpretations As expected, Key Pose had a significant effect on the Number of Correct Interpretations \((F(4,72)=6.89, p<\) 0.01 , partial \(\eta^{2}=0.99\) ). This indicates that overall, when displayed with movements, the key poses were not all equally well recognized. Post-Hoc tests (Least Significant Difference) showed that the poses for Sadness and Pride were recognized better than the others \((p<0.01)\).

Effect on Valence Key Pose had a significant effect on Valence \(\left(F(4,72)=33.26, p<0.01\right.\), partial \(\left.\eta^{2}=0.65\right)\). Post-hoc tests (Least significant Difference) showed that the pose for Sadness was perceived as more negative than the rest of the poses ( \(p<0.01\) for all of them). The key pose for Anger was perceived as more negative than Happiness

Figure 3: Effect of Changing the Key Pose on Arousal

( \(p<0.01\) ) and Pride \((p<0.01)\). There was however no significant difference between Anger and Neutral \((p=0.29)\). Pride was perceived as significantly more positive than the rest of the key pose ( \(p<0.05\) for all of them). Happiness was perceived as significantly more positive than Sadness ( \(p<0.01\) ), Anger ( \(p<0.01\) ) and Neutral ( \(p<0.05\) ) (Figure 2)

These results indicate that participants' perception of Valence was affected by the Key Pose being displayed. Overall, negative key poses were interpreted as such and positive key poses were interpreted as positive (Figure 2).

Effect on Arousal Key Pose had a significant effect on Arousal \(\left(F(4,72)=13.29, p<0.01\right.\), partial \(\left.\eta^{2}=0.42\right)\). Post-Hoc tests(Least Significant Difference) showed that Sadness was perceived as less aroused than Anger ( \(p<0.01\) ), Pride \((p<0.01)\), and Happiness \((p<0.05)\). There was no significant difference between Sadness and Neutral ( \(p=\) 0.21 ). Anger was perceived as more aroused than Neutral ( \(p<0.01\) ). However, there was no significant difference with Happiness \((p=0.26)\) and Pride \((p=0.37)\). Pride was perceived as less aroused than neutral \((p<0.01)\). There was a trend toward Pride being perceived as less aroused than Happiness \((p=0.06)\).
These results indicate that perception of Arousal was affected by the key pose being displayed (Figure 3).

\section*{Effect of Velocity}

Effect on Interpretation Velocity had a significant effect on the number of correct interpretation \((F(2,36)=\) 11.02, \(p<0.01\), Partial \(\left.\eta^{2}=0.98\right)\). This effect was further investigated while looking at the interactions between the dependent variables.

Effect on Valence Although it did not reach significance, there was a trend of Velocity affecting Valence \((F(2,36)=\) \(3.14, p=0.06\), partial \(\eta^{2}=0.15\) ). Post-Hoc tests (Least Significant Difference) showed that there was a trend of Slow movement perceived as less positive than Fast \((p=0.07)\). There was no difference between the Slow and Medium con-

Table 2: Effect of Velocity and Jerkiness on Interpretation per Key Pose
\begin{tabular}{|c|c|c|}
\hline Key Pose & Effect of Velocity & Effect of Jerkiness \\
\hline Sadness & \[
\begin{aligned}
& F(2,34)=5.34, p<0.05, \eta^{2}=0.24 \\
& \text { Slow }>\text { Medium }(p<0.05) \\
& \text { Slow }>\text { Fast }(p<0.01) \\
& \text { Medium }=\text { Fast }(p=0.31) \\
& \hline
\end{aligned}
\] & \[
\begin{aligned}
& F(1,17)=11.73, p<0.01, \eta^{2}=0.41 \\
& \text { Regular }>\operatorname{Jerki}(p<0.01)
\end{aligned}
\] \\
\hline Anger & \[
\begin{aligned}
& F(2,34)=6.21, p<0.01, \eta^{2}=12.43 \\
& \text { Fast }>\text { Medium }(p<0.05) \\
& \text { Fast }>\operatorname{Slow}(p<0.01) \\
& \text { Medium }=\operatorname{Slow}(p=0.45)
\end{aligned}
\] & \(F(1,18)=0.79, p=0.39, \eta^{2}=0.04\) \\
\hline Neutral & \[
\begin{aligned}
& \left.F(2,36)=48.69, p<0.01, \eta^{2}=0.73\right) \\
& \text { Slow }>\operatorname{Fast}(p<0.01) \\
& \text { Medium }>\operatorname{Fast}(p<0.01) \\
& \text { Slow }=\operatorname{Medium}(p=0.1) \\
& \hline
\end{aligned}
\] & \(F(1,18)=0.00, p=1, \eta^{2}=0.00\) \\
\hline Pride & \[
\begin{aligned}
& F(2,36)=17.95, p<0.01 \eta^{2}=0.50 \\
& \text { Slow }>\text { Fast }(p<0.01) \\
& \text { Medium }>\text { Fast }(p<0.01) \\
& \text { Slow }=\text { Fast }(p=0.19)
\end{aligned}
\] & \(F(1,18)=1.09, p=0.31, \eta^{2}=0.06\) \\
\hline Happiness & \[
\begin{aligned}
& \left.F(2,36)=5.36, p<0.01, \eta^{2}=0.23\right) \\
& \text { Fast }>\operatorname{Slow}(p<0.01) \\
& \text { Fast }=\operatorname{Medium}(p=0.09) \\
& \text { Medium }=\operatorname{Slow}(p=0.17) \\
& \hline
\end{aligned}
\] & \(F(1,18)=1.20, p=0.29, \eta^{2}=0.06\) \\
\hline
\end{tabular}
ditions ( \(p=0.34\) ). The Medium condition was perceived as significantly less positive than the Fast condition ( \(p<0.05\) ).

These results indicate that the fast movement condition was perceived as more positive than the other two.

Effect on Arousal Velocity had a significant effect on Arousal \(\left(F(2,36)=93.60, p<0.01\right.\), partial \(\left.\eta^{2}=0.84\right)\). Post-Hoc tests (Least Significant Difference) showed that the Slow condition was perceived as less aroused than the Medium condition \((p<0.01)\) which in turn was perceived as less aroused than the Fast condition \((p<0.01)\).

These results indicate that overall the faster the movement is, the more aroused the expression is perceived.

\section*{Effect of Jerkiness}

Effect on Interpretation There was a trend of Jerky being more correctly interpreted than the same display in the Regular condition \(\left(F(1,18)=4.21, p=0.55\right.\), partial \(\left.\eta^{2}=0.49\right)\). This was further explored while considering the interactions between the dependent variables.

Effect on Valence Jerkiness had no significant effect on Valence \(\left(F(1,18)=0.26, p=0.62\right.\), partial \(\left.\eta^{2}=0.01\right)\). These results indicate that overall, participants' perception of Valence was not affected by the Jerkiness of the movements.
Effect on Arousal Jerkiness had a significant effect on Arousal \(\left(F(1,18)=27.51, p<0.01\right.\), partial \(\left.\eta^{2}=0.60\right)\).

Post-Hoc tests showed that the "Jerky" condition was perceived as more aroused than the Regular one ( \(p<0.01\) ).

\section*{Interaction between the independent variables}

Interpretation There was an interaction between Key Pose and Velocity of movements over the Number of Correct Interpretation \(\left(F(8,144)=13.15, p<0.01\right.\), partial \(\left.\eta^{2}=1\right)\). Similarly, there was an interaction between Key Pose and Jerkiness \(\left(F(4,72)=2.54, p<0.05\right.\), partial \(\left.\eta^{2}=0.69\right)\). This indicates that the interpretation of emotion depended both on the Key Pose being displayed, on the Velocity of movement and on the Jerkiness. This was further investigated using repeated measures ANOVAs on the different Key Pose and Ve-

Table 3: Effect of Velocity on Valence per Key Pose Displayed
\begin{tabular}{|l|l|}
\hline Key Pose & Repeated Anovas \\
\hline Sadness & \(F(2,36)=0.43, p=0.65\), partial \(^{2} \eta^{2}=0.02\) \\
\hline Anger & \(F(2,36)=1.46, p=0.25\), partial \(\eta^{2}=0.08\) \\
\hline Neutral & \(F(2,36)=0.86, p=0.43\), partial \(\eta^{2}=0.05\) \\
\hline Pride & \(F(2,36)=1.57, p=0.22\), partial \(^{2}=0.08\) \\
\hline Happiness & \begin{tabular}{l}
\(F(2,36)=10.24, p<0.01\), partial \(^{2} \eta^{2}=0.36\) \\
Fast \(>\operatorname{Slow}(p<0.01)\) \\
Fast \(>\) Medium \((p<0.01)\) \\
Medium \(=\operatorname{Slow}(p=0.33)\)
\end{tabular} \\
\hline
\end{tabular}
locity conditions (Table 2). Table 2 shows that the highest recognition rate for Sadness was with Slow and Regular movements, for Anger, it was with Fast movements (no effect of jerkiness), neutral was better interpreted with Slow and Medium speed. Pride was better interpreted at Slow and medium speed. For Happiness, it was with Fast and Medium speed.
Valence There was a significant interaction between Velocity and Key Pose on Valence \((F(8,144)=5.85, p<\) 0.05, partial \(\left.\eta^{2}=0.11\right)\). This indicates that the effect of Velocity depends on the Key Pose. This was therefore investigated in details using 3(Velocity) Repeated Measure Anovas on the different Key Pose individually (Table 3).
Arousal There was a significant interaction between Key Pose and Velocity on Arousal \((F(8,144)=5.81, p<\) \(0.01, \operatorname{partial} \eta^{2}=0.24\) ). Repeated Measures Anovas were therefore conducted on the different Key Pose conditions separately. The results of these showed that the pattern were constant for all of them and that the Fast condition was perceived as more aroused than the Medium condition ( \(p<0.01\) for all the Key Poses) which in turn was perceived as more Aroused than the Slow condition ( \(p<0.01\) for all the Key Pose).

\section*{Discussion}

Valence and Arousal As expected, Key Pose had a strong effect on Valence and Arousal. More precisely, the perceived Valence and Arousal were consistent with the respective positions of each Key Pose within the Affect Space (Figures 2 and 3). Moreover, Velocity had a marginal effect on Valence. However, the interactions between Velocity and Key Pose suggest that the difference in Valence was due to the key pose for happiness (Table 3) as it was found that for all the other key poses, Velocity had no effect on Valence. Similarly, Jerkiness did not affect the perceived Valence of the display. This is consistent with existing results in psychology which suggest that Arousal is a formless cue that relates directly to the movement kinematics while Valence seems to be related to the relations between the different limb segments (Pollick, Paterson, Bruderlin, \& Sanford, 2001).
However, both Velocity and Jerkiness were found to increase the perception of Arousal. Taken together, the results suggest that the perceived Valence depended on the Key Pose displayed without taking into account the different dynamic conditions. In contrast, the perceived Arousal depended on all three dependent variables. Hence, participants relied only on the body posture to assess Valence. However, all the inform-
ation available (Key Pose, Velocity and Jerkiness) was used to rate Arousal.

Interpretation Participants were able to correctly identify the different static key poses. Whilst the recognition rate for Anger was lower than for the other key poses, it was still above chance level. This low recognition rate could be due to the modification done to the material as the robot was sitting down. The key pose was better recognised in previous experiment with the robot standing up (Beck, Stevens, Bard, \& Cañamero, 2012) and the lack of significant difference between the key poses for anger and neutral on Valence that was found in this study could be due to the key pose for anger being misinterpreted in most of the conditions. This will have to be investigated in future work.

Moreover, when compared with static poses, the recognition rates for the display with movements clearly show that adding appropriate dynamic elements improves significantly the expressivity of the key pose (Table 1). Although it was not possible to capture this statistically, Velocity seems to have a consistent effect on interpretation. For instance, the key pose for sadness was interpreted as sad in slow motion (resulting in the very high recognition rate in this condition); however, as the Velocity increased, it shifted toward anger and frustration. This is consistent with the results found with regards to the effect of Velocity on Valence (Table 3) which show that, with the exception of happiness, Velocity had not effect on Valence. Thus, these shifts in interpretation can be explained by the effect of Velocity on Arousal. In other words, a negative expression, remains negative, but its level of Arousal increases along with Velocity shifting from sadness to anger and frustration. The interpretations of the key poses were affected by the Velocity and the Jerkiness of the movements. More precisely, the dependence between Key Pose and Velocity with regards to the interpretation shows the importance of matching the Velocity and the Jerkiness of movements to the Key Pose in order to express specific areas of the Affect Space. The drop in recognition for Sadness in the Jerky condition suggests the importance of regular movement for this expression.

Even though pride was correctly labeled, the rating of Arousal was higher than what could have been expected. This was also the case in (Beck, Cañamero, \& Bard, 2010) and could be due to this specific posture. It could also be related to the physical aspect of the Nao robot, as the arm joints are very salient in this key pose.

Limitations and Future Work It is important to highlight that the key poses used for this study are prototypical and were intentionally selected to be expressive. This is appropriate and beneficial for the development of an expressive system. However, it is likely that the use of prototypical expressions had an effect on the results found in this study. Moreover, the Jerkiness condition could have been implemented by manipulating the number of Harmonics and the Frequency of the noise. This could result in different visual
results with different effects on the perception of emotion. It should also be noted that Perlin noise does not capture the relationship that exists between the rotation of one joint and another. This may result in unrealistic animations (Egges \& Magnenat-Thalmann, 2005). Although this did not seem to be the case in this study as the material was carefully checked, it could still have affected the results.

This study did not consider the effect of context on the perception of the body language displayed. However, it can be argued that interpretation of emotion is context dependent and that changing the context could change the perception of the expressions generated by this Affect Space. On the other hand, work on facial expressions of emotion has shown that at least for a few basic emotions, context is not necessary to identify the expressed emotion. In other words, the expression of an emotion is to a certain extent independent from the context, as evidenced by the widespread use of FACS. Similarly, the high recognition rates obtained in this study suggest that these expressions could convey the intended emotion in different contexts. However, people's reaction to the emotional expression are likely to differ. This will be investigated as part of the ALIZ-E project.

\begin{abstract}
Recent evidence shows tense-response compatibility effects only when the task relates to sentence tense (Ulrich \& Maienborn, 2010). In two eye-tracking experiments, we investigated tense-response compatibility effects. In our first experiment (E1, where sentence tense was relevant to the task) we found compatibility effects at the beginning of the sentence (e.g., Yesterday versus Tomorrow), which shifted to interference effects by sentence end. Overall, we also found compatibility effects in response times, replicating Ulrich and Maienborn. Both compatibility effects in Experiment 1 (E1) were stronger for low- compared to high-WM readers. In Experiment 2 (E2, where tense was irrelevant), we found compatibility effects for high-WM readers, but only in early reading measures. These results suggest that compatibility effects are weaker depending on the task, but not eliminated; an implication which may help refine a strict view of embodied cognition.
\end{abstract}

Keywords: Mental timeline, embodiment, individual differences, eye-tracking.

\section*{Introduction}

Research over the last decade has continued to refine embodiment theory (Barsalou, 1999; Glenberg, 1997), and this refinement was prodded along by criticism (Machery, 2007; Mahon \& Caramazza, 2008). For example, Mahon \& Caramazza argued that embodiment theory could not adequately explain how JUSTICE and other abstract concepts are understood through bodily experience because they do not reliably correspond to sensory or motor information. However, conceptual metaphor theory has laid out the groundwork for how abstract concepts such as TIME are mapped onto concrete concepts such as SPACE (Lakoff \& Johnson, 1980; 1999). Torralbo, Santiago, \& Lupiáñez (2006) found evidence that corroborated this potential mapping mechanism. In their Experiment 1, participants saw the silhouette of a human head looking either rightward or leftward on a screen. A word with a temporal connotation in a speech bubble was presented either in front of or behind the silhouette. Participants judged whether the person represented via the silhouette was contemplating the past or the future. When a past word appeared on the left, responses were faster than when it appeared to the right; when a future word appeared on the right side, responses were faster than
when it appeared to the left (this interaction of responselocation with tense has been credited to a 'mental timeline', i.e., the use of a spatial left-right line to represent time in our mind). These results suggest that left- and right-hand response preparation interacts with linguistic temporal cues (past and future tense respectively). Thus it appears that abstract concepts such as TIME are grounded in experiential and bodily schemas. Meanwhile, the focus of inquiry in this area has changed from whether grounding effects occur for abstract concepts to how rapidly they occur and whether they are task-dependent. In addition, the role of participants’ working memory in these kinds of congruence effects is unclear. To contribute to these research questions we examined the time course of time- response location congruence effects during sentence comprehension as (low and high working memory) participants planned a right or left hand movement in two different tasks. Below we motivate in more detail the investigation of tense-response location congruence effects are modulated by task and working memory.

\section*{Accommodating tense-response-location congruence effects}

Task appears to play an important role for tense-response location congruence effects. In a recent study, compatibility effects of tense (e.g., past versus future) and left/right response locations were eliminated in a task where tense was irrelevant. When participants paid attention to sentence tense, tense-response location compatibility effects emerged. For example, participants pressed a button labeled Past on the left in response to a past tense sentence more quickly than when the Past button was on the right. A similar compatibility effect was found for future-tense sentences and right-hand responses. However, when the task was time-irrelevant (sentence-sensibility judgments), compatibility effects were eliminated, suggesting that timeresponse location compatibility effects occur only when people pay attention to time. If that were the case, then both embodied (e.g., Barsalou, 1999) and non-embodied accounts such as amodal symbol systems (Collins \& Loftus, 1975, Collins \& Quillian, 1969) could accommodate these results. Non-embodied accounts could accommodate the
results via a traditional spreading activation network composed of disembodied, or amodal, symbols. A similar reasoning has been proposed for emotion and embodiment, but it was ruled out as it was shown that compatibility effects between emotional sentences and facial expression were task-independent (Glenberg, Havas, Becker, \& Rinck, 2005). Nevertheless, the lack of tense-response compatibility effects in a time-irrelevant task (Ulrich and Maienborn, 2010) left the door open for accounts via hybrid embodiment theories (Mahon \& Caramazza, 2008; Louwerse \& Jeuniaux, 2008) or via cross-modal integration (Kemmerer \& Gonzalez-Castillo, 2010).

There are at least two key differences between hybrid embodiment accounts and views of embodiment in which mental representations are strictly composed of perceptual symbol systems (henceforth 'strict embodiment'). First, hybrid accounts argue that the hierarchical processing of amodal symbols occur before additional top-down context from perceptual symbols (Kemmerer \& Gonzalez-Castillo, 2010) and this takes more time than a direct mapping of TIME onto SPACE. Second, strict embodiment proposes automaticity (Glenberg, 1997, p4). Automaticity refers to whether the sensorimotor system is involved in processing the meaning of abstract concepts (temporal cues in a sentence) regardless of task. Strict embodiment would thus have predicted task-independent activation of the mental timeline. Ulrich \& Maienborn's results of task-dependent tense-response location compatibility effects appeared to support a hybrid view of embodiment; however, they did not explicitly address the implications of their findings for this debate. Moreover, we cannot be certain that the lack of tense-response location compatibility effects with timeirrelevant tasks is at least in parts due to the coarse-grained response time measure they used. By monitoring eye movements during reading in addition to response times at sentence end in the same tasks that they used, we can assess the time course of tense-response location compatibility effects and determine whether the null findings are due to the nature of the measure.

\section*{Working memory and embodiment}

Strict embodied cognition draws on attention and memory functions (Barsalou, 1999; Glenberg, 1997). For example, Glenberg and Gallese (2010; Koziol, Budding, \& Chidekel, 2011) argued that higher order processes such as executive function are for motor control, and also part of language comprehension (see Repovš \& Barch, 2012 for a possible link between working memory (WM) and cerebellum function). However, the notion of working memory as an important component of theories in cognitive psychology (see Baddeley, 2012 for a review) and psycholinguistics (Huettig, Olivers, \& Hartsuiker, 2011; Lewis, Vasishth, \&

Van Dyke, 2006), has been studied very little by strict embodiment theorists like Glenberg or Barsalou \({ }^{1}\).

Due to the scarcity of research on embodiment and working memory, we drew from work on temporal order and working memory (Münte, Schiltz, \& Kutas, 1998). This previous research suggested that participants with high-WM used temporal cues such as Before versus After immediately to aid sentence processing. For example, in the following sentences, the initial temporal adverb and verb tell the reader that this sentence describes an event that occurred in the past (1) or the future (2):
(1) Früher in dieser Woche ADV \(\mid\) faltete \(_{\mathbf{V P}} \mid\) Jennifer \(_{\text {NP1 }}\) im Wohnzimmer \({ }_{\mathbf{P P}} \mid\) die Wäsche \({ }_{\mathbf{N P 2}}\).
\({ }^{\prime}\) Earlier this week \({ }_{\mathbf{A D V}} \mid\) folded \(_{\mathbf{V P}} \mid\) Jennifer \(_{\mathbf{V P}}\) in the living room \(_{\mathbf{P P}} \mid\) the laundry \({ }_{\mathbf{N P 2}}\) '.
(literal translation).
(2) Später in dieser Woche \(_{\text {ADV }} \mid\) faltet \(_{\mathbf{V P}} \mid\) Jennifer \(_{\mathbf{N P} 1}\) im Wohnzimmer \(_{\mathbf{P P}} \mid\) die Wäsche \(_{\mathbf{N P} 2}\).
\({ }^{\prime}\) Later this week \({ }_{\mathbf{A D V}} \mid\) folds \(_{\mathbf{V P}} \mid\) Jennifer \(_{\mathbf{V P}}\) in the living \(\operatorname{room}_{\mathbf{P P}} \mid\) the laundry \({ }_{\mathbf{N P 2}}\) '.

It would be consistent with the findings of Münte, Schiltz, and Kutas (1998) if high- (but not low) WM immediately processed the temporal cue 'Earlier / Later'. A question that could be asked with respect to the role of working memory in embodied cognition is whether participants immediate integrate temporal cues in addition to response-location as they make a sensibility judgment about a sentence.

\section*{The present study}

Using eye-tracking, the present studies thus investigated the time course of tense-response location compatibility effects as a function of (a) task (time-focus vs. no time focus), and (b) participants' working memory. The use of eye tracking and a between-experiment task manipulation permitted us to test the strict embodied hypothesis.

In Experiment 1, participants performed a tense evaluation task (was the sentence in the past or in the future)? One gaze pattern in support of strict embodiment would be an early-peaking, quickly decaying Simon-like effect consistent with the action and perception literature (Symes, Tucker, \& Ellis, 2005). This pattern would suggest both a rapid (tied to first-pass measures) and automatic (insensitive to task) tense-response location congruence effects in first-pass times at the verb and potentially also the

\footnotetext{
\({ }^{1}\) We would like to thank an anonymous reviewer for suggesting the Coherent Working Models theory proposed by Santiago and colleagues. Unfortunately, due to time and page limit constraints, we have not integrated their proposal with our current framing or the discussion of our results. However, we will review the data supporting the Coherent Working Models theory, and how well our results fit with it in an extended manuscript in preparation.
}
next sentence region. If it is rapid and automatic but quickly decays, then there may be no effect in a relatively late and course-grained measure such as response times. By contrast, the amodal views would predict no tense-response compatibility effect for time-irrelevant tasks: symbols representing the concepts of FUTURE and PAST would not become bound to right and left procedural symbols and in turn not become activated. Hybrid accounts, would predict task-independent effects but these should occur later than in strict embodiment accounts.

We further hypothesized that high-WM readers would rapidly process the sentence-initial temporal cue (see Münte, Schiltz, \& Kutas, 1998). In order to come up with a hypothesis regarding working memory and tense-response location congruence effects, we drew from one of the more important ideas in embodied cognition which is that people can "offload" cognition to the environment (Clark, 1997; Spivey, 2008). To the extent that cognitive load can be offloaded onto the environment, a left-right mental timeline in which left indexes the past and right the future could assist in processing temporal information. And if the results from Münte et al. generalize to tense-response location congruence effects, then high-WM participants should process tense-response location congruence earlier. We predicted longer first-pass times in the subject noun phrase region (NP1 in sentences (1) and (2)) for incompatible (vs. compatible) tense-response location for high-WM participants because the region is potentially where participants would shift their attention from the tense processing to the sensibility judgment. This effect could extend to the locative prepositional phrase region as well because the attention shift could take time even for highWM readers (see sentences (1) and (2)). By contrast, for low-WM readers congruence effects should emerge at the end of the sentence, because in Münte et al. low-WM readers did show evidence that they were processing the temporal cues but later than the high-WM readers. In response times, both groups should show a compatibility effect replicating Ulrich and Maienborn (2010).

When time is not relevant for the task (Experiment 2), and if the null effect in Ulrich and Maienborn is an artifact of the post-sentence response time measure, then we should see similar yet more subtle effects than in E1 (compatibility effects in first-pass times, potentially also earlier for highWM than low-WM readers). However, these patterns of reading times should not result in compatibility effects in response times based on the findings by Ulrich and Maienborn.

\section*{Experiment 1: Time-relevant task}

In Experiment 1, we replicated the procedure of the first experiment by Ulrich and Maienborn (2010). Participants were asked to pay attention to sentence tense and registered their decision via a button press if the sentence made sense. Thinking about time was part of the task because participants made explicit decisions about sentence tense.

\section*{Method}

Participants 48 members (17 male with mean age 24; \(S D=\) 3 years) of Bielefeld University participated in the experiment. All participants were native German speakers with no second language exposure prior to 6 years of age; had normal or corrected-to-normal vision; were naïve with respect to the purpose of the study; and received \(€ 6\) for their participation or course credit. All gave informed consent.
Materials Items consisted of 48 past and future tense sentences beginning with a temporal adverb and 48 nonsense sentences of the same syntactic structure The nonsense sentences included the same words as those used in Ulrich and Maienborn (2010), but were restructured to be similar to the critical sentences, where the temporal adverb was always at the beginning of the sentence.

Procedure Participants were asked to judge whether the sentence referred to the past or future. However, they were also asked to respond only if the sentence made sense (see Figure 1). For nonsense sentences, participants were instructed to wait until the trial timed out. Their eyemovements were recorded at 1000 Hz using an Eyelink 1000 desktop mounted tracker. Participants' WM was tested by the automated reading span test (Unsworth, Redick, Heitz, Broadway, \& Engle, 2009).

Figure 1: Example trial from E1.

\section*{Analysis}

Prior to analysis fixations were cleaned using a 4-stage procedure. In the first stage fixations less than 80 ms were merged with the nearest neighboring fixation if it was longer than 80 ms and within 0.5 degrees of visual angle away along the \(x\)-axis. Similarly, in the second stage fixations less than 40 ms were merged with the nearest neighboring fixation if it was longer than 40 ms and within 1.25 degrees away along the \(x\)-axis. In stage 3 , every interest area was checked for at least three fixations less than 140 ms and none larger than 140 ms . If an interest area was found that met these criteria, these fixations were merged with the larger ones. Lastly, all fixations less than 80 ms and 1200 ms were
removed. Trials with incorrect answers and nonsense sentences were not analyzed. Participants were split into high- and low-WM groups using a tertile split forming three groups of 16 people each, but only the high- and low-WM groups were included in order to do an extreme groups analysis. We conducted a 2 (WM) x 2 (tense) x 2 (response location) linear mixed effects model analysis to test for tense-response compatibility effects in each sentence region; starting with the full model and removing parameters until we found the most parsimonious model that best fit the data (Baayen, Bates, \& Davidson, 2008) \({ }^{2}\).

\section*{Results}

There were no significant effects in first-pass reading times for any sentence region. In total dwell times in the sentenceinitial temporal adverb region, we found a significant tenseresponse compatibility effect, \(t(30)=-2.16, p<0.05\) (see Fig. 2). Further, low-WM readers showed the compatibility effect, whereas high-WM readers did not, as evidenced by a 3-way interaction, \(t(30)=2.22, p<0.05\) (see Fig. 3). Surprisingly, interference effects emerged at sentence end for both groups, \(t(30)=2.08, p<0.05\) (see Fig. 4). In response times, we replicated the congruence effect from Ulrich \& Maienborn, (2010), \(t(30)=-3.87, p<0.05\). However, the congruence effect was driven by the low-WM group as evidenced by a 3-way interaction, \(t(30)=2.71, p<\) 0.05 (see Fig. 5).

Figure 2: Tense-response location compatibility effects for both WM groups for total dwell times in the temporal adverb region. Error bars indicate the standard error (SE).

\footnotetext{
\({ }^{2}\) Thank you to an anonymous reviewer for pointing out the fact that eye-tracking researchers enjoy many degrees of freedom in their research (e.g., regions of interest, first-pass readings versus total times, etc...). And further that our effects are quite small and potentially would not stand up to Bonferroni correction. Because we are in a crisis in psychology of false positives and failures to replicate, we used linear mixed effect models, backward model selection, and report the pMCMC values (Barr, Levy, Scheepers, \& Tily, 2013).
}

Figure 3: Tense-response location compatibility effects for low- (left) and high-WM (right) groups for total dwell times in the temporal adverb region. Error bars indicate the \(S E\).

\section*{Discussion}

The response time results from Experiment 1 replicate prior tense-response location congruence effects in response times (Experiment 1 in Ulrich and Maienborn, 2010). However, the pattern of the compatibility effects over the course of the sentence, and as a function of working memory showed that there is more to the story. The response time compatibility effects in the low-WM group, but not the high-WM, are similar to the pattern for both groups. The same pattern can also be seen in the total reading times of the sentence-initial region (e.g., 'earlier' / 'later') for low-WM readers only.

Figure 4: Tense-response location interference effects in total times in the sentence-final region. Error bars indicate the \(S E\).

Figure 5: Tense-response location compatibility effects for low- (left) and high-WM (right) groups for response times. Error bars indicate the \(S E\).

Next, we attempted to replicate the procedure of Ulrich and Maienborn's (2010) Experiment 2 to assess whether we would find early compatibility effects undetectable in fullsentence response time, and how that may vary as a function of working memory ability. Participants' task was to make a
sentence-sensibility judgment, and then press a button to indicate their decision. In this case thinking about time is irrelevant to the task, because it is not the decision that participants have been asked to make about the sentence.

\section*{Experiment 2: Time irrelevant task}

\section*{Method}

Participants We tested a further 48 students (11 male with the mean age of 23; \(S D=3\) years) who met the same criteria as those in E1.
Materials and Procedure The materials were identical to those in E1. Participants judged sentence sensibility, thus time, or tense, was irrelevant to the task (Fig. 5). This procedure is identical to the second experiment in Ulrich \& Maienborn (2010). Again, the only difference was that the sentences always had the same word order and always included a prepositional phrase after the verb.

Figure 6: Example trial from Experiment 2.

\section*{Results}

Data filtering and separating of participants into two WM groups was done in the same way as in E1. For first-pass reading times, we found a significant 3-way interaction in the verb region, \(t(30)=-2.07, p<0.05\) (see Fig. 7).

Figure 7: Sentence-tense compatibility effects for low- (left) and high-WM (right) groups for first-pass reading times in the verb region. Error bars indicate the standard error.

Next, both first-pass, \(t(30)=2.11, p<0.05\), and regression-path duration, \(t(30)=2.15, p<0.05\), revealed a significant interaction in the sentence-initial temporal adverb region. For both measures, durations were longer when the adverb indicated a past tense sentence and the participants were planning a left response compared to a right response, whereas for future-indicative adverbs there was no reliable difference between left and right response locations. Lastly, we replicated the absence of reliable
compatibility effects in response times for tense (see Figure 8 and Ulrich \& Maienborn, 2010).

Figure 8: This figure illustrates the absence of sentencetense compatibility effects for low- (left) and high-WM (right) groups in response times. Error bars indicate the \(S E\).

\section*{General Discussion}

Consistent with Ulrich and Maienborn (2010), we found compatibility effects in the response times when participants judged sentence tense (Experiment 1, E1) but not when they judged sentence sensibility (Experiment 2, E2). However, eye tracking revealed additional details about the time course and individual differences of the compatibility effects in E1 and the null finding in E2.
When the task was to decide on sentence tense (E1), we found compatibility effects in the earliest sentence region (e.g., 'Earlier'), but in a relatively "late" measure; in total times. This replicated the region of the sentences where temporal processing occurred, similar to Münte et al. (1998) but it is later in the time course than we initially predicted. In contrast to Rapid Serial Visual Presentation used by Münte et al., total times include re-readings and thus potentially later processes. One possible reason why compatibility effects emerge only at this region and not in the verb region is because that region is central to judging sentence tense, and foregrounds tense processing.

Two further unexpected findings in Experiment 1 were the sentence-final interference effect and that the response time compatibility effect was driven by the low-WM readers. The interference effect could index that as participants' prepare for the tense decision and gauge sensibility at the end of the sentence, they may momentarily inhibit temporal information. Because the temporal information has already been mapped into the environment, freeing up resources from WM needed for further language comprehension may be aided by the suppression of environmental patterns, in this case tense-response mappings (Glenberg, 1997, p4). The compatibility effects for low-WM readers at the sentence-initial temporal region are consistent with this idea: Perhaps low WM-readers are slower than high-WM readers to inhibit tense information, and thus show compatibility effect in total times at the sentence-initial region while these effects are absent for high-WM readers. The assumption here is that low-WM readers are slower because they have more difficulty updating their WM, which according to Glenberg is a conscious and effortful use of memory.

For Experiment 2, when the task did not involve a sentence-tense decision, we replicated the absence of a
tense-response location compatibility effect in response times (Ulrich \& Maienborn, 2010). By contrast, compatibility effects emerged as predicted at the verb region in first-pass reading times, but only for high-WM readers. The null effect for low-WM readers may indicate that unless the temporal information is part of the task, low WM readers do not integrate tense information in relation to response location.

Overall, thus, tense-response location compatibility effects varied as a function of task and comprehenders' working memory. Our findings highlight the importance of using continuous measures: While end-of-sentence response times suggested task can eliminate compatibility effects, these effects were clearly present in gaze measures during sentence reading even when the task did not ask participants to focus on tense cues. With regard to embodiment theory, it seems that tense-response location compatibility effects are not eliminated by tasks in which tense is irrelevant but there is a need to accommodate their variation by task and working memory.

\begin{abstract}
When a child first begins to acquire a lexicon, the sources of word-meanings must be available from the situational context. However, it has been argued that the situational availability of the meanings of relational terms, such as verbs, is lower than that of whole-object labels, such as nouns. In this paper, we present a corpus of child-directed language, paired with situational descriptions, that enables us to explore the situational availability of word-meanings using a computational learner.
\end{abstract}

Keywords: word learning; relational meaning; corpus development; computational modeling

\section*{Introduction}

However the lexical acquisition process in infants develops beyond the earliest stages, the seeds of the first word meanings must be found in the immediate situational context of early linguistic interaction (Gleitman, 1990). Bootstrapping these early meanings across a variety of situations, so-called cross-situational learning (Akhtar \& Montague, 1999), is one of the early cognitive tasks that children need to perform. For cross-situational learning to work, the situational contexts have to contain information that can be extracted and used to determine what the caregiver is likely referring to. However, relatively little is known about the information actually contained in situational contexts.

In this paper, we present a corpus of child-directed language in which the situational context, as found in the accompanying video material, is described in a precise, formalized manner. Not only have the basic-level categories of objects been coded, but also some of their properties and the observable relations among agents and objects. This annotated corpus enables us to explore the situational availability of these various sources of meaning using computational modeling techniques. As such, we demonstrate the use of computational models as a methodological tool to gain insight the information that children have available in their natural learning environment, and that can contribute to cross-situational learning of word meaning.

The process of cross-situational learning has been studied using a multitude of methodologies, each with its limitations. Experimental set-ups must trade off control of the stimuli with the naturalism of the interaction, and thus typically underestimate the complexity of the situations caregiver-child interactions normally take place in (as Medina, Snedeker, Trueswell, and Gleitman (2011) recently noted again). Some computational studies use child-directed language from transcribed child language corpora, which require the researchers to automatically enrich the corpora with artificial meaning representations (Fazly, Alishahi, \& Stevenson, 2010).

Interest has grown in the use of multimodal material for computational studies of word-meaning acquisition, since it contains language embedded in a video of the situation of its use. There have been experiments with virtual environments (Fleischman \& Roy, 2005), natural environments in which participants were asked to label objects and actions (Yu \& Ballard, 2003; Roy \& Pentland, 2002), and natural caregiver-child interaction (Roy et al., 2006; Frank, Goodman, \& Tenenbaum, 2009). Despite the greater potential for naturalistic data, these corpora also suffer from limitations. First, some only code whole-object labels, thus restricting themselves to the meaning of one sort of words, viz. nouns (Roy et al., 2006; Frank et al., 2009). In others, the language is not child-directed (Fleischman \& Roy, 2005; Yu \& Ballard, 2003), or the language and situation are unrealistically temporally aligned (Yu \& Ballard, 2003). In this paper, we also overcome the above limitations by developing a corpus of child-directed language paired with a precise description of the situational context. Unlike other corpora, the restriction of our corpus to a particular structured activity allows us to precisely describe situational aspects that are relevant to the meanings of various sorts of content words, although the resulting corpus is necessarily small.

One topic we explore in detail is the extent to which words with observable relational meanings (i.e., physical actions and spatial relations) can be bootstrapped from cross-situational learning. As Gentner (1978) argues, mapping words to relations is more difficult than to objects because relations can typically be construed in more ways. Gleitman (1990) shows how even observable relations are often not present at the time of uttering a word referring to them. This paper shows, using a different methodology, that relational terms are indeed harder to glean from the situational context.

\section*{A Situated Corpus of Child-Directed Language}

Our goal is to construct a corpus that contains situational information that is available to a learner and that can be used in learning the meaning of a variety of content words. For developing such a corpus, there are two requirements. At a minimum, in very early word learning at least, we assume that the information that contributes to a word's meaning must be situationally available - that is, the information must be reflected in the situation that is perceivable at or near the time that the word is uttered. But it must also be the case that the learner can process this information and understands its relevance to the interaction with an interlocutor-i.e., the information must be cognitively available as well.

In recent work on coding the available whole objects in
video data paired with child-directed language (Roy et al., 2006; Frank et al., 2009), generally only situational availability need be considered, because the cognitive availability of the objects is implicitly assumed. Turning to relational terms, as we do here, we must explicitly argue that the appropriate meanings are cognitively available, because of the evidence that gleaning the appropriate relational meanings from a situation is more difficult (cf., Gentner, 1978). Here we assume that, although child-caregiver interactions take place in the complex world of everyday life, cognitive availability of meanings for the child is eased (again, early on) because of the highly-structured nature of such situations, along with the joint attention caregivers and children share for their objects, relations, goals and consequences, which function to narrow down the set of meanings communicated (cf., Tomasello, 2003). Thus we focus the annotation on those meanings we argue to be cognitively available to the child, which are not all the objects and relations in the situation, but only the subset that pertains to the current activity.

The result is a corpus that provides information on both the situationally and cognitively available objects, properties of objects, and relations between objects. These annotations rely on relatively lean assumptions about the cognitive availability of this information. To the best of our knowledge, this is the first corpus that pairs observed objects, properties and relations with spontaneously produced language. As such annotation is costly, the corpus is necessarily small. It can, however, give us insight into the availability of the sources of lexical meaning in the situational context, and the problems a lack of availability may bring about. In that respect this small but naturalistic corpus complements earlier annotated corpora in enabling us to explore what is and is not available at the time some word is uttered.

The source of our material is a collection of 131 videotaped dyadic interactions (recorded for other purposes) between Dutch-speaking mothers and their 16-month-old daughters, containing activities such as playing games and eating. In the videos, each dyad played a game of putting variously-shaped blocks in a bucket with holes of matching shapes in the lid. A set of 32 block games ( 152 minutes of video) was selected for our annotation. The first author (a native speaker of Dutch) transcribed all speech according to CHAT-guidelines \({ }^{1}\), and two assistants coded the video data for the objects, properties and relations in the situations. The transcriptions contained 7842 word tokens ( 480 types) in 2492 utterances. The language mostly refers to aspects of the game.

The situational coding was done according to guidelines developed by the first author. As the situation consists of just one type of activity (playing the game), the set of objects, properties and relations is relatively limited. The most common objects are the bucket, lid, blocks, holes and the two participants, mother and child. The feature color=\{red, green, yellow, blue \(\}\) was coded for the blocks and the feature shape \(=\{\) square, round,

triangular, star\} for blocks and holes. The relations and their roles are in Table 1.

For every three-second interval of video, all coderobserved relations, their associated objects and their properties were coded. \({ }^{2}\) The actions (first four rows of Table 1) denote simple manual behavior, which we assume children can recognize (Baillargeon \& Wang, 2002). The spatial relations reflect basic categories of containment and support (in,on) and their negation (out,off), as well as two relations denoting non-containment and non-support contact (at) and nearness (near). Understanding basic spatial relations precedes the onset of meaning acquisition and can thus be assumed to be in place (Needham \& Baillargeon, 1993; Hespos \& Baillargeon, 2001), although many specifics may be languagespecific (Choi, 2006). \({ }^{3}\) The match or mismatch with a hole was furthermore inferred from these relations. Spatial relations were deemed salient if a change in the relation occurred (e.g., if a block was the Figure of an in-relation in the current interval, when it was not in the previous interval).

The coding procedure was evaluated for inter- and intracoder agreement (Carletta, 1996). All relations were coded reliably both within and between coders (Cohen's \(\kappa>0.8\) ), except position (intercoder: \(\kappa=0.51\), intracoder: \(\kappa=\) 0.47). When the coders disagreed, the first author decided the annotation. A sample of the resulting data is given in Table 2.

\section*{The Computational Model}

We use the probabilistic alignment-based word learning model of Fazly et al. (2010), which has been shown to perform well using naturalistic data. Using a computational model, we can manipulate input, and doing so, explore the situational and cognitive availability of information, as well as how changes in the input affect learning (Experiment 2).

The model incrementally takes as input a pair of an utterance (a set of words) and a situation (a set of primitive meanings). The learning algorithm has two phases. In the alignment phase, the words and meanings in the input are prob-

\footnotetext{
\({ }^{2}\) Using ELAN (Brugman \& Russel, 2004).
\({ }^{3}\) Ideally, one would encode the range of construals of a situation, including 'tightness-of-fit'. As a first attempt at relational coding of situations, we opted for convenient, yet widely known, universal notions like 'containment' and 'support'.
}

abilistically mapped to each other; this process is guided by the conditional probabilities of the meanings given the words ("the learned meanings"). Second, in the update phase the obtained alignments are used to update the word-meaning associations by adding the alignment score to the association. The word-meaning associations, next, are used to calculate the learned meanings, which are then used in the alignment phase of the next input. These probabilities are based on the association mass a meaning has for a word, relative to all other meanings associated with that word. For a formal explanation, we refer the reader to Fazly et al. (2010).

\section*{Experiment 1: Exploring the Corpus}

Using the computational model and the corpus, we aim to gain insight into questions such as: what kind of and how much information is derivable from the situational contexts? And is the information equally valuable for different kinds of words (relational words like verbs and prepositions, and non-relational words like adjectives and nouns)?

\section*{Running the Model}

A set of each utterance's lemmatized word forms is used as the linguistic input. As the model takes a set of primitive meanings as the other part of its input, we considered all content elements from the structured meaning annotation of the interval containing the start of the utterance as the set of situation primitives. An example of an input item is:

> Utterance: \(\{\) nee lieverd hier passen hij niet \}
> Situation: \{ point, mother, hole, triangular, child, position, block, yellow, near, round, mismatch \}

We set the two smoothing parameters of the model to reflect the size of the lexicon, as in Fazly et al. (2010).

\section*{Evaluation}

We need to understand how the model learns various types of words that refer to aspects of the situational context. To

Table 3: A sample of the lexicon of target words
\begin{tabular}{ll}
\hline type & examples \\
\hline action & duwen \(=\) force, halen \(=\{\) move, off, out \(\}\) \\
spatial & in \(=\) in, af \(=\) off, dicht \(=\{\) lid, on, bucket \(\}\) \\
object & gat \(=\) hole, emmer \(=\) bucket \\
property & rood \(=\) red, ster \(=\) star \\
\hline
\end{tabular}
this end we need some sort of gold standard, as well as some measure of how well the model approximates this standard.

Many words in the utterances have no semantic representation in the coded situations (articles, modals, discourse particles). As we cannot expect the model to learn anything about them, we do not consider them in our evaluation. This leaves us with a small subset of lemmas \((n=41)\) that do refer to possible aspects of the situation. These are verbs of manipulation (e.g., pakken 'grab') and placing (e.g., stoppen 'put into'), spatial relations (e.g., op, 'on'), object labels (e.g., blok 'block') and properties (vierkant 'square'). As some words have multiple meanings (stoppen meaning put and in), we have to determine which set of meanings should be associated with each word. Table 3 gives a sample of words and their relevant gold-standard (true) meanings.

We evaluate the learned meanings using two measures. First, we look at the summed meaning probabilities over the set of true meanings (Summed Conditional Probability or \(S C P\) ). This measure tells us what proportion of the probability mass is correctly assigned.
\[
\begin{equation*}
S C P=\sum_{f \in \text { true meanings }(w)} p(f \mid w) \tag{1}
\end{equation*}
\]

Second, we look at how high the true meanings are ranked among all learned meanings, and do so using Average Precision \((A P)\), calculated as follows:
\[
\begin{equation*}
A P=\sum_{k=1}^{n} P(k) \Delta r(k) \tag{2}
\end{equation*}
\]

Figure 1: Development of the lexicon's mean \(S C P\) and \(A P\)
where \(k\) is the rank, \(n\) the total number of ranks, \(P(k)\) is the number of true meanings found up to and including \(k\), divided by the number of meanings found up to and including \(k\), and \(\Delta r(k)\) is the change in recall between \(k-1\) and \(k\), which is the number of true meanings found at \(k\) divided by the total number of true meanings (which is zero in case no true meanings are found at rank \(k\) ). This tells us whether the true meanings are more or less prominent than the irrelevant ones.

\section*{Results}

Table 4 presents the global results, binned per meaning type (properties, objects labels, spatial relations, and actions). We can see that the meanings of non-relational word meanings are ranked higher than those of relational word meanings (compare \(A P=0.81\) and \(A P=0.25\) for properties and object labels, with \(A P=0.19\) and \(A P=0.15\) for spatial relations and action labels), although \(S C P\) does not differ much between the categories. In general, the probability distributions of the learned meanings do not have very strong peaks: the highest ranking meanings rarely have a learned meaning probability of more than 0.20 . Nevertheless, with 78 primitive meanings, the model does learn well beyond a baseline of \(\frac{1}{78}=0.013\).

Looking at the development of the \(S C P\) and \(A P\) values over time (Fig. 1), we see strikingly little development in the \(S C P\), whereas the \(A P\) rises for a time, then shows a slight decline.

Splitting the developmental curves out over some of the words (Fig. 2), we see that the words are learned rather heterogeneously. Looking at the \(A P\) first, some words are acquired instantly, with \(A P=1\) (i.e., the correct meaning ranking first) from early on (groen and rond), others gradually

\section*{Table 4: Results of Experiment 1}
\begin{tabular}{llllll}
\hline & property & object & spatial & action & total \\
\hline\(S C P\) & 0.10 & 0.05 & 0.09 & 0.07 & \(\mathbf{0 . 0 8}\) \\
\(A P\) & 0.81 & 0.25 & 0.19 & 0.15 & \(\mathbf{0 . 3 1}\) \\
\hline
\end{tabular}

Figure 2: Development of \(S C P \& A P\) over time for 9 words
approach \(A P=1(g a t)\), while for most words, the true meanings remain low ranked. There is, however, a development towards a higher \(A P\) for many of these words, except for halen and uit. The \(S C P\) remains low in all cases, even when the true meaning is ranked first (as in groen and rond), although note that for several words there is some improvement in \(S C P\) over time. Recall that the model has only seen 2492 utterances at this point, and that more data may increase the \(S C P\) further.

\section*{Discussion}

In this experiment, the model does not learn most words well. One potential reason is the small data set, representing only three hours of interaction. We observe that many developmental curves seem not to have reached their asymptotes yet, suggesting that further learning could occur with more data. We also, admittedly, have the model discard valuable information from the data. Both the linguistic structure (syntax) and the semantic structure (predicate-argument relations) are currently ignored by the model but could be useful in creating the mapping.

In addition, the highly structured and restricted nature of the data, which we expected to help by focusing the learning, may actually be hindering performance. We observe that some words have a very high ranking for their true meanings (high \(A P\) ), yet have low learned probability mass (low \(S C P\) ). (For example, see the words groen and rond in Figure 2.) On the one hand, the structured and restricted nature of the blocks game entails that a word's true meaning often consistently appears with it. On the other hand, however, the limited nature of the interactions in the data also entails that many irrelevant meanings consistently appear with the word. For example, the object of a grab action is almost always a block, so that the learner cannot rule out block as a possible
meaning of pakken 'grab'. The lack of situational variability in the input is thus an obstacle to cross-situational learning, because it requires a consistent co-occurrence of true meanings with a word coupled with variability in the presence of irrelevant meanings to help rule them out.

A first solution that comes to mind is a corpus representing a wider variety of activities, with less situational uniformity, for true cross-situational learning. The corpus from which we drew our dyads here does have a number of other types of situations we can include in future annotation. Second, even with relatively homogeneous situations, we expect the learner's attentional mechanisms to help filter out irrelevant meanings. Adding attentional mechanisms, such as the ones in Nematzadeh, Fazly, and Stevenson (2012), is a next step

A final issue we observed with the data is that the true meanings for words in an utterance are sometimes not present within the situational interval paired with the utterance. This problem is very salient for relational meanings, which are often displaced in time from the utterance that refers to them (e.g., Go grab that one! or Don't take the lid off now!). This might explain why spatial relation terms and verbs display weaker associations with their true meanings than do words for objects and their properties. In the case of positive imperatives, we do find that the actions are often carried out slightly later than the utterance. In Experiment 2, we explore whether this problem of temporal displacement can be mitigated.

\section*{Experiment 2: Widening the Temporal Scope}

Our hypothesis is that presenting the model with situational meanings only from the time of the utterance impedes the learning of relational terms. Here we explore expanding the temporal scope of the situational input to the model.

\section*{Motivation and Set-up}

Suppose that in word learning, the learner is not narrowly focussed on the situation at exact moment of the utterance, but also considers some of the situational context taking place around that moment. That is: not only the situation at the very moment of the utterance is cognitively available to a learner, but also some of the surrounding situations. To make this notion precise, we assume that the learner may consider as relevant to an utterance \(U_{i}\) any meanings in the situational context starting from the interval of the previous utterance \(U_{i-1}\) up to and including the interval of the next utterance \(U_{i+1}\). (That is, we assume that the relevance of situations overlaps previous and subsequent utterances.) We thus evaluate the model on three possible "windows" \(W\) of situational context for utterance \(U_{i}\) : all video intervals up to and including the previous and next utterance in the corpus ( \(W=U_{i-1}: U_{i+1}\) ); only the interval of \(U_{i-1}\) up to the current interval ( \(W=U_{i-1}: U_{i}\) ), or the current interval up to \(U_{i+1}\left(W=U_{i}: U_{i+1}\right)\).

\section*{Results}

Using the same parameter settings and evaluation metrics as in Experiment 1, we obtain the results in Table \(5\left(W=U_{i}: U_{i}\right.\)

Table 5: Results of Experiment 2
\begin{tabular}{lllllll}
\hline\(W\) & & prop. & object & \multicolumn{3}{c}{ spatial action } \\
\hline\(W\) & total \\
\hline \multirow{2}{*}{\(U_{i}: U_{i}\)} & \(S C P\) & 0.10 & 0.05 & 0.09 & 0.07 & \(\mathbf{0 . 0 8}\) \\
& \(A P\) & 0.81 & 0.25 & 0.19 & 0.15 & \(\mathbf{0 . 3 1}\) \\
& \(S C P\) & 0.10 & 0.04 & 0.09 & 0.07 & \(\mathbf{0 . 0 7}\) \\
\(U_{i-1}: U_{i}\) & \(A P\) & 0.80 & 0.17 & 0.20 & 0.14 & \(\mathbf{0 . 3 1}\) \\
& \(S C P\) & 0.11 & 0.06 & 0.11 & 0.08 & \(\mathbf{0 . 0 8}\) \\
\(U_{i}: U_{i+1}\) & \(A P\) & 0.79 & 0.45 & 0.24 & 0.18 & \(\mathbf{0 . 4 0}\) \\
& \(S C P\) & 0.08 & 0.05 & 0.10 & 0.08 & \(\mathbf{0 . 0 7}\) \\
\multirow{2}{*}{\(U_{i-1}: U_{i+1}\)} & AP & 0.79 & 0.41 & 0.22 & 0.20 & \(\mathbf{0 . 3 9}\) \\
\hline
\end{tabular}
is the window-setting used in Experiment 1). The windowsetting that only draws situational context from the intervals between the previous utterance and the current one ( \(W=\) \(U_{i-1}: U_{i}\) ) does not improve over \(W=U_{i}: U_{i}\). As hypothesized, however, due to utterances that refer to future actions, the results show that having a window that includes meanings from the intervals up to the next utterance enables the model to learn the object, spatial and action words better (at least according to our \(A P\) measure). The trade-off is a negligible decline in the learning of property words.

\section*{Discussion}

Some important information for acquiring the meaning of relational words can be found in the situations unfolding after the utterance has been produced. Clearly, this needs to be interpreted within the context of playing a game, in which the relevant topics of communication (the game goals) often lie in the future w.r.t. the moment of communication. While expanding the situational window adds some irrelevant as well as true meanings, the balance struck by this pragmaticallydefined windowing approach seems to help the model acquire the meaning of relational terms (as well as objects!) somewhat better, with little negative impact on property words. Note that the improvement from adding the post-utterance meanings is found mainly in the \(A P\) metric: the \(S C P\) values remain similar across the simulations. Even though the probability mass of the true meanings is not changed much, they are now more often better than the irrelevant meanings. This means that the probability values are close to each other and a very small change may improve the rankings visibly.

\section*{General Discussion and Future Directions}

In this research, we have developed a corpus of caregiverchild interactions in which video is annotated with transcribed utterances and a precise description of the depicted situational context. Unlike other recent multimodal corpora, our annotation of the situational context includes meaning elements that correspond not only to objects and their properties, but to relations as well. Thus the meaning annotations support the learning of various word types, including nouns, adjectives, prepositions/particles, and verbs. Our initial work has explored how we can use this corpus with a computational
model of cross-situational word learning to explore what information must be available to the child from the situation to support word learning, and to examine the relative ease or difficulty of learning various types of words in early acquisition.

Despite the small size of the target lexicon, the model did not perform robustly in the learning task, revealing a number of potential areas of improvement for both the corpus and the model itself. First, due to the cost of annotation, the size of the corpus (only 8,000 word tokens) almost certainly limits the learning. Nonetheless, even this small corpus can be a complementary source of information to larger corpora that are semantically less naturalistic, or contain only object labels. Second, the corpus seems to lack sufficient crosssituational variability for many words to be learned. In more general child-caregiver interactions, a word occurs across a wider variety of contexts (eating scenes, bed-time procedures and so on), enabling a child to rule out as possible meanings those aspects of the context that are irrelevant to the word. Third, regardless of the uniformity or variability of the data, a realistic model of word learning needs to incorporate an attentional mechanism that helps it focus on those aspects of the situation that are likely to be referred to.

Even with this restricted corpus, we find that relational words (verbs, prepositions) are particularly problematic to learn compared to words for objects and properties, in line with a wealth of psycholinguistic observation to this effect (Gleitman, 1990; Gentner, 1978). Because the situational context to which a relational term refers is often displaced, expanding the temporal window of situational context for each utterance led to an improvement in the learning of relational terms, but surprisingly led to even greater improvement in the learning of words for objects.

Perhaps, following Gleitman, more structured learning is necessary for acquiring the meaning of relational words, but the exact source and nature of this structured learning, and its integration with methods of cross-situational learning, is an exciting open issue. Important to look into, and perhaps problematic, is the high proportion of closed-class items in childdirected utterances (e.g., pronouns, aspectual and modal auxiliaries, and particles) that have received little attention in word-learning models, but may play a crucial role in using the structure of an utterance to help determine the meaning of unknown lexical items. More research into the degree to which this information, as found in actual child-directed language, can help is a question in want of an answer, and modeling techniques combined with good data can help us approach it.

\section*{Acknowledgments}

We gratefully acknowledge the funding of BB through NWO of the Netherlands (grant 322.70.001) and AF, AN and SS through NSERC of Canada, and the Faculty of Arts \& Science, University of Toronto. We would like to thank Marinus van IJzendoorn and Marian Bakermans-Kranenburg for making the video data available, and Arie Verhagen and two anonymous reviewers for helpful comments.

\title{
Visual Support for Instructional Analogy: Context Matters
}

\author{

}

\begin{abstract}
Instructional analogies can overload children's executive function and working memory resources (see Richland, Morrison \& Holyoak, 2006), though structure-mapping lies at the core of recommended pedagogy in mathematics instruction (National Mathematics Panel, 2008; NRC, 2001). Videotaped mathematics instruction was manipulated to test the role of visual representations in instructional analogy. Pretest, posttest, and delayed posttest measures assessed 1113 year old children's learning from one of three versions of the same lesson in which three solution strategies (one a misconception) were compared. Analogs were either a) Not Visible (NV) - presented only orally, b) Partially Visible (PV) - only the most recent solution was visible, or 3) All Visible (AV) - all solutions were visible throughout the instruction. Overall, AV students experienced greater learning gains in procedural knowledge, procedural flexibility, and conceptual/ schematic knowledge compared to PV students. These results persist after one-week delay. Apart from procedural knowledge, the same trend is evident when comparing AV students' to NV students' immediate learning gains. Overall, visual representations of analogs within an instructional analogy appear to support schema formation only when they are all visible simultaneously and throughout structuremapping. Showing students visual representations of analogs but not enabling them to be simultaneously visible led to the lowest performance overall, suggesting this may lead to more object-level encoding than schema formation.
\end{abstract}

Keywords: analogy; comparison; mathematics education; video stimulus; misconception; executive function.

Comparing different student solutions to a single instructional problem is a key recommended pedagogical tool in mathematics, however the cognitive underpinnings of successfully completing this task are complex. Students must represent the multiple solutions as relational systems, align and map these systems to each other, and draw inferences based on the alignments (and misalignments) for successful schema formation (see Gentner, 1983; Gick \& Holyoak, 1983; Richland, Zur \& Holyoak, 2007).

Orchestrating classroom lessons in which learners successfully accomplish relational structure mapping is not straightforward, particularly because opportunities for learning through structure mapping often fail in laboratory contexts (e.g., Gick and Holyoak, 1983; Ross, 1989). Specifically, reasoners regularly fail to notice the utility of aligning and mapping two or more available relational structures.

The low success rate with which participants notice and use relational structure mapping, or analogy, within laboratory studies to solve problems may in part reflect limitations in the working memory system (see Waltz, Lau, Grewal \& Holyoak, 2000). Working memory is required to relationally represent systems of objects, in this case steps to solution strategies, to re-represent these systems of relations so that their structures can align and map together, to identify meaningful similarities and differences, and to derive conceptual/ schematic inferences from this structuremapping exercise to better inform future problem solving (see Morrison, Krawczyk, Holyoak et al 2004).

The current study tests the role of visual representations of the source and target analogs within an opportunity for structure-mapping. The manipulation assesses whether 1) making source and target analogs visual (versus oral) increases the likelihood that participants will notice and successfully benefit from structure mapping opportunities, and 2) whether the visual representations must be visible simultaneously during structure-mapping in order to increase the likelihood of future success in problem solving and schema formation. The former is likely to increase the salience of the relational structure of each representation, while the latter is likely to reduce the working memory load and executive function resources necessary for participants to engage in structure-mapping and inference processes.

These are research questions with high ecological validity. A cross-cultural study of \(8^{\text {th }}\) grade mathematics instruction revealed that comparing verbal and visual structured representations is a common practice in U.S. mathematics classrooms as well as in higher achieving regions (Hong Kong and Japan), but that U.S. teachers are less likely to make visual representations visible during a structure-mapping episode than the teachers in higher achieving countries (Richland, Zur \& Holyoak, 2007). Thus findings from this experiment will yield both theoretical insight into the resource load necessary for complex structure mapping and schema formation, and practice relevant implications for everyday mathematics teachers.

Because the study takes ecological validity and the complexity of everyday classrooms as serious constraints, a novel methodology was used to derive rigorous, experimental data that incorporates the complexities of situated cognition. Specifically, the stimuli for the experiment derive from videotapes of a public school
teacher in her naturalistic classroom, teaching a lesson codesigned with the research team. This methodology and its motivation are next explained in more detail, followed by a report of the experiment itself.

\section*{Video-editing as a Tool to Bridge Laboratory and Classroom Settings}

Classrooms are vibrant, complex environments in which the high level of unexpected variability makes experimental control often impossible (Brown, 1992). The overarching commitment to controlled manipulation of experimental contexts within psychological research has led much cognitive scientific study of learning behavior to be conducted in controlled laboratory settings. While in some ways this model leads to the production of data that can be easily interpreted (x behavior derived from y manipulation), the meaningfulness of these results for educational practice have been less clear. Theoretically, this research epistemology has also meant that the search for universal cognitive processes of learning can best be accomplished through the design and examination of cognition within atypical, impoverished environments (see Schweder, 2012). The assumption that cognitive mechanisms underlying classroom learning are not moderated by environmental factors is unexplored.

Figure 1. Still images illustrating the experimental conditions created by video editing the same lesson, from left to right: Not Visible, Part Visible, and All Visible.

The current study does not interrogate that question but rather reduces the assumption by situating the stimuli creation in the naturalistic classroom context itself. A naturally occurring classroom lesson is videotaped using three cameras that capture different features of the lesson, (e.g., teacher only and teacher plus visual representations) though the same classroom discourse, affect, eye gaze, and many other potentially important features of the context are held constant across cameras. The distinct camera angles are then used to create different conditions of a videotape of the
same lesson, which are then shown to a new group of classroom students. This is clarified in the below description of stimuli creation for the current study.

\section*{Experiment: Impact of Visual Support for Instructional Analogy}

\section*{Method}

Participants. Participants were drawn from a suburban public school with a diverse population. Five students that scored in the bottom \(5 \%\) of the participant pool were also excluded from analyses. The final analyses included 78 students ( 46 boys, 32 girls) with ages ranging between 1112 years old. Within classrooms, students were randomly assigned to condition, with 25 students in the All Visible condition, 27 students in the Part Visible condition, and 26 students in the Not Visible condition.

Materials. Materials for the intervention consisted of a worksheet, a netbook, and a pre-recorded video-lesson embedded in an interactive computer program. The lesson used in the current study was developed by the authors in collaboration with a public school teacher. Three cameras were used simultaneously to videotape a classroom lesson on ratio. Ratio was chosen for this study for two reasons: (a) it is part of the common core standards for elementary mathematics instruction and (b) previous research has shown that ratio problems prompt diverse systematic student responses, useful for charting trajectories of reasoning change across the study. One camera was set to a wide shot, captured the teacher, parts of the classroom, and all visual representations of the three solution analogs throughout the lesson (All Visible -AV). A second camera was more tightly focused, capturing the teacher, some of the class, and only the visual representation of a solution as it was being produced (Part Visible - PV). The third camera focused only on the teacher and students, and did not capture any of the visual representations of the solutions written onto the white-board (Not Visible - NV; see Figure 1 for an illustration of each condition).

The video-lesson was made interactive by embedding clips of the video in a computer program. These stimuli were then used experimentally with students in other classrooms. This methodological approach of stimuli creation, provided a rigorous level of experimental control of a highly dynamic context - an everyday classroom. Further, it allowed for randomization within each classroom, which to the authors knowledge has not been previously done using a video teacher's guidance.

Figure 2. Gain scores for immediate and 1-week delayed posttest calculated by subtracting mean pretest score with respective posttest score.

Table 1. Mean Gain Scores by Knowledge Type for Each Construct Calculated by Subtracting Pretest from Respective Posttest.

\end{tabular}

Assessment. The assessment was designed to assess schema formation and generalization. Mathematically, the assessment included three constructs, procedural knowledge, flexibility, conceptual knowledge, and negative transfer. The first three constructs were conceptually derived from Rittle-Johnson and Star (2007; 2009), and adapted to the core concepts and procedures underlying ratio problems (Figure 3). Scores for each construct were averaged to yield an overall mean for that particular construct.

Ken and Yoko shot several freethrows in their basketball games. The result of their shooting is shown in the table. Who is better at shooting free throws?
\begin{tabular}{|c|c|c|}
\hline & Shots Made & Total Shots Tried \\
\hline Ken & 12 & 20 \\
\hline Yoko & 16 & 25 \\

Adelina and Marcos have both set up lemonade stands. Adelina's lemonade recipe uses 2 cups of lemon juice and 1 cup of water. Marcos' lemonade recipe uses 3 cups of lemon juice and 2 cups of water.

Figure 3. Procedural/Procedural flexibility problem (left) used in the video-lesson and assessments, and conceptual problem used in assessments. For procedural flexibility students were told to solve a problem similar to the one on the left using two different strategies.

Procedural Knowledge. Procedural problems on the pretest evaluated whether students had the basic skills necessary to solve ratio problems and designed to test students' knowledge of producing solutions of familiar and transfer problems. Cronbach's alpha was .89 at posttest, .92 at delayed posttest, and .86 at pretest.

Procedural Flexibility. The procedural flexibility construct measured: (a) students' adaptive production of solution methods ( \(n=3\) ), (b) their ability to identify the most efficient strategy ( \(\mathrm{n}=1\) ), and (c) students' ability to identify a novel solution method which was related to a taught strategy ( \(\mathrm{n}=1\) ). Cronbach's alpha on the flexibility construct was .67 at posttest, .67 at delayed posttest, and .57 at pretest.

Conceptual Knowledge. The conceptual construct was designed to probe into students' explicit and implicit knowledge of ratio. Cronbach's alpha was .66 at posttest, .64 at delayed posttest, and .42 at pretest.

Negative Transfer. The purpose of the negative transfer construct was to measure whether students will overextend their knowledge of ratio to similar looking problems for which a strategy shown to be invalid during instruction subtraction, is correct. While this construct was expected to assess overextensions of the taught strategy, due to its high similarity with the taught problems, it can also help diagnose whether conditions that do not eliminate the misconception appear to be sensitive to variations in the
problem type. Cronbach's alpha was .68 at posttest, .81 at delayed posttest, and .58 at pretest.

Efficient Strategy. The aim for this measure was to assess learners' ability to utilize the most efficient solution as instructed during the video lesson. This has also been called adaptive choice of strategy (Siegler, 1996). Efficient strategy was assessed by scoring all problems taking the form of the problem taught in the video lesson to evaluate whether students used the most efficient strategy taught - the division method.

Common Misconception. Misconceptions are mistakes that students make, which obstruct learning (Smith, diSessa, Roschelle, 1994). Based on a published lesson (Shimizu, 2003), pilot data, and pretest data, a solution involving subtraction was expected to be the most common misconception participants would bring to the study. This score assessed students' ability to overcome their misconceptions about how to solve rate and ratio problems as well as the conditions under which students confirm invalid biases. The common misconception measure examined students' use of subtraction by scoring problems that looked like the instructed problem in the video lesson.

Design \& Procedure. Students who were not in the original classroom lesson interacted with videotaped lesson clips via computer. The study followed a standard experimental procedure (pretest, intervention, immediate posttest, and 1-week delayed posttest). Students within a classroom were randomly assigned to either watch an instructional video version video-edited so that no solutions were visible on the board - Not Visible ( \(\mathrm{n}=26\) ), a version where the most recent solution was visible - Part Visible (n \(=27\) ), or a version of the video that showed all solutions on the board throughout the lesson - All Visible ( \(\mathrm{n}=25\) ). All students were given a packet on which they recorded their answers to prompts from the videotaped lesson. Students underwent the intervention before being introduced to rate and ratio.

\section*{Results}

First, between-subjects regression analyses revealed no differences between conditions on any of the outcome constructs. Boys and girls also did not differ in performance. Separate univariate one-way between-subjects ANCOVAs were run for each construct with posttest or delayed posttest as a dependent variable and pretest as a covariate. Average gain scores at posttest for the main constructs are shown in Figure 2, and the full set of gain scores immediately and after a delay are provided in Table 1. Table 2 provides all statistics, revealing that the All Visible condition outperformed the Part Visible condition in procedural knowledge, procedural flexibility, conceptual knowledge and efficient strategy both on immediate and

delayed posttests. The inverse was true for the negative transfer on immediate posttest and common misconception construct on both posttests, which is indicating that most students are being misled by the appearance of the problems (which are similar to the ratio problems) and assume they are solving for a ratio problem, not a simple subtraction problem. Thus, PV students may have used the misconception throughout all problems, regardless of whether it was correct or not. Students in the All Visible condition also outperformed students in the Not Visible condition in the flexibility and conceptual knowledge constructs on the immediate posttest. For AV and NV students the differences do not seem to hold at a delayed posttest. The NV students were better than PV students when measured for use of efficient strategy and common misconception, after a 1-week delay.

\section*{Discussion}

The results of this study clarify the role of visual representations in supporting structure-mapping and generalization from instructional analogies. The manipulation revealed that making source and target analogs visual (versus oral) increased the likelihood that participants notice and benefit from structure mapping opportunities. As noted above, the use of a visual representation of a structured relational analog was hypothesized to be likely to increase the salience of the relational structure of each representation, while maintaining their visibility was predicted to reduce the working memory load and executive function resources necessary for participants to engage in structure-mapping and inference processes.

The data revealed that this variation in visible representations had a great impact on their learning. Seeing all problem solutions on the board simultaneously during structure-mapping led to the most robust and generalizable, flexible knowledge acquisition in the context of this intervention. Having all visual representations available throughout the lesson may provide students with the necessary working memory supports to attend to key elements in the source and target representations, enabling the child to represent the solutions as systems of relations, map these representations together, and correctly identify elements that are in alignment (or misalignment). Thus, children in the AV condition may have successfully accomplished and benefitted from structure-mapping, while children in the PV and NV conditions may have benefited less from the instructional analogy itself, though both groups did show knowledge acquisition. This may explain the AV students' greater gains in flexible use of strategies
and conceptual knowledge, compared to PV students (on both posttests) and NV students (on immediate posttest).

These data coalesce with results from Rittle-Johnson and Star (2007; Star \& Rittle-Johnson, 2009), who administered measures of procedural flexibility and conceptual knowledge with pre-algebra concepts and found that having pairs of students compare representations simultaneously was more effective than sequentially for students with adequate entry level knowledge of estimation strategies. The current study provides specificity to instructional techniques and supports previous findings with more ecologically valid stimuli, but also provides more detailed data on the role of visual representations of source and target analogs.

The data for the implications of constructing visual representations of analogs but not leaving them visible throughout the lesson are quite different. The least flexible learning derived from the PV condition. This may be because the use of the visual representation did draw learners' attention to the structure of the discussed solution representations, but these learners did not have the resources to move beyond these representations to perform structuremapping and schema generalization.

In contrast, the NV participants may not have had the executive function and working memory resources available for complex structure mapping between representations, they may have also encoded less of the lesson and the first solution (a misconception), may have been less instantiated for them. The delayed data support this interpretation. While the difference in learning gains between AV and PV students remained after one-week delay, this was not so when comparing AV and NV students, highlighting that lack of visual information was less detrimental to overall learning than providing one visual representation at a time.

In fact, students in the Not Visible condition outperformed students in the Part Visible condition in procedural knowledge significantly at a delayed test, and this difference approached significance at immediate posttest. Perhaps, keeping only the latest representation visible on the board may be detrimental for teachers looking to challenge students' misconceptions. Students who see a instantiate a solution modeled on the board as valid, particularly if it is easier, (e.g. subtraction is easier than division), despite teachers' efforts to show it is incorrect.

Previous research suggests that students seek to validate their misconceptions (Chinn and Brewer, 1993) and having the misconception visible, but not throughout the entire lesson in which it was compared to two more accurate solutions, may have helped students in doing that, even more than if it was never visible. Understanding the cognitive processes at play that reconcile these results
warrants further investigation. Outcomes in negative transfer and common misconception provides further support that seeing one problem at a time is detrimental for students attempting to learn by drawing connections between solution strategies.

A reverse trend is apparent for students overextending instructed strategies to problems appearing similar to taught problems, but where the common misconception is the correct solution strategy. The results for the negative transfer measure show that PV students outperform AV students on immediate posttest, which may have been a result of the PV students using the misconception as a correct strategy for all problems that appeared like the problem used in the lesson. This is supported by the fact that PV students also used the common misconception more than AV students on both posttests. Recall that in the video lesson, the common misconception was modeled and was discussed only to be exemplified as an invalid strategy. Challenging misconceptions by modeling and discussing them is common practice in higher achieving countries (e.g. Japan and Hong Kong) and recommended by researchers as a way for students to overcome them (Berry and Graham, 2006; Kuhn, 1989). However, students who did not see the misconception compared with valid solution strategies, despite hearing the same verbalization, may have failed to overcome this challenge and instead may have led them to memorize the misconception as a valid strategy.

Zook (1991) conceptualizes two factors that may be responsible for developing misconceptions from analogies. The first is learner-generated and the second is teachergenerated, either leading to misconceptions, which Zook (1991) defines as: (a) difficulties of the learner attending to key elements increases the potential for misconceptions, and (b) difficulties in leading learners' attention to key elements increases the potential for misconceptions. An interplay of these factors may have negatively affected students in the Part Visible condition in their procedural knowledge, because the valid solutions were not visible throughout the lesson. From the teacher's perspective, there were not sufficient visual cues to support the verbal explanations provided in the instruction, so, from a students' perspective, students had difficulty attending to key mathematical ideas necessary to overcome their misconceptions.

Misconceptions are common throughout the curriculum, and researchers focused on the potential of analogies to overcome these through conceptual change have revealed the real challenges of teaching children to reconsider their misconceptions. For example Chinn and Brewer (1993) provide evidence that many students finish high-school and University without giving up pre-Newtonian perspectives of motion (e.g., Clement, 1982).

Overall, teaching through instructionally supported structure-mapping has the potential to enhance students' conceptual knowledge, procedural flexibility, and procedural knowledge in mathematics. Visual representations can augment these benefits, though it is important to note that the overall advantages in procedural
flexibility in this study were driven by students who saw all the solutions on the board at all times, where students who saw only one solution at a time did most poorly. Strikingly, for procedural knowledge, students who only saw one solution at a time performed worse than students who did not see any solutions throughout the lesson. Thus, students in the Part Visible and Not Visible condition may not have learned by analogy due to insufficient supports.

\section*{Implications for Theory and Practice}

The findings from this study have the potential to positively shape U.S. teaching practices as well as contribute to several areas of cognitive scientific literatures. Utilizing teaching by comparison is critical for learning deep mathematical conceptual knowledge (Rittle-Johnson and Star, 2007, 2009; Star and Rittle-Johnson, 2009; National Mathematics Panel, 2008a, 2009b). Teachers in the U.S. rarely scaffold instructional comparisons adequately (Richland, Zur, and Holyoak, 2007; Heibert et al., 2005), this has been partly due to a lack in specificity in recommendations on how to improve these practices (Hiebert et al., 2005). Recent work that has used cognitive science research in the classroom has provided positive evidence in this direction (Rittle-Johnson and Star, 2007, 2009; Star and Rittle-Johnson, 2009), but even these studies do not examine instructional strategies as they unfold in a real classroom lessons.

The current study uses a novel theoretical perspective and methodological approach that bridges analogy research in laboratory settings with studies of instructional practice in classroom environments. From a theoretical standpoint, these findings support previous laboratory-based results indicating that visual representations can support schema formation and learning from analogy (Gick and Holyoak, 1983), and extend them to an applied setting. The current study provides data on a relevant instructional scaffold that facilitates learners' ability to draw connections between mathematical solution strategies. Comparing representations is common to everyday mathematics instructions, and making all source and target representations visible for the length of the analogy requires only a small time investment and modification of current practice. Thus this intervention is highly feasible to integrate into current teaching practices. Using more ecologically valid stimuli to test teaching practices with the use of a videotaped teacher guided lesson, instead of static written learning materials, thus allows for greater generalizability and specificity for instructional recommendations. Further research that uses these experimental methods is underway, and the authors encourage interdisciplinary researchers to consider the use of video stimuli when designing educational studies.

One must note that we cannot interpret these results to indicate that making analogs visible simultaneously will necessarily lead to successful structure-mapping and mathematical schema formation. Key to improving educational practice is certainly ensuring the instruction uses optimal structured analogs, and ensuring that any misconceptions are identified and compared well with an
alternative and more accurate representation.. Much is still unknown about the ideal combination of support for instructional analogy. At present, further studies are being conducted to examine the impact of the following practices: (a) the teacher's gestures when presenting and linking key ideas, (b) the visual organization of solutions on the board, and (c) the sequencing of chosen solutions (i.e. beginning with a common misconception versus a correct strategy). The first of these two practices (a) and (b) were observed by Richland, Zur, and Holyoak (2007) to correlate with the practices used in our experiment, but they remain to be tested experimentally.

Lastly, from a technology perspective, these findings could have implications for current trends to replace classic chalk or white-boards with smartboards, the highly popular electronic innovations that enable teachers to use their board very actively as a dynamic connection to their computer. While there is the potential for rich activity, there is little room to write, since the smart boards are about a third of typical white boards. These data suggest that smartboards may be highly effective at instantiating single visual representations at a time, much as in our part visible condition, which led to the lowest learning gains, greatest rate of misconceptions, and least flexible knowledge. In summary, instructional attention should be paid to carefully considering the role of visual representations in balancing the benefits for improved encoding of relational structure with ensuring that students align, map, and compare these structured representations to ensure broader generalization, misconception revision, and appropriate schema formation.

\title{
Priming and Conceptual Pacts in Overhearers' Adoption of Referring Expressions
}

\begin{abstract}
Current theories of communication yield predictions about the expression choice of overhearers as well as primary discourse participants. We discuss three such theories and evaluate them with reference to new data on object naming elicited through a confederate priming paradigm. Our results show that participants adopt primed referring expressions if they are highly involved in the task, but mere exposure to the object labels yields very limited priming effects. Also, common ground is a relatively marginal factor in expression choice here. We interpret these results as supportive of the importance of grounding and challenging for interactive alignment-based accounts of expression choice.
\end{abstract}

\section*{Introduction}

Inter-personal communication is customarily taken to involve processes of cooperation and coordination between interlocutors at a number of levels. At the level of the conversational turn, speakers cooperate with hearers by making their contribution appropriate to the current purpose of the talk exchange, as observed by Grice (1975). They also coordinate with hearers by making their intentions understood (Grice 1957). At a discourse level, speaker and hearer work together to achieve conversational goals, which might involve the sharing of information, the making and satisfying of requests, the formation of joint plans, etc. (Clark 1996).

A diverse range of theories have been proposed to account for how speakers and listeners successfully engage in this process of communication, with particular reference to dyadic interactions such as dialogues. An influential account of dialogue, the interactive-alignment model (Pickering \& Garrod 2004), places low-level processes of priming at the heart of communication. In this account, interlocutors align their representations as a result of dialogue. This alignment commences at a surface level, in that the dialogue participants converge at a lexical and syntactic level, due to the priming effects exerted by the use of particular words and syntactic forms. The resulting alignment then percolates up through the system, eventually reaching the level of situation models. The goal of communication, on this account, is to accomplish the alignment of situation models. However, the fundamental drivers of this are low-level, automatic and unconscious processes, specifically priming processes. Consequently, this account posits little involvement of strategic factors in the success of dyadic communication.

A contrary viewpoint is that interlocutors are highly aware of each other's mental states and that this awareness informs their behaviour. Clark and Schaefer (1989) argue that successful contributions to a discourse requires grounding; that is, speaker and hearer must mutually believe that the speaker's meaning has been understood. The notion of common ground (CG) - the shared knowledge, beliefs and assumptions of the interlocutors (Clark \& Marshall 1981) - thus becomes relevant here. The goal of the interaction involves building and updating

CG, and doing this requires consideration of the existing CG state. A simple example is the use of a referring expression: if a speaker predicates a new property of an entity (e.g. "John is away"), this can only be successful as a discourse contribution if the hearer correctly identifies the entity. This requires the speaker to take account of the hearer's knowledge about how this entity is labelled. Such knowledge may be presumed on the basis of linguistic community membership, but it may also arise from previous referential success, or on the basis of the formation of "conceptual pacts" (Brennan \& Clark 1996). Distinctively, conceptual pacts involve the establishment of partner-specific labels for entities, which can then be successfully used in interaction with that specific partner but are not preferred for general use with other interlocutors.

An intermediate position between these two viewpoints is occupied by Keysar (2007). He argues that "when people communicate, they do not routinely take into account the mental states of others" (ibid., p.72). Instead, drawing upon evidence from Theory of Mind experiments, he argues for the primacy of egocentric processing, and contends that "one's own perspective is dominant...the consideration of others' beliefs is not automatic" (ibid., p.75). Unlike the interactive-alignment model, this approach entails conscious reasoning about the choice of referring expression, but unlike Clark and colleagues, Keysar considers CG to be a relatively peripheral issue, and the role of the hearer and his/her mental state to be a marginal factor in the speaker's choice of expression. In support of this, Barr and Keysar (2002) provide experimental evidence that people (unconsciously) expect new conversational partners to adhere to conceptual pacts that have previously been established, even though the new partner is not privy to this pact. This in turn suggests that conceptual pacts are not triadic relations between two interlocutors and an entity, in which both agree to refer to this entity in a particular way within their interaction, but rather pairs of relations in which both parties separately agree to refer to this entity by a particular label.

Experimental work on dialogue has been conducted from numerous theoretical perspectives, including those outlined above. However, relatively little attention has been paid in this literature to non-dyadic interactions, for instance those in which a third individual is present but not directly engaged in the conversation \({ }^{1}\). In this paper, we aim to extend findings about the choice of referring expression into the domain of non-dyadic interactions. There are several motivations for this move. First, the potential relevance of third parties in conversation has long been acknowledged (see Clark \& Carlson 1982) but the implications of this for expression choice have attracted relatively little attention. Secondly, such

\footnotetext{
\({ }^{1}\) A partial exception to this is Keysar and Henly (2002), but their primary focus is on using overhearers to evaluate the likely communicative success of utterances, rather than on examining the effect of dialogue on overhearers themselves
}
situations are common in everyday interaction, and understanding the dynamics of conversation in such settings is an end in itself. Thirdly, and perhaps most importantly, non-dyadic interactions represent a testing ground in which the factors governing expression choice can be disentangled to a certain extent, thus offering useful insights as to the relative strengths of the competing factors.

In the following section, we consider how the competing theories of Pickering and Garrod, Clark, and Keysar naturally yield distinctive predictions about the behaviour of overhearers in a non-dyadic setting. We then introduce an experiment to test the effects attributable to priming, egocentricity and conceptual pacts, specifically examining whether and under what conditions overhearers select referring expressions according to their status in a preceding dialogue.

\section*{Critical Predictions about Overhearer Behaviour}

Although the specific accounts discussed in the previous section are primarily oriented towards explaining dyadic interactions, the mechanisms that they posit should apply also in non-dyadic interactions. If so, predictions can be drawn about overhearer behaviour, as we articulate in the following paragraphs. Of course, the falsification of such a prediction would not imply the incorrectness of the theory in the dyadic case. However, it would suggest that additional machinery would need to be posited to cover non-dyadic interactions. We would interpret it as favourable for a theory if it makes correct predictions about both types of interaction without further stipulation.

In particular, we focus on a specific scenario of nondyadic interaction. In this scenario, two interactants are playing a game in which they match picture cards that display tangram figures. Both have matching packs of cards. One of them (the 'director') selects a card and describes the figure, and the other (the 'matcher') has to identify which card is being talked about. There is also an overhearer, who does not participate in the game. When the game is completed, the overhearer plays the game, taking the role of director. The question is whether, and to what extent, the overhearer will re-use the descriptions that were used by the original director in the previous phase of the game.

Turning first to Pickering and Garrod's (2004) account, priming is predicted to occur automatically upon exposure to the relevant labels. They predict stronger alignment effects for addressees than overhearers (ibid., 174), on the basis that the former engage their production systems during the interaction (anticipating that they will speak at some point) whereas the latter do not need to. However, overhearers are still expected to exhibit some priming effects. Crucially, this does not depend upon the establishment of full common ground, which is argued only to occur "when radical misalignment becomes apparent" (ibid., 179). Rather, it relies merely on implicit common ground, defined as the information shared between the interlocutors, to which the overhearer might reasonably be supposed to have access. Hence, in this
experimental paradigm (where there are no observable failures in communication), their account predicts priming of overhearers, a possible effect of involvement, and no effect of common ground. It further predicts that priming will be boosted if the overhearer's production system is activated.

Contrastingly, for Clark and colleagues, high-level conscious processes are critical to determining whether the overhearer adopts the referring expressions that have been used. These expressions should be used only if they have been observed to be successful, which entails that the overhearer is sufficiently engaged in the dialogic process to determine whether this is the case: merely hearing the expressions will not do. In particular, where conceptual pacts have been formed, the status of the addressee with respect to these pacts should also be relevant. When addressing someone who was involved in the conceptual pact (in our scenario, someone involved in the first phase of the game), the former overhearer is predicted to re-use the established referring expression to a greater extent than they would if addressing a new individual. So in brief, this account predicts no priming unless the overhearer is sufficiently involved in the discourse, and more priming when common ground is also present.

The predictions arising from Keysar's (2007) account differ from Clark's with respect to common ground. According to Keysar, the choice of expression should be egocentrically motivated in the first instance, and therefore it should be irrelevant whether or not the hearer has a prior conceptual pact about that referent. Whether the overhearer should adopt any of the expressions used by the previous director is not clear on this account: as Keysar does not posit a role for low-level priming, this should not occur automatically, although it might be feasible for the overhearer to learn new labels under certain conditions (see General Discussion). In sum, we take this account to predict no priming unless the overhearer is sufficiently involved in the discourse, but no effect of common ground.

\section*{Establishing Baseline Naming Probabilities}

In order to establish our baseline naming probabilities, we ran an online elicitation study with EFS Survey (http://www.unipark.info). Participants were asked to provide names for 50 configurations of tangram pieces, which were presented in silhouette. One tangram was presented per page, with the task being to give a name to the presented graphical display (no information was given as to whether the display was a picture or representation of a specific object).

331 participants were recruited via the University's mailing list and leaflets around the campus. All were students and native speakers of German. Participants were entered into a prize draw to win \(€ 10\) cash or one of \(10 € 10\) Amazon vouchers.

For the following experiments, we selected 15 tangrams for each of which a specific response had occurred at rates of \(5-15 \%\). These responses could be considered plausible but dispreferred, in that they were neither unique to an individual respondent nor were they the 'obvious' description for the tangram in question. The
use of such items in the following experiments reduces the probability that the participant selects the target expression just by chance. The mean rate of usage for the relevant descriptions across these 15 tangrams was \(8.29 \%\) (278/3353).

\section*{Experiment 1: Effects of Involvement and Common Ground}

Experiment 1 was designed to show whether an overhearer's involvement in the interaction, and the extent to which they shared common ground with their subsequent addressee, influenced their uptake of dispreferred referring expressions.

\section*{Participants}

86 participants ( 47 female), all native speakers of German, were paid for participation in the experiment. They were divided randomly between the four test conditions.

\section*{Materials}

Three sets of 15 white cards ( \(74 \times 105 \mathrm{~mm}\) ) were used, each with a black tangram on the upper half of the card. The confederate director and the matcher each had one set of cards. Each set of cards showed identical figures: the confederate director's cards also showed the names that were to be used for the tangrams. Video and audio recordings were made of each trial.

\section*{Procedure}

For each condition, the experimental setting comprised an interacting dyad of director and matcher, plus an overhearer. All three individuals were separated by opaque screens. They were instructed that they were to play a game in which the object was to match the order of 15 cards. The director's cards were arranged in a stack in the correct order, while the matcher's cards were arranged on the table top and all were visible. Both were instructed not to change the orientation of the cards.

The director was instructed to proceed by naming the card on top of the pile so that the matcher could find the corresponding card, using names that were as short and spontaneous as possible but as long as necessary. Matchers were allowed to ask for additional descriptions but were told that they would lose points for doing so. These instructions were devised to avoid the use of detailed descriptions rather than impressionistic names for the tangrams.

The experiment proceeded in two phases, using the confederate priming paradigm. In the first phase, the director was a confederate and used pre-specified descriptions (chosen from the pre-test results as discussed above). The matcher was also a confederate, and the experimental participant was the overhearer. In the second phase, the game was played again, with the participant now playing the role of director, but having no direct access to the list of descriptions that had previously been used.

A \(2 \times 2\) design was used, within which levels of involvement and common ground were manipulated. In the high-involvement conditions, overhearers were
presented with a sheet displaying all 15 tangram shapes prior to the first matching phase of the experiment. In the low-involvement conditions, overhearers were not shown the shapes that were being discussed. Instead, they were asked to count the number of times that /t/ was uttered during the interaction (cf. Bavelas, Coates \& Johnson 2000), in order to ensure that they were attending to the linguistic material being uttered. In the high common ground condition, the confederate who was the director in phase 1 of the experiment became the matcher in phase 2 of the experiment, whereas in the low common ground condition, a new confederate who had not participated in phase 1 of the experiment was the matcher in phase 2.

The transcript of phase 2 was analysed in order to establish whether the participant preferentially re-used descriptions that had been used by the confederate in phase 1. The participant's descriptions were considered according to two criteria: a strict lexical priming criterion, in which only identical or similar words (modulo morphosyntactic alternations) were considered to 'match', and a more liberal semantic criterion, in which expressions of similar concepts and synonyms were also considered as matches.

\section*{Results}

The results are summarised in Table 1, for semantic priming, and Table 2, for lexical priming.

Table 1: \% semantic priming effects in Experiment 1
\begin{tabular}{|l|l|l|}
\hline Condition & - CG & + CG \\
\hline - involvement & 14.8 & 15.3 \\
& \((49 / 330)\) & \((46 / 300)\) \\
\hline+ involvement & 41.0 & 50.4 \\
& \((129 / 315)\) & \((174 / 345)\) \\
\hline
\end{tabular}

Table 2: \% lexical priming effects in Experiment 1
\begin{tabular}{|l|l|l|}
\hline Condition & - CG & + CG \\
\hline - involvement & 13.0 & 14.3 \\
& \((43 / 330)\) & \((43 / 300)\) \\
\hline+ involvement & 36.2 & 47.0 \\
& \((114 / 315)\) & \((162 / 345)\) \\
\hline
\end{tabular}

In all conditions, the use of primed expressions was significantly higher than their rates of spontaneous use in the pre-study (binomial, all p < 0.001). We applied a logistic mixed model with full random slopes to the semantic priming results. This showed a highly significant main effect of involvement ( \(\beta=1.88, \mathrm{SE}=0.259, \mathrm{Z}=\) \(7.28, \mathrm{p}<0.001\) ), but the main effect of common ground did not reach significance ( \(\beta=0.255\), \(\mathrm{SE}=0.203, Z=\) \(1.26, \mathrm{p}=0.21\) ), despite the numerical trend in the high involvement condition. In a second model we also posited an interaction term, but this did not reach significance ( \(\beta=\) \(0.58, \mathrm{SE}=0.411, \mathrm{Z}=1.4, \mathrm{p}=0.16\) ), while involvement remained significant and common ground non-significant. This pattern of effects was replicated for the lexical priming results.

\section*{Discussion}

The results of Experiment 1 indicate that the degree of the participants' involvement is highly relevant to their uptake of dispreferred referring expressions. In the conditions in which overhearers were allowed to see the set of tangram figures, they were effective at acquiring the labels used in phase 1 of the experiment. When they were not allowed to see the figures, they exhibited much smaller priming effects, using the primed labels only slightly more frequently than would have been expected in spontaneous, unprimed description.

The presence of common ground led to numerically more frequent reuse of primed descriptions, but this effect did not reach significance in our sample after subject and item effects were taken into consideration.

We interpret these results as potentially supportive of the positions of Clark or Keysar. In particular, it is not the case that overhearers frequently use dispreferred descriptions just as a consequence of having heard these object labels; they must also be aware of the referent picked out by the label. In the terminology of Clark and Brennan (1991), the use of the label must be "grounded". It could of course be argued that the overhearers in our experiment do not have the opportunity to ground the labels with certainty, even in the high involvement conditions, as they cannot be sure which referent is picked out by which expression. Nevertheless, the results suggest that our participants were generally adept in solving this mapping problem, and having done so, used this information to inform their choice of referring expression.

These results can be reconciled with the account of Pickering and Garrod (2004) if we assume that the participant in the high involvement condition is sufficiently engaged in the discourse to have an activated production system, making them effectively a discourse participant rather than merely an overhearer. From that perspective, we could see these results as indicative of the degree of involvement that is required in order for the third individual to be subject to substantial priming effects. On this account, although the priming effect still persists in the absence of the referents (in that primed expressions are used at above-baseline rates), it is very much weakened.

The lack of a strong effect of common ground speaks in favour of the egocentric view proposed by Keysar and colleagues. However, the trend towards greater reuse of priming expression to familiar interlocutors in the high involvement condition suggests that some participants may be influenced by the existence of a prior conceptual pact. If this were the case, it would challenge both the egocentric account and the assumption of Pickering and Garrod (2004) that common ground is only consulted when there is some kind of difficulty in the dialogue, such as deceit or extensive repair. Further work is required to confirm or exclude the existence of this trend.

\section*{Experiment 2: Task-Specific Effects}

A question arising from the first experiment is whether the manipulation of involvement also influenced the participants' expectations about their task. Could it be the case that the participants who were presented with a copy of the tangram pictures inferred that their task was to learn
how to describe these images? This could in turn result in greater activation of their production mechanisms, predicted by Pickering \& Garrod (2004) to lead to greater priming effects. To address these possibilities, we conducted a further experiment in which the overhearers were not given access to pictures of the tangrams, similarly to the original low involvement condition, but were told that after the first part of the experiment, they would then be playing the game, in the role of director.

\section*{Participants}

41 participants (27 female), all native speakers of German, and none of whom participated in Experiment 1, were paid for participation in the experiment. They were assigned to the two new test conditions (common ground and no common ground, as in Experiment 1).

\section*{Materials}

The same materials were used as in Experiment 1.

\section*{Procedure}

The same procedure was used as in the low involvement condition of Experiment 1, with the exception that the participants were not asked to perform t-counting, on the basis that this might interfere with their ability to follow the task (and potentially the engagement of their production systems). Instead, they were instructed to listen to what was going on and told that they would be asked about how successful the interaction had been. Before the experiment began, participants were told that they would be taking the role of director in the second part of the experiment.

\section*{Results}

The results are summarised in Table 3.
Table 3: Results of Experiment 2
\begin{tabular}{|l|l|l|}
\hline Condition & \begin{tabular}{l} 
Semantic \\
priming \%
\end{tabular} & \begin{tabular}{l} 
Lexical \\
priming \%
\end{tabular} \\
\hline- CG & 16.0 & 13.0 \\
& \((48 / 300)\) & \((39 / 300)\) \\
\hline+ CG & 15.9 & 15.2 \\
& \((50 / 315)\) & \((48 / 315)\) \\
\hline
\end{tabular}

In both conditions, the use of primed expressions was significantly higher than their rates of spontaneous use in the pre-study (binomial, both \(\mathrm{p}<0.001\) ). Comparing these results with the low involvement conditions of Experiment 1, logistic regression analyses showed no significant main effect of task awareness.

\section*{Discussion}

The results of Experiment 2 suggest that awareness of the potential usefulness of the descriptions that are employed does not suffice, on its own, to enable the overhearer to pick up dispreferred expressions in this paradigm. Without access to depictions of the referents, the participants in this experiment exhibited very limited evidence of priming effects. This suggests that the higher rates of priming
attested in the high involvement condition of Experiment 1 are largely attributable to the perceptibility of the figures, rather than the participants drawing any specific inferences about the way in which they were expected to perform the task.

\section*{General Discussion and Conclusions}

Our experiments strongly suggest that overhearers are able to acquire dispreferred labels for objects, but that they do so to a very limited degree if they do not have perceptual access to the object that is being referred to.

We take these results to point to limitations in the power of 'pure priming' effects; that is, the view that access to the phonetic content of labels will lead to their adoption by hearers, as a consequence of percolation (Pickering \& Garrod 2004). In the confederate priming paradigm, it appears that such access is not enough: the label must also be associated with an object in order for it later to be adopted. This suggests that the process by which speakers align on object labels is not merely bottom-up, but requires the presence of a referent or meaning as well as the verbal label.

Nevertheless, it could be argued that our results do point to non-zero priming effects, with increased uptake of primed expressions even among uninvolved overhearers who do not see the potential referents and are not attending to the dialogic process that is occurring. Such effects could indeed be attributable to the type of processes that Pickering and Garrod (2004) posit. However, at least in this paradigm, these effects are much smaller than the priming effects in the high involvement condition.

A possible explanation of the effect of involvement, within the Pickering and Garrod account, is that the overhearers' production mechanisms are more highly activated in the high involvement condition. Given the results of Experiment 2, we consider this unlikely to be the sole cause of the involvement effect. The results of experiment 2 suggest that, even when participants are explicitly informed that they will later be called upon to describe the same figures, and hence might be assumed to engage their production systems in preparation to participate in a dialogue, they do not exhibit greater uptake of the primed expressions.

Of course, it may be the case that the effect of involvement is a matter of attention, and that overhearers in the low involvement condition are less engaged in the task in general. However, in experiment 1, these overhearers are obliged to attend to the phonetic content of the utterances, which should in principle be sufficient to initiate priming effects via percolation. This explanation might be tenable if we modify the 'pure priming' account to require that lexical items must be heard and understood in their entirety in order to be primed.

The strong effect of involvement is straightforwardly explicable in Clark's approach: according to this view, expressions are re-used as a result of their observable effectiveness in the prior interaction, and it is the highly involved participants who are in a position to discern this. However, it can also be captured by the egocentric approach, articulated by Keysar and colleagues. Here we must also posit that the condition of high involvement -
which presented participants with a visual representation of the tangram figures being talked about - enabled the overhearers to learn the referring expressions corresponding to (some of) these figures. Given that there were no 'right' or 'wrong' answers in our experiment, it is perhaps slightly counter-intuitive that 'egocentric' overhearers should bother to learn the names of tangrams, when they could simply describe them as they saw fit. It is possible that learning the names in this way represents an economical strategy that obviates the need for any decisions about how to describe the tangrams later on (although participants in Experiment 1 were not told that they would need to do so). We cannot, therefore, exclude the possibility that hearing the primed names in the high involvement condition merely shaped the egocentric preferences of the overhearers, and that this was later manifested in their choice of expression.

Our experiments documented a numerical tendency towards common ground effects, but this might be attributable to random variation. If this effect is replicated in further research, it would more seriously challenge Keysar's (2007) claim that the speaker's choice of referent should initially be egocentrically motivated, irrespective of conceptual pacts. Note that, in this experiment, there were no failures of communication (as the matcher was a confederate), hence there was no need for the director to reformulate his or her utterance: purely egocentric behaviour would, to all intents and purposes, have done just as well. The preferential reuse of primed expressions when the matcher was familiar would suggest that awareness of conceptual pacts may, at least for some speakers and on some occasions, be influencing the initial choice of utterance.

In short, our results so far do not permit us to exclude the possibility of egocentrism on the part of our participants, and can be reconciled with a slightly modified version of the form-based priming account of Pickering and Garrod (2004). Nevertheless, the results appear to fit most naturally with the viewpoint articulated by Clark and colleagues. Specifically, in order for expressions to be adopted, it appears to be broadly necessary for overhearers to understand the purpose of the expressions or to experience them being used effectively (our experiments do not distinguish these possibilities). Crucially, it is not sufficient merely to hear expressions that are not grounded, even if you know that you will be called upon to produce similar expressions in the future. However, two aspects of these results are unexpected from the perspective of Clark's approach: firstly, as discussed above, the effect of conceptual pacts is, at most, marginal in these experiments. A definitive absence of such effects would speak in favour of Keysar's view. Secondly, expressions can (occasionally) be picked up spontaneously by uninvolved overhearers without awareness of the current discourse goals, as predicted by the model of Pickering and Garrod. Further investigations might show whether the apparent examples of this in our data are actually attributable to the overhearer attending to the discourse, or whether they should be treated as genuine instances of automatic priming effects that are not predicted by Clark's theory.

\begin{abstract}
Task influence has long been known to play a major role in the way our eyes scan a scene. Interestingly, how the task modulates attention when interacting with objects has been less investigated. Only few studies have contrasted the distribution of eye fixations during viewing and grasping objects. How is attention differently deployed when different actions have to be planned on objects in contrast to a purely perceptual viewing condition? To investigate these issues, we conducted an eyetracking experiment showing participants 2D images of realworld objects. In blocks of trials, participants were asked either to assign the displayed objects to one of two classes (classification task), to mimic lifting the object (lifting task), or to mimic opening the object (opening task). Mean fixation locations and attention heatmaps show different modes in gaze distribution around task-relevant locations, in accordance with previous literature. Reaction times, measured by button release in the manual response, suggest that the more demanding the task in terms of motor planning the longer the latency in movement initiation. Results show that even on simplified, two dimensional displays the eyes reveal the current intentions of the participants. Moreover, the results suggest elaborate cognitive processes at work and confirm anticipatory behavioral control. We conclude with suggesting that the strongly predictive information contained in eye movements data may be used for advanced, highly intuitive, user-friendly brain-computer interfaces.

\section*{Introduction}

Since the early works of Buswell (1935) and Yarbus (1967) top-down, task-related guidance has been shown to strongly influence the way people move their gaze upon pictures. In the second study, depending on the question asked, different patterns of scanning were observed. Such an influence is so critical that, as soon as a specific task is given, low-level, bottom-up visual saliency is basically overridden and plays quite a minor role in explaining eye fixations w.r.t. higherlevel cognitive factors (Henderson, Brockmole, Castelhano, \& Mack, 2007; Einhäuser, Rutishauser, \& Koch, 2008). Similarly, moving from pictures to real-world scenes and to tasks involving motor actions, it is even more striking how eye movements are precisely planned to provide information for the execution of the current piece of action. This has been shown in different settings, from tea-making (Land, Mennie, \& Rusted, 1999) to sandwich-making (Hayhoe, Shrivastava, Mruczek, \& Pelz, 2003) to a wealth of other more or less complex motor tasks (Land \& Tatler, 2009). In this case, anyway, the nature of attention deployment is quite different. The purpose of vision is here indeed less to get sense of the scene and more to direct effectors and coordinate a much slower
and more complex behaviour than scanning. Strategies like 'look-ahead' and 'just-in-time' fixations (Hayhoe et al., 2003; Ballard, Hayhoe, \& Pelz, 1995) support the idea that vision is deeply intertwined with the needs of motion planning and supervising.

Further, in the context of the theory on the duplex nature of vision (Goodale \& Milner, 1992), distinct neural pathways subserving the different functional demands of object categorization and object manipulation were suggested. This dissociation between vision-for-action and vision-for-perception has often been investigated by means of grasping tasks contrasted to perceptual judgement tasks, with visual illusions or in covert attention settings (Goodale, 2011), but contrasting evidence has emerged and it seems reasonable to assume a strict interaction between the two systems.

How the differences between perceptual and motor task are reflected in eye-movements has been less investigated. In a seminal paper for eye-hand coordination, Johansson, Westling, Backstrom, and Flanagan (2001) recorded both eye- and hand movements data during a motor task involving grasping a bar, avoiding an obstacle, touching a goal position and placing the bar back. Subjects almost exclusively fixated landmark positions on the bar or in the experimental set-up, before making contact to them. The preparation of an action upon an object defines an attentional landscape (Baldauf \& Deubel, 2010), (covertly) encoding in parallel locations relevant for the subsequent serial motor execution.

This evidence suggests that visual cues are sought and weighted differently depending if the task is a skilled movement or a perceptual judgement. Gaze behaviour in viewing and grasping was investigated by (Brouwer, Franz, \& Gegenfurtner, 2009) and (Desanghere \& Marotta, 2011). The first ones used simple geometric shapes to be simply viewed or grasped, while in the latter study Efron blocks were used and in the viewing condition a perceptual judgement had to be made. In both cases, the viewing condition produced first fixations closer to the center-of-gravity (COG) of the object (in accordance with (Foulsham \& Underwood, 2009), among others), while the grasping condition was characterized by first fixations closer to the index finger location (or to the more difficult to grasp location).

In this paper, we present an experiment building on that of Brouwer et al. (2009). The main novelty of our approach is the use of real object stimuli (displayed on a monitor) and the comparison of three simple but realistic tasks, one 'passive' (classification) and two 'active' (lifting and opening).

We were interested in investigating to what extent eye movements subserve and anticipate the task demands, in the form of information collection for movement planning, and the relation to affordances (Gibson, 1979). This relation was expected to show in different scanning strategies determined by the different landmarks associated to each task. Even though the interaction with real objects in our daily life heavily relies on depth perception, Westwood, Danckert, Servos, and Goodale (2002) showed how subjects can effectively program actions to 2D pictures, suggesting that the dorsal stream does not critically rely on binocular information for prehension movements (see also (Kwok \& Braddick, 2003)). This turned out to be the case in this study, where indeed familiar objects were used and the scanning patterns were similar to those described for real objects.

\section*{Experiments}

We conducted a main eye-tracking experiment and a parallel experiment aimed at extracting Regions Of Interest (ROI) from every stimulus in every condition. This was done to have an objective measure of the contact point regions that would be chosen for an actual grasp instead of arbitrarily choosing some expected ROIs. Both experiments are detailed in the following subsections.

\section*{Participants}

Eleven participants ( 6 women, 5 men, aged 22-41) carried out the eye-tracking experiment in all 3 conditions (task). One female participant's data was discarded because of very bad quality. All subjects were right-handed with corrected to normal vision. Ten different ( 4 men, 6 women, aged 18-41) participants carried out the ROI extraction experiment. All of them were confirmed right-handed. In both experiments participants were compensated with study credits or money.

\section*{Stimulus material}

Stimuli were chosen from the ALOI dataset (Geusebroek, Burghouts, \& Smeulders, 2005), containing pictures of 1000 daily-use objects in different light/view conditions. 14 objects (plus 2 test objects) were chosen such that all of them could be easily lifted and had an opening part. They are all portrayed in a frontal view against a black background. Six objects are displayed upright, six lie horizontally with the opening part on the right. Two objects present a handle on the right and the opening on the top. All 14 stimuli are showed in Fig.1. Each picture is \(768 \times 576\) pixels. In each condition they were presented at mid-height on the right of the screen.

\section*{Apparatus and Procedure}

Participants sat in front of the screen, where the object stimuli were presented. In the eye-tracking experiment their head was resting on a chin rest, about 70 cm away from the monitor, \(1680 \times 1050\) pixels, subtending \(45.3^{\circ} \times 28.3^{\circ}\) of field of view. Stimulus pictures subtended \(20.7^{\circ}\), with the center of the picture lying at \(12.3^{\circ}\) from the center of the monitor.

Figure 1: Stimuli pictures used in the experiment.

Eye movements were recorded via a binocular remote eyetracker (EyeFollower, LC Technologies) working at 120 Hz . A keyboard was placed between the chin rest and the monitor to record reaction times. Participants had to look at the same stimuli with three different tasks in mind - each in one block. The task order was randomized across participants, so was the stimulus order within each block. For each task, every object was presented five times, resulting in 210 trials per participant. For training purposes, 30 more test trials were conducted on 2 other objects before the main experiment.

In the classify task, participants were asked to look at the presented object and to decide whether it could contain liquid or not. The response was given by a left/right arrow key press. This served the purpose of both having participants looking at the objects each time and making a manual response as in the other conditions. In the lift condition, participants had to reach to the screen and to mimic lifting the presented object in front of the screen. Analogously, in the open condition, they reached to the screen and mimicked opening the object. They were instructed to use only the right hand. To grasp objects, they were asked to always perform a grasp frontally, either with the thumb rightwards or downwards or by the handle, where present. As to the opening, they were told to imagine that the objects were glued to the shelf so they could open them with just one hand. They were asked to execute the movement as naturally as possible and to act on the object according to the perceived size \({ }^{1}\). In each trial, participants were asked to press the spacebar until they were ready to execute the proper response. Each trial proceeded as follows: 1) the task (classify/lift/open) is displayed as a reminder at the center of the screen for \(1.5 \mathrm{~s} ; 2\) ) the fixation cross is presented for at least 1 s (or as long as the space bar is not pressed); 3)

\footnotetext{
\({ }^{1}\) The displayed object stimuli were all of the same size, so that objects were presented larger or smaller than they typically are in reality. However, this scaling was not excessively pronounced so that the action to perform was still plausibly and naturally performable.
}
the stimulus appears on the right side of the screen; 4) Phase A: eye data and reaction times are collected up to the release of the space bar; 5) Phase B: eye data collected during the execution of the motor response; 6) the hand goes back to the spacebar and the next trial starts.

In the ROI extraction experiment, the same objects were presented to different participants. In just 2 blocks (lifting and opening), they were asked to place the tips of their fingers on the object, picturing the requested action. These points were recorded via a touch screen. After each trial, the participant was shown the selected points and, if not satisfied, she could repeat the trial. Every object was presented 3 times per block, resulting in 84 trials total per participant.

\section*{Data Processing and Analysis}

Fixations for the phase A and B were extracted for each trial via the dispersion algorithm (Salvucci \& Goldberg, 2000) with a temporal threshold of 100 ms and a spatial dispersion threshold of \(1.5^{\circ}\). Data collected during phase A are supposed to be indicative of the information extraction and motor planning preceding movement initiation. Still, since in many cases there was just one or even no phase A fixation on the stimulus, quantitative evaluations were done on the first 3 fixations (or up to the third fixation) and on the mean of these first three fixations. This choice was motivated by the consideration that 3 fixations amount to about 1 s of stimulus presentation, sufficient to retrieve necessary visual information and start the movement (according to reaction times), while later fixations could be more arbitrary and dependent on the subjects' preference and interest for the object. For qualitative evaluation and informative visualization, heatmaps were computed from fixation data. These were obtained by placing a Gaussian with \(\sigma=1^{\circ}\), centered on each fixation and height proportional to the duration of the fixation, so that longer fixations would be weighted more in the heatmap surface. Each map was scaled between 0 (not fixated) and 1 (longest fixated) to make maps comparable. Regions of interest were extracted considering the distribution of the finger points in each condition. In the 'open' condition, points were compactly concentrated around the opening region, hence mean and variance of the point coordinates sufficed to identify a rectangle containing the underlying region. In the case of 'lift', points were more evidently multi-modal, resulting in two major clusters one, smaller, for the thumb and one for the rest of the fingers. To include both clusters in the ROI, points were clustered via k -means, and a rectangle containing the region underlying both clusters was identified (see Fig.6, left, for an example of extracted ROIs). In most objects the two ROIs were well-separated. In a few cases, they were slightly overlapping and just in one case there was a major overlap. This, nevertheless, did not hamper the comparison with the heatmaps.

\section*{Results}

\section*{Heatmaps}

As a first qualitative impression of the general patterns of behavior observed in the three examined conditions, we compared heatmaps obtained from fixations of phase A, from first 3 fixations (in total and separated) and for the mean of the first 3 fixations. The same pattern was shown at different extents across all maps and objects, namely a maximum left of the object center in the 'classify' condition, a slightly higherleft of the center maximum in the 'lift' condition and a clear maximum on the opening region in the 'open' condition. Fig. 2 shows the phase A maps for one of the up-right objects and one of the horizontal objects. Already in phase A, taskdependent differences in eye fixations are evident.

Figure 2: Heatmaps of the phase A fixations superimposed on corresponding stimuli. From left to right: 'classify', 'lift' and 'open' condition.

Figure 3: Heatmaps of the first, second and third fixation (left to right). From top to bottom: 'classify','lift' and 'open' condition.

An evolution in time across the first 3 fixations/conditions for one object is presented in Fig.3. If the first fixation is usually close to the COG (with some undershoot) for all conditions, already by the second fixation is possible to infer where the scanpath will lead. The first fixation was a 'phase A' fixation in \(90 \%\) of cases, the second fixation in \(53 \%\), while the third just in \(28 \%\). Of 5733 examined fixations, 3359 were
phase A. While for the first fixation phase A fixations are equally distributed across tasks (1832 A fixations, \(34 \%\) classify, \(32 \%\) lift, \(34 \%\) open), in the second the proportion is in favor of lifting and opening (1037 A fixations, \(24 \%\) classify, \(33 \%\) lift, \(43 \%\) open), by the few third A fixations mostly for the 'active' tasks motion had not yet initiated (490 A fixations, \(17 \%\) classify, \(38 \%\) lift, \(45 \%\) open).

\section*{Average Fixations}

The mean of the first three fixations (or up to 3 ) on each stimulus image was extracted for each trial. Often the first fixation was in the direction of the COG of the object but landed either on the black background or on the edge of the object, hence showing some undershoot along the x -axis (we use image coordinates since the objects are not shown in a completely frontal view but in perspective, hence the center of the object outline would not correspond to the COG). A repeated measures ANOVA on the \(x\) coordinate of the average fixation with task and object as within-subject factors showed a main effect of task \((F(2,18)=36.9, p<.001)\), a main effect of object \((F(13,117)=19.87, p<.001)\), and and interaction effect of object and task \((F(26,234)=13.73, p<.001)\). The mean X coordinates according to object and task are presented in Fig. 4. For most objects, the 'classify' mean position was the most left and the 'opening' the most right. This is of course more extreme for horizontal objects, e.g, the gel tube, the white jar, the juice bottle, while for three up-right objects (yellow tea pot, orange tea pot, and chips tube) the lifting mean position is to the right of the opening position either because the handle was on the right or the plastic lid was best opened by exerting force with the right thumb.

Figure 4: Mean X coordinate of each object across task.
An analogous analysis was performed on the vertical mean location. Again the effect of task was significant \((F(2,18)=\) \(51.58, p<.001)\) as that of object \((F(13,117)=134.02\), \(p<.001)\) and interaction \((F(26,234)=28.13, p<.001)\).

The mean Y coordinates according to object and task are presented in Fig. 5. In this case the ordinate is expressed in image coordinates, with origin in the top left corner. Up-right objects (such as the green can or the chips tube) present of course the most extreme mean vertical location for the 'open' task, while for horizontal objects the mean y location is always at the same height with a slight tendency upwards in the 'lift' condition.

Figure 5: Mean Y coordinate of each object across task. Note that the \(y\) axis is in picture coordinates, hence the lower the value the higher the location in the picture.

\section*{Comparison Heatmaps-ROI}

To gain a more specific insight regarding to what extent the fixation map can predict the region on which the motor action is performed, we compared the ROIs extracted for the two 'active' conditions with the peak of the corresponding heatmaps achieved considering the first three fixations (see Fig.6). The peak of the fixation map (where the map has value 1) consistently falls within the corresponding ROI. The mean distance between the peak and the center of the ROI for the 'lift' condition was \(91.1 \pm 59.52\) pixel, while for the 'open' condition was \(63.2172 \pm 35.53\). In both conditions the distance between the peak and the center of the corresponding ROI was always smaller than that to the center of the other ROI (one-tailed t-test, \(p<.001\) ).

\section*{Reaction Times}

Mean reaction times in releasing the spacebar significantly increase from 'classify' to 'lift' to the 'open' condition. The difference is most pronounced between 'passive' and 'active' conditions (classify: \(0.596 \pm 0.052 \mathrm{~s}\), lift: \(0.805 \pm 0.126 \mathrm{~s}\), open: \(0.826 \pm 0.110 \mathrm{~s})\). A repeated measures ANOVA on the average reaction time with task and object as withinsubject factors showed a main effect of task \((F(2,18)=7.04\), \(p=0.006)\) and a main effect of object \((F(13,117)=2.14\),

Figure 6: Left: touched points and Regions Of Interest extracted for one of the stimuli (green: 'lift' condition; magenta: the 'open condition'). Center: heatmap of the first 3 fixations in the 'lift' condition (in green the center of the corresponding ROI). Right: heatmap of the first 3 fixations in the 'open' condition (in green the center of the corresponding ROI).
\(p=0.016\) ). The mean reaction times for object and task are presented in Fig.7. Three objects (spice bottle, basket, and yellow tea pot) obtained shorter reaction times for opening than for lifting, in contrast to the general pattern - possibly because of the size difference compared to the real object, which made the decision on how to lift the object more difficult, and because of the particularly obvious opening action for all three objects. It must be noted that longer reaction times in the active tasks may be due not only to motion planning and affording points selection but also to the extraction of 3D information in absence of disparity cues.

Figure 7: Mean reaction times of each object across task.

\section*{General Discussion}

The presented experiment was aimed at assessing different eye movement strategies employed in identifying an object in contrast to tasks in which actual interactions had to be performed on the object. The distinct tasks as well as the objectspecific affordance points were expected to strongly influence the distribution of eye fixations on each object. Indeed, we found significant differences in the scanpath behavior in the 3 conditions, suggesting for each one the construction of a spe-
cific attentional landscape around the informative/affording points.

In the classification task, the mean position of the first three fixations was mostly in the direction of the COG of the object. When grasping an object to lift it, fixations concentrated on a position to the left of and slightly higher than the COG. On the one hand, it seems reasonable that instead of fixating both contact points in an alternate fashion, fixating near the center of the object allows both contact points to be in the fovea and para-fovea, as suggested in (Desanghere \& Marotta, 2011). On the other hand, for up-right objects a preference to fixate more on the side of the thumb could be observed, while horizontal objects were on average fixated closer to the rest of the fingers. In the case of the two objects with a handle, there was a smaller peak in the center of the object (suggesting a first brief fixation there) and a higher mode on the handle, where later, longer fixations concentrated. In both cases it is possible that due to the objects' reduced size, subjects first considered lifting them with a power grasp and then went for the handle. In the case of opening, the fixation distribution presented a clear peak well localized on the opening region, which required the most processing for the planning of the finer motor operation (usually performed with a precision grip). Even if the overall distribution of fixations is already indicative, the different patterns in the unfolding of the scanpath are best appreciable when looking at the temporal evolution of the first three fixations. The distributions of the first fixation is hardly distinguishable across tasks, but already by the second fixation (at which point the reaching movement often had not been initiated, yet) the task 'signature' became evident.

These results confirm the general predictive nature of eye movements. Beyond that, however, our data indicate that tracking eye movements may be exploited in even more subtle ways, inferring the exact intention of how a user may interact with an object. Such discriminability of eye scanpaths according to the intended interaction goal may substantially help in devising machine learning algorithms to timely infer the intention of impaired patients and possibly inform assistive interfaces to control prosthetic devices without the need of cumbersome training. The reliability with which the fixation mode consistently fell within the specific ROI supports considerations.

It seems plausible that the general flow of processing is first concerned with locating the object of interest (first fixation close to the COG). Next, it moves towards the most informative points - either for decision making in the case of the classification task, or for the purpose of executing anticipatory behavior control (Hoffmann, 2003; Butz, Sigaud, Pezzulo, \& Baldassarre, 2007) towards interaction-relevant points (for lifting/opening) with proper behavioral interaction routines. In the former case, just the ventral system would be involved, pooling resources for recognition and decision-making. In the latter, 'active' conditions, also the dorsal pathway and premotor cortical regions would be substantially involved. After object localization and recognition, object-relative behavior needs to be planned, which involves reference-frame transformations of position, size, and shape and planning of reaching and grasping motions with properly aligned hand shapes (Jeannerod, Arbib, Rizzolatti, \& Sakata, 1995; Cisek, 2007; Herbort \& Butz, 2011). The consequentially more elaborate motion planning is also confirmed by significantly longer reaction times when an active motor task, different for every object, has to be planned anew.

In conclusion, as for more complex behavior, even for single actions to be performed within the same object, the eyes extract visual information in a goal-oriented, anticipatory fashion, incrementally revealing the interaction intentions.

\begin{abstract}
Self-explanation is an important constructive cognitive process that helps students learn in such a way that they can flexibly transfer their knowledge to solve novel problems (Chi, Bassok, Lewis, Reimann, \& Glaser, 1989). However, research has not addressed what leads students to spontaneously self-explain, in the absence of prompting. The present study experimentally manipulates student motivation (in terms of achievement goals) and measures what influence this has on self-explanation and transfer. Participants ( \(N=\) 140) received goal framings that reflected either a masteryapproach goal (striving to develop one's understanding), a performance-approach goal (an aim to outperform others), a performance-avoidance goal (avoid doing worse than others) or a no-goal control. This framing was applied to a set of learning and test tasks on basic statistics, which participants completed while thinking aloud. Results showed a benefit for a performance-avoidance condition in terms of both higher levels of self-explanation and transfer. This unexpected result is discussed in terms of theories of motivation and learning, and their potential impact on educational practice.
\end{abstract}

Keywords: Knowledge Transfer, Motivation, Achievement Goals, Self-Explanation, Education

\section*{Introduction}

A fundamental goal of instruction is to foster learning which leads to successful, flexible, and useful knowledge transfer. Research and theoretical development which elucidates how knowledge transfers has a long history in psychology and cognitive science, and continues to be important for educational psychologists and learning scientists. Continuing to advance our understanding of what sorts of learning activities lead to transfer allows for recommendations on how to improve educational practices.

Evidence has accumulated that a promising method for promoting flexible knowledge transfer is to increase the conceptual quality of the original learning (Pashler et al., 2007). As such, constructive learning processes which promote the acquisition of more abstracted knowledge (e.g., schemas) are likely to promote successful knowledge transfer. A representative example of such a process is selfexplanation (Chi, Bassok, Lewis, Reimann, \& Glaser, 1989), which is the process by which students generate, for themselves, explanations which go beyond the text, inferring underlying principles and highlighting important interrelations. Chi et al. (1989) documented a large
difference in the amount and quality of self-explanations between those students who ultimately go on to flexibly transfer their knowledge and those who do not. A number of studies since have documented that students can be prompted to engage in self-explanation (e.g. Aleven \& Koedinger, 2002) with beneficial effects for learning and knowledge transfer. However, a fundamental question about self-explanation has been left unaddressed; what leads students to engage in self-explanation, in the absence of prompting? It is clear that some students do so, to their benefit, while others do not. It is also likely that whether students are capable of self-explaining profitably is not the sole limitation, given the experimental literature which shows a benefit for self-explanation prompts. In the present research, we address the possibility that student motivation leads to the spontaneous use of self-explanation during learning, and that this can influence the likelihood of successfully transferring. While Chi et al. (1989) conjectured that higher levels of self-explanation are "a natural consequence of wanting to understand the solution example better" (pg. 160), no research has systematically tested this claim. As we will review in the subsequent section, this sort of motivation has been studied extensively by researchers of "achievement goal theory," which has documented just such a desire, labeling it a "masteryapproach" goal. The present study leverages achievement goals as a tool for experimentally investigating how motivation influences self-explanation and transfer.

\section*{Achievement Goal Motivation}

Achievement goals are the reasons people have for engaging in achievement settings, such as school or work. An achievement setting is one that is organized around one's competence in a domain, and an achievement goal describes a goal a person has in relation to this competence, such as wanting to use it demonstrate how good they are in this domain, or wanting to develop their competence so that they can complete more challenging work. A large body of research and theory development has led to a generallyaccepted framework which proposes three main classes of goals (Elliot, McGregor, \& Gable, 1999); mastery-approach, performance-approach, and performance-avoidance. A mastery-approach goal is an aim to improve or develop one's competence or understanding. A performance-
approach goal reflects striving to demonstrate one's competence by doing better than one's peers, while a performance-avoidance goal occurs when one strives not to demonstrate one's incompetence, compared to peers \({ }^{1}\).

Research has shown that these goals produce a characteristic pattern of effects on various learning behaviors, affective states, and measures of performance. Specifically, performance-avoidance goals tend to be associated with negative outcomes, such as lower performance and worse study strategies (e.g., Elliot, Shell, Henry \& Maier, 2005, Elliot, McGregor, \& Gable, 1999). Performance-approach goals have been associated with a mixed pattern of results, such that they are sometimes associated with positive effects on grades, but also with more shallow learning strategies (e.g., Elliot, McGregor, \& Gable 2001). Mastery-approach goals tend to be associated with positive affective outcomes, such as increased interest (Harackiewicz, Barron, Pintrich, Elliot, \& Thrash, 2002). Results relating to grades are inconsistent, with the majority of studies finding no relationship between grades and transfer (Linnenbrink-Garcia, Tyson, \& Patall, 2008). Critically for understanding the present study, masteryapproach goals have been linked to better performance on more difficult tasks (Utman, 1997), as well as self-reported constructive learning processes (e.g., Elliot, McGregor, \& Gable, 1999). Additionally, a small number of studies have documented a link between mastery-approach goals and knowledge transfer (e.g., Belenky \& Nokes-Malach, 2012).

It is important to note that the prevailing method for measuring achievement goals in this research literature is through self-report questionnaires and assessed at the level of academic courses. That is, goals for a particular course are assessed at the beginning of a semester and then are correlated to self-reports of learning behaviors collected during the semester, as well as achievement measures such as grades on a final exam. However, this "course-based" style of measurement may inadvertently measure more than goal motivation. That is, it may reflect other personality characteristics (e.g., Need for Cognition; Cacioppo \& Petty, 1982), beliefs (e.g., Naïve theories of intelligence, Dweck, 1999) and other variables that are not motivation, per se. Developing a strong theory of how motivation influences behavior requires a narrower focus on a task-by-task basis.

As such, in the current study, we focus on "task-based" achievement goals, and draw upon the literature that experimentally manipulates these goals for a given task. In studies of this nature experimenters provide some information to frame the task for participants in such a way that leads to the adoption of a particular achievement goal.

The question addressed in the present research is whether one can produce a change in self-explanation behaviors by manipulating motivation for the task, such that a benefit is

\footnotetext{
\({ }^{1}\) Readers familiar with achievement goal research may note the exclusion of mastery-avoidance goals in this discussion. As these goals are a newer addition to the field, and have less empirical studies to establish their effect on learning and transfer, they are not a focus of the current work.
}
observed for knowledge transfer. Specifically, we test the hypothesis that manipulated mastery-approach goals predict increased self-explanation, compared to performanceapproach or performance-avoidance goals. Additionally, we expect that the mastery-approach condition will produce higher levels of transfer, as observed for course-based goals in prior research using similar materials (Belenky \& NokesMalach, 2012).

\section*{Method}

\section*{Participants}

The participants were 140 undergraduates from the University of Pittsburgh, who participated in exchange for course credit. The first 105 participants were randomly assigned to the mastery-approach, performance-approach, or performance-avoidance conditions ( 35 each). The no-goal control was collected the following academic semester.

\section*{Materials}

The materials were presented to participants in binders. Within each packet was a pre-test, a set of learning activities, activity questionnaires, a post-test, and a final set of questionnaires.
Learning Activities. The learning materials were adapted from the "Tell-and-Practice" materials used in prior research (Belenky \& Nokes-Malach, 2012; Schwartz \& Martin, 2004). These materials comprise worked examples and problems that introduce, model, and give practice problems on two basic statistical concepts; mean deviation and standardized scores.

Specifically, participants first received a worked example on how to calculate mean deviation, which demonstrates the standard procedure. This was followed by a learning activity problem that presented data from four pitching machines and asked the participant to decide which of the four is the most reliable. The datasets are designed in such a way that contrasting between them should help focus participants' attention to the critical features of the mean deviation formula (and their conceptual underpinnings), such as the number of data points, the spread, etc. However, with the tell-and-practice nature of the activity, these aspects could be ignored in favor of a "plug-and-chug" method.

After completing this problem, participants moved on to the next worked example, which described a scenario where two students in different classes want to know who did better on a test, given that their teachers may grade differently. The worked example showed the participant how to draw a histogram for each of the classes, and then how to map the given information about means, mean deviations, and the particular students' scores onto the histogram. Finally, it explains how the participant can use this information to decide which is better. This procedure is roughly equivalent to graphically estimating a standardized score. Immediately following this worked example was another learning activity problem; this one asked students to decide which of two world records, from two different track and field events, was "more shattered." Students were given
a set of scores from two different events and two exceptional values for each, and told to use the procedure they had just learned to help them decide which had a more impressive performance, given the rest of the competitors.
Test Materials. The pre-test consisted of a procedural fluency measure, a transfer problem, and a graphical representation problem. The post-test included, in order, three procedural fluency items, a worked example on standardization, a mean deviation word problem, an openended explanation problem, and a transfer problem. This manuscript will focus exclusively on the transfer measures, which dealt with the target concept of using standardized scores to compare values from two different distributions. These problems presented an exceptional value from each of two different distributions, along with their means and standard deviations, and asked the participant to decide which of the two values was more impressive. One problem dealt with the distance of homeruns, and the other with scores on a driving test. Correctly solving these problems requires calculating a standardized score, so that the degree to which each value is exceptional, compared to the distribution it comes from, can be determined.

In accordance with research on transfer as Preparation for Future Learning, a worked example was embedded in the post-test, a few problems before the transfer. This worked example describes a scenario (with data) in which a standardized score is needed to help determine which of two performances in different athletic events was better, demonstrates the formula for a calculating a standardized score, and uses that formula to solve the problem. This is followed by another very simple problem and a prompt to use the formula to solve it, which all participants solved correctly. Correctly solving the subsequent transfer problem indicates that participants learned this procedure well, and understood that it could help them solve problems where they need to compare across two different distributions.
Activity Questionnaires. Following the learning activities, participants completed two pages of questionnaires. The first page contained a manipulation check modeled on prior research (e.g., Elliot et al., 2005). The second measured their task-based goal adoption during the learning activity, which serves as another measure to ensure that the goal manipulations produced the anticipated effects. The manipulation check asked students "At the beginning of the learning phase, you were asked to focus on just one goal for this study. What was it?" (the manipulation will be described in the next section). It asked participants to check only one of the possible responses, which corresponded to performance-avoidance, performance-approach, and mastery-approach.

The second page was a measure of their achievement goal adoption during the just-completed learning phase. Specifically, this questionnaire had six Likert-scale (1-7) items that each started with the stem, "While completing these activities," which was followed by descriptions of either a mastery-approach (skill development and improved understanding), performance-approach (doing better than
others), and performance-avoidance (not doing worse than others) goal. Two items of each of these goal types was included, and, after ensuring that they had adequate reliability (Cronbach's \(\alpha=.65\) for mastery-approach, .84 for performance-approach, .88 for performance-avoidance) a construct score was created for each by averaging across the two items.
Final Questionnaires. The questionnaires administered at the end of the experiment assessed participants' task-based goal and strategy adoption during the experiment, their course-based achievement goals for mathematics, selfreported strategy usage during the experiment, and demographic information. These will not be addressed in the current manuscript, but the general pattern of results on the goal-related measures was similar to that on the activity questionnaire and manipulation check, which will be presented in the results section.

\section*{Procedure}

The procedure followed the order of the packet, with additional instructions provided by the experimenter on the talk-aloud protocol and the goal manipulation, which both occurred after the pre-test. Specifically, the procedure consisted of: pre-test ( 5 minutes), talk-aloud training (2 minutes), goal manipulations ( 5 minutes), learning activities and activity questionnaires ( 20 minutes), post-test (20 minutes), final set of questionnaires, and a short debriefing ( \(\sim 8\) minutes). Important aspects of the procedure carried out by the experimenter will be described next.
Talk-Aloud Training. After the pre-test, the experimenter informed the participants that they would be recorded as they talked aloud during parts of the experiment. To practice doing so, participants were given a sheet with simple arithmetic problems and asked to talk aloud as they solved them. The experimenter listened and gave corrective feedback if participants were not talking aloud properly (i.e., without reflection, but simply saying what was in their working memory at the time; see Ericsson \& Simon, 1993).
Goal Manipulations. After the talk-aloud training, participants in the experimental conditions received the goal manipulation. The manipulations focused on the reasons that the study was being conducted, and how that should influence the goals participants should adopt as they went through the study. These were constructed based on reported studies (e.g., Elliot et al., 2005) and were delivered verbally by the experimenter in a conversational manner, as additional information about the study. Specifically, all participants first heard a general statement about how people can have different goals in different situations before receiving the manipulation specific to their condition. Among other aspects of the manipulation (see Table 1), the mastery-approach condition was told that their goal should be "to develop your understanding of these materials and your skill in solving these types of problems." The performance-approach condition was told to focus on the

\end{tabular}
goal "to perform well compared to other participants." The performance-avoidance condition was told their goal should be "to not perform poorly compared to other participants."

\section*{Protocol Coding}

Transcriptions were made of the verbalizations participants produced during the learning phase, the worked example in the test, and the transfer problem. These were then broken down into utterances (defined as one classifiable thought, usually at the level of a sentence). Each utterance was then coded according to a rubric which was developed based on prior research on self-explanation, and refined to reflect the statements made by participants through a process of iterated revisions. Although the full rubric covered a number of categories, this manuscript will focus on a small set that were a priori considered the most theoretically interesting. In particular, we focus on those statements coded as self-explanations and as comparisons between the transfer problem and the earlier worked example, as these are considered strong evidence of constructive learning processes (Renkl, 1997).

\section*{Results}

The first set of analyses deal with the question of how successful the manipulations were in influencing goal adoption. The two measures of goal adoption reported here are the manipulation check - which asked participants in the three experimental conditions to recall the goal they had been asked to focus on - and the activity questionnaire.

The forced-choice manipulation check clearly demonstrated that participants knew which goal they were asked to focus on, \(\chi^{2}(4, N=105)=176.35, p<.001\), with \(94 \%\) of the participants in the experimental conditions correctly choosing their condition. Each of the activity questionnaire goal adoption scores (calculated as described in the methods section) were also analyzed in separate oneway ANOVAs. There were significant differences between the three conditions for each of the mastery-approach, performance-approach, and performance-avoidance goal adoption scores, \(F \mathrm{~s}(2,102)>9.35, p \mathrm{~s}<.001\).

Additionally, a series of planned comparisons was conducted between each pair of conditions on each goal adoption score. On the measure of mastery-approach goal adoption, the mastery-approach condition was significantly higher than the performance-approach, \(t(68)=2.59, p=\)
.012 , and performance-avoidance, \(t(68)=4.13, p<.001\), conditions on mastery-approach goal adoption, but not significantly different from the control condition, \(t(68)=\) 1.53, \(p=.130\), (see Table 2). For performance-approach goal adoption, the performance-approach condition was significantly higher than the mastery-approach, \(t(67)=\) \(9.17, p<.001\), or control condition, \(t(68)=6.36, p<.001\) but not significantly higher than the performance-avoidance condition, \(t(67)=1.90, p=.062\). Finally, performanceavoidance goals were adopted the least by the masteryapproach condition, \(t\) s \((68)>4.42, p \mathrm{~s}<.001\). All other conditions did not differ statistically in their performancevoidance goal adoption, ts \((68)<.86, p \mathrm{~s}>.39\).

All told, the manipulations clearly created a different pattern of results across the mastery, control, and performance conditions. However, the performanceapproach and performance-avoidance conditions did not differentiate as cleanly.

\end{tabular}

\section*{Goals and Transfer}

Given that the manipulations seemed to produce the desired goal adoption, we turn to the first hypothesis; namely, that mastery-approach goals would lead to better transfer. As the transfer problem was coded dichotomously, correct or incorrect, logistic regression was used to assess differences between the conditions in the likelihood of correctly solving the transfer problem. The logistic regression model predicting the likelihood of transfer based on the categorical variable of condition was significant, \(\chi^{2}(3, N=140)=\) \(11.24, p=.011\). This analysis revealed that both the control (54\%) and mastery-approach (49\%) conditions were significantly less likely to transfer than the performance-
avoidance condition (83\%). There was no significant difference between the performance-approach (69\%) and the other three conditions.

While the mastery-approach condition did not increase the likelihood of transfer, it is possible that the degree to which a student adopts a mastery-approach goal would benefit transfer. To analyze this prediction, goal adoption (as measured by the construct scores from the activity questionnaire) was entered as a predictor of a transfer in a logistic regression model. This model was significantly better than a constant-only model, \(\chi^{2}(3, N=140)=11.92, p\) \(=.008\). Within this model, the only variable which is significantly different from zero is the performanceapproach construct score, Wald's \(\chi^{2}(1, N=140)=9.36, p=\) \(.002, \operatorname{Exp}(B)=1.19\). For every unit increase in adopted performance-approach goals, the likelihood of transfer increased by \(19 \%\).

To summarize, it appears that mastery-approach goals did not lead to an increased likelihood of transfer \({ }^{2}\). Instead, the performance-avoidance condition had the highest levels of transfer, and, in terms of goal adoption, only the degree to which performance-approach goals were endorsed predicted transfer.

\section*{Goals and Self-Explanation}

The second hypothesis being investigated was that masteryapproach goals would lead to more self-explanation. Results for the three experimental conditions are reported here, as coding for the control condition remains ongoing. One participant from the mastery-approach condition is not included in these analyses, as her think aloud data was lost due to a technical error.

There were no significant differences between the experimental conditions in the number of self-explanations made overall, \(F(2,101)=.01, \mathrm{p}=.995\), or on time spent making self-explanation statements, \(\mathrm{F}(2,101)=.93, \mathrm{p}=\) .40. Subsequent analyses examined self-explanations made during each of the particular components of the study that were coded (the learning phase, worked example, and transfer problem). There were no differences between the conditions on self-explanations made during the learning phase, \(F(2,101)=.37, p=.689\). For the worked example on standardization, there was a significant difference between conditions, \(F(2,101)=4.00, p=.021, \eta^{2}=.073\). Post-hoc analysis revealed a higher degree of explanation statements for the performance-avoidance condition ( \(M=\) \(.94, S D=1.49\) ) compared to the performance-approach condition ( \(M=.37, S D=.54\) ) and the mastery-approach condition ( \(M=.38, S D=.49\) ). Finally, for the transfer problem, there was no difference between conditions on self-explanation, \(F(2,101)=2.39, p=.097\).

The other type of constructive learning behavior that was analyzed was comparisons back to the worked example during the transfer problem. For example, statements like

\footnotetext{
\({ }^{2}\) The same pattern of results is observed when controlling for pre-test transfer performance.
}
"So we'll just, um do that procedure we were doing before... like the standardized number" were coded as referencing back to the worked example. There were significant differences in this type of elaboration, \(F(2,101)\) \(=3.15, p=.047, \eta^{2}=.059\). Post-hoc analysis revealed that the performance-avoidance condition ( \(M=.37, S D=.60\) ) produced significantly more of these statements than the performance-approach condition ( \(M=.06, S D=.24\) ), but there were no differences between the mastery-approach condition ( \(M=.26, S D=.67\) ) and either of the other two.

In summary, the performance-avoidance condition generated the most self-explanation statements during the worked example. Additionally, this condition referenced the worked example more during the transfer problem than the performance-approach condition.

\section*{Discussion}

The current study experimentally manipulated achievement goals for a learning and transfer task, and found that a performance-avoidance goal manipulation had a positive effect on transfer. This condition produced the most selfexplanations during the worked example, and made the most references back to the worked example during the transfer problem. This is a different pattern of results than was expected, as course-based performance-avoidance goals are usually associated with negative outcomes, and almost never associated with positive ones. We will discuss possible reasons for these results, and describe how future research can confront the issues this research presents.

One obvious possibility is that task-based and coursebased goals do not reflect the same constructs, and produce different effects. As discussed earlier, measures of coursebased achievement goals may reflect other individual differences, like personality traits and beliefs. These (typically unmeasured) individual differences may in fact be responsible for the observed pattern of results found in prior research, rather than achievement goals themselves. Benefits that have been associated with course-based mastery-approach goals (e.g., interest, better study strategies, transfer) may actually be due to individual differences like need for cognition (Cacioppo \& Petty, 1982) or incremental theories of intelligence (Dweck, 1999), which may lead to both a higher level of mastery-approach goal endorsement, as well as self-reports of positive learning behaviors and grades. If this were so, manipulations that only target task-based goals would be unlikely to aid learning. However, this is somewhat contradicted by the present results, which do find a benefit for performance-avoidance goals. It will be important for researchers to consider in what ways course-based and taskbased goals are similar and in what ways they are different.

While the performance-avoidance condition did seem to perform the best, other measures indicate that it may be premature to tout the utility of this type of goal. Students in both performance goal conditions reported similar goal adoption, and only performance-approach goal adoption was predictive of transfer. The current results indicate that
performance goals may help guide students towards generating explanations and knowledge transfer, but research on the relative impact of each type of goal is needed. This is especially important giving the general consensus in the literature that performance-avoidance goals do not aid learning.

An interesting avenue for future research will be to explore how different types of learning activities can influence motivational effects. It is possible that performance-avoidance goals are particularly beneficial for learning simply material and for nearer transfer, compared to more challenging materials. Participants may have perceived the learning materials in this study as quite straightforward. For example, correctly solving the transfer problem required a direct application of the procedure in the worked example to the transfer problem. The performanceavoidance condition produced more self-explanation during the worked example, and referenced the worked example during the transfer problem more frequently than the other conditions, indicating a relatively direct transfer of knowledge. Mastery-approach goals may benefit "further" transfer than what was required for this task. Using goal manipulations across a variety of learning and performance tasks will allow for a richer picture to emerge. Research on regulatory fit (e.g. Higgins, 2000), for example, has shown that prevention goals (similar to avoidance goals) improve performance in tasks organized around minimizing losses, while promotion goals (similar to approach goals) help with tasks based on maximizing gains. Similar interactions may occur between achievement goals and different task structures encountered while learning.

While the results did not support the hypothesis that mastery-approach goals promote self-explanation and transfer, the study did achieve one of its aims. Specifically, a short motivational intervention produced a change in taskbased goals, which led to different levels of self-explanation and transfer. While important questions were raised as to which goal may be most beneficial in which settings, the fundamental premise (that goals influence learning behaviors and transfer) was supported. This research can provide a basic paradigm for further inquiry.

The study of motivation in academic settings is a fruitful enterprise, as it can inform both cognitive psychology theories of how people learn, as well as educational practice to improve learning outcomes. Future research should continue to address what influence adopted goals have on behavior, as theories of motivation are useful inasmuch as they can be used to predict behaviors. Measures of coursebased goals seem quite predictive of long-term success, and of certain self-reported attitudes, behaviors, and affective experiences, but it is less clear what effect they have on moment-to-moment behaviors. More broadly, incorporating motivation into theories of learning and knowledge transfer (see Nokes \& Belenky, 2011) remains an important goal for cognitive scientists who wish to have an impact on educational practice, while also furthering our understanding of the human cognitive architecture.

\begin{abstract}
We investigated the behavior of participants tasked with communicating in a novel environment. Participants had to use their mouse to draw graphical representations (termed squiggles in the game) of human faces in order to communicate with fellow players. Experiment 1 investigated the effect of varying features of the input images on the resulting drawings. Experiment 2 introduced varying comprehension conditions that were predicted to produce differences in how features of faces would be graphically represented. In experiment 1 , the features of the different faces significantly shaped the structure of the resulting squiggles. In experiment 2, the structure of the squiggles was influenced by the environment in which they were interpreted.

\section*{Introduction}

For an individual learner, language can be described as a moving target (Christiansen \& Chater, 2008; Chater, Reali, \& Christiansen, 2009). Languages are commonly assumed to undergo changes at various levels. Recent studies have sought to identify the extra-linguistic factors that may determine the direction of these changes. These perspectives articulate an adaptive approach to our communication system: Any existing variability in a population of language users may have their language move in particular directions because some of those variants are more useful or successful than others at propagating. For example, recent studies have argued that the social environment of languages is a very important factor for these changes and developments (Lupyan \& Dale, 2010; Wray \& Grace, 2007). In addition, humans are able to invent new communication systems on the fly, with the emergence of Nicaraguan Sign Language and Al-Sayyid Bedouin Sign Language being two of the most impressive cases (Meir et al., 2010).

In recent years, a number of studies have been conducted with a focus on the structure of new communication systems that emerge in a given environment. In these studies, participants have to use novel symbols to successfully communicate with other participants. Over time, participants achieve more efficiency in their communication by aligning their symbols (Fay et al., 2010; Galantucci, 2005; Garrod et al., 2007).

In another line of research, the same question has been tackled by the use of different "generations" of participants. The first generation of participants learns simple word-object patterns, and then passes this information on to a new generation of learners. After a couple of generations, struc-
ture emerges that was absent in the original language system (Kirby, Cornish, \& Smith, 2008).

This literature offers new insights, and importantly new techniques, for exploring artificial communication systems as a testbed for the forces that may drive communicative change. The present paper aims to shed light on the ways structure emerges in a new communication system by combining these two experimental frameworks in a large-scale interactive communication game. Specifically, we look to how the structure of a referential environment - the space of things that a community is going to talk about, and how these things are encountered - shapes the manner in which individuals in that community communicate. A first, exploratory experiment investigated the different strategies participants would employ to communicate a given image and how this given image influences the structure of the produced symbol. A further experiment introduced different environmental conditions that affected the way symbols were structured.

\section*{Previous Work}

The current study expands on previous work by Dale and Lupyan (2010), in which players connect via the Internet to a gaming platform, where they had to create and comprehend visual signs for objects in order to communicate with other participants. Successful communication was achieved when players where able to match a previously drawn sign to its corresponding object.

The experiment consisted of two trial types: the production (speaking) and comprehension (listening) trials. In a speaking trial, participants were shown an object, and after a short delay, had three seconds to "squiggle" an image by clicking and dragging their computer mouse on a provided canvas. Such a method is akin to putting a temporal bandwidth on the ability of the user to sketch the image. This was designed to avoid their using English orthography or detailed sketches. Participants had to focus on essential aspects of an image to relay it. A different approach was used by Galantucci (2005), who used a rotating tablet to keep subjects from using orthography. Because this game framework is used online, the temporal bandwidth is a straightforward way of doing this, while also moving the game along more quickly.

In a listening trial, players were shown a previously drawn squiggle, along with two pictures of objects. The participant then had to choose the matching picture by clicking on it. Feedback is given whether they chose the correct picture. In the original work, squiggles in the listening trial were cho-
sen according to an evolutionary algorithm factoring in the novelty of the squiggle and its previous comprehensibility. Squiggles that performed badly in listening trials thus "die out" and are no longer used.

Data from 60 users were collected, which resulted in around 1,400 produced squiggles and around 4,100 listening trials. Feedback by the players was generally very positive and many found it to be entertaining and rather addictive.

Results from this study supported the findings from other studies: a) Squiggles get simplified. The average size of a squiggle shrinks over gameplay; b) The evolutionary algorithm produced stability for most squiggles, despite opportunities for novel squiggles to replace them during listen trials and c) Squiggles were at first drawn highly iconically, but gradually evolved towards more simplified symbols as participants continued playing.

In the current paper, we utilize this framework as a testbed for exploring how environments shape the squiggles as participants play. The central hypothesis guiding the study was that users' squiggles are shaped by their "listening" environments (i.e., distribution over the foil-target pairs). In what follows, we first describe our redesign of the system, and an initial exploration (Experiment 1) of how aspects of objects can predict aspects of squiggles. Following this, we describe a comparison of two conditions (Experiment 2) meant to more subtly explore the role of the distribution of listening trials in determining squiggle composition.

\section*{Experiment 1}

\section*{Method}

Game Design The approach in Dale and Lupyan (2010) was replicated in the present study. However, the game was re-written to take into account new technological developments to ensure maximal compatibility with current browsers. We chose a specific domain of objects for squiggles to make "reference" to: human faces. While the previous study used a non-standardized set of pictures, all pictures were now taken from the Face Database (Minear \& Park, 2004). This had the advantage that all picture used the same light conditions, background, facial expressions and dimensions. Variability on those parts was thus excluded. 120 pictures were chosen with respect to their age and gender, using a \(2 \times 2\) matrix, with 30 pictures in each set (cf. Table 1). In order to reduce the number of salient features in these images, pictures with very distinguishing features such as birthmarks and earrings were not chosen.

Table 1: Summary statistics for the different picture sets
\begin{tabular}{|l|c|c|c|}
\hline Group & M (Age) & SD (Age) & Range (Age) \\
\hline Young Males & 21.35 & 2.35 & \(18-28\) \\
Young Females & 21.53 & 2.85 & \(18-28\) \\
\hline Old Males & 73.37 & 7.47 & \(61-91\) \\
Old Females & 73.80 & 6.69 & \(61-85\) \\
\hline
\end{tabular}

Participants connected to the gaming platform via the Internet. Players were instructed to squiggle the displayed images so that other players are able to match a squiggle to the correspoding image later.

In the speaking trial, one of the 120 pictures in the data set was randomly shown to the participant along with a framed "canvas" on which participants could draw (Fig. 1). Participants had five seconds (without delay) to draw on the canvas before a listening trial appeared. The time limit was increased from the earlier study as the delay until the countdown started was removed. The remaining time for the speaking trial was shown to the user below the canvas.

In the listening trial, a squiggle previously produced by a fellow player is animated on a canvas using the original speed and directions of the user who had drawn the squiggle. The matching image was then placed either above or below this squiggle, with a competitor image taking up the other position (Fig. 2). Players had to click on the matching image in order to successfully communicate, and received visual feedback whether they had made the right choice. The ratio of speaking to listening trials was 1:3.

An important constraint on communication was time - participants were given only 5 seconds to create the squiggle.

Remember: Draw a Squiggle representing
the person you see so that other people can make the connection later!

Figure 1: An example of a speaking trial.

Expectations Experiment 1 mainly served as a first step in testing the impact that different image dimensions have on the behavior of participants. It also served as an exploratory study of this behavior. We were interested in the different strategies employed by players to communicate. Which salient features were chosen and which were the most efficient? The input images were believed to have an effect on the way squiggles were structured by the participants; that is, we expected dimensions such as age and gender to influence squiggle strategies.

It was predicted that users would perform better in the listening trials with more practice, and hypothesized that the

Remember: Click the picture you think the Squiggle is representing!

Figure 2: An example of a listening trial.
complexity of produced squiggles would shrink over time. Players were expected to become more efficient with more exposure to the communication system in both the listening and speaking trials.
Participants 100 participants from the United States were recruited via Amazon Mechanical Turk and compensated financially (\$0.75) for taking part in the study. The use of Amazon Mechanical Turk had the indispensable advantage that players signed up almost instantaneously and simultaneously, which created a community of speakers playing at the same time and communicating with each other. Participants had to produce thirty squiggles and the respective number of listening trials (90) in order to receive compensation.

\section*{Data}

On speaking trials, measurements of coordinates were taken along the paths drawn by the players. Time stamps were collected at each sampled \(x, y\) coordinate. The length in pixels of each squiggle was calculated using the stored coordinates. The number of unique strokes was collected as well.

In the listening trial, unique identifiers for the player, squiggle and corresponding image as well as the competitor image were stored. The comprehension of the result whether the correct picture was chosen - was stored in a binary fashion along with the time it took the player to decide.

Data by participants who produced fewer than thirty squiggles were excluded, leaving data from 96 participants.

\section*{Results}

Communication Strategies (Speaking) We performed a linear mixed-effects model on the relationship between the total length of a squiggle in pixels and the interaction of age, gender and progression of gameplay. Random effects consisted of the subject and item. \(p\)-values were obtained by calculating the likelihood of the corresponding \(t\)-values in a normal distribution. We found main effects for gender and age of the target, as well as for the progression of gameplay. Additionally, there was an effect for the interaction between age and gender. Squiggle length decreased for male input images \((t=-9.47, p<0.0001\) ) by 129.6 pixels \(\pm 13.68\) (standard error). Squiggle length decreased for young input images \((t=-3.19, p=0.001)\) by 43.33 pixels \(\pm 13.68\). Length increased slightly over time by 1.1 pixels \(\pm 0.39(t=2.71\), \(p<0.0001\) ). The interaction of age and gender meant that squiggles for young males were 42.24 pixels \(\pm 19.37\) longer than for old males ( \(t=3.91, p<0.0001\) ), negating the main effect of age for males (Fig. 3).

Figure 3: Average length of squiggles grouped by item age and gender

To account for possible differences in compositionality, we carried out a linear mixed-effects model on the relationship between the number of strokes and the interaction of age, gender and progression of gameplay. \(p\)-values were obtained by calculating the likelihood of the corresponding tvalues in a normal distribution. We obtained main effects for age, gender and progressing gameplay. Squiggles contained more features \((+0.195 \pm 0.08)\) if depicting a male \((t=\) \(-2.42, p=0.015\) ) or young person \((+0.38 \pm 0.08, t=4.80\), \(p<0.0001\) ). The number of strokes also increased slightly by \(0.008 \pm 0.002\) with more practice \((t=3.43, p<0.001)\). An effect of the interaction between age and gender \((t=-3.55\), \(p=0.0004\) ) meant that the main effect of age was negated for males, as old males elicited slightly more strokes (0.02) than young males (Fig. 4).

Comprehension Performance (Listening) Overall, participants chose the correct image \(71 \%\) of the time, demonstrating that successful communication in novel environments is

Figure 4: Average number of strokes grouped by item age and gender.
achievable even in a short period of time.
A linear-mixed effects model on the relationship of comprehension and the interaction of age, gender and progressing gameplay was constructed. An additional fixed effect was the time it took participants to make their decision. This variable was log-transformed to reform skew. Random effects were the users, items and the competitor images. The analysis revealed no significant effect for age, gender and progressing gameplay. The model produced a main effect for decision time \((z=-3.56, p=0.0004)\). Scores decreased by \(0.18 \pm\) 0.05 the longer users contemplated their decision.

\section*{Discussion}

As predicted, squiggles varied in structure and appearance depending on the image drawn. For females, participants focused on the hair form and length, which resulted in longer squiggles for females than males. Players tended to encode several, short features for younger females and fewer, but longer, features for old females. The increased number of strokes for young females can be explained by a preference for drawing hair which required several strokes (cf. Fig. 5a). Both strategies performed with the same level of accuracy in listening trials, which shows that each strategy chose the right aspects to be encoded.

Salient features of young males were often hair or head form, and on average, squiggles contained more features for males than for females. Old males were typically depicted by focusing on wrinkles and mouth form, which resulted in very short squiggles containing several features. The number of strokes did not vary much across age for males, as in both categories several features were encoded. A range of strategies across ages and genders is shown in figure 5 . These were successful strategies, in that the squiggles were easy to be recognized among those who "listened" to it.

Both the number of encoded features and the total length of squiggles increased over time. This does not support our hypothesis that the complexity of squiggles would shrink over time. There are two explanations for this which are not mu-
tually exclusively. First, participants did not play the game long enough to get an effect. Second, there is no explicit pressure on the participants to reduce complexity. The time limit given in the speaking trial is sufficient enough to encode several features, and there is no motivation for users to change their strategy.

The fact that players have ample time in the speaking trial to produce detailed squiggles without much practice means that squiggles are comprehended right away. This leads to a ceiling effect and participants do not get better at comprehending squiggles over time. A decrease of the time limit in the speaking trial will very likely produce a decrease of comprehensibility at the beginning of the game, as players will not be able to produced detailed enough squiggles. Accuracy of comprehension should, however, increase over time in this scenario.

This initial study simply aimed at identifying basic strategies of players, observing the dynamics of gameplay (effect of time on production/comprehension), and whether squiggles can be quantified as having particular properties associated with particular classes of stimuli.

Figure 5: Different strategies employed in successful squiggles

\section*{Experiment 2}

\section*{Method}

Game Design After the initial experiment, a second, more refined experiment was carried out. We introduced a second condition in the listening trial, in which the competitor of the
displayed squiggle was always of the opposite age and gender. While age is normally a continuous variable, we chose the pictures in such a way that made a binary distinction possible (see above). For example, if the squiggle depicted a young male, the competitor would now always be an old female. The new condition provides additional contextual clues to the players: In order to match a squiggle, only age and gender need to be discriminated against instead of focusing on individual features. The other condition remained as in experiment 1, i.e. the competitor was randomly chosen with no regard to age or gender. A simple encoding of age and gender is not be sufficient in this condition.

The ratio of speaking trials to listening trials was changed additionally in both conditions. The higher rate of language comprehension in the early stages of language acquisition was modeled by increasing the number of listening trials to 10 for the first three speaking trials, and then slowly decreasing the number back to 3 . Participants had to go through 20 speaking trials and 110 listening trials in total. No further changes were made to the game setup.
Expectations We predicted that the a changed comprehension environment would result in subsequent changes in the production of squiggles. In particular, we hypothesized that squiggles in the new condition would require less detail and complexity in order to achieve successful communication than squiggles in the control condition. The difference should be clearly visible after a short acquisition time. We expected a difference to occur roughly after the third speaking trial after which the number of listening trials was slowly decreased.

The expected differences in the structure of squiggles were predicted to not impact the performance of players in listening trials. Experiment 1 has shown that players choose the matching item with a high accuracy with little practice, and this accuracy is believed to stay constant in this experiment.
Participants 25 participants were recruited through Amazon Mechanical Turk and compensated financially by receiving \(\$ 0.75\).

\section*{Results}

A linear mixed-effects model was conducted with the number of strokes as the dependent variable, and the interaction of the conditions with progressing gameplay as the fixed factor. Intercepts for subjects and items were used as random effects. We found a main effect of condition \((t=-3.31, p<0.001)\), showing that the number of strokes decreased by \(1.06 \pm 0.32\) in the between condition. The interaction of between condition and the progressing gameplay proved to be significant ( \(t=-2.91, p=0.0036\) ), lowering the number of strokes by \(-0.07+ \pm 0.02\), despite an increase of \(0.07 \pm 0.01\) generally over time ( \(t=5.2, p<0.0001\) ).

We also performed a linear mixed-effects model to check for possible effects on comprehension of the interaction of conditions, progression of gameplay and the time it took the participants to make their choice. Random effects controlled
for participants, items and competitor images. The variable time was log-transformed to remove skew. The model revealed no effects on comprehension.

\section*{Discussion}

As predicted, the number of strokes increased after roughly three speaking trials in the condition in which the competitor image was chosen randomly, but not in the condition in which comprehension only required discriminating between gender and age categories. (Fig. 6). Additionally, the number of strokes continuously dropped in the latter condition as the game progressed. This sudden change after a short acquisition time is in line with other studies, which have shown that novel strategies are picked up rapidly by the majority of the population after a short period of time (Steels, 2011). The number of strokes should stabilize in each condition if players continue playing. Figure 7 shows examples of successful squiggles with differing numbers of strokes and encoded features.

Both conditions performed equally well in the listening trial, which shows that both conditions adapted to their given environment successfully. Importantly, fewer details were needed in the between-category condition to achieve the same accuracy as squiggles with more complexity in the condition in which the competitor was chosen completely arbitrarily.

Figure 7: Different number of encoded features corresponding to the number of strokes a player drew.

\section*{General Discussion}

Experiment 1 used a simple design in order to study the impact that visual and conceptual properties of have on the structure of squiggles drawn to communicate these objects. Input images differed in age and gender, and the produced squiggles varied in their structure according to these factors. Participants were able to adapt quickly to the given environment and performed well in comprehending squiggles from the start. The second experiment examined the impact of different comprehension conditions. An increase of listening trials at the start of the game and the introduction of different conditions led to varying squiggle structures across time and conditions. The referential environment had a profound impact on squiggle production. Specifically, we observed a decrease in squiggle complexity in the environment where the

\section*{Number of Strokes grouped by condition}

Figure 6: The evolution of the number of strokes over time across conditions
referents had to be distinguished categorically (although the participants were never informed of this constraint).

This method developed here to explore the evolution of communication in a simple graphical environment lends itself to numerous experimental manipulations. The impact of several parameters can be explored in this context. For example, a decreased time limit in the speaking trial will increase pressure on participants to draw more efficiently and to focus on fewer features. This may lead to a greater influence of the referential environment: Conditions in which categorical information (age and gender) is sufficient for successful communication lead to squiggles with simpler surfacestructure, a likely starting place for the emergence of morphemes and compositional structure. The emergence of such morphemes could be sped up by using a system of immediate feedback, in which players are repeatedly informed how successful their squiggles perform in the listening trials, i.e. whether other players recognize their squiggles. Immediate feedback allows players to establish more common ground and has been shown to drastically increase communication performance (Garrod et al., 2007).

This study shows that humans rapidly create efficient communication systems in a novel shared environment by integrating contextual clues. Comprehension and production were tightly interconnected in this communication game, and the referential environment significantly affected the structure of the produced squiggles. This lends further support to the idea that communication systems adapt to the environment in which they are learned and used.

\begin{abstract}
Analogical reasoning and its applications are gaining attention not only in cognitive science but also in the context of education and teaching. In this paper we provide a short analysis and a detailed formal model (based on the Heuristic-Driven Theory Projection framework for computational analogy-making) of the Calculation Circular Staircase, a tool for teaching basic arithmetic and insights based on the ordinal number conception of the natural numbers to children in their first years of primary school. We argue that such formal methods and computational accounts of analogy-making can be used to gain additional insights in the inner workings of analogy-based educational methods and tools.
Keywords: Analogy, Education, Teaching, Arithmetic, Formal Model, Computational Analogy-Making, HDTP.
\end{abstract}

\section*{Introduction}

Analogical reasoning is the ability to perceive, and operate on, dissimilar domains as similar with respect to certain aspects based on shared commonalities in relational structure or appearance. This has been proposed as an essential aspect of the ability to learn abstract concepts or procedures (Gentner, Holyoak, \& Kokinov, 2001), and is recognised as ubiquitous in human reasoning and problem solving (Gentner, 1983), representational transfer (Novick, 1988), and adaptation to novel contexts (Holyoak \& Thagard, 1995).

Inherent in the structure of analogical reasoning is its role in education and learning: new ideas can be constructed and explored in relation to familiar concepts. While substantial research has been carried out into the role of analogical reasoning and science education (see, for instance, (Duit, 1991; Arnold \& Millar, 1996; Guerra-Ramos, 2011)), its role in mathematics education has been somewhat less explored although notable exceptions include (Pimm, 1981; English, 1997). These studies support our assumption that analogies can be used for facilitating the understanding of concepts and procedures in abstract and formal domains, such as mathematics, physics or science. The pedagogical use of analogies as a means of triggering, framing and guiding creative insight processes still needs to be widely recognised as part of teaching expertise and incorporated into innovative teacher education schemes (Akgul, 2006).

In this paper, we want to contribute to a deeper understanding of the role and the mode of operation of analogy in an educational context by first providing a description and short analysis of the analogy-based Calculation Circular Staircase used for teaching basic arithmetic to children attending their initial mathematics classes at the beginning of
primary school (Schwank, 2003; Schwank, Aring, \& Blocksdorf, 2005), before showing how a computational analogymaking framework as Heuristic-Driven Theory Projection (HDTP) (Schwering, Krumnack, Kühnberger, \& Gust, 2009) can be used to provide a formal computational reconstruction of the staircase as a prototypical example of analogy-use taken from a real-life teaching situation. We thereby also continue the work started in (Besold, 2013) with a far more complex and deep-rooted case study. By doing so, we aim to show one way (amongst several) of how analogy-engines and their corresponding background theories can fruitfully be applied to modeling and analysis tasks from the field of psychology of learning, education, and didactics.

\section*{Heuristic-Driven Theory Projection (HDTP)}

There is much work on both theoretical and computational models of analogy-making. Heuristic-Driven Theory Projection (HDTP) (Schwering et al., 2009) is one such perspective: this is a formal theory and corresponding software implementation, conceived as a mathematically sound framework for analogy-making. HDTP has been created for computing analogical relations and inferences for domains which are given in the form of a many-sorted first-order logic representation. Source and target of the analogy-making process are defined in terms of axiomatizations, i.e., given by a finite set of formulae. HDTP tries to produce a generalization of both domains by aligning pairs of formulae from the two domains by means of anti-unification: Anti-unification tries to solve the problem of generalizing terms in a meaningful way, yielding for each term an anti-instance, in which distinct subterms have been replaced by variables (which in turn would allow for a retrieval of the original terms by a substitution of the variables by appropriate subterms).

HDTP in its present version uses a restricted form of higher-order anti-unification. In higher-order anti-unification, classical first-order terms are extended by the introduction of variables which may take arguments (where classical firstorder variables correspond to variables with arity 0 ), making a term either a first-order or a higher-order term. Then, antiunification can be applied analogously to the original firstorder case, yielding a generalization subsuming the specific terms. The class of substitutions which are applicable in HDTP is restricted to (compositions of) the following four cases: renamings (replacing a variable by another variable of the same argument structure), fixations (replacing a variable by a function symbol of the same argument structure), ar-

Figure 1: The "big" Calculation Circular Staircase (as depicted in (Schwank et al., 2005)): Numbers from 1 to 9 are represented by orange balls in the inner circle, numbers from 10 to 19 by green and orange balls in the outer one, the white door on the right marks the transition point between circles.
gument insertions, and permutations (an operation rearranging the arguments of a term). This formalism has proven capable of detecting structural commonalities not accessible to first-order anti-unification, as for instance also structural commonalities between functions and predicates within the logical language can be found and exploited (whilst the firstorder formalism would in these be limited to the respective argument positions only), allowing for a better recognition of relational mappings (as opposed to mere attribute mappings). Once the generalization has been computed, the alignments of formulae together with the respective generalizations can be read as proposals of analogical relations between source and target domain, and can be used for guiding an analogybased process of transferring knowledge between both domains. Analogical transfer results in structure enrichment on the target side, which corresponds to the addition of new axioms to the target theory, but may also involve the addition of new first-order symbols.

\section*{The Calculation Circular Staircase}

Dedekind (Dedekind, 1887/1969) argued that ordinal numbers and insights into the basic structure of the natural numbers play a crucial role in understanding (and thus also teaching) the foundations of arithmetic. About a century later, studies by Brainerd (Brainerd, 1979) also showed that a deeper understanding of the ordinals supports and facilitates the learning of basic arithmetic operations in children. Based on this line of thought, the Calculation Circular Staircase (Schwank, 2003; Schwank et al., 2005) has been developed.

\section*{A Teaching Tool for Basic Arithmetic}

Learning by analogy requires conceiving of and performing a transfer mapping of concepts and relational structures from a
better-known base domain into a less familiar target domain. This mapping is typically established by a pairwise matching of individual elements from the respective domains, resulting in a set of systematic correspondences. In the context of mathematics education and mathematical reasoning, children are required to understand abstract relations and operations (such as equality, addition, and subtraction) which can best be taught by drawing parallels between similar examples in less abstract domains (Clement, 1993). Still, the availability of supportive cues for the analogy is crucial for the success of the learning process (Glynn, Duit, \& Thiele, 1995).

The Calculation Circular Staircase (cf. Fig. 1) offers children a means of developing an understanding of the interpretation of numbers as results of transformation operations. This goal shall be achieved by enabling a mental functional motor skill-based way of accessing the foundational construction principles of the number space and the corresponding basic arithmetic operations: The numbers from 0 to 9 are represented in the inner circle by a corresponding number of orange balls, numbers from 10 to 19 are represented in the outer circle at the respective places (corresponding to the inner circle's ordering) by 10 green balls and a corresponding number of orange ones. A little door indicates the point of transition between circles. Arithmetic operations are introduced via "magical" signs (showing " + " or "-") carried by toy figures. When equipped with the respective sign, a toy figure can perform jumps on the staircase - before moving, a decision for a sign has to be taken (involving the child in a responsible and motor active way instead of assigning the role of a passive spectator). Addition corresponds to an ascending movement, subtraction to a movement in descending direction. This enables children to experience subtraction as a proper inverse operation to addition, arising naturally from the "wish" of a toy figure to also descend the staircase.

Decimal structure-based analogies between different computations (e.g. between " \(5-4=1\) " and " \(15-4=11\) ") are made accessible to children's understanding via synchronous movements of two toy figures in the inner and outer circle, respectively: The 10 green balls in the outer circle stay constant, with respect to the orange balls identical movements yield identical results. The door between the circles provides children with a natural "resting point" for simplifying difficult computations involving a decimal transition: If e.g. \(13-5\) shall be computed, the toy figure (carrying the "-" sign) first moves to the column representing the number 10 (being the only column in the outer circle not containing an orange ball and being directly next to the door, naturally corresponding to the 0 -column in the inner circle), losing as many orange balls in height as were initially situated below the figure. The remaining height difference of 2 is now accounted for in a second step, thus transforming the original task into the easy to handle \(10-2\) and making the decimal transition attractive for the children. Also, the number 0 obtains a natural position in the number system of the Calculation Circular Staircase, simply corresponding to the result of performing
another step down from the first stair. Having the caesura between the two circles after the representation of the number 9 becomes meaningful to the children once they write down the corresponding numbers, there also encountering a significant difference between the initial one-digit numbers and the two-digit numbers starting with 10.

At the level of cognitive analysis, the idea underlying the Calculation Circular Staircase is an active recruitment of the "functional thinking" approach to mathematics (cf., e.g., (Schwank, Gelfman, \& Nardi, 1999)). As opposed to a "predicative thinking"-style understanding of relationships within mathematics, which uses equality as ordering principle when conceptualizing mathematical structures (i.e., mathematics being conceptualized on the basis of the repeated applicability of certain predicates), the "functional thinking" perspective bases its conceptualizations on differences between mathematical concepts which can then be used to conceive of a construction process for the respective class of structures (i.e., mathematics being conceptualized on the basis of repeated constructive steps). In their interaction with the Calculation Circular Staircase, the children are naturally led into taking the "functional thinking" approach across repeated stages of play, each time actively becoming aware of the individual steps a toy figure has to take when changing from one position on the staircase to another one. Instead of post hoc merely checking whether a certain distance has been covered between the initial step and the final one (i.e., whether a predicate indicating a certain value for the difference between both steps holds), they experience an active construction process explicating the guided transition from the initial step to the final one.

\section*{An HDTP-Based Model of the Staircase}

We now reconstruct the "big" Calculation Circular Staircase (i.e., the version equipped with two circles or 19 steps) as an analogy-based model for understanding and learning among others important aspects of the ordinal number conception of the natural numbers in the range from 0 to 19 .

The analogy uses the Calculation Circular Staircase as a base domain, transferring the structure and relational conception children acquire by playing with the staircase into their previously acquired knowledge about natural numbers as target domain. The latter domain is most likely initially still very poor as compared to the Calculation Circular Staircase domain as only very little (if any at all) internal structure or relations have been acquired besides the mere ordering of the number terms from one to nineteen that had been committed to memory in previous lessons. And even for this ordering it can be assumed that the ordering has mostly only been developed on basis of isolated neighboring tuples of the form \((n, n+1)\), for each number term only remembering its immediate successor. The arithmetic operations " + " (addition) and "-" (subtraction) are known as abstract concepts (as are their corresponding addition and subtraction tables), but have not yet been developed into a grounded, constructively applicable conceptualization. Table 1 gives a formal HDTP-style

Table 2: Formalization of an idealized form of the children's initial conception of the number domain.
exhibits a rich structure, both concerning facts and laws alike. The facts represent the easily accessible structure of the staircase, namely the order of succession of the steps, the distinction between the inner and the outer circle, and the placement of the door between steps nine and ten. The laws cover the transformational and constructive insights accessible to the children via interaction with the staircase: For instance ( \(s_{46}\) ) to ( \(s_{49}\) ) encompass the previously described process of having the toy figure move up or down the staircase, and ( \(s_{50}\) ) and \(\left(s_{51}\right)\) then add a counting principle keeping track of the number of steps passed by the figure (which in reality allows children to determine the distance the toy figure may move on the staircase). ( \(s_{52}\) ) and ( \(s_{53}\) ) serve for converting the distance measured in steps into a natural number, i.e., represent the children's mental process when realizing that distances on the staircase correspond to a more abstract number concept, i.e., are not bound to the individual stairs but can be generalized. Concerning the final two laws, \(\left(s_{55}\right)\) introduces the previously mentioned concept of singular steps in the Calculation Circular Staircase which are similar in that they form the base of one closed part of the staircase (namely of the inner or outer circle) or are marked by being preceded by the door as caesura, and ( \(s_{56}\) ) concludingly introduces the concept of structure-based analogs amongst the steps.

The formalization of the target domain of the later analogy, i.e., of an idealized version of the children's initial conception of the number domain, contains mostly facts the children have learned by heart, namely the order of the number terms

Table 3: Generalized theory of the Calculation Circular Staircase and the children's number domain, already expanded by the generalized forms of the candidate elements for analogical transfer from base to target domain (marked with \(*\) ).
between zero and nineteen, and addition and subtraction tables within this range. In reality it has to be assumed that the addition and subtraction tables are significantly more sparsely populated than in our formalization, corresponding to incomplete recall of the memorized full tables.

The HDTP mechanism can now be used for computing a
common generalization of both domains, yielding a generalized theory like given in Table 3. The main domain elements defining the alignment of formulae are the matching between the entities of sort steps and number, between the functions diff and apply, the alignment of the respective sign entities, as well as the matching between the direction and operation entities (induced by the alignment of the respective interpretation functions). Here it has to be noted that in order to analogically match the two domains it is not only necessary to generalize facts and laws but in this case also sorts have to be generalized, for two sorts yielding the least general supersort. This is needed, for instance, when pairing up the representation of the staircase's steps (conceived as mere pillars) and the number terms known to the children.

In conclusion, the generalized theory forms the basis for transferring knowledge in an analogy-based way from the (originally richer) Calculation Circular Staircase domain to the children's number domain, resulting in an expanded theory for the numbers as given in Table 4. The important aspect in this expanded version of the domain is the availability of the constructive relations and insights obtained in the interaction with the Calculation Circular Staircase, e.g., providing a means to give meaning to the number terms via the assignment of the corresponding natural number values (using the diff function in \(\left(e_{381} *\right)\) ) or via laws ( \(\left.e_{373} *\right)\) to ( \(\left.e_{378} *\right)\) allowing for the independent computation of parts of the addition and subtraction table that might not be obtainable from memory (i.e., that would not explicitly be present as a fact in a more realistic formalization of the number domain).

\section*{Related Work and Conclusion}

We are not the first to consider the use of formal models and computational analogy-making systems in the context of education and teaching-related topics. Among many others, for example in (Thagard, Cohen, \& Holyoak, 1989), the authors present a theory and implementation of analogical mapping that applies to explanations of unfamiliar phenomena, and (Siegler, 1989) briefly conjectures how the StructureMapping Engine (SME) (Falkenhainer, Forbus, \& Gentner, 1989) as a prototypical analogy-engine could be used to gain insights about developmental aspects of analogy use. General cognitive theories of analogical reasoning and associated computation models are also highly relevant to analogies as learning mechanisms. These include Gentner's structure mapping theory and engine, in which relations between objects are preserved (and relations which contribute to higher order predicates are mapped preferentially), and attributes of objects are not mapped (Gentner, 1983); Holyoak and Thagard's multi-constraint theory, in which mappings are evaluated according to constraints of structural consistency, pragmatic centrality and semantic similarity (Holyoak \& Thagard, 1997); and Hummel and Holyoak's theory of analogy formation, which integrates memory access and structural mapping, implemented in LISA (Hummel \& Holyoak, 2003) (see (Gentner et al., 2001) for a review of computational models of

Table 4: Analogically enriched formalization of the idealized version of the children's conception of the number domain.
analogy). Our HDTP model of the Calculation Circular Staircase is intended to complement such approaches, showing how formal methods and computational accounts of analogymaking can be used to gain additional insights in the inner workings of analogy-based educational methods and tools. By providing a detailed formal description of the involved domains, also sketching how the domains relate to each other in terms of their joint generalization and how this relation can be used to transfer knowledge from the staircase domain into the number domain, we managed to explicate the structural relations and governing laws underlying the Calculation Circular Staircase as teaching model of the natural number domain, and to point out how the identified constructive and transformation-based conceptualizations then also can provide additional support and a deeper-rooted model for the childrens' initially very flat and sparse conception of the number domain.

We see this work as a first step towards the design of analogy-based teaching material, both specifically in arithmetic and, more generally, in mathematics and other disciplines. Modelling educational analogies provides another perspective on a particular analogy, in terms of which information is transferred, what the limitations of the analogy are, or whether it makes unhelpful mappings; and what potential extensions to the analogy it suggests. We envisage that our model of the Calculation Circular Staircase can be used in order to design a lesson plan on the natural number domain. Its usefulness would then be evaluated via empirical studies on the students, testing the depth of their understanding of cardinal and ordinal numbers and basic operations, and whether the students' understanding (and misunderstanding) mirrors the inferences made by the model.

\begin{abstract}
We formalize the biased activation theory of anchoring using a bidirectional associative memory network. Anchors determine the starting state of this network. As the network settles, we show that the nodes representing numerical responses activate and deactivate consecutively, generating sequential adjustment. By demonstrating that anchoring as adjustment emerges naturally from the dynamics of the biased activation process, we are able to unify the two main theories of the anchoring effect, and subsequently provide a parsimonious explanation for a large range of findings regarding anchoring, and its determinants. Although we focus largely on phenomena related to anchoring, the results of this paper apply equivalently to all judgments under the influence of bidirectional processing, including those involving constraint satisfaction.
\end{abstract}

Keywords: Decision Making, Neural Networks, Dynamic Processes, Anchoring Effect, Constraint Satisfaction

\section*{Introduction}

Anchors have a powerful effect on human judgment. Responses to simple questions involving magnitude or time are systematically affected by uninformative numbers, known as anchors, displayed to the decision maker prior to the judgment task. High anchors generate high responses, low anchors generate low responses, and final judgments can be manipulated by selecting the appropriate anchor.

The anchoring effect has been shown to emerge in a large number of domains, and is one of the best studied judgment biases in psychology. Yet despite its importance, the cognitive mechanisms responsible for the anchoring effect are still being debated. In their seminal paper on heuristic choice, Tversky and Kahneman (1974) proposed that anchoring is caused by an imperfect sequential adjustment process. At each step in this process, decision makers evaluate the validity of a particular response. The judgment process terminates if the response in consideration is adequate; otherwise it moves on to the next feasible value. Anchors determine the starting point in this process, and adjustment is insufficient. Subsequently responses are closer to the anchor than optimal.

This explanation for the anchoring effect has been popular for many decades, and formal models of the anchoring effect have assumed that anchoring operates through sequential adjustment (Johnson \& Busemeyer, 2005, but see also Choplin \& Tawney, 2010). A more recent approach, however, claims that anchoring is the product of biased
activation (Chapman and Johnson, 1994, 1999; Mussweiler \& Strack, 1999). Anchors, according to this view, increase the accessibility of cues supporting the anchor. This evidence subsequently generates final responses that are closer to the anchor than optimal.

Is anchoring caused by sequential adjustment or biased activation? Both theories are supported by a large number of empirical findings (discussed in later sections), but neither is able to predict all of these findings by itself. In this paper we provide a simple answer to this question. We show that these processes are not necessarily distinct: sequential adjustment emerges from the dynamics of biased activation. Anchoring, thus, is caused by both these mechanisms simultaneously, and a large range of findings regarding anchoring and its moderators, can be explained within a unitary, parsimonious, theoretical framework.

\section*{Bidirectional Associative Memory}

Consider a very simple judgment task. The decision maker is asked to select one of \(N\) responses based on \(M\) cues stored in memory. We assume, for simplicity, that the relationship between the responses and the cues is binary, with each cue either supporting or opposing each response. We can write a response \(i\) as \(r_{i}\), and a cue \(j\) as \(c_{j}\). If \(c_{j}\) supports \(r_{i}\) then we can write \(s_{i j}=+1\), and if it opposes \(r_{i}\) then we can write \(s_{i j}=-1\).

These responses can be numeric, as in typical anchoring tasks, or non-numeric as in more general judgment tasks. For numeric responses, we assume that the \(N\) nodes are ordered in a sequence \(r_{1}, r_{2}, \ldots, r_{N}\), corresponding to the sequence of available responses. For example, when considering the percentage of African countries in the United Nations, with responses in intervals of \(1 \%, r_{1}, r_{2}, \ldots\), \(r_{100}\) correspond to the responses \(1 \%, 2 \%, \ldots, 100 \%\).

We can implement this structure in a two layer neural network, with the first layer consisting of \(M\) nodes representing the \(M\) different cues, and the second layer consisting of \(N\) nodes representing the \(N\) response options. The activation of the node corresponding to \(c_{j}\), at time \(t\), can be written as \(C_{j}(t)\), and the activation of the node corresponding to \(r_{i}\), at time \(t\), can be written as \(R_{i}(t)\).

The connections from the cue layer to the response layer are equal to the strength of support provided by the cues to the responses. As activated response options (such as anchors) also affect the activation of the available cues, these connections can be assumed to be recurrent. Hence the connections from \(c_{j}\) to \(r_{i}\) and from \(r_{i}\) to \(c_{j}\) are both simply \(s_{i j}\).

At a given time \(t\), the activated nodes in the response layer first send inputs, weighted by \(s_{i j}\), into the cue layer. This affects the activation of the nodes in the cue layer. The activated nodes in the cue layer subsequently send inputs weighted by \(s_{i j}\) into the response layer, affecting the activation of the response nodes at \(t+1\), at which point the process repeats.

In addition to the inputs from the response layer, we assume that the nodes in the cue layer receive constant exogenous inputs with strength \(I=1\). These inputs ensure that evidence nodes are activated even when none of the response nodes are active, and that the judgment process can begin in the absence of a response bias. We also assume that all of the nodes in our network have the same binary activation function, with a threshold at zero. With this assumption we can write the activation functions of any \(r_{i}\) as \(R_{i}(t)=H\left[q_{i}\right]\), and any \(c_{j}\) as \(C_{j}(t)=H\left[b_{j}\right]\) such that \(q_{i}=\sum s_{i j} C_{j}(t-\) 1), \(b_{j}=\sum s_{i j} \cdot R_{i}(t)+1\), and \(H\) as the unit step function with \(H[x]=1\) for \(x>0\) and \(H[x]=0\) for \(x \leq 0\).

We can now formalize the effect anchors have on the judgment process. We assume that anchors determine the starting state of the network. Hence if \(r_{i}\) is the anchor, then at \(t=1\), we have \(R_{i}(1)=1\), and \(R_{k}(1)=0\) for \(k \neq i\). In the absence of an anchor, the network begins with \(R_{k}(1)=0\) for all \(k\). Finally, we assume that responses active once the network stabilizes are the ones that are selected, and that the response time is proportional to the time it takes for the network to settle.

The proposed network is motivated primarily by the memory structure assumed to be at play in anchoring and related judgment tasks: indeed, it is one of the simplest possible cognitive instantiations of the biased activation theory of anchoring, which posits a recurrent relationship between cues and responses. That said, this network is ultimately a special case of the bidirectional associative memory (BAM) network, introduced in Kosko (1988). BAM itself generalizes the Hopfield network, which BAM resembles when node updating is asynchronous.

Figure 1: The BAM network.

\section*{Activation and Stability}

What determines the responses that get activated at any time period, in the BAM network? The answer is cue overlap. Assume that only \(r_{i}\) is activated at time \(t\). This activation causes only the cues that support \(r_{i}\) to be activated at \(t\). Intuitively, the decision maker focuses on the cues that support the activated response and suppresses the cues that oppose the activated response. Once these cue nodes are activated, the activation pattern in the response layer
changes. At \(t+1\), responses supported by most of the cues activated at \(t\) turn on. These include \(r_{i}\), but also other novel responses, that overlap sufficiently with \(r_{i}\) in cue support. Eventually at \(t+2\) these responses activate other responses that they overlap with, and this process continues until the network stabilizes. Stability is always guaranteed: any BAM network with any memory structure, starting at any point, will stabilize in a finite number of time steps (Kosko, 1988).

\section*{Defining Sequential Adjustment}

We hope to show that this settling process of the BAM network in the presence of anchors resembles sequential adjustment. Before we can do this, however, we need to understand what sequential adjustment really is. Sequential adjustment is generally defined as the successive movement through the range of responses available to the decision maker. In the simplest case, this definition imposes a form of serial processing, according to which only one response is considered at any given time. For example, when judging the proportion of African countries in the U.N., decision makers may first consider 1\%. After rejecting this response they would consider \(2 \%\). If this too is inadequate they would move on to \(3 \%\), and so on. We consider the more general (and more realistic) case in which multiple responses can be considered at the same time. This allows decision makers to focus on all the responses within a particular interval, such as \(1-10 \%\), simultaneously, before moving on to the next interval in the sequence.

Such a dynamic is compatible with the general idea underlying sequential adjustment, as long as the responses activated are contiguous. Sequential adjustment does not permit the simultaneous consideration of different, nonneighboring responses. For example decision makers who consider both \(1 \%\) and \(99 \%\) simultaneously, without considering the responses between these two numbers, would not appear to be displaying sequential adjustment.

This then allows us to formalize the first requirement for sequential adjustment. This requirement, titled contiguous activation, states that sequential adjustment must not involve the simultaneous activation of multiple nonneighboring responses. Responses must be considered individually or in contiguous intervals.

Settling dynamics that display contiguous activation do not necessarily resemble sequential adjustment. It is possible for the decision maker to consider responses in contiguous intervals at any given time, but transition across different intervals in a non-sequential manner. For example, when evaluating the proportion of African countries in the U.N., decision makers could begin by considering the interval \(1-10 \%\), and then move to the interval \(20-30 \%\), without considering the interval \(10-20 \%\).

We thus need an additional requirement for our definition of sequential adjustment, in order to rule out these types of dynamics. This requirement, titled sequential transitions, states that sequential adjustment must not involve changes in activation that skip over a set of responses. Changes to response activation must be successive.

\section*{Connected Memory}

Do the dynamics of the anchored BAM network satisfy contiguous activation and sequential transition? Not necessarily. However with a simple assumption about the underlying memory structure, these requirements can indeed be satisfied. This assumption relates to the distribution of cue support for the responses. In numeric judgments, cues can seldom support two disparate responses without supporting intermediate responses. For example, when judging the proportion of African countries in the UN, any cue that supports the \(10 \%\) response, and the \(12 \%\) response, should, in general, support the intermediate \(11 \%\) response. This property, titled connectedness, more formally requires that a cue that supports \(r_{i}\) and \(r_{k}\), also supports \(r_{l}\) for \(i<l<k\). Memory structures displaying this property involve cues with a single, connected, interval of supported responses, where as those that do not display this property have cues with multiple, fragmented, intervals of supported responses.

While connectedness may not be satisfied in all judgment tasks, it is certainly a reasonable assumption when responses are ordered, as with the numerical scales used in anchoring tasks. Cues in these settings generally provide support for "large" responses, or "small" responses, or "medium" responses, or some other connected interval of responses. Very few cues provide support for a set of nonneighboring responses, distributed sporadically across the response scale. Indeed it is quite difficult to think of memory structures with diagnostic cues for numerical responses that do not satisfy the connectedness property.

\section*{The Emergence of Sequential Adjustment}

When memory structures satisfy connectedness, then the resulting BAM network, with the anchored response activated at the start of the decision process, satisfies both contiguous activation and sequential transition. Of course, satisfying these properties does not imply that the decision maker necessarily adjusts away from the anchor. It may be the case that the anchor is stable. If there is adjustment, however, the adjustment is guaranteed to be sequential. Anchors trigger a cascade of activation in the response layer: Neighboring responses activate and deactivate consecutively. There are no jumps in response activation, nor do multiple non-neighboring responses activate, without the activation of the intermediate responses.

Figure 2: The emergence of sequential adjustment.
How does the connectedness property satisfy contiguous activation and sequential transitions? While the proof of this claim is in the appendix, the intuition for it is as follows. Due to connectedness, cues that support both the anchor and
a non-neighboring non-anchored response must also support any intermediate responses, lying between the anchor and the non-neighboring response. Thus if the activation of the anchor activates cues that subsequently activate nonneighboring responses, these cues must also activate all of these intermediate responses. Subsequently, response activation at \(t=2\) must be contiguous, and any transitions that may have happened at \(t=1\) must be sequential. This intuition however also applies for the contiguous interval of responses activated at \(t=2\), implying that any further changes to activation after \(t=2\) must be sequential. Additionally, once a contiguous interval of responses is activated, we can show that connectedness implies that this interval cannot splinter into smaller, non-contiguous activated intervals, implying that contiguous activation must also be satisfied after \(t=2\). Mathematical induction shows that these properties then hold at all times.

Connected BAM memory structures guarantee sequential activation. But can they generate insufficient adjustment? Let us consider the case with one correct response. When the memory structure is such that two nodes lying between the anchor and the correct response do not overlap on an appropriate number of cues, the sequential adjustment process described above will be insufficient: it will stabilize with the activation of response values closer to the anchor than the correct response.

The intuition for this is fairly straight forward. If, for a low anchor, there exist two response nodes between the anchor and the correct response, whose cue support does not overlap sufficiently, then the activation of the lower response node will not lead to the activation of cues that activate the higher response node. As activation must be contiguous and transitions must be sequential, no higher nodes can be activated, the network will stabilize with the activation of incorrectly low responses, and the correct response will remain turned off. The same intuition holds for tasks involving a high anchor, in which the network will stabilize with the activation of incorrectly high responses, and the correct response will remain turned off.

\section*{Demonstrations}

The above sections have shown that the BAM network with connected memory structures satisfies contiguous activation and sequential transition, and can generate insufficient adjustment. While this is an analytical result, proved in the appendix, and guaranteed to hold regardless of any underlying parameters, demonstrations of the types of sequential adjustment generated by connectedness can provide important insights regarding the behavior emerging from the BAM network.

Figure 3 provides one such demonstration. It shows a hypothetical distribution of cue support for a sequence of responses, and the settling dynamics of the corresponding BAM network with a high anchor, low anchor, and without any anchor. The correct response in this network is \(r_{4}\), and this is the stable response in the absence of an anchor. When anchored at \(r_{6}\) (a high anchor), however, the network
stabilizes at \(r_{5}\). Similarly when anchored at \(r_{1}\) (a low anchor), the network stabilizes at \(r_{3}\). These behaviors indicate the presence of the anchoring effect. Additionally, the settling dynamics with these anchors display sequential adjustment: response nodes activate and deactivate consecutively until the network stabilizes.

Why do we observe these behaviors? \(r_{1}, r_{2}\), and \(r_{3}\) overlap on the component cues in such a way that the set of cues supported by \(r_{i}\) also on average support \(r_{i+1}\), for \(i=1,2\). This means that activating \(r_{1}\) leads to the activation of \(r_{2}\), which then activates \(r_{3}\). The set of cues supporting \(r_{3}\) and \(r_{4}\) do not however overlap in this way, implying that the cascade of activation begun by anchoring the network at \(r_{1}\) ends with the stable activation of \(r_{3}\). A similar property holds for \(r_{5}\) and \(r_{6}\). Also note that the network satisfies connectedness, which implies that the activation dynamics generated by the anchor display contiguous activation and sequential transitions, leading to sequential adjustment.

Figure 3: Distribution of cue support, and resulting network dynamics for low, high and no anchors.
These dynamics also emerge with larger, randomly generated memory structures. Consider a setting with \(N=100\) responses and \(M=1000\) cues. Let us randomly generate support or opposition between these cues and these responses. For each cue we can pick a number from the normal distribution with mean 50 and variance 25 , and round it to its nearest integer. We can subsequently take an interval of length 20 around this integer, to generate the set of responses supported by the cue. All other responses are opposed by the cue. Taking an interval of responses around the randomly chosen number generates a "blurring" in the underlying memory structure: it is seldom the case that individual cues support point estimates; rather their support is distributed across an interval of responses.

As the randomly generated memory structure satisfies connectedness, it should be able to generate sequential adjustment. Figure 4 displays the dynamics of the BAM network instantiating this randomly generated memory structure, with a high anchor, \(r_{100}\) and a low anchor, \(r_{1}\). Note that the stable responses for the two anchors are different, with the stable responses for the low anchor lower than the stable responses for the high anchor. Additionally, activation at all points of time is contiguous, and all transitions are sequential: we can observe a cascade of activation in the response layer over time, with intervals of
responses activating and deactivating consecutively before finally stabilizing.

Note that the dynamics observed in figure 4 also emerge with alternate parameters in the model. In general, however, increasing the ratio of total responses to total cues and increasing the blurring in the cue support for the responses generates a higher likelihood of adjustment, as well as longer sequences of adjustment. This subsequently leads to weaker anchoring effects. Overall the anchoring bias is strongest when there are many relevant cues, and each cue supports few neighboring responses.

Figure 4: Network dynamics for high and low anchors, with randomly generated memory.

\section*{Explaining Anchoring Phenomena}

Anchoring is a well-studied phenomenon and the sequential adjustment and biased activation theories of anchoring have a large range of behavioral findings that they must be able to account for. The above sections have shown that these theories are almost identical: the process assumed by one, emerges directly from the process assumed by the other. This section shows how this result can explain most of the findings documented in anchoring research.

Using a lexical decision task, Mussweiler and Strack (2000) find that decision makers identify "cold" related words quicker and more accurately after temperature judgments with low anchors, and identify "hot" related words quicker and more accurately after temperature judgments with high anchors. Sequential adjustment theory is unable to account for this finding, however, the BAM framework allows for both sequential adjustment and anchor dependent cue accessibility biases to emerge simultaneously: once the network settles, the cues that support the stable responses are themselves stable. If the judgment began with a low anchor then stable cues are more likely to support the low anchor than the high anchor. The opposite holds if the judgment began with a high anchor.

The biased activation theory of anchoring also predicts that exogenous factors influencing cue accessibility can affect anchoring. This has been verified by Chapman and

Johnson (1999) and Mussweiler et al. (2000). Unlike sequential adjustment theory, the BAM model can explain these findings. If we assume that exogenous influences on cue attention affect the inputs, \(I\), into the cue layer, then directing attention towards cues that oppose the anchored response \(r_{i}\), leads to stronger inputs, \(I>1\), into these cues. Due to these inputs, these cues are not inhibited by feedback from the activated anchor in the response layer. Subsequently all cues are activated at the start of the decision process, the pattern of activation on the cue layer resembles the pattern observed in the absence of an anchor, and the network stabilizes without an anchoring bias.

According to the traditional sequential adjustment theory, all types of anchors, regardless of underlying cue support, should lead to the anchoring effect. Research by Chapman and Johnson (1994), however, finds that implausible anchors (anchors that are not supported by any cues) have a much weaker effect than plausible anchors. BAM provides a simple explanation for this result. When implausible anchors are activated at the start of the decision process, all cues are suppressed (as these anchors are not supported by any cues). Subsequently none of the response nodes activate in the next time period. This leads the network to a state identical to the starting state of the network in the absence of an anchor. Implausible anchors thus do not generate an anchoring effect.

A fourth finding supporting the biased activation theory of anchoring pertains to the effect of multiple anchors. Sequential adjustment theory predicts that the decision maker adjusts sequentially away from the one anchor presented in the decision task. This theory cannot make predictions for settings with multiple anchors. Switzer and Sniezek (1991) and Whyte and Sebenius (1997), however, demonstrate that multiple anchors affect judgment differently relative to single anchors. Single anchors paired with more extreme anchors generate a stronger anchoring effect than the single anchors alone, whereas single anchors paired with less extreme anchors generate a weaker anchoring effect than the single anchors alone.

BAM can account for the effect of multiple anchors. The activation of multiple response nodes at the start of the judgment process leads to the activation of all the cues supporting these anchors. When a single anchor is paired with a more extreme anchor then the set of cues activated are more likely to support extreme responses, relative to when the single anchor is activated by itself. This can lead to the stable activation of responses close to the extreme anchor, generating a stronger anchoring effect. The opposite happens when a single anchor is paired with a less extreme anchor. Here the activated cues are less likely to support extreme responses. This can lead to the ultimate stable activation of responses close to the moderate anchor, generating a weaker anchoring effect.

The cue accessibility, exogenous attentional influence, implausible anchor and multiple anchor results discussed above present strong evidence for the biased activation theory of anchoring. The standard biased activation theory
cannot however provide a comprehensive account of all the moderators of the anchoring effect. Research by Reitsmavan Rooijen and Daamen (2006), for example, finds that time pressure increases the anchoring effect. This has traditionally seen as providing evidence for the sequential adjustment theory of anchoring, according to which time pressure limits the number of adjustments possible, thereby increasing the strength of the anchoring effect. As the BAM network proposed in this paper generates sequential adjustment, it is able to provide an explanation for these results as well. The BAM network often does not settle at its stable response in one time step; rather its response nodes activate and deactivate consecutively over time, before stabilizing at the final response (as in e.g. figure 4). When the decision maker is faced with time pressure, the network is not allowed to stabilize and the adjustment process generated in this network is curtailed, generating a stronger anchoring effect.

Another finding providing evidence for sequential adjustment theory relates to the role of incentives on anchored judgment. Particularly, Simmons et al. (2010) find that financial incentives reduce the anchoring effect. This cannot be explained by biased activation theory. If, however, we assume that incentivized decision makers send stronger inputs into the cue activation layer (perhaps due to increased attention towards all cues relevant to the decision task) then the BAM network can in fact explain this effect. As discussed above, when \(I>1\), the exogenous inputs override the inhibitory feedback from the anchor in the response layer. Cue activation subsequently resembles the unbiased decision process, and the anchoring effect disappears.

\section*{Anchoring as Constraint Satisfaction}

The bidirectionality assumed in this paper is a property of a general class of models that have been used to explain findings on inference across a variety of domains. These are models of constraint satisfaction (see e.g. Holyoak \& Simon, 1999 for a review). Constraint satisfaction models provide a powerful approach to studying the interrelationships between cues and responses, and the ways that these relationships affect the dynamics of the decision process. Indeed, the anchoring effect can be seen as just a specific instantiation of the general type of starting point sensitivity displayed by these models: if the memory structures in these models satisfy connectedness then these models will also generate sequential adjustment. In this light, the BAM network is not just a model of anchoring, but rather a model of constraint satisfaction; one which provides a tractable framework with which to understand the cognitive dynamics that constraint satisfaction entails, and the behaviors that these dynamics can generate.

\section*{Conclusion}

We have used the bidirectional associative memory network to study the anchoring effect. The BAM network provides a simple model for the biased activation theory of anchoring.

We have shown that the settling dynamics of this BAM network generate sequential adjustment. Anchors trigger a cascade of activation in the response layer of the BAM network, with nodes in this layer activating and deactivating consecutively. This progression of activation is generally insufficient and final responses depend critically on starting anchor values. By reconciling two contrasting theories within one framework, the BAM network is able to provide a parsimonious explanation for a wide range of findings regarding anchoring and its moderators.

\section*{APPENDIX}

Here we shall show that BAM networks with connected memory structures satisfy contiguous activation and sequential transition. Let us define \(\boldsymbol{D}_{\boldsymbol{i}}\) to be the set of cues supporting \(r_{i}, \boldsymbol{D}^{t}\) to be the set of cues activated at \(t, \boldsymbol{E}_{j}\) to be the set of responses supported by \(c_{j}\) and \(\boldsymbol{E}^{\boldsymbol{t}}\) to be the set of responses activated at \(t\). \(|\boldsymbol{X}|\) shall indicate set \(\boldsymbol{X}\) 's cardinality. Now consider the following propositions:

Proposition la: If a contiguous interval of responses, \(r_{i}\), \(r_{i+1}, \ldots r_{k}\) is activated at \(t\) (and all other responses are deactivated at \(t\) ), and for \(l>k, r_{l}\) is activated at \(t+1\), then it is the case that \(r_{k}, r_{k+1} \ldots r_{l-l}\) are activated at \(t+1\). Proof: \(c_{j} \in \boldsymbol{D}^{t}\) implies \(c_{j} \boldsymbol{D}_{\boldsymbol{i}} \cup \boldsymbol{D}_{i+1} \ldots \cup \boldsymbol{D}_{\boldsymbol{k}}\). Since \(r_{l} \in \boldsymbol{E}^{\boldsymbol{t + 1}}\), we have \(\left|\boldsymbol{D}_{l} \cap \boldsymbol{D}^{t}\right|>\left|\boldsymbol{D}^{t}\right| / 2\). Connectedness implies that if \(c_{j} \in \boldsymbol{D}_{i} \cup \boldsymbol{D}_{i+1} \ldots \cup \boldsymbol{D}_{k}\) and \(c_{j} \in \boldsymbol{D}_{l}\) then \(c_{j} \in \boldsymbol{D}_{l}\), for \(l>l^{\prime} \geq k\). Hence if \(\left|\boldsymbol{D}_{l} \cap \boldsymbol{D}^{t}\right|>\left|\boldsymbol{D}^{t}\right| / 2\) we also have \(\left|\boldsymbol{D}_{l}, \cap \boldsymbol{D}^{t}\right|>\left|\boldsymbol{D}^{t}\right| / 2\) for all \(l>l \geq k\), which means that \(r_{l} \boldsymbol{E}^{t+1}\) implies \(r_{l} \in \boldsymbol{E}^{t+1}\) for \(l>l^{\prime} \geq k\).

Proposition \(1 b\) : If a contiguous interval of responses, \(r_{i}\), \(r_{i+l}, \ldots r_{k}\) is activated at \(t\) (and all other responses are deactivated at \(t\) ), and for \(l<i, r_{l}\) is activated at \(t+1\), then it is the case that \(r_{l+1}, r_{l+2}, \ldots r_{i}\) are activated at \(t+1\). Proof: The proof for this is identical to that for proposition 1a.

Proposition 2: If a contiguous interval of responses, \(r_{i}\), \(r_{i+l}, \ldots r_{k}\) is activated at \(t\) (and all other responses are deactivated at \(t\) ), then for any \(p\) and \(q\) with \(k>p>q>i\), if \(r_{q}\) and \(r_{p}\) are activated at \(t+1\) then so is any \(r_{l}\) for \(p>l>q\). Proof: \(c_{j} \in \boldsymbol{D}^{t^{t}}\) implies \(\left|\boldsymbol{E}_{j} \cap \boldsymbol{E}^{t} \geq\left|\boldsymbol{E}^{t}\right| / 2\right.\). As \(\boldsymbol{E}_{j}\) is contiguous (by connectedness), and \(\boldsymbol{E}^{t}\) is contiguous, \(\boldsymbol{E}_{j} \cap \boldsymbol{E}^{\boldsymbol{t}}\) is also contiguous. Hence if \(c_{j} \boldsymbol{D}^{t}\) it supports at least \(\left|\boldsymbol{E}^{t}\right| / 2=(k\) \(i+1) / 2\) contiguous responses in \(\boldsymbol{E}^{t}\). Assume that \(q<(k+i) / 2\). If \(c_{j} \in \boldsymbol{D}_{\boldsymbol{q}} \cap \boldsymbol{D}^{t}\) then as \(c_{j}\) supports at least ( \(k-i+1\) )/2 neighboring responses in \(\boldsymbol{E}^{t}\), we must also have \(c_{j} \boldsymbol{D}_{q+\boldsymbol{1}}\). Hence if \(\left|\boldsymbol{D}_{q} \cap \boldsymbol{D}^{t}\right|>\left|\boldsymbol{D}^{t}\right| / 2\), as is implied by \(r_{q} \boldsymbol{E}^{t+1}\), then we have \(\left|\boldsymbol{D}_{q+1} \cap \boldsymbol{D}^{t}\right|>\left|\boldsymbol{D}^{t}\right| / 2\), which implies that \(r_{q+1} \boldsymbol{E} \boldsymbol{E}^{t+1}\). Now we can use this method again to show that \(r_{q+2} \epsilon \boldsymbol{E}^{t+1}\), and keep iterating it to show that \(r_{l} \boldsymbol{E}^{t+1}\) for all \((k+i) / 2 \geq l \geq q\). Now if \((k+i) / 2 \geq p\) then our proof is done. If not then note that we can use the same logic as above to show that \(r_{l} \in \boldsymbol{E}^{t+1}\) for \(p \geq l \geq(k+i) / 2\). This then gives us our result.

Now, propositions 1a and 1b show that if a contiguous interval of responses is activated at time \(t\) then a response that does not neighbor this contiguous interval, cannot be activated at \(t+1\) without activating all intermediate responses. Proposition 2 shows that if a contiguous interval of responses is activated at time \(t\) then this interval cannot splinter into two or more non-contiguous intervals of
activated responses at \(t+1\). Together these results imply both contiguous activation and sequential transitions.

\begin{abstract}
Distributed models of lexical semantics increasingly incorporate information about word order. One influential method for encoding this information into high-dimensional spaces uses convolution to bind together vectors to form representations of numerous \(n\)-grams that a target word is a part of. The computational complexity of this method has led to the development of an alternative that uses random permutation to perform order-sensitive vector combinations. We describe a simplified form of order encoding with convolution that yields comparable performance to earlier models, and we discuss considerations of neural implementation that favor the use of the proposed encoding. We conclude that this new encoding method is a more neurally plausible alternative than its predecessors.
\end{abstract}

Keywords: semantic memory; convolution; random permutation; vector space models; distributional semantics

\section*{Introduction}

The well-known 'semantic space' approach to modeling word meanings is frequently employed by researchers interested in understanding how the brain represents lexical information. At its most simple, the approach involves encoding word co-occurrence statistics from natural language corpora into a set of high dimensional vectors (e.g. Landauer \& Dumais, 1997; Lund \& Burgess, 1996; Jones \& Mewhort, 2007). The spatial relationships between such vectors are then taken to reflect semantic relationships amongst corresponding words. Experiments involving semantic space models have produced impressive results matching human data from studies of category typicality (e.g., Jones \& Mewhort, 2007) and synonym identification (e.g., Landauer \& Dumais, 1997), amongst other things.

However, one concern with the traditional semantic space approach is that it fails to take into account information about how words are sequentially related to one another (Jones \& Mewhort, 2007). For example, the latent semantic analysis (LSA) model developed by Landauer and Dumais (1997) functions by building a word-document frequency matrix that treats all words occurring in a single document equivalently. Similarly, Lund and Burgess' (1996) hyperspace analog to language (HAL) model simply counts the frequency of words occurring within a multi-word window around a target term. This indifference to sentence structure has led to HAL and LSA being referred to as 'bag of words' models of lexical semantics (Jones \& Mewhort, 2007; Recchia et al., 2010).

More recently, two techniques have been developed to incorporate word order information into semantic vectors. The first, developed by Jones and Mewhort (2007), uses circular convolution (proposed by Plate (2003) as a vector binding operation) to create vector representations of the numerous \(n\)-grams a target word is a part of. The second, developed by Sahlgren, Holst, and Kanerva (2008), uses random vector permutation to index the positions of neighboring words in relation to a target word. Functionally, the two approaches are quite similar, but random permutation is much more computationally efficient than convolution (Sahlgren, Holst, \& Kanerva, 2008). Moreover, a recent analysis indicates that convolution and random permutation offer similar degrees of accuracy during information retrieval, and that they perform comparably on a set of basic semantic tasks involving synonym identification (Recchia et al., 2010).

Given that computational efficiency favors the use of random permutation, the aim of this paper is to develop a simplified version of convolution encoding that can replicate many of the important functional properties of Jones and Mewhort's (2007) method. More specifically, we use convolution with position-indexing vectors to produce a single \(n\)-gram for each occurrence of a target word in a corpus (cf. Sahlgren, Holst, \& Kanerva, 2008). Encoding a single \(n\)-gram per word occurrence is much simpler than Jones and Mewhort's technique of encoding multiple \(n\) grams per word occurrence, and we demonstrate that this simplification provides good model performance on a range of order-specific tasks involving phrase-completion.

In addition, we argue that our encoding is more biologically plausible for two reasons:
1) All of the required vector representations can be instantiated using simulated spiking neurons.
2) All of the required computations on these representations can also be instantiated using simulated spiking neurons.

To substantiate these claims, we rely on prior work. Eliasmith and Anderson (2003) describe a method for representing and transforming high dimensional real-valued vectors in neural systems through a combination of the nonlinear encoding of a signal into a pattern of neural spikes, and the weighted linear decoding of these spikes. Simple operations such as vector addition are easily implemented
using these methods, and Eliasmith (2005) extends such work to describe a neural implementation of the circular convolution operation. Since our encoding method utilizes only circular convolution and vector addition, these remarks indicate that it is therefore a neurally plausible method.

In contrast, the approach of Sahlgren, Holst and Kanerva employs binary vectors, which are not naturally implemented in neural models (Stewart \& Eliasmith, 2012). Moreover, the approach of Jones and Mewhort employs a series of computations that are arguably too complex to scale appropriately if implemented in neurons. Our position encoding approach, on the other hand, has been utilized in a portion of what is currently the world's largest functional brain model (Eliasmith, et al., 2012), capable of a range diverse tasks involving perception, cognition, and action.

In what follows, we first review the convolution-based encoding algorithm presented by Jones and Mewhort (2007), along with the random permutation algorithm presented by Salhgren, Holst, and Kanerva (2008). We then introduce our own encoding algorithm. Next, we report results from a series of simulations conducted to assess model performance. We conclude that convolution with position indices offers an equally useful but more biologically plausible strategy for incorporating order information into semantic space models.

\section*{Two Approaches to Encoding Word Order}

The main challenge facing efforts to encode syntactic information into high-dimensional spaces is to find an appropriate, order-preserving mathematical operation for recursively combining vectors. Given that standard vector operations, such as superposition, are inadequate for this purpose, researchers have proposed a number of multiplicative binding methods instead. Examples include Smolensky's (1990) tensor products, Kanerva's (1994) binary spatter codes, and Plate's (2003) holographic reduced representations. Plate's approach has been particularly attractive to researchers interested in language because of its use of circular convolution, which ensures that all recursively bound vectors are of the same dimensionality. In absence of preserved dimensionality, it becomes difficult to compare vectors representing differently structured linguistic objects (e.g. phrases of different lengths; Jones \& Mewhort, 2007).

Before getting into the details of encoding with convolution and random permutation, it is worth noting that the point of departure for comparing the two methods is Jones and Mewhort's (2007) BEAGLE \({ }^{1}\) model, which assigns each word in a modeled corpus a unique environmental vector ( \(e\) ), along with a zero-valued memory vector \((m)\). Each time a word is encountered in the corpus, its memory vector is updated with context information provided through the superposition of the environmental vectors for every other word in the surrounding sentence.

\footnotetext{
\({ }^{1}\) The acronym stands for 'bound encoding of the aggregate language environment'.
}

Simultaneously, the memory vector is also updated with a vector describing the ordering of the target word in relation to a limited range neighbors. As whole, the process conforms to the following expression:
\[
\begin{equation*}
m_{i}=m_{i}+c_{i}+o_{i} \tag{1}
\end{equation*}
\]
where \(i\) indexes the word being represented, while \(c_{i}\) and \(o_{i}\) refer to vectors describing context and order information for a given word occurrence. \({ }^{2}\) The primary difference, then, between the approaches of Jones \& Mewhort (2007) and Sahlgren, Holst, and Kanerva (2008), is in the calculation of \(o_{i}\). In BEAGLE, \(o_{i}\) incorporates a range of \(n\)-grams that a target word is a part of. To give an example of how this works, consider the sentence 'make hay while the sun shines' and the target word 'hay'. The order vector, o ohay, is then calculated as the sum of various \(n\)-grams that 'hay' is a part of:
\[
\begin{aligned}
& \text { bigram }_{1}=e_{\text {make }} * \Phi \\
& \text { bigram }_{2}=\Phi * e_{\text {while }} \\
& \text { trigram }_{1}=e_{\text {make }} * \Phi * e_{\text {while }} \\
& \text { trigram }_{2}=\Phi * e_{\text {while }} * e_{\text {the }} \\
& \text { ngram }_{i}=\ldots
\end{aligned}
\]
where, * denotes the circular convolution operation, \(\Phi\) denotes a placeholder vector for the target word, and \(n\) sets size of the window around the target word from which order information is drawn. The value of \(n\) is typically set to 7 .

Overall, this method is quite computationally expensive given that each word occurrence prompts the generation of numerous sequences of convolutions, each of which must be computed in \(O(n \log n)\) time (Jones \& Mewhort, 2007). Moreover, because convolution is a commutative operation, permutations are applied to distinguish vectors of the form A * B and B * A. This adds an additionally layer of complexity when encoding large sequences of ordered vectors.

In light of this computational complexity, Sahlgren, Holst, and Kanerva's (2008) proposal is to recursively apply a random permutation to the environmental vectors to indicate their position relative to the target word. The random permutation, \(\Pi\), scrambles the order of the elements in a vector, and its recursive application indexes positions at varying distances from the target word:
\[
o_{\text {hay }}=\Pi^{-1} e_{\text {make }}+0+\Pi^{1} e_{\text {while }} \ldots+\Pi^{4} e_{\text {shines }}
\]

Here, the positive superscripts indicate the number times the permutation is applied to an environmental vector, and the negative superscripts indicate the number of times the inverse of the permutation is applied. One important feature of this method is that each occurrence of a target word in the

\footnotetext{
\({ }^{2}\) The context and order vectors are normalized prior to being combined and incorporated into the memory vector.
}
corpus results in the memory vector being updated with only a single \(n\)-gram containing every word in the order window. The resulting order vector, \(o\), is thus structurally quite different from vectors produced through the summing of multiple \(n\)-grams (Sahlgren, Holst, \& Kanerva, 2008).

For information retrieval in this framework, the inverse of a particular position permutation is applied to a memory vector. This process yields a vector that is most similar to environmental vectors that have been frequently bound into the memory vector in this position. Thus, one can extract information about which words are likely to occur in various positions around a target word. For example, \(\Pi^{-1} m_{\text {hay }}\) would yield a vector most similar to words that have frequently been bound into the first position succeeding 'hay' in various order vectors generated over the course of scanning the corpus. Depending on the statistical properties of this corpus, a comparison (i.e. cosine measure) between \(\Pi^{-1} m_{\text {hay }}\) and the environmental vectors will likely yield an environmental vector such as \(e_{\text {bale }}\) as most similar.

Overall, when comparing these methods for generating memory vectors, three things are important to keep in mind. First, there are a number of further differences between BEAGLE and Sahlgren, Holst, and Kanerva's model beyond the use of random permutation for order encoding. For example, the latter model uses binary environmental vectors, while Jones and Mewhort's model uses environmental vectors whose elements are picked from a Gaussian distribution of a mean of zero and variance equal to \(1 / D .{ }^{3}\) Moreover, Sahlgren, Holst, and Kanerva apply a smaller window for calculating context information that ignores sentence boundaries. These differences limit the ability to conduct performance comparisons based on the use of random permutation alone.

Second, to the extent that such comparisons have been made, they focus almost exclusively on storage capacity measures and performance on simple synonym identification tasks. However, one of the more compelling attributes of the BEAGLE model is its ability to reflect experimental effects involving things like category typicality, priming, and semantic constraints on stem completion. It has not been demonstrated that models built using random permutation have comparable capabilities.

Third, the BEAGLE model is computationally expensive, but uses real-valued vectors (which are efficiently implementable in a biologically plausible network; Eliasmith \& Anderson, 2003), whereas the permutation model is computationally efficient, but uses binary vectors (which have not been demonstrated to be efficient to implement biologically). Past work has not proposed a representation that is both computationally and biologically efficient.

Here, we describe a new representation that is comparable to the BEAGLE model in that it preserves the functional

\footnotetext{
\({ }^{3}\) These properties are needed to ensure that convolution can be used effectively as an operation for binding and unbinding vectors (Plate, 2003).
}
properties of its memory vectors, but it uses a single \(n\)-gram order encoding method that is structurally similar to Sahlgren, Holst, and Kanerva's technique while employing real-valued vectors.

\section*{Convolution with Position Vectors}

Our proposal is to encode order information with a set of reusable, real-valued, unitary, randomly generated 'position vectors'. \({ }^{4}\) These vectors are convolved with environmental vectors and summed to give an order vector of the following form:
\[
\begin{equation*}
o_{i}=\ldots p_{-1} * e_{-1}+0+p_{1} * e_{1}+p_{2} * e_{2} \ldots \tag{2}
\end{equation*}
\]
where \(p_{1}\) is the vector that indexes the first position succeeding the target word, \(p_{-1}\) is the vector that indexes the first position preceding the target word, and so forth. \(e_{1}, \mathrm{e}_{2}\), etc. are the environmental vectors of the words in each position around the target word. Structurally, this approach shares the property of position indexing with the model of Sahlgren, Holst and Kanerva (2008), but computationally, it shares the use of convolution of real-valued vectors with the model of Jones and Mewhort (2007).

To make the proposal clearer, consider again the word 'hay' in the sentence 'make hay while the sun shines'. The order vector produced with our method would be
\[
o_{\text {hay }}=p_{-1} * e_{\text {made }}+0+p_{1} * e_{\text {wwile }} \ldots+p_{2} * e_{\text {sthines }}
\]

Once this order vector is incorporated into the memory vector for 'hay', this memory vector will become slightly more similar to other vectors with have had 'hay' bound into the first position to the right too.

To retrieve order information from a memory vector, we can use one of two methods, both adapted from Jones \& Mewhort (2007). The first is to convolve the inverse of a position vector with a memory vector to extract a representation that is most similar to the environmental vectors that have been frequently bound into the memory vector in this position. For example:
\[
m_{\text {hay }} * p_{1}^{-1} \approx e_{\text {while }}
\]

Note that this method can be used to extract words commonly found in any of the twelve positions for which order information is encoded.

The second form of information retrieval involves constructing a probe corresponding to particular ordering around a target word, and then identifying which memory vectors have most frequently encoded the ordering of

\footnotetext{
\({ }^{4}\) To index position, a single unitary vector could also be selfconvolved multiple times. This would avoid the use of random vectors for each position, but it is functionally equivalent to the present formulation.
}
interest. To give an example, one could construct the following probe vector:
\[
\text { probe }=p_{-1} * e_{\text {make }}+0+p_{1} * e_{\text {wwile }}+\ldots+p_{3} * e_{\text {stimes }}
\]

If this vector is compared to all memory vectors generated from the corpus, it will match most closely with words that have frequently encoded the order sequence 'make while the sun shines'. Provided that the corpus does not contain a multitude of words that repeatedly occupy the blank position in relation to the same the surrounding words, the comparison will return the memory vector \(m_{\text {hay }}\) as the closest match.

Overall, information retrieval is made quite simple when position encoding is conducted via convolution with position vectors. As important, however, is whether or not the encoding enables good model performance.

\section*{Simulations}

We test the effects of the position encoding method for performance on a range of tasks involving semantic similarity and phrase completion. As per Jones and Mewhort (2007), context vectors are calculated as the superposition of environmental vectors in the sentence surrounding a target word, and environmental vectors are randomly generated with elements drawn from a Gaussian distribution. A list of stop words is used to prevent frequently occurring function words from being overrepresented in the context vectors, and order information is calculated using position indices ranging from -6 to +6 . This range is chosen because it captures the same set of words that would be included in order vectors calculated using Jones and Mewhort's original method. Finally, context vectors and order vectors are normalized prior to inclusion in the overall memory vector for a given word.

All simulations are run, for efficiency, on a subset of the same TASA corpus used in tests of both BEAGLE and Sahlgren, Holst, and Kanerva's (2008) random permutation model. Approximately 27,000 unique words are modeled using roughly 110,000 sentences, and words occurring less than twice in the corpus are ignored to exclude misspellings and typographical errors.

\section*{A Nearest Neighbors Task}

As an initial qualitative assessment of model performance, we calculated the nearest neighbors to the memory vectors for four common words found in the TASA corpus. We chose the same four words used in Table 3 of Jones and Mewhort (2007). The results, shown in Table 1 below, indicate that encoding order information with position vectors instead of an array of \(n\)-grams results in plausible model performance for each of the four words. All reported activation values are cosines of the angle between two vectors in the semantic space. The context space is comprised of memory vectors only updated with context information, while the order space is comprised of memory
vectors only updated with order information. The combined space includes memory vectors calculated in accordance with Equation 1.

As with the comparison between BEAGLE and the model of Sahlgren, Holst, and Kanerva (2008), subtle differences in things like the selection of stopwords and the formation of the environmental vectors make quantitative comparisons impractical, so we present these results as an independent demonstration of model performance.

Table 1: Nearest Neighbors in Three Spaces
\begin{tabular}{|c|c|c|c|c|c|}
\hline \multicolumn{2}{|l|}{Context} & Order & \multicolumn{3}{|c|}{Combined} \\
\hline \multicolumn{6}{|l|}{EAT} \\
\hline food & 0.69 & get & 0.89 & get & 0.78 \\
\hline get & 0.65 & buy & 0.87 & make & 0.75 \\
\hline animals & 0.63 & make & 0.86 & take & 0.70 \\

\hline writing & 0.61 & business & 0.64 & your & 0.61 \\
\hline skimming & 0.59 & power & 0.62 & or & 0.61 \\
\hline may & 0.56 & food & 0.62 & this & 0.59 \\
\hline \multicolumn{6}{|l|}{SLOWLY} \\
\hline little & 0.63 & quickly & 0.75 & quickly & 0.62 \\
\hline around & 0.63 & again & 0.67 & and & 0.60 \\
\hline back & 0.62 & ran & 0.65 & down & 0.60 \\
\hline across & 0.60 & to & 0.65 & then & 0.59 \\
\hline move & 0.59 & brought & 0.65 & to & 0.59 \\
\hline
\end{tabular}

\section*{Retrieval with Decoding}

Retrieval through decoding, again, involves convolving a memory vector with the inverse of a position vector, and then comparing the output of this process to a library of environmental vectors to find closest matches. In this simulation, we use the decoding retrieval method to find the most likely word to occur both before and after a particular target word. Results are reported in Table 2.

One point to note about these decoding results is that the activation values for the words in each column indicate nonrandom correspondence with the target word if the similarity value is greater than \(\sim 0.1\) (see Jones and Mewhort, 2007, p. 13). Accordingly, the decoding does a good job of picking out words that are likely to follow before or after a given word.

Table 2: Decoding Around a Target Word
\begin{tabular}{cccc}
\hline Word Before & \multicolumn{3}{c}{ Word After } \\
\hline LUTHER & & \\
martin & 0.29 & king & 0.21 \\
straightening & 0.17 & gravity & 0.17 \\
latest & 0.17 & 1733 & 0.16 \\
coinage & 0.16 & puff & 0.16 \\
so-called & 0.16 & conscience & 0.16 \\
\hline KING & \multicolumn{4}{c}{} \\
the & 0.54 & was & 0.19 \\
experienced & 0.17 & tens & 0.17 \\
boundaries & 0.17 & bowing & 0.17 \\
kites & 0.17 & lawfully & 0.17 \\
donor & 0.16 & pasture & 0.16 \\
\hline
\end{tabular}

\section*{Retrieval with Resonance}

Resonance retrieval, again, involves constructing a probe by superposing a number of bound environmental and position vectors. This probe vector is then compared to all of the memory vectors to find items that have frequently occurred within the sequence of words described by the probe.

Table 3: Resonance Around a Target Word
\begin{tabular}{|c|c|c|c|}
\hline Word Before & \multicolumn{3}{|c|}{Word After} \\
\hline \multicolumn{4}{|l|}{KING} \\
\hline rex & 0.38 & midas & 0.42 \\
\hline luther & 0.22 & tut & 0.42 \\
\hline rumbles & 0.17 & aietes & 0.39 \\
\hline hamlet & 0.17 & farouk & 0.36 \\

\hline
\end{tabular}

To assess model performance with resonance, we simulate a task involving retrieval around a set of four target words drawn from Table 4 of Jones and Mewhort (2007). The results from this simulation are presented in Table 3. Despite the intrusion of a few unexpected items into these lists of nearest matches (e.g. 'sensitivity'), the overall trend here provides further evidence that order encoding with position vectors can produce a functioning semantic space model.

\section*{Phrase Completion with Resonance}

To go beyond the retrieval of words either immediately to the left or to the right of a target word, we next simulate a set of tasks in which probe vectors corresponding to short phrases are compared to the memory vectors. Initially, only a limited amount of information is included in the probe vector, but subsequently, the probe is enriched to represent a more and more specific order sequence (see Jones \& Mewhort, 2007). As more information is incorporated into the probe in this way, the model increasingly converges on a single word that best fits the blank region in the probe phrase. We use phrase materials drawn from Jones and Mewhort (2007). Results are reported in Table 4 below.

Once again, the model generally meets performance expectations. Preliminary results also indicate that the model generally performs well with other phrases similar to the ones shown. Further work is ongoing in this area.

\section*{Discussion}

At this point, it seems clear that the method of encoding with position vectors performs well enough to be considered a plausible alternative to earlier methods. However, it is worth considering the criteria by which one might select amongst the three forms of encoding discussed in this paper. Computational efficiency, again, favors the use of a single \(n\)-gram encoding method like random permutation or encoding with position vectors.

Then, to decide between convolution and random permutation, one could look to performance measures of the sort just examined. Here, position vector encoding has the advantage of a demonstrated ability to perform a variety of phrase completion tasks; the performance credentials of random permutation have yet to be comparably established. It is possible that random permutation supports the same degree of functionality as demonstrated here, and future work might bear out such a prediction.

However, even if this is the case, we think that independent considerations of neural implementation favor the use of the position vector encoding method. First, note that vector space models of language have appealed to cognitive researchers in part because they possess certain properties suggestive of neural plausibility (Jones \& Mewhort, 2007; Recchia et al., 2010). Connectionist models, for example, have long been used to implement computations defined over vectors, and one of the main attractions of these models is their use of neurally inspired processing mechanisms. So, because semantic space models

Table 4: Highest Word Activations as an Order Sequence is Filled in Around a Target Position

\hline
\end{tabular}
are constructed through computations defined over vectors, and connectionist models can implement such computations, it follows that semantic space models can share to some extent in the claim of being consistent with how the brain processes information.

Second, models with a high degree of neural plausibility have been built using vector symbolic architectures that employ real-valued vectors and convolution as a binding operator. The same cannot be said for binary vectors. For instance, neurally implemented convolution operations play a key role in a recent model of working memory (Choo \& Eliasmith, 2010), and more significantly, what is currently the world's largest functional brain model (Eliasmith et al., 2012). So, the argument in favor of using convolution with position vectors to encode word order into semantic space models is straightforward: doing so is consistent with the architectural principles that guide state-of-the-art models of complex cognition. Put simply, there is a good deal evidence from these models that the convolution operation accommodates the computational constraints of neural systems.

Together with the demonstrated functionality of semantic space models built using convolution encoding, we think that these considerations of neural implementation provide a compelling case in favor of the method we demonstrate here. Convolution with position vectors provides an approach to building an order-sensitive semantic vector space that is functional, neurally plausible, and relatively computationally efficient. We leave it to future work to determine whether methods utilizing random permutation can display a similar range of strengths.

\title{
Visualizing the Invisible: Generating Explanations of Scientific Phenomena
}

\author{
Eliza Bobek (ebobek@packer.edu) \\ The Packer Collegiate Institute \\ Brooklyn, NY 11238 USA
}

\begin{abstract}
This study investigated the ability of learner-generated visualizations to improve learning in science. The hypothesis was tested in two domains, a mechanical system and a chemical system, and the results were analyzed separately to compare low and high spatial ability learners. The production of visual explanations of a mechanical system, a bicycle tire pump, increased understanding of the pump particularly for participants with low spatial ability. In the domain of chemical bonding, visual explanations were more effective than verbal explanations for all participants. Visual explanations often included crucial yet invisible features; their accurate construction requires and provides a check for completeness of explanations.
\end{abstract}

Keywords: learning; drawing; external representation; structure; function; spatial ability; self-generated explanation

\section*{Introduction}

Many topics in science are notoriously difficult for students to learn. Mechanisms and processes that exist on a scale outside student experience, such as gravitational pull, chemical bonding, and cellular processes, present particular challenges. When students attempt to learn these phenomena, they often experience difficulty because they must understand not only the individual components of the process (structure) but also the interactions and mechanisms (function). While instruction often involves visualizations, students typically explain in words, spoken or written. Visualizations have many advantages over verbal explanations, especially for science, so asking student to produce visual rather than verbal explanations should improve their learning.

\section*{Learner-generated Explanations}

When learners make connections between information, knowledge, and experience, by generating headings, summaries, pictures, and analogies, deeper understanding develops (Wittrock, 1990). Mayer and colleagues have conducted several experiments that have shown a learning benefit to generative activities in domains involving invisible components, including electric circuits (Johnson \& Mayer, 2010), lightning formation (Johnson \& Mayer, 2009), and the chemistry of detergents (Schwamborn et al., 2010). Hausmann \& Vanlehn (2007) addressed the possibility that generating explanations is beneficial because learners merely spend more time with the content material. In their study in the domain of physics, provided
explanations were not as effective as generated explanations.

\section*{Learner-generated Explanations in Visual and Verbal Formats}

The cognitive processes underlying the development of understanding may differ for visual and verbal explanations. Language has words for some parts, configurations, actions, and causes, but complex and complete descriptions of spatial and dynamic systems can be difficult to produce. Visualizations can readily depict the parts, shape, and configuration of a system, but it may be more difficult to depict the operation of a system, its functionality, and its causal mechanisms. Of course, the configuration provides clues for the system's operation and causality, and visual information can be supplemented with non-depictive diagrammatic devices, notably arrows (Heiser \& Tversky, 2006; Tversky et al., 2000, Tversky, 2002, 2011). Importantly, visual explanations demand completeness. Like other types of models, all of the essential parts of a system need to be represented in the proper configuration for it to work. In this way, drawings provide a visual check for completeness that verbal descriptions do not require. Inferences can then be made from diagrams that preserve and map the parts and configuration of the represented system or process. In an experiment that asked students to take notes while reading a text that they could later use to answer questions about the text, many students used only language, but those who made diagrams performed better (Schneider et al., 2010). Furthermore, requiring diagrams benefited all students.
Some researchers have demonstrated visual explanations' superiority over written explanations. Gobert \& Clement (1999) investigated the effectiveness of student-generated diagrams versus student-generated summaries on understanding plate tectonics after reading an expository text. Students who generated diagrams scored significantly higher on a post-test measuring spatial and causal/dynamic content, even though the diagrams contained less domainrelated information. Hall, Bailey, \& Tillman (1997) showed that learners who generated their own illustrations from text performed equally as well as learners provided with text and illustrations. Both groups outperformed learners only provided with text. In a study concerning the law of conservation of energy, participants who generated drawings scored higher on a post-test than participants who wrote their own narrative of the process (Edens \& Potter, 2003). In addition, the quality and number of concept units present in the drawing/science log correlated with
performance on the post-test. Van Meter (2001) found that drawing while reading a text about Newton's Laws was more effective than answering prompts in writing. Finally, Witherspoon et al. (2007) showed that generating external representations while studying the circulatory system increased scores compared to re-reading the provided text.

\section*{The Role of Spatial Ability in Learner-generated Explanations}

Developing an ability to visually manipulate a model of scientific processes is complicated. In constructing a visual representation of a scientific process, people may need to first imagine actions. Kozhevnikov, Hegarty, \& Mayer (2002) found that low spatial ability participants interpreted graphs as pictures, whereas high spatial ability were able to construct more schematic images and maniupulate them spatially. Hegarty \& Just (1993) found that the ability to mentally animate mechanical systems correlated with spatial ability, but not verbal ability. In their study, low spatial ability participants made more errors in movement verification tasks. However, Leutner, Leopold, \& Sumfleth (2009) found no effect of spatial ability on the effectiveness of drawing compared to mentally imagining text content.

\section*{Experiment 1: Explaining the Function of a Bicycle Tire Pump}

\section*{Method}

Participants Participants were \(1277^{\text {th }}\) and \(8^{\text {th }}\) grade students, ages 12-14, enrolled in an independent school in New York City. Of the 127 students, 59 were females, and 68 were males.

Materials Each participant was given a 12 -inch Spalding bicycle tire pump, a blank \(8.5 \times 11\) sheet of paper, a 16 question post-test, and the Vandenberg-Kuse Mental Rotation Test (MRT). Half of the participants received instructions to create a verbal explanation in writing; the other half received instructions to create a visual explanation in a drawing.

Procedure On the first of two non-consecutive school days, participants completed the MRT as a whole-class activity. Participants were read aloud the instructions, and were given untimed practice on several items. They were then given three minutes to complete items 1-10, and an additional three minutes to complete items 11-20. On the second day, participants were given the pump and instructions to try to understand how it worked. This segment was untimed. The next set of instructions asked students to verbally explain how the pump worked (in words) or to visually explain how the pump worked (in a drawing). Upon completion of the explanation, participants were given the 16 question post-test.

\section*{Coding}

Coding for Structure and Function. A maximum score of twelve points was awarded for the inclusion and labeling of six structural components: chamber, piston, inlet valve, outlet valve, handle, and hose. Information was coded as functional if it depicted or described the function/movement of an individual part, or the way multiple parts interact. There was no maximum imposed on the number of functional units.
Coding of Essential Features. Explanations were also coded for the inclusion of information essential to its function according to a four-point scale (adapted from Hall, Bailey, \& Tillman, 1997). One point was given if both the inlet and the outlet valve were clearly present in the drawing or described in writing, one point was given if the piston inserted into the chamber was shown or described to be airtight, and one point was given for each valve if they were shown or described to be opening/closing in the correct direction. The maximum score for essential features was four points.
Coding of Invisible Features. The presence of three invisible features (the inlet valve, the outlet valve, and the movement of air) were coded separately, with one point given for the presence of each valve, and three points given for movement of air (entering, moving through, and exiting the pump). The maximum score for invisible features was thus five points.
Coding Visual Elements: Arrows and Multiple Steps. Arrows were coded for three purposes: label for a part or action, to show motion, or to indicate sequence. Each use of arrows was coded for one of these purposes and a score tallied for each use. The use of multiple steps/frames was used to show starting and ending positions, and change in location of parts of the pump and air.

\section*{Results}

Spatial ability. Participants scores' on the MRT were used to divide participants into low and high spatial ability groups based on a median split in the data. Scores on the MRT range from 0-20; the mean score for participants was 10.56, and the median was 11 . Scores were significantly higher for males \((M=13.5, S D=4.4)\) than for females \((M=\) \(8.8, \mathrm{SD}=4.5), \mathrm{F}(1,126)=19.07, \mathrm{p}<.01\).
Structure and Function. Both visual and verbal explanations contained from two to ten structural components. Visual explanations contained a significantly greater number of structural components \((\mathrm{M}=6.05, \mathrm{SD}=2.76)\) than verbal components \((M=4.27, S D=1.54), F(1,126)=20.53\), \(\mathrm{p}<.05\), while there was no difference in the number of expressed functional components between visual and verbal explanations.
Essential Features. Scores for the inclusion of essential information were significantly higher for visual explanations \((\mathrm{M}=1.78, \mathrm{SD}=1.0)\) than for verbal explanations \((\mathrm{M}=1.20, \mathrm{SD}=1.21), \mathrm{F}(1,126)=7.63\), \(\mathrm{p}<.05\). No significant differences were found between low ( \(\mathrm{M}=1.34, \mathrm{SD}=1.04\) ) and high spatial participants \((\mathrm{M}=\)
\(1.45, \mathrm{SD}=1.2\) ). Essential features were also found to positively correlate with delayed post-test scores, \(r=.197\), \(\mathrm{p}<.05\) ).
Invisible Features. Scores for the inlet valve were higher for visual explanations \((\mathrm{M}=.67, \mathrm{SD}=.45)\) than verbal explanations ( \(\mathrm{M}=.51, \mathrm{SD}=.5\) ), however the effect was only marginally significant, \(\mathrm{F}(1,126)=3.13, \mathrm{p}=.07\). Scores for air movement also showed a marginally significant difference, \(F(1,126)=2.93, p=.09\), with visual explanations \((\mathrm{M}=2.35, \mathrm{SD}=1.28)\) containing a greater number than verbal explanations \((M=1.88, \mathrm{SD}=1.45)\). No significant differences between visual ( \(\mathrm{M}=.92\), \(\mathrm{SD}=.43\) ) and verbal explanations \((M=.79, S D=.65)\) were found for the outlet valve. Analysis of the invisible parts between low and high spatial participants also failed to show any significant differences in the inclusion of the inlet valve, the outlet valve, or air movement. Finally a total score for the inclusion of invisible parts was calculated for each participant by totaling the scores for the inlet valve, the outlet valve, and for air movement. The mean score was 3.26, \(\mathrm{SD}=1.25\). The data was analyzed using linear regression, and revealed that the total score for invisible parts significantly predicted scores on the post-test, \(\mathrm{F}(1\). \(118)=3.80, \mathrm{p}=.05\).
Multiple Steps. The number of steps used by participants ranged from one to six. Participants whose explanations contained more than a single step scored significantly higher ( \(\mathrm{M}=.76, \mathrm{SD}=.18\) ) on the post-test than participants whose explanations consisted of a single step \((\mathrm{M}=.67, \mathrm{SD}=.19)\), \(\mathrm{F}(1,126)=5.02, \mathrm{p}<.05\).
Learning Outcomes. Scores on the post-test by group and spatial ability are shown in Figure 1. A test of the overall interaction between group and spatial ability was significant, \(F(1,124)=4.094, p<.01\). In particular, low spatial participants who generated verbal explanations had significantly lower scores \((M=.609, S D=.145)\) than low spatial participants who drew explanations ( \(\mathrm{M}=.716\), \(\mathrm{SD}=\) .121). Analyzing structure and function questions separately on the post-test found no differences in performance between low and high spatial participants on structural questions. However, analyzing performance on functional questions found a significant effect: low spatial participants who generated verbal explanations \((\mathrm{M}=.502, \mathrm{SD}=.194)\) scored significantly lower than low spatial participants that drew ( \(\mathrm{M}=.678, \mathrm{M}=.122\) ), see Figure 2.

\section*{Discussion}

The results of Experiment 1 show that low spatial ability participants were able to learn as successfully as high spatial ability participants when they first generated an explanation in a visual format. Importantly, this result was particularly strong for functional understanding. Visual explanations were more likely to contain certain invisible features of the pump, such as the valves. Including the inlet valve and attempting to explain its function is crucial because then it is performing its function it is inside the chamber and air entering or exiting cannot be felt by the user.

Figure 1: Scores on the post-test, by group and spatial ability.

Figure 2: Scores on functional questions on the post-test, by group and spatial ability.

As mentioned previously, drawing encourages completeness. They force learners to decide on the size, shape, and location of parts/objects, and how the parts are related. Understanding the "hidden" function of the invisible parts is key to understanding the function of the entire system and requires an understanding of how both the visible and invisible parts interact. The visual format may have been able to elicit components and concepts that are invisible and difficult to integrate into the formation of a mental model.

Finally, an analysis of the visual explanations revealed that \(67 \%\) also added written components to accompany their explanation. Arguably, some types of information may be difficult to depict visually, and our verbal language has many possibilities that allow for specificity. Indeed, several studies by Mayer and colleagues have found that
understanding a system is enhanced when text and pictures are presented simultaneously to learners (e.g. Mayer \& Gallini, 1990).

The utility of visual explanations may differ for scientific phenomena that are more abstract, or contain elements that are invisible due to their scale. '

\section*{Experiment 2: Explaining the Process of Chemical Bonding}

\section*{Method}

Participants Participants were \(1268^{\text {th }}\) grade students, ages 13-14, enrolled in an independent school in New York City. Of the 126 students, 58 were females, and 68 were males.

Materials Each participant was given an immediate posttest, a delayed post-test, a blank \(8.5 \times 11\) sheet of paper, and the Vandenberg-Kuse Mental Rotation Test (MRT). Half of the participants received instructions to create a verbal explanation in writing; the other half received instructions to create a visual explanation in a drawing. In addition, the experimenter showed all participants a pre-recorded video lesson on bonding ( 13 minutes, 22 seconds long). The video began with a brief review of atoms and their structure, and introduced the idea that atoms combine to form molecules. Next, the lesson discussed how location in the periodic table affects behavior and reactivity of atoms, and makes atoms more or less likely to gain, lose, or share electrons. Examples of atoms, their valence shell structure, stability, charges, transfer and sharing of electrons, and the formation of ionic, covalent, and polar covalent bonds were discussed. The immediate post-test and delayed post-test each consisted of seven multiple-choice items and three freeresponse items.

Procedure On the first of three non-consecutive school days, participants completed the MRT as a whole-class activity, following the same procedures as Experiment 1. On the second day, participants viewed the recorded lesson on chemical bonding. They were instructed to pay close attention to the material but were not allowed to take notes on material presented in the video. Immediately following the video, participants were administered the immediate post-test of chemical bonding knowledge. Participants were given twenty minutes to complete the test; all participants finished within this time frame. On the third day, the particpants were randomly assigned to either the visual or verbal condition. The next set of instructions asked students to either visually or verbally explain how atoms bond and how ionic and covalent bonds differ). Upon completion of the explanation, participants were given the delayed posttest.

\section*{Coding}

Coding for Structure and Function. Visual and verbal explanations were coded for structural and functional
components. Table 1 and Table 2 show the components that were coded for structure and function, respectively.

Table 1: Coding Guide for Structure
Structural Components (1 pt. each)
Atoms with the correct number of electrons/valence
electrons
Atoms with the correct charges (magnitude,
positive/negative)
Bond between appropriate elements (i.e. between non-
metals for covalent molecules and between a metal and a
non-metal for ionic molecules)
Ionic bonds depicted/described as crystalline structure
Covalent bonds depicted/described as individual
molecules

Table 2: Coding Guide for Function
Functional Components (1 pt. each)

Transfer of electrons in ionic bonds
Sharing between atoms in covalent bonds
Attraction between ions of opposite charges
Outcome of bonding shows atoms with stable valence electron shell configurations.

Outcome of bonding shows molecules with overall neutral charge

Coding system for arrows. Arrows were present in \(92 \%\) of visual explanations. Their use was categorized into the use of arrows as labels and to show movement/action. Each use was tallied for each explanation.
Coding system for the use of specific examples. Explanations were coded for the use of specific atoms, such as NaCl to illustrate ionic bonding.
Coding for the use of multiple representations. Explanations were coded as symbolic (e.g. NaCl ), atomic (showing structure of atom(s), and macroscopic (visible).

\section*{Results}

Spatial ability. As in Experiment 1, participants' scores on the MRT were used to divide participants into low and high spatial ability groups based on a median split in the data. Scores were significantly higher for males \((M=12.5, S D=\) 4.8) than for females \((\mathrm{M}=8.0, \mathrm{SD}=4.0), \mathrm{F}(1,125)=\) 24.49, \(\mathrm{p}<.01\).

Structure and Function. The maximum score for structural and functional information was five points. Visual explanations contained a significantly greater number of structural components \((M=2.81, S D=1.56)\) than verbal
components \((\mathrm{M}=1.30, \mathrm{SD}=1.54), \mathrm{F}(1,125)=13.69\), \(\mathrm{p}<.05\), while there was no difference in the number of expressed functional components between visual and verbal explanations. Structural information was more likely to be depicted in pictures \((M=3.38, S D=1.49)\) than described in words \((\mathrm{M}=.429, \mathrm{SD}=1.03), \mathrm{F}(1,62)=21.49, \mathrm{p}<.05\), but functional information was equally likely to be expressed in pictures \((\mathrm{M}=1.86, \mathrm{SD}=1.10)\) and words \((\mathrm{M}=1.71, \mathrm{SD}=\) 1.87). Functional information in words added to visual explanations significantly predicted scores on the post-test, \(\mathrm{F}(1,62)=21.603, \mathrm{p}<.01\). As in Experiment 1, there were no significant differences in the amount of structural information contained in explanations created by low and high spatial ability participants. However, explanations created by high spatial participants contained significantly more functional components, \(\mathrm{F}(1,125)=7.13, \mathrm{p}<.05\).
Arrows. \(83 \%\) of visual explanations contained arrows. The use of arrows was positively correlated with scores on the post-test, \(\mathrm{r}=.293, \mathrm{p}<.05\).
Specific examples. High spatial participants \((\mathrm{M}=1.6, \mathrm{SD}=\) .69) used specific examples in their explanations more often than low spatial participants \((\mathrm{M}=1.07, \mathrm{SD}=.79)\). The difference was marginally significant \(\mathrm{F}(1.125)=3.65\), \(\mathrm{p}=.06\). There were no significant differences in the use of specific examples between visual and verbal groups. The inclusion of a specific example was positively correlated with scores on the delayed post-test, \(\mathrm{r}=.555, \mathrm{p}<.05\).
Multiple representations. Multiple representations were included in \(65 \%\) of the explanations. Participants generated significantly more when creating visual explanations ( \(\mathrm{M}=\) 1.79 , \(\mathrm{SD}=1.20\) ) compared to verbal explanations ( \(\mathrm{M}=\) \(1.33, \mathrm{SD}=.48), \mathrm{F}(1,125)=6.03, \mathrm{p}<.05\). However, the use of multiple representations did not significantly correlate with delayed post-test scores.

Learning outcomes. The immediate post-test was scored so that the maximum score was ten points. Each of the seven multiple choice questions and three free-response questions was given one point for the correct answer. The mean score (defined by proportion correct) on the immediate post-test was \(.463, \mathrm{SD}=.469\). Scores did not differ significantly between participants in the visual group ( \(\mathrm{M}=.486, \mathrm{SD}=.308\) ) and the verbal group \((\mathrm{M}=.443\), \(\mathrm{SD}=\) \(.260), \mathrm{F}(1,125)=.740, \mathrm{p}>.05\). Scores between high spatial ( \(\mathrm{M}=.532, \mathrm{SD}-.421\) ) and low spatial participants \((\mathrm{M}=.402\), \(\mathrm{SD}=.390)\) also did not differ significantly, \(\mathrm{F}(1,125)=\) \(2.72, \mathrm{p}>.05\).
